2015v1.0

MANIFESTATIONS OF DISEASE

Abdominal distention and constipation, 106
Abnormal coat length and density, 184
Abnormal mentation, 131
Abnormal peripheral pulse, 93
Abnormal pigmentation, 187
Abnormal respiratory noise (stridor), 71
Alterations in lactation, 209
Alterations in male sexual function, 189
Anestrus, 194
Anuria and oliguria, 173
Behavior, abnormal, 131
Blindness, 131-135
Blood, fibrin, and/or mucus in feces (dysentery), 106
Cardiac arrhythmias, 84
Cardiac murmurs, 87
Cardiovascular exercise intolerance, weakness, and syncope, 89
Causes of collapse and sudden death, 228
Cervical spinal cord abnormalities, 138
Circling, 134
Colic (abdominal pain), 102
Collapse versus sudden death, 227
Cough, 43
Cranial nerve abnormalities, 135-138
Crystalluria, 171
Cyanosis, 68
Cyclic irregularity of estrus, 193
Deafness, 136
Dental abnormalities, 113
Deviated or dropped jaw, 135-136
Diarrhea, 95
Dysphagia, 110, 136
Dysphonia, 136
Dystocia, 205
Dysuria, stranguria, and incontinence, 166
Enlarged lymph nodes, 92
Epistaxis and hemoptysis, 57
Exercise intolerance and poor performance in horses, 75
Facial hypalgesia or analgesia, 135-136
Facial paresis or paralysis, 136
Fescue toxicosis, 200
Fever, 36
Focal analgesia, 139
Galactorrhea (inappropriate lactation), 211
Head tilt, 134, 136
Hematuria and pigmenturia, 169
Hypermetria, hypometria, dysmetria, 134-135
Hyperthermia, 33
Hypothermia, 42
Icterus (jaundice), 113
Incoordination, 134-135
Intention tremor, 134-135
Lethargy, stupor, coma, dementia, 131
Mammary gland, enlarged, 209
Mechanisms of decreased growth and decreased weight gain, 141
Melena, 105
Muffled heart sounds, 88
Muscle atrophy, reduced muscle tone, flaccid paresis, 139
Nasal discharge, 51
Nodules, tumors, and swellings, 181
Nystagmus, 134, 136
Obesity, 164
Ocular abnormalities, 131-134
Oral vesicles, erosions, ulcers, or growths, 111
Painful peripheral swellings, 92
Papules, pustules, and vesicles, 182
Paresis (quadraparesis, hemiparesis, paraparesis), 136-138
Peripheral edema, pleural effusion, and ascites, 82
Pica, 165
Polyuria, 172
Pregnancy loss, 198
Prolonged gestation, 204
Pruritus, 179
Pupil size and light responses, abnormal, 135
Pyuria, 170
Regurgitation and vomiting, 108
Repeat breeder, 196
Respiratory distress (dyspnea), 60
Retained fetal membranes, 207
Scaling and crusting, 183
Seizures and collapse, 131
Strabismus, ocular paresis/paralysis, 135
Stridor, 136
Tachypnea, 60
Udder edema, 210
Ulcerations and erosions, 182
Uremia, 173
Urinary incontinence and urine retention, 139
Venous distention and pulsations, 90
Weight loss, 152

VetBooks.ir

DISORDERS AND MANAGEMENT OF THE NEONATE

VetBooks.ir

FOAL DISORDERS

Abdominal exam and ultrasound, 250, 251
Anemia, 289
Apgar score, 248
Assessment of newborn foal, 247
Assessment of the mare during late gestation, 237
Blood gas abnormalities, 254
Blood gas values, 254
Cardiac arrhythmias, 252
Cerebrospinal fluid assessment, 257
Cleft palate, 247
Colostrum management and assessment of FPT, 258, 259
Colostrum supplements and replacements, 382
Contracted or lax tendons, 258
Dental abnormalities, 249
Diarrhea in neonatal foals, 299
Effects of placental insufficiency, 241
Foal resuscitation, 244
General principles of treatment and care of the abnormal foal, 262
Goiter, 247
Hematology and biochemistry values, 259, 260
Hypoglycemia, 259, 260
Inguinal hernia, 251
Management of the high-risk late-gestation mare, 243
Maternal behavior, 248
Maturity, 290
Meconium impaction, 250
Milk replacers, 387
Mucous membranes, abnormal, 249
Neonatal encephalopathy, 281
Neurologic abnormalities, 256, 257
Noninfectious causes of lameness, 280
Ocular abnormalities, 249
Other neurologic conditions, 288
Perinatal asphyxia syndrome, 245
Physical exam, 248
Placentitis, 242
Respiration, 294
Respiratory distress, 253
Ruptured urinary bladder, 255, 255
Seizures, 281
Sepsis, 267
Septic arthritis and osteomyelitis, 274
Systemic disease in the mare, 242
Umbilical enlargement, 255, 256
Vertebral anomalies, 250

RUMINANT DISORDERS

Abdominal distention, 347
Anemia, 380
Cyanosis, 380
Diarrhea, 351
Failure to thrive: cachexia and weak calf syndrome, 381
Fever, 380
Heart murmur, 381
Icterus, 381
Lameness and reluctance to walk, 378
Respiratory difficulty, 343
Umbilical enlargement, 379
Weakness and/or depressed mentation, 335

COLLECTION OF SAMPLES AND INTERPRETATION OF LABORATORY TESTS

MAJOR BIOCHEMICAL ABNORMALITIES OR PROBLEMS ENCOUNTERED

Agglutination of RBCs, 426
Anemia, 426
Anion gap, 410
Base excess or deficit, 411
Basophilia, 432
Bicarbonate, 411
Bilirubin, 415
Blood loss, 427
Causes of elevations of serum enzymes and bilirubin, 412
Coombs test, 426
Creatinine, 416
Decreased erythrocyte production, 427
Decreased plasma antithrombin III, 446
Eosinophilia, 432
Equine gastrointestinal pathogens, 470
Equine miscellaneous pathogens, 471
Equine neurologic pathogens, 469
Equine respiratory pathogens, 467
Erythrocyte morphology, 425
Erythrocytosis (polycythemia), 427
Fibrin/fibrinogen degradation products, 446
Fluid and electrolyte balance, 401
Fractional urinary clearance of electrolytes, 419
Genetic diseases, 475
Hematocrit, 424
Hemoglobin, 424
Hemolysis, 427
Hemostatic function, 448
Hypercalcemia, 406
Hyperchloremia, 405
Hyperglobulinemia and the acute phase response, 438, 439
Hyperglycemia, 416
Hyperkalemia, 404
Hypermagnesemia, 407
Hypernatremia, 403
Hyperphosphatemia, 407
Hyperproteinemia, 436
Hypoalbuminemia, 440
Hypocalcemia, 406
Hypochloremia, 405
Hypofibrinogenemia, 447
Hypoglycemia, 416
Hypokalemia, 403
Hypomagnesemia, 407
Hyponatremia, 402
Hypophosphatemia, 407
Hypoproteinemia, 440
Lymphocytosis, 432
Lymphopenia, 433
Mean cell hemoglobin concentration and mean cell hemoglobin, 424
Mean cell volume, 424
Metabolic acidosis, 408
Metabolic alkalosis, 408
Metabolic profiling, 397
Microarrays and restriction fragment length polymorphism, 474
Mixed acid-base imbalances, 410
Molecular diagnostics in large animals, 462
Molecular testing for infectious diseases in cattle, sheep, and goats, 471
Molecular testing for infectious diseases in horses, 466
Monocytosis, 433
Multiplex PCR, 474
Neutropenia, 432
Neutrophilia, 431
Normal values (clinical chemistries, serum proteins), 397
Osmolality and osmolal gap, 405
Packed cell volume, 424
Panhyperproteinemia, 436
Panhypoproteinemia, 441
Platelet function defects and von Willebrand disease, 444
Prolonged partial thromboplastin time, 445
Prolonged prothrombin time, 444
Real-time PCR, 464, 474
Red blood cell count, 424
Respiratory acidosis, 409
Respiratory alkalosis, 410
Sequence analysis, 475
Serum proteins, 417
Serum/plasma urea, 401
Southern blots, northern blots, and dot-blots, 472
Standard polymerase chain reaction and nested PCR, 464, 473
Strong ion difference (SID), 411
Strong ion gap (SIG), 411
Thrombocytopenia, 442
Thrombocytosis, 444
Thromboelastography, 448
Total carbon dioxide (TCO_2), 411
Urinalysis, 418

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

TO

Yibi, Chris, Bonnie, Kate, Everett, Alex, Mary-Lee, Brianna, Olivia Smith, Jill Higgins, Lucas and Lia Pusterla for their love and support.

Robin, Aaron, and Joe Van Metre, with gratitude for their love and laughter; and to Drs. Bill Rebhun, Tom Divers, Steve Dill, Susie Fubini, Chuck Guard, and Norm Ducharme—Thank you for showing the way.

AND TO

the authors and consulting editors who worked so hard to advance large animal internal medicine to new levels.

VetBooks.ir

David Copley Van Metre

1964-2019

Esteemed colleague, wonderful human being. He will be missed by all.

University of Missouri
Columbia, Missouri

M. Keith Chaffin, DVM, MS, DACVIM
Professor & Associate Department Head for Clinical Programs
Large Animal Clinical Sciences
Texas A&M University
College Station, Texas

Berkley Chesen, DVM, DACVS-LA
Equine Comprehensive Wellness
Santa Fe, New Mexico

Munashe Chigerwe, BVSc, MPH, PhD, DACVIM
Associate Professor
Medicine and Epidemiology
University of California, Davis
Davis, California

Bruce W. Christensen, DVM, MS, DACT
Owner
Theriogenology
Kokopelli Assisted Reproductive Services
Woodland, California

Gemma Chuck, BVetMed, PhD
Veterinary Operations-Dairy
Apiam Animal Health Limited
East Bendigo, Victoria, Australia

Kristin A. Clothier, DVM, PhD, DACVIM
Bacteriology Discipline Head
California Animal Health & Food Safety Lab;
Associate Professor
Department of Pathology, Microbiology, and Immunology
University of California—Davis
Davis, California

Johann (Hans) F. Coetzee, BVSc, CertCHP, PhD, DACVCP, DACAW, DECAWSEL
Professor and Department Head
Anatomy and Physiology
Kansas State University
Manhattan, Kansas

Michelle C. Coleman, DVM, DACVIM
Assistant Research Scientist
Large Animal Clinical Sciences
Texas A&M University
College Station, Texas

Robert J. Collier, PhD, MS, BS
Professor Emeritus
School of Animal and Comparative Biomedical Sciences
University of Arizona
Tucson, Arizona

Victor S. Cortese, BS, DVM, PhD, DABVP, DAVBP
Technical Services
Zoetis Animal Health
Parsippany, New Jersey

Lais R. Costa, MedVet, MS, PhD, DACVIM, DABVP
Research Veterinarian
Department of Medicine and Epidemiology
University of California
Davis, California

Beate M. Crossley, DVM, PhD, MPVM
Professor
California Animal Health and Food Safety Laboratory
University of California, Davis
Davis, California

Jennifer L. Davis, DVM, PhD, DACVIM (LA), DACVCP
Associate Professor of Clinical Pharmacology
Department of Biomedical Sciences and Pathobiology
Virginia-Maryland College of Veterinary Medicine
Blacksburg, Virginia

Melody Anne de Laat, BVSc, PhD, MANZCVS, GradCertAcadPrac, FHEA
Senior Lecturer
Biosciences
Queensland University of Technology
Brisbane, Queensland, Australia

Fabio Del Piero, DVM, PhD, DACVP
Professor of Pathology
Pathobiological Sciences
Louisiana State University
Baton Rouge, Louisiana

André Desrochers, DVM, MS, DACVS, Dip. ECBHM
Professor
Clinical Sciences
Faculty of Veterinary Medicine
Université de Montréal
Saint-Hyacinthe, Québec, Canada

VetBooks.ir

Padraic Martin Dixon, MVB, PhD, MRCVS, Dip EVDC (Equine), FRCVS
Professor of Equine Surgery
Division of Veterinary Clinical Studies
The University of Edinburgh
Midlothian, Scotland, Great Britain

Charles C. Dodd, DVM, MS, PhD
Research Assistant Professor
Diagnostic Medicine/Pathobiology
Kansas State University College of Veterinary Medicine
Manhattan, Kansas

Brandon J. Dominguez, DVM, MS
Clinical Associate Professor
Department of Veterinary Large Animal Clinical Sciences
Texas A&M University
College Station, Texas

Vincent Dore, DVM, MSc, DACVIM
Clinical Instructor
Large Animal Clinical Sciences
University of Tennessee
Knoxville, Tennessee

Gerald E. Duhamel, DVM, PhD, DACVP
Professor
Biomedical Sciences
Cornell University, College of Veterinary Medicine
Ithaca, New York

Bettina Dunkel, DVC, PhD, DACVIM, Dip ECEIM, Dip ACVECC, FHEA, MRCVS
Senior Lecturer in Equine Medicine
Clinical Science and Services
The Royal Veterinary College
North Mymms, Herts, Great Britain

Jack Easley, DVM, MS, DABVP (Equine)
Equine Veterinary Practitioner
Equine Dentistry
Equine Veterinary Practice LLC
Shelbyville, Kentucky

Kari J. Ekenstedt, DVM, PhD
Department of Basic Medical Sciences
College of Veterinary Medicine
Purdue University
West Lafayette, Indiana

John A. Ellis, DVM, MS, PhD, DACVP, DACVM
Western College of Veterinary Medicine
University of Saskatoon
Saskatoon, Saskatchewan, Canada

Pablo Espinosa-Mur, DVM, DACVS, DECVS
Associate Veterinarian
Equine Surgery
School of Veterinary Medicine
University of California, Davis
Davis, California

Ronald J. Erskine, DVM, MS, PhD
Department of Large Animal Clinical Sciences
Michigan State University
East Lansing, Michigan

Krista E. Estell, BS, DVM, DACVIM
Clinical Assistant Professor of Equine Medicine
Marion duPont Scott Equine Medical Center
Virginia Maryland College of Veterinary Medicine
Leesburg, Virginia

Timothy J. Evans, DVM, MS, PhD, DACT, DABVT
Associate Professor
Department of Veterinary Pathobiology
University of Missouri
Columbia, Missouri

Darien Feary, BVSc, MS, DACVIM, DACVECC, GradDipClinEduc
PhD Candidate
Department of Science (VetSci)
Charles Sturt University
Wagga Wagga, New South Wales, Australia

Gilles Fecteau, DMV, DACVIM
Clinical Sciences
Université de Montréal
Saint-Hyacinthe, Québec, Canada

Marie-Eve Fecteau, DVM, DACVIM
Associate Professor of Food Animal Medicine and Surgery
Clinical Studies–New Bolton Center
University of Pennsylvania, School of Veterinary Medicine
Kennett Square, Pennsylvania

M. Julia B. Felippe, MedVet, MS, PhD, DACVIM
Professor of Medicine
Department of Clinical Sciences
Cornell University College of Veterinary Medicine
Ithaca, New York

C. Langdon Fielding, DVM, DACVECC, DACVSMR
Hospital Director
Department of Emergency Medicine
Loomis Basin Equine Medical Center
Penryn, California

Carrie J. Finno, DVM, PhD, Diplomate ACVIM
Associate Professor
Population Health and Reproduction
University of California, Davis
Davis, California

Sherrill A. Fleming, DVM, DACVIM, DABVP (Food Animal)
Associate Professor, Food Animal Medicine
Pathobiology and Population Medicine
College of Veterinary Medicine, Mississippi State University
Mississippi State, Mississippi

VetBooks.ir

David Francoz, DMV, MSc, ACVIM
Full Professor
Clinical Sciences
Université de Montréal, Faculté de médecine vétérinaire,
Saint-Hyacinthe, Québec, Canada

Nicholas Frank, BSc, DVM, PhD, DACVIM
Professor and Associate Dean
Cummings School of Veterinary Medicine
Tufts University
North Grafton, Massachusetts;
Honorary Professor
Division of Medicine
University of Nottingham School of Veterinary Medicine and Science
Sutton Bonington, Leicestershire, Great Britain

Robert W. Fulton, DVM, PhD, DACVM
Emeritus Regents Professor
Veterinary Pathobiology
Center for Veterinary Health Sciences
Oklahoma State University
Broken Arrow, Oklahoma

Lisa E. Fultz, DVM, MS, DACVIM
Associate Veterinarian
Equine Medicine
Equine Medicine Specialists of South Florida
Palm Beach Gardens, Florida

Tam Garland, DVM, PhD, DABVT
Garland, Bailey & Associates
Toxicology Consultants
Private Consulting
College Station, Texas

Franklyn Garry, DVM, MS, DACVIM
Professor
Department of Clinical Sciences
Colorado State University
Fort Collins, Colorado

Anne J. Gemensky-Metzler, DVM, MS, DACVO
Professor—Clinical
Department of Veterinary Clinical Sciences
The Ohio State University College of Veterinary Medicine
Columbus, Ohio

Philippa Gibbons, BVetMed(Hons), MS, DACVIM(LA) CertVetEd
Assistant Professor
College of Veterinary Neducube
Lincoln Memorial University
Harrogate, Tennessee

Steeve Giguère, DVM, PhD, DACVIM
Professor and Hodgson Research Chair in Equine Studies
Large Animal Medicine
University of Georgia
Athens, Georgia

Sandra Godden, DVM, DVSc
Professor
Department of Veterinary Population Medicine
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota

Jesse Paul Goff, DVM, PhD
Anderson Chair in Veterinary Medicine
Department of Biomedical Sciences
College of Veterinary Medicine
Iowa State University
Ames, Iowa

Kathleen Casey Gonda, DVM, MS, DACVIM-LA
Specialty Equine Internal Medicine
Keswick, Virginia

Liara M. Gonzalez, DVM, PhD, DACVS
Assistant Professor of Gastroenterology and Equine Surgery
Clinical Sciences
North Carolina State University
Raleigh, North Carolina

Gretchen P. Grissett, DVM, MS, DACVIM (LA)
Assistant Clinical Professor
Department of Pathobiology and Population Medicine
Mississippi State University
Starkville, Mississippi

Alison A. Gunn, BVSc MVS MACVSc Grad Cert HE
Faculty of Veterinary Science
University of Sydney
Camden, New South Wales, Australia

Santiago D. Gutierrez-Nibeyro, DVM, MS, DACVS, DACVSMR
Clinical Associate Professor
Veterinary Clinical Medicine
University of Illinois
Urbana, Illinois

Faisal Ghazi Habasha, BVM&S, MSC, PhD
Professor of Medicine
Dept. of Vet. Internal & Preventive Medicine
College of Veterinary Medicine
University of Baghdad
Baghdad, Iraq

Tiffany L. Hall, DVM, DACVIM, DACVECC
Associate
Internal Medicine and Critical Care
Equine Medical Center of Ocala
Ocala, Florida

Spring K. Halland, DVM, CVA, DACVIM
Assistant Professor
Large Animal Internal Medicine
Western University of Health Sciences College of Veterinary Medicine
Pomona, California

VetBooks.ir

Gayle D. Hallowell, MA, VetMB, PhD, CertVA, DACVIM-LAIM, DipACVECC, PFHEA, MRCVS
Professor in Veterinary Internal Medicine and Critical Care
School of Veterinary Medicine and Science
University of Nottingham
Sutton Bonington, Leicestershire, Great Britain

Joanne Hardy, DVM, PhD, DACVS, DACVECC
Clinical Associate Professor
Large Animal Clinical Sciences
Texas A&M University
College Station, Texas

Kelsey A. Hart, DVM, PhD, DACVIM (LAIM)
Associate Professor of Large Animal Internal Medicine
Department of Large Animal Medicine
University of Georgia
Athens, Georgia

Amanda K. Hartnack, DVM, MS, DACVS-LA
Assistant Professor
Veterinary Large Animal Clinical Sciences
Texas A&M University
College Station, Texas

Daniel A. Heinrich, DVM, DACVP
Assistant Clinical Professor, Clinical Pathology
Department of Veterinary Clinical Sciences, College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota

Meera Heller, DVM, PhD
Assistant Professor of Clinical Livestock Medicine
Veterinary Medicine and Epidemiology
University of California Davis
Davis, California

Troy Herthel, DVM, Dip. ACVS-LA
Staff Surgeon
Equine Surgery and Lameness
Alamo Pintado Equine Medical Center
Los Olivos, California

Sharon K. Hietala, PhD
Professor Emeritus
California Animal Health and Food Safety Laboratory
University of California, Davis
Davis, California

Kenneth W. Hinchcliff, BVSc, MS, PhD
Professor
Faculty of Veterinary Science
University of Melbourne,
Co-Editor-in-Chief
Journal of Veterinary Internal Medicine
Melbourne, Victoria, Australia;
President and CEO
Trinity College
Parkville, Victoria, Australia

Melissa T. Hines, DVM, PhD, DACVIM
Professor
Large Animal Clinical Sciences
University of Tennessee
Knoxville, Tennessee

John K. House, BSc, BVMS, PhD, DACVIM
Associate Professor
Livestock Veterinary Teaching and Research Unit
University of Sydney
Camden, New South Wales, Australia

Lynn R. Hovda, RPH, DVM, MS, DACVIM
Director of Veterinary Medicine
Veterinary Medicine
Safetycall International & Pet Poison Helpline
Bloomington, Minnesota;
Adjunct Assistant Professor
Dept of Veterinary & Biological Sciences
University of Minnesota College of Veterinary Medicine
St. Paul, Minnesota;
Chief Commission Veterinarian
Minnesota Racing Commission
Shakopee, Minnesota

Angela M. Hughes, DVM, PhD
Veterinary Genetics Research Manager
Research & Development
Wisdom Health
Vancouver, Washington

Pamela J. Hullinger, DVM, MPVM, DipACVPM, DACVPM
Director
California Animal Health and Food Safety Laboratory
University of California, Davis
Davis, California

PREFACE

VetBooks.ir

Large Animal Internal Medicine is an encyclopedic volume for the veterinary student or large animal veterinarian working with horses, cattle, sheep, or goats. Using the same popular format as the fifth edition, this edition provides the most current information available by utilizing more than 250 experts as authors. This edition contains additional pages of new color plates and more than 1210 figures, boxes, tables, color plates, and radiograph, ultrasound, computed tomography, and magnetic resonance images. The popular section on ultrasound of the equine abdomen has been updated and the ruminant abdominal ultrasound section completely rewritten by a new author. Many sections have been strengthened by the addition of outstanding new authors and new subjects, and chapters have been revised and improved with new references cited. Important new information regarding animal welfare is now included in Chapters 1 and 2 and new approaches to pain management described in Chapter 3. New genetic tests, which are rapidly developing, are described in Chapters 51 and 52. Many websites where important up-to-date information can be found are cited in this edition.

Problem-Oriented Approach to Disease Diagnosis

The catch-22 of most textbooks is that the clinician must know the diagnosis to locate and read about a specific disease. *Large Animal Internal Medicine* is formatted such that the early sections allow the clinician to use the problem-oriented approach to create a differential diagnosis for a vast number of diseases of horses, cattle, sheep, and goats. More than 130 clinical signs or manifestations of disease are discussed. They are listed alphabetically in Parts 2 and 3; this list can be used to locate a particular manifestation of disease. These same manifestations are listed by organ system at the beginning of Chapters 3 through 20. A favorite feature of the previous editions is the differential diagnosis boxes. These were largely created using Cornell's Consultant program, found at www.vet.cornell.edu/consultant. We have retained these invaluable diagnostic tools in this edition. Throughout Part 2, complete lists of common, less common, and uncommon diseases associated with manifestations or signs of disease are shown in these easy-to-find boxes. The clinician is given an approach to each manifestation of disease and a method to work toward a diagnosis. The pathophysiology of a particular manifestation of disease is concisely summarized. Even if a final diagnosis is not reached, the animal with diarrhea, cough, or other problem can be treated symptomatically, a practice that is commonly used in the everyday world.

Similarly, abnormalities in laboratory test results are discussed in Part 4, and complete lists of diseases associated with a given laboratory abnormality are found in easy-to-read boxes. Interpretation of abnormalities in clinical chemistry, hematology, blood proteins, clotting tests, and bone marrow is facilitated. For example, if the problem is elevated serum calcium, the causes of hypercalcemia are discussed concisely, and diseases associated with this abnormality are listed. The clinician can then proceed to a rational approach to the particular laboratory abnormality. Many readers have found the table for conversion from "American" units to SI units extremely useful.

Organization

The basic organization has not changed from the fifth edition. The book is divided into seven parts:

Part 1: History, Physical Examination, and Medical Records (with added material on welfare assessment)
Part 2: Manifestations of Disease
Part 3: Disorders and Management of the Neonate
Part 4: Collection of Samples and Interpretation of Laboratory Tests
Part 5: Disorders of the Organ Systems
Part 6: Preventive and Therapeutic Strategies
Part 7: Congenital, Hereditary, Immunologic, and Toxic Disorders

A neonatal disease section (Part 3), organized by presenting problem, includes everything from prepartum care, to care of the newborn, to solving problems ranging from diarrhea to septicemia of foals, calves, lambs, and kids. To aid the clinician in arriving at the proper diagnosis, lists of diseases are given for each manifestation of neonatal disease. Differences in approach to diagnosis or treatment of neonates and adult animals are cross-referenced throughout the text.

Part 5 is organized according to body system and includes internal medicine approaches. Diagnostic tests used in each system are described, including ultrasound (greatly expanded), endoscopy, radiography, thermography, computed tomography, magnetic resonance imaging, sample collection techniques, electrocardiography, cerebrospinal fluid collection, and biopsy of organs. Numerous illustrations include photographs, ultrasound images, radiographs, electrocardiogram tracings, and endoscopic views. Additional videos and images are available on the website. These chapters are written by experts in the field of large animal internal medicine and give details of the most up-to-date treatments available. *Large Animal Internal Medicine* complements existing texts dealing with current therapy.

Preventive and Therapeutic Strategies, Part 6, includes chapters with practical information on critical care and fluid therapy, antimicrobial therapy, infection control, prevention and detection of foreign animal diseases, vaccines and vaccination programs, and parasite control programs. Chapter 50 addresses nutrition of the sick animal and gives formulas for both enteral and parenteral support.

A detailed discussion of each disease is contained in Parts 5, 6, and 7 of *Large Animal Internal Medicine*. Once the reader has a list of diseases that fit the current problem, specific diseases can be found in these latter sections of the book. The organization is that of a traditional disease-oriented text:

Definition and Etiology
Clinical Signs and Differential Diagnosis
Clinical Pathology
Pathophysiology
Epidemiology
Necropsy Findings
Treatment and Prognosis
Prevention and Control

Chapters 51 and 52 deal with genetic disorders and genetic tests, most of which have only recently been developed.

Popular Features Retained

Color Inserts

Chapter 28, Collection and Analysis of Bone Marrow, includes color plates that show various bone marrow biopsy techniques and results. Chapter 31, Diseases of the Respiratory System, features 11 color plates. Chapter 32, Diseases of the Alimentary

VetBooks.ir

Tract, includes color plates that feature endoscopic views of equine alimentary tract disorders. Chapter 39, Diseases of the Eye, contains color plates of ophthalmologic conditions that are best depicted in full color. Chapter 40, Diseases of the Skin, features color plates of some dermatologic disorders, and Chapter 54, Disorders Caused by Toxicants, includes new photographs that show several important toxic plants.

Printed Endsheets

The printed endsheets found in the front and back of the text provide information that is referred to frequently:

- Manifestations of Disease
- Disorders and Management of the Neonate
- Collection of Samples and Interpretation of Laboratory Tests
- Reference Intervals for Ruminants and Horses
- Normal Values for Leukogram Data (Adult Animals)
- Normal Serum Protein Values for Horses, Cows, Sheep, and Goats
- Clinical Chemistry: Normal Range for Large Animals

New to This Edition

New Topics

The range of new topics is noteworthy. A sampling of new topics includes information on assessing animal welfare, the latest on pain management, additional information on colostrum supplements and substitutes, antigen detection tests and polymerase chain reaction, and new aspects of critical care. The neonatal chapters incorporate the latest in diagnostic and therapeutic modalities and techniques. The revised clinical pathology section includes four new experts as authors. The respiratory diseases chapter includes new findings on diagnosis and treatment options. Also included are new discussions on legal requirements for use of pharmaceuticals in food animals; infection control methods for a large animal hospital; and the prevention of, detection of, and response to foreign animal diseases. New genetic tests and the labs that perform them are included. Ultrasound images continue to be widely used, including a new section on the ruminant abdomen. National Research Council tables have been updated. Also included are advances in vaccines, diagnosing and treating temporohyoid osteopathy and bone fragility disease in horses, and advances in endocrine and muscle disorders. The section on snakebite has been expanded and the toxicology chapter completely rewritten.

Index

The index of *Large Animal Internal Medicine* is thorough and extensive, making it an easy-to-use reference to find the answer to any question you may have.

Acknowledgments

The motivation for undertaking *Large Animal Internal Medicine* came, in large part, from having been influenced in our professional careers by many teachers and colleagues with high standards. Our gratitude to them and respect for them runs deep. During our many years as teachers, we had the good fortune of working with many talented, inquisitive, and dedicated colleagues. Perhaps the individuals who have the greatest influence on a teacher are the students and residents who through their inquisitiveness keep us interested.

Many people worked hard to make *Large Animal Internal Medicine* the quality text that it is. More than 250 authors contributed in their area of expertise. This book would not be possible without them.

Special thanks to Jennifer Catando, Kathleen Nahm, Josh Rapplean, Rachel McMullen, Tara Delaney, and all the others at Elsevier who worked so hard on this project.

USE OF *CONSULTANT* FOR DEVELOPMENT OF THIS TEXTBOOK

Maurice E. White

Each edition of *Large Animal Internal Medicine* has been facilitated by the online diagnostic system *Consultant.*

Consultant comprises the thousands of diseases described in the veterinary literature; for each disease there is a brief description, references with links to journal articles, and clinical signs. *Consultant*, which I developed and have maintained at Cornell University's College of Veterinary Medicine, has been used by millions; by modem and discs from 1985–1997, on the web at http://www.vet.cornell.edu/consultant/consult.asp since 1997, and by Android and Apple apps since 2017.

Two characteristics of *Consultant* are the keys to its use for this textbook. Online editing is rapid, and information from the literature appears in the database quickly; this rapid updating combined with the large number of information sources allows *Consultant* to contain a breadth of up-to-date material. The second important factor is the ability of the user to enter a clinical sign or signs (e.g., cough, colic, abortion) for a given species and be presented with a list of diseases for which they have been reported.

Much of this textbook is organized by clinical signs. *Consultant* provided a broad overview of possible causes for clinical signs that authors were encouraged to incorporate into their lists of differential diagnoses. Contributors were encouraged to compress, rank, and add to *Consultant*-generated lists on the basis of clinical experience. The use of the database in this fashion assisted in the organization of sign-based chapters.

Consultant and this textbook are symbiotic. The database can be thought of as a generalist that knows some up-to-date information on almost every disease in veterinary medicine. Despite that, it remains merely a tool for the clinician who uses it. For example, there are dozens of causes of epistaxis in the horse, and it is simple to get a complete list of them from *Consultant.* The clinician must take that list and decide which causes to pursue in an individual patient, in what order, by what means, at what cost, and to what treatment or prognostic end. When such decisions must be made, expert opinions such as those found in this book are of great help. Cooperation such as that between *Consultant* and *Large Animal Internal Medicine* allows practitioners and students to benefit from the linkage between the tireless memory and ease of retrieval of the computer and the convenience of expert knowledge in book form.

CHAPTER 13

VIDEO 13.1
Examination of stifle for fluid effusion and joint laxity.

VIDEO 13.2
Regional intravenous anesthesia of the lower limb.

VIDEO 13.3
Visible instability of the stifle joint during walking associated with cranial cruciate ligament rupture.

VIDEO 13.4
Overflexion of the hock during weight bearing associated with partial rupture of the gastrocnemius muscle.

VIDEO 13.5
Bilateral intermittent spastic contracture of the gastrocnemius muscle associated with spastic syndrome.

CHAPTER 30

VIDEO 30.1
Left-to-right shunt *(green turbulent flow)* associated with a membranous VSD in a horse with AF and CHF. There is also a trace amount of AR. This is a video obtained from the right parasternal window.

VIDEO 30.2
Large VSD in a horse with Tetralogy of Fallot with an overriding aorta, right ventricular hypertrophy, and a post-stenotic dilatation of the pulmonary artery. This is a video obtained from the right parasternal window.

VIDEO 30.3
Long (A) and short (B) axis view of endocarditis lesions *(thick and round echoic areas)* on all three leaflets of the aortic valve in a horse presented for fever of unknown origin. These videos were obtained from the right parasternal window.

VIDEO 30.4
Vibrating left coronary cusp of the aortic valve with a parallel fibrous band lesion creating a high-velocity turbulent jet that is causing a vibration of the right coronary cusp of the aortic valve and concurrent vibration of the basilar (dorsal) portion of the interventricular septum in an aged horse with moderate to severe aortic regurgitation. This is a video obtained from the right parasternal window.

VIDEO 30.5
A small aortic root *(vessel in the center)* and the large pulmonary artery *(round circular vessel at lower right)* in a young horse with tachycardia and CHF secondary to a nutritional cardiomyopathy. This is a video obtained from the right parasternal window.

VIDEO 30.6
Severe myocardial dysfunction with poor left ventricular free wall and interventricular septal motion and a small pericardial effusion obtained from a young horse with nutritional cardiomyopathy. This is an image obtained from the right parasternal window.

VIDEO 30.7
Large pericardial effusion viewed from the left parasternal window showing smaller than normal cardiac chambers and right atrial collapse *(lower right chamber on the bottom right)* indicative of cardiac tamponade, obtained from a young horse with pericarditis. Notice also the small layer of echoic fibrin lining the epicardial surfaces of the heart.

CHAPTER 32

VIDEO 32.1
Focus on the biphasic contraction of the reticulum, which is recognized by its hyperechoic wall. Abomasal content and atrial wall of the rumen are observed when the reticulum is moving dorsally during contraction. (Courtesy Dr. Sébastien Buczinski.)

VIDEO 32.2
Small intestine peristalsis in a healthy Holstein cow. The intestinal content is seen moving as well as intestinal loops. Large variation of small intestine diameter is seen during peristalsis. The shape of intestinal loop is highly variable during contraction and allows the progression of small intestine content. (Courtesy Dr. Sébastien Buczinski.)

VIDEO 32.3
Small intestine ileus in a 3-day-old calf with atresia coli. The general small intestine motility is decreased by contrast in the previous video. Intestinal wall thickening is observed due to wall congestion. The small intestinal loops tend to be generally distended with little variation of shape (i.e., circular section). (Courtesy Dr. Sébastien Buczinski.)

Ruminant History, Physical Examination, Welfare Assessment, and Records

RONALD L. TERRA and JAMES P. REYNOLDS, *Consulting Editors*

Obtaining the History

Obtaining an anamnesis and performing a physical examination are the initial and often the most important diagnostic tests conducted in the diagnostic approach to the sick ruminant. The anamnesis can be performed before or during the physical examination and is accomplished by asking questions of the owner or manager. The signalment can be derived by either observation or questioning the owner. Information related to the chief, or presenting, complaint should be determined, especially the duration; whether the onset was gradual or sudden; and any associated signs that may have been noted. For females, one must know when the last parturition occurred, and for dairy cows, what the production parameters were in the previous lactation, as well as in the current lactation. With dairy cows a drop in milk production is often the only sign noted by the owner. Weight can be either approximated, via heart-girth measurements, or determined exactly if facilities exist. What and how the animal is fed are questions to be asked. Does the animal refuse any or all of the feed offered? Is there more than one ration or feeding regimen for this particular operation? If so, are these same signs noted in animals exposed to different feeding practices? The examiner also obtains vaccination and worming history and inquires about pasture or housing practices to determine the influence that management factors have on the incidence of the disease. Previous diseases noted in the herd, therapeutic regimens used, and resolutions of previous problems are pertinent aspects. Finally, the examiner should note the treatment history of the patient. An example of a history questionnaire that can be used for ruminants is included (Fig. 1.1). Specific problems that are noted in the history or physical examination can be found in the list at the beginning of Part Two: Manifestations of Disease, and lists of differential diagnoses can be considered. Alternatively, one can determine the pathophysiology(ies) that would present with the signs (problems) noted and then generate a list of diseases or disorders that would lead to that (those) pathophysiology(ies) noted.

Examination

A complete examination should always be performed even if the presenting complaint is easily recognizable. The physical examination provides the veterinarian with information that is used to assess the health status of the patient. This information, combined with that obtained while taking the history, enables the practitioner to determine which specific signs of disease are present (i.e., what the problem[s] is/are) and aids in the localization of the disease process to specific organ systems. Performing a physical examination also helps determine which ancillary diagnostic tests should be performed. Additional information gathered during the examination may reveal disorders other than the presenting complaint that warrant further attention and may have a profound influence on the prognosis of the case. Realistically, economic and temporal constraints preclude full examinations in some cases. In these situations the veterinarian must be familiar enough with the complete physical examination to know which aspects can be excluded and which should be performed.

A systematic approach to the animal must be developed and used in every physical examination. The first step is to form an initial overall impression by observing the animal from a distance. The animal is then restrained and examined topographically, beginning on one side, moving to the other, and then evaluating the rear and finally the head and neck. Thus individual organs and systems are examined completely, although disjointedly, and the information gained is correlated to form the complete diagnosis.

Visual Examination

As observations are made and a physical examination is performed, it is important to follow a systematic approach and to record findings. A checklist has been found to be extremely useful (Fig. 1.2). While observing the animal from a distance, the examiner should assess its posture, gait, behavior, and physical condition. Observation of the other members of the flock or herd helps differentiate normal from abnormal characteristics under each particular management system, because normal may vary from farm to farm and because what is considered "normal" for a farm by the owner or herdsman might actually be abnormal; this information is valuable for assessing the incidence of a disease or disorder that is caused by management. As more animals in more herds are observed, a background of knowledge is gained, allowing the practitioner to assess these management deficiencies more reliably.

The general appearance and conformation of the animal are included in determining posture. These are assessed in light of the age and breed of the patient. Determining abnormalities in posture can be difficult; however, noting these subtle changes can contribute greatly to the diagnosis of a disease process. Conformation is recognized by looking at the overall size and shape with particular regard to height, width, and relationship of the head, neck, and legs to the trunk. The general appearance of the patient in light of overall conformation can then be assessed. Determining a body condition score

can also be noted with other disease processes when these produce pain in the ventral abdomen. Lateral curvature of the spine could indicate a congenital defect or a chronic spinal lesion. Carrying the tail up away from the body is seen with conditions resulting in pain or irritation in the perineal region, vagina, or rectum. Standing with all four legs in the classic "saw-horse" stance with the neck and tail held erect is typical of tetanus. Abduction of the elbows is seen in disorders that cause thoracic pain. Lameness can be noted by observing unwillingness to bear weight fully on the affected limb while either standing or walking. Loss of extensor or flexor capabilities of the joints is seen in nerve paralysis or paresis; it can also

VetBooks.ir

be caused by tendon and/or joint contractures, in which case joints are rigid. Walking as if all four feet are sore may indicate laminitis. With bright and alert recumbent animals, a thorough examination to rule out fractures or severe joint trauma is essential. Once these have been ruled out, inability to stand may be indicative of generalized muscular paresis or paralysis. These can be of a primary nature, as with lesions within the spinal column causing cord compression, or secondary to mineral or electrolyte deficiencies (e.g., hypocalcemia, hypomagnesemia, hypokalemia).

To be able to judge the behavior of the animal as being normal or abnormal, the observer must call on a large amount of experience. Observing the animal from a distance allows assessment of eating and drinking behavior, as well as assessment of the subject as it is ruminating, urinating, and defecating. How the animal gets up or lies down and how it ambulates are important. Signs indicative of estrus or signs commonly seen with calving might be considered normal or abnormal, given the history and behavior of the animal during these events. Observing the patient during the milking process may also be beneficial. The influence of the manager on animal behavior is important, as is the overall temperament of the particular breed or herd in question. Normal animals react to the approach of a human being by moving away; however, those that have had extensive contact with people may be more inquisitive. Within a herd one can note animals that are more tolerant than others, more stubborn, more restless, and more anxious. These traits are not necessarily abnormal and need to be differentiated from behavior that would be considered secondary to disease. In general, one must determine whether the behavior is one of a depressed or apathetic animal or of a hyperexcitable or frenzied animal.

Nutritional status and physical condition are assessed by means of observation and palpation. Special attention is paid to the dewlap, the spinous processes of the thoracic and lumbar vertebrae, the transverse processes of the lumbar spine, the shoulder area, and the area around the tailhead. Determination of body condition will then result in a classification of the animal as being anywhere from severely emaciated or cachectic to extremely overconditioned or fat (see Chapter 9 for body scores). Next it must be determined whether the condition is of a primary or nutritional nature or the result of disease. Disease processes can influence or be influenced by the animal's body condition. Extremely thin animals are seen in primary undernutrition and also with chronic disease. Females carrying multiple fetuses and lactating animals with metabolic abnormalities secondary to abomasal displacements would also show signs of weight loss. Overconditioned animals are at greater risk for a wide variety of disorders primarily related to the accumulation of fat in the liver and excessive fat storage in the omentum.

Physical Examination

With the animal properly restrained, the physical examination can now progress to specific palpation, auscultation, and percussion. Obtaining a sample of urine for urinalysis is of great value if incorporated into the physical examination; it is easy to perform with the use of dipsticks such as N-Multistix (Bayer AG, Leverkusen, Germany). Stroking the perineal region can aid in eliciting urination in the female bovine; however, even this is futile if the animal is apprehensive. Consequently, it is recommended that this be done first, while the patient is still fairly relaxed. In the male, elicitation of urination is slightly more difficult and requires massaging of the preputial orifice. Another method is to wash the outside of the prepuce with warm water, but this is less successful. In the female sheep and goat, stroking the perineal area can be attempted, but positive results are rarely achieved. A method that has been reported but which causes the animal great stress is to prevent it from breathing until urination is stimulated. In male or castrated male sheep and goats, gentle massage of the prepuce sometimes results in urination. If that fails, the breath-holding technique can be used. Because of the extreme stress associated with this induced hypoxic state, the author cautions against using this technique and further recommends that it not be attempted on patients that are severely compromised because of any disease process. (See Chapter 22 for further information on interpretation of the urinalysis.)

TABLE 1.1

Normal Values for Temperature in the Ruminant[1-3]

Animal	Degrees Celsius	Degrees Fahrenheit
Cattle		
Adult	38-39	100.5-102.5
Calf	39-40.5	101.5-103
Sheep		
Adult	39-40	102-103.5
Lamb	39.5-40.5	102.5-104
Goat		
Adult	38.5-39.5	101.5-103.5
Kid	39-40.5	102-104

Body temperature is then measured with a rectal thermometer. Normal values for each species are given in Table 1.1. There are no absolute values, and the upper and lower limits should be adjusted as needed to account for ambient temperature and housing. For example, if the ambient temperature is greater than 37.5° C (100° F), a body temperature of 39.5° C (103° F) may still be considered normal for the adult bovine, especially if the animal is not allowed access to shade. When body temperatures approach 41° C (106° F), as a result of high ambient temperatures, heat stroke may occur. Keep in mind that the animal tries to maintain its body temperature within these normal limits, and marked deviation from the norm would be indicative of a disease process. A markedly elevated temperature is seen in acute, severe inflammatory processes. Pathologic lowering of the body temperature is seen in disorders that cause an inhibition of metabolism such as postparturient paresis, neonatal hypoglycemia, the end stages of a chronic disease, or severe septicemia resulting from gram-negative bacteria. There is a normal diurnal variation in body temperature of as much as 0.5° to 1° C (1° to 2° F). In the female there can also be a slight increase in temperature in the days preceding estrus. Neonates are poor thermoregulators and often have a normal body temperature that is 0.5° to 1° C (1° to 2° F) higher than that of adults.

In the evaluation of the thoracic and abdominal cavities, the initial step is the ballottement of the abdomen on the right side. Hearing "sloshing" sounds while performing this ballottement of the abdomen would be presumptive evidence of intraabdominal fluid. An increase in fluid being sequestered intraabdominally could be related to some degree of intestinal or ruminal stasis or associated with an increase in peritoneal fluid, as with peritonitis or ruptured bladder. Ballottement can also reveal whether any firm mass such as a fetus, impacted abomasum, abscess, or tumor is located in the abdomen. In goats the abdominal fat pad is quite prominent and tends to obscure any significant finding on ballottement. Deep palpation of the paralumbar fossa can sometimes reveal masses in this region, including lymphomas, fat necrosis, or abscesses. In goats, lambs, and calves, two hands are used to deeply palpate the abdomen; the normal freely movable left kidney is usually readily palpable. On the right side an enlarged or painful liver

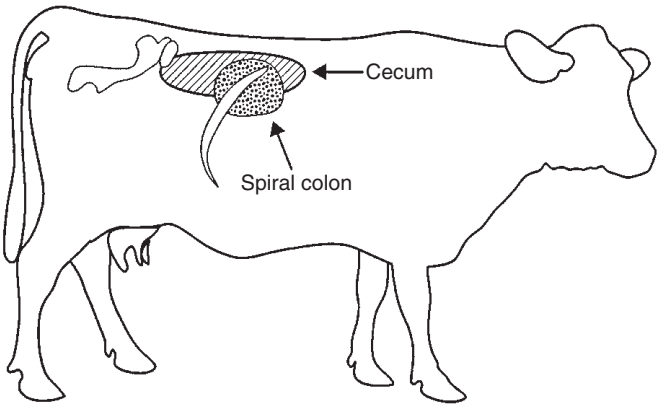

FIG. 1.3 Schematic representation of areas of gas pings elicited by percussion of the cecum and spiral colon.

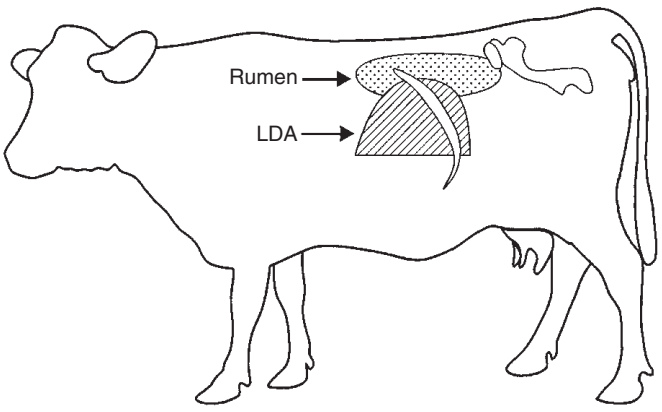

FIG. 1.5 Schematic representation of the area of the gas ping percussed in association with a left displaced abomasum *(LDA)* or gas ping in the rumen.

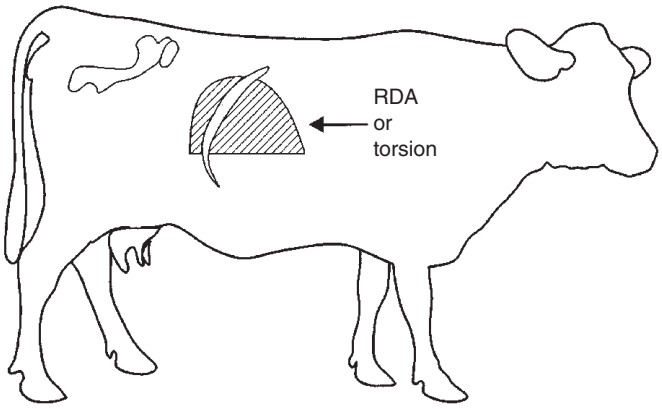

FIG. 1.4 Schematic representation of the area of the gas ping percussed in association with a right displaced abomasum *(RDA)* or abomasal torsion.

or kidney can be noted. Palpation of an abnormal swelling or firmness, especially with the elicitation of pain, indicates a problem that must be further evaluated.

The spinal column and ribcage are then palpated; the presence of fractures, enlargement of the costochondral junctions, or the elicitation of pain is noted. Enlargement or fractures of the costochondral junctions are commonly seen in young animals with deficiencies of calcium, copper, or vitamin D.

Auscultation with concurrent percussion by snapping the finger against the thoracic and abdominal walls is the next procedure. Gas trapped within abdominal viscera elicits a "pinging" sound that can be heard with the stethoscope. Localization of these gas pings to certain areas within the abdomen is helpful in determining which alimentary structure is involved (Figs. 1.3 to 1.5). If the cecum is enlarged and gas filled, an abdominal ping can be heard. This can extend caudally to the tuber coxae and cranially through the paralumbar fossa and under the ribcage on the right side (see Fig. 1.3). The diameter of this area can be variable and range from 6 inches (15 cm) in a cecal displacement to 3 feet (1 m) horizontally in cecal torsions. Spiral colon pings are generally localized to the right dorsocranial paralumbar fossa and rarely extend farther forward than the tenth intercostal space. They tend to be round areas 10 inches (25 cm) or less in diameter centered high under the last rib (see Fig. 1.3). Although commonly found in sick cattle that are anorectic, these spiral colon pings have no specific diagnostic significance and can be seen in normal cattle occasionally. Gas pings associated with a right-sided displacement or torsion of the abomasum can extend as far cranially as the ninth intercostal space and caudally into the paralumbar fossa (see Fig. 1.4). The diameter of displacements is usually 18 inches (45 cm), whereas that of torsions can be up to 3 feet (1 m). In cases of abomasal volvulus, the animal is usually exhibiting other systemic signs such as increased heart rate, dehydration, depression, scleral injection, and mild colic. In simple right-sided displacements or dilations of the abomasum, the only significant finding may be the small gas ping localized to the abomasum in a cow with depressed appetite and decreased milk production.

On the left side, gas pings can be noted as originating from the peritoneum, the rumen, or a left displaced abomasum (LDA). The auscultation of a gas ping that is primarily localized to the dorsal aspect of the paralumbar fossa and auscultable on both sides of the spinal column would be indicative of a pneumoperitoneum. The extent of these pings can be from the thoracolumbar junction caudally to the retroperitoneal space. Pings associated with ruminal tympany occupy the whole of the paralumbar fossa and can extend dorsally to the spinal column but generally do not extend over to the right side (see Fig. 1.5). LDA results in a gas ping that is localized, easily outlined, and approximately 12 to 18 inches (30 to 45 cm) in diameter. Caudal extent of the displacement is generally the 13th rib; however, it can extend into the paralumbar fossa, in which case the outline of the abomasum can be easily palpated. The LDA should ping over the 11th rib on a line from the hip to the elbow (see Fig. 1.5). Rumen gas associated with a left-sided ping will rarely ping at this location. Identification of a fluid line within the displacement can aid in diagnosis and is accomplished by balloting the left paralumbar fossa while auscultating the area of the gas ping concurrently, a process known as *succussion*. LDA often gives a pitch that changes in tone as it is percussed, as a result of movement of the rumen behind the abomasum. Often with LDA, intermittent gas bubbling or "sloshing fluid" sounds are heard. Rumen gas can be further differentiated from gas trapped in an LDA by rectal palpation of the rumen. One can also differentiate rumen gas from that trapped in an LDA by passage of a stomach tube into the rumen. Blowing into the rumen yields obviously auscultable sounds unless an LDA is present, in which case the sounds are muffled as the practitioner listens over the area of the ping. Performing a rumen or abomasal tap, the Liptac test, can further differentiate whether the ping originates from an LDA or the rumen. Fluid collected from an LDA would have a pH of less than 4, whereas that of the rumen should be 6 or higher, although cattle suffering from ruminal acidosis, or "grain overload," can have a ruminal pH approaching 4.

The rumen is examined by both auscultation and palpation. It should have a doughy texture with a small gas cap in its

Goat		
Adult	28	15-40
Kid	50	40-65

dorsal regions and usually is not distended above a plane formed by the coxofemoral joints. Increased accumulation of gas within the rumen would be seen with acute primary frothy bloat and also with free gas bloat. The rumen contractions should be counted, observed, and auscultated. Normally, primary ruminal contractions occur one and one-half to three times per minute, and the force of the contraction should displace the lateral body wall at least ½ to 1 inch (1 to 2 cm). When auscultated, the ruminal contraction sounds like a dull roar that starts quietly, rises to a peak, and dies away. Hypocalcemia and peritonitis are examples of disorders that result in weak or absent ruminal contractions. Hypermotility is rarely seen but can occur and has been described in association with vagal indigestion.

The cardiac region of the thorax is auscultated next. Heart rate and rhythm are determined at this time. Rate varies among species, and age differences within species are noted. In general, older or larger animals have a slower heart rate. Table 1.2 lists the ranges of heart rate that are considered normal for the ruminant species, depending on age. Tachycardia can be seen in animals that have been stressed or excited, as in the process of restraint. However, with time the rate should return to within a more normal range. Any deviation from the normal heart rate in a quiet, relaxed animal implies a general disturbance of the normal health of the animal. Increased heart rate can be seen with fever, inflammation, pain, hypocalcemia, or metabolic disturbances that result in hypovolemia. Bradycardia is seen with conduction disorders within the cardiac muscle and with some metabolic disorders (uremia, hypokalemia). The most common causes of arrhythmias are atrial fibrillation in adult cattle and hyperkalemia in diarrhetic neonates. Location and intensity of the heart sounds are also important to note, because muffling or displacement of the sounds can indicate space-occupying lesions within the thorax, pericardium, or mediastinum. With pericardial effusion the heart sounds are initially dull but develop splashy washing machine sounds as a gas-fluid interface develops. This often takes weeks. Normally the heart occupies a space on the ventral thorax between the third and sixth ribs. Most of the heart mass is located on the left side of the chest; thus the heart sounds should be louder on that side. However, if the heart is muffled on the left side and louder than normal on the right, one should consider the possibility of inflammation of the pericardium or lung lobes on the left side of the chest. Displacements of the heart sounds caudally are an indication of a space-occupying lesion in the anterior thorax or mediastinum, such as an abscess or neoplasm. Cranial displacements of the heart sounds would be noted with distention of the ruminoreticulum, eventration of abdominal viscera into the thorax through a diaphragmatic hernia, or other space-occupying lesions as noted previously. If any murmurs are noted on auscultation, an attempt should be made to localize the murmur to a specific heart valve. While the heart is auscultated, the pulse should also be palpated. The easiest point to find a pulse while the heart is being auscultated is at the vascular notch of the mandible where the facial artery is easily palpated. Pulse deficits in conjunction with an increase in heart rate are seen in atrial fibrillation and premature ventricular contractions. The heart rhythm is also noted. Dropped beats, gallop rhythm, and sinus arrhythmias should be compared with other clinical signs to determine importance.

The prefemoral and prescapular lymph nodes are palpated. Enlargements would be seen with inflammatory processes occurring in the regions that they drain. The skin is then palpated, starting along the top line and moving down over the abdominal and chest walls to the ventral midline. The presence of subcutaneous gas or edema is noted, as is any elicitation of pain. Emphysema can have iatrogenic causes (e.g., be secondary to abdominal surgery) or result from pulmonary alveolar rupture, gas gangrene, or puncture wounds. Edema, if noted, is usually ventral and is the result of lowered plasma oncotic pressure or increased venous pressure. Right-sided heart failure, as seen in traumatic reticulopericarditis, pericarditis, mediastinal masses, or severe pulmonary disease, results in increased venous pressure. If this is the case, a distention of the jugular veins with jugular pulse should also be evident. Protein-losing enteropathies or nephropathies are causes of lowered oncotic pressure, as is liver failure, which results in a lack of synthesis of plasma proteins. Fluid and gas from subcutaneous injection of large volumes of medications such as calcium gluconate can sometimes be confusing.

The thorax is then auscultated and percussed. Respiratory rate (Table 1.3) and pattern are determined at this time, and the lungs are auscultated. If increased inspiratory or expiratory effort is noted, it should be correlated with auscultatory and percussive findings in an effort to determine lung pathology. Normal ruminant lung sounds vary greatly among species. In calves, sheep, and goats the relatively thin chest wall allows one to hear inspiratory sounds ventrally and over the large airways, whereas expiratory sounds are minimal (except in sheep, where they are frequently audible because of the large amount of mucus in sheep airways). In larger cattle, only faint inspiratory sounds are normally heard. Lung sounds can be classified as normal or harsh (tubular) or as wheezes or crackles. These sounds can vary over the different areas of the thorax or can be found singularly over the entire lung field. Significant pulmonary pathology may be present in ruminants *without* any

VetBooks.ir

auscultatable abnormalities. Total absence of lung sounds ventrally indicates pleural effusion or pulmonary abscessation with loss of airways. When ventral consolidation of the lung occurs, airway sounds are transmitted well and easily heard ventrally as pipestem sounds similar to those heard over the trachea, whereas percussion reveals a marked increase in ventral lung density. The trachea should also be auscultated. Inspiratory dyspnea and stridor are usually the result of extrathoracic obstructions to airflow (nose, pharynx, larynx, extrathoracic trachea). Pneumothorax can also result in loss of auscultatable airway sounds, which may be absent dorsally or entirely over the entire side if the lung has collapsed completely.

Place the middle finger in the intercostal space and slap the finger with the opposite hand or use a tablespoon and rubber hammer to accomplish percussion of the chest wall to determine the ventral lung border. Percussion is most useful in goats and calves. In sheep the wool precludes effective use of the technique, and in adult cattle the chest wall is often too thick to effectively evaluate changes in percussion tones. The chest is percussed in a dorsal-to-ventral direction, moving caudal to cranial on the chest wall. A change in resonance is noted when the ventral border is reached; a line demarcating this change in resonance is the junction of the diaphragm to the thoracic wall. In the ruminant this line should be described by joining a point at the junction of the 11th rib and the epaxial musculature dorsally to a point at the middle of the 9th rib, then cranially to the point of the olecranon. The cranioventral portion of the percussed thorax is dull because of the heart field (≈3 inches [7.5 cm] above the olecranon in adult cattle; 1 to 2 inches [2.5 to 5 cm] in calves, sheep, and goats). Finding an increased area of dullness in the cranioventral lung field associated with harsh lung sounds would be an indication of lung consolidation as seen in *Pasteurella* pneumonia. Pulmonary emphysema (atypical interstitial pneumonia) should be considered when the lung field is larger than expected, the animal is dyspneic, and airway sounds are minimal, whereas a ventral border that is markedly elevated and in a straight line could be an indication of pleural effusion. In this case auscultation would reveal decreased lung sounds ventrally and possibly the presence of pleural friction rubs. Acoustic percussion of the lung field can extend into the chest only to a depth of 2 to 2 and ½ inches (5 to 6 cm); therefore lesions within the thoracic cavity that lie deeper than this cannot be percussed.

The next step in the physical examination is to assess for evidence of pain in the ventral portion of the abdomen and thorax. This can be accomplished through the use of the withers pinch test or by ballottement of the xiphoid region. The withers pinch test involves auscultating the trachea while the withers are simultaneously squeezed and pushed ventrally. Painful lesions result in the ruminant resisting normal ventral movement of the spine and/or emitting a grunt or holding its breath when this test is performed. Ballottement of the xiphoid is also done while the trachea is auscultated. The xiphoid region is pushed with a knee or struck with a closed fist, and an elicitation of a grunt would indicate pain in this region. The examiner can then ballotte the remainder of the ventral abdomen and thorax to classify the lesion as localized or diffuse. If localized, the region affected should be identified. It should be noted that the animal may kick the examiner during the xiphoid ballottement test; thus proper precautions should be taken.

The subcutaneous abdominal veins are assessed next and palpated along their length for the presence of thickened walls, distention, or pulses. Distention and pulses may be abnormal if they correlate with other clinical evidence of right-sided heart failure. Thickening of the wall or evidence of thrombosis is often a consequence of faulty intravenous injection of irritating substances or of injuries that result in hematomas or abscesses.

If the animal is lame or has postural abnormalities, the feet and legs are palpated next. If the animal is uncooperative, it may be necessary to sedate and/or cast it. If sedation is necessary, it should be performed at the end of the physical examination. Care should be exercised for obvious reasons. The examination consists of comparing one foreleg with the other and then comparing both with the expected norm. The same procedure is followed for the hind legs. Abnormalities in the shape of the claw may be hereditary or may be caused by nutritional deficiencies, poor leg conformation, poor housing, or as a sequela to laminitis. The coronary bands should be palpated for evidence of pain or increased heat. An attempt should be made to pick up all four feet individually and observe the soles and interdigital regions for necrotic areas, areas of bruising or swelling, draining tracts, or presence of foreign bodies. The fetlock, carpal and tarsal, stifle, and elbow joints are all easily accessible and should be examined for swelling, tenderness, edema, heat, instability, and crepitation. Each joint should be tested over its full range of motion, and any elicitation of pain should be noted. Physical findings should be consolidated into a decision as to whether the joint problems are infectious or traumatic. Sheep or goats with acute polyarthritis most commonly have mycoplasma or chlamydial infection. Chronic joint pain in goats (often with soft tissue thickening and enlargement caused by synovitis) is frequently attributable to caprine arthritis encephalomyelitis. Conformation of the legs should be analyzed because this could contribute to a joint or foot problem. The pelvic girdle does not lend itself to extensive examination; however, one can note symmetry or asymmetry and further evaluate during the rectal examination. Fractures of the tuber coxae, subluxation of the sacroiliac junction, acetabular fractures, fractures of the head or neck of the femur, and dislocation of the coxofemoral joint may all be diagnosed by evidence gained during palpation and observation of the pelvic area. The dislocated or fractured limb is frequently shorter than the normal opposite limb. The tail can also be examined for evidence of fractures, paresis, or paralysis.

The perineal region is examined by noting the external condition of the genitals and rectum. Anal sphincter tone can be assessed, and the presence of vaginal discharge can be noted. In males the testicles, spermatic cord, and epididymis should be palpated for the presence of nodules or areas of fibrosis. The testicular circumference can be measured and compared with what is expected for age and breed. These measurements are noted in Tables 1.4 and 1.5. The perineal part of the penis can be palpated for the presence of hematoma or swelling and pain (cellulitis or abscess). In the female the supramammary lymph nodes can be felt at the attachment of the udder to the perineum. Enlargement of these nodes occurs with mastitis or lymphosarcoma. The udder is palpated for the presence of fibrotic areas, commonly seen secondary to staphylococcal mastitis or associated with *Trueperella pyogenes* (formerly called *Arcanobacterium [Actinomyces] pyogenes*) abscesses. The presence of a swollen quarter or quarters with pain and heat may be associated with mastitis caused by gram-negative bacteria. Cold damp areas of skin on the udder that are discolored, necrotic, and possibly sloughing are evidence of gangrenous mastitis. In lactating animals, milk should be present in each quarter

TABLE 1.4

TABLE 1.5

Expected Values for the Scrotal Circumference of the Ram at Different Body Weights[5]

Body Weight (kg)	Scrotal Circumference (cm)
<45	23-27
45-70	27-33
70-90	30-36
90-115	31-37
115-135	33-38
135-160	36-40

and some of this milk should be expressed for examination. The milk should be of normal color and consistency and should not have any appreciable smell. The presence of leukocytic flakes or clots (garget) is an indication that the udder is mounting an inflammatory response. This response can be measured qualitatively by using the California Mastitis Test (CMT). One should also collect individual quarter samples from those quarters showing garget or those that test positive on the CMT for bacterial culture and sensitivity.

The next step is to evaluate the head and neck regions. The head should be symmetric in appearance, and any asymmetry should be evaluated to determine whether the deviation is caused by a neuromuscular or skeletal defect. Facial nerve paralysis results in one type of asymmetry, whereas a frontal sinusitis with concurrent displacement of the frontal bone appears differently. Discharges from the eyes, ears, nose, or mouth are noted and correlated with other physical findings. The oral cavity is examined by grasping the tongue with the hand and extending it out through the interdental space. Muscular tone of the tongue is evaluated at this time. The normal animal will resist extraction of the tongue and will quickly retract the tongue into the oral cavity when released. Increased ease of extraction and delayed retraction are indicative of diseases resulting in flaccid paralysis or paresis of skeletal muscle (e.g., as seen in botulism). The tongue and oral mucosa are examined for the presence of erosions, ulcerations, foreign bodies, or areas of necrosis. The dental arcade is evaluated for age of animal, absence of teeth, loose teeth, or necrotizing gingivitis. The color of the mucous membranes is noted. Icterus, pallor, hyperemia, cyanosis, excessive reddening, or brown "mud-colored" mucous membranes can all be noted, depending on the underlying disorder. Mucous membrane color is best evaluated in the eyes and/or vulva because of the presence of pigments in the oral mucosa of many ruminants. The smell of the breath is noted and, if fetid, might be an indication of a retropharyngeal abscess caused by trauma, lung abscess, or gangrenous pneumonia. If the breath is foul, deep palpation within the oral cavity for an abscess or necrotic area is indicated.

The mucous membranes of the nares are examined, and erosions and ulcerations are noted. Nasal discharges can be an indication of a pulmonic problem but can also be seen with sinusitis. Bilateral discharge is most commonly associated with pneumonia, and unilateral discharge is more often an indication of a sinus problem. However, percussion of the sinuses is necessary to fully evaluate the presence of a discharge. Normal sinuses percuss with a hollow sound, much like that of a hollow tree, and dullness on percussion might indicate sinusitis, sinus cyst, or other fluid or mass in the sinus.

The eyes are examined next. The sclera and mucous membranes are evaluated in much the same manner as the oral and nasal mucous membranes. The corneas are examined for the presence of opacities, discolorations, ulcerations, and lacerations. The position and size of the corneal opacities or ulcerations can be helpful in determining the cause. Foreign bodies such as plant awns and seeds beneath the third eyelid often cause opacity of the medial aspect of the cornea. Infectious bovine keratoconjunctivitis (pinkeye) is usually localized to the central cornea and causes severe corneal ulceration. When the mucosal diseases cause corneal opacities, they generally do so at the junction of the cornea and sclera and usually do not ulcerate the cornea. The anterior chamber should be examined for the presence of hyphema or hypopyon. These can sometimes be seen in animals with severe bacteremia, especially in neonates with failure of passive transfer. The animal should be evaluated for the presence of a menace reflex (absent in normal neonates for up to 2 weeks), and the pupillary light responses should be observed. Nystagmus and strabismus should be characterized, if present, because the direction is important in localizing the lesion. Nystagmus or strabismus or a deficit noted in the pupillary light reflex or menace reflex is indicative of underlying neurologic or ophthalmologic disease.

The ears should be palpated and evaluated as to their temperature and the presence of skin lesions. They should be warm to the touch. Ears that are cold are an indication that there is decreased blood flow to the periphery, as seen in hypocalcemic states, with decreased cardiac output, or in severe toxic states resulting in peripheral vasoconstriction. The presence of small crusty areas or erosions of the skin of the pinna is seen in some of the mucosal diseases such as bluetongue or bovine virus diarrhea. In sheep with acute bluetongue, edema of the face and ears sometimes occurs. If aural discharge or head tilt is present, the ear canal should be examined grossly and with the use of an otoscope for the presence of foreign body or parasites. Purulent discharge can be noted and is an indication of otitis externa. Noting that the eardrum has ruptured along with the purulent discharge is diagnostic of otitis media (and possibly otitis interna). Animals that have suffered trauma to the laryngeal or throat latch region and have a basisphenoid fracture can have bloody discharge from the aural canal. Correlation of the otoscopic findings with other clinical findings is necessary to arrive at a definitive diagnosis.

The palpable lymph nodes of the head and neck include the parotid, the submandibular, and the deep retropharyngeal. The deep retropharyngeal lymph nodes can be palpated externally, if enlarged, in the sheep, goat, and calf. They can be examined in the adult bovine by extending the hand through the mouth and palpating the pharynx. By keeping the animal's mouth open with one hand and guiding the other hand along the dorsum of the tongue to its base, the examiner can then extend the hand aborally into the pharynx. Enlargements of the deep retropharyngeals, abscesses, or other masses can then be palpated. The most common causes of masses or abscesses in the pharyngeal region are infectious or iatrogenic (e.g., secondary to trauma from a balling gun, paste wormer gun, or other instrument). The submandibular nodes are located in the intermandibular space and are identified by slipping the skin and underlying tissue through the fingers. These nodes are oval and about the size of a walnut, or 1 to 2 inches in diameter (2.5 to 5 cm). The parotid lymph nodes are almond shaped and are located just caudal to the ramus of the mandible and about 4 inches (10 cm) ventral to the ear. In overconditioned animals, the submandibular lymph nodes and the parotid lymph nodes are often impalpable due to the amount of fat deposited subcutaneously.

The skin of the neck is palpated, with attention paid to the presence of abscesses, lacerations, or other lesions. Skin turgor can be assessed by tenting the skin and measuring the time it takes for the skin to return to normal shape. This is used to determine the state of hydration. In normal, hydrated animals the skin returns to normal position within 1 second. Using other factors such as sunken eyes, dryness of mucous

membranes, abnormal heart rate, and degree of illness, an estimation of percent dehydration is made. Dehydration is first noted clinically when the animal is approximately 5% dehydrated, and death occurs at 12% to 15% dehydration.

The larynx should be palpated for enlargement and the presence of pain. The trachea should also be palpated for the presence of fractured tracheal rings, collapsed areas, and pain on palpation. The jugular veins are examined for the presence of distention and pulses. Thrombosed veins should also be noted because this condition may alter the desired course of therapy and often prevents placement of a catheter. The venous stasis test is performed on the jugular by holding off the vein in the midcervical region. Normally the vessel fills above the point of occlusion and remains collapsed below. With restricted venous blood flow, as seen in cases of right-sided heart failure, a positive stasis test can result. In these cases, the vessel below the occluded point fails to collapse or takes a prolonged time to do so and a jugular pulse is frequently present.

The final step in the physical examination is rectal palpation. This cannot be accomplished in small ruminants, so this section is directed primarily toward the bovine. The pelvic area is evaluated for the presence of retroperitoneal abscesses or fractures of the pelvic bones. The left kidney is more easily palpated than the right kidney because of its location within the abdominal cavity. Both kidneys are located to the right of midline, as the left kidney is displaced by the rumen and is located caudally to the right kidney. The kidney should be palpated for overall size and shape, which is normally lobulated in cattle, and the kidney can be gently squeezed to determine if pain is evident. The rumen should be palpated and the findings compared with those noted on percussion and auscultation. If there is any evidence of intraabdominal gas pings, an attempt should be made to palpate the suspected organ. This can provide information that may be helpful in determining therapeutic or diagnostic directions. The rectal palpation can reveal the presence of masses that were not palpable externally, such as fat necrosis or tumors. Adhesions and evidence of peritonitis can also be palpated rectally, and attempts should be made to localize them to a specific area of the abdomen to establish potential cause. The preiliac (or internal iliac) lymph nodes are located by sweeping the hand along the craniodorsal face of the ilium. These nodes normally have the size and shape of a walnut. Enlargements are noted with lymphosarcoma, peritonitis, and severe limb inflammation. The lymph nodes of the aortic bifurcation are small and not easily palpated. Their ability to be palpated would be evidence of abnormal enlargement. Palpation of the genital tract is directed toward establishing size, shape, and presence of abnormalities. These contents could be normal, as with a pregnant animal bearing a fetus, or abnormal, as seen with a pyometra. If it is determined that a cow is not pregnant, the ovaries and oviducts should be palpated for structures and abnormalities. In the bull, particular attention should be paid to the prostate, seminal vesicles, and bulbourethral gland.

Diagnostic imaging using an ultrasound probe in conjunction with rectal palpation can add to the information already gathered during the physical examination to further refine the problem and aid in prognostication and development of the therapeutic plan. Proper manipulation of the probe can allow for imaging the kidney, uterus, bladder, and rumen wall. Abnormal structures noted on palpation of the abdominal cavity can also be imaged. The accessory sex glands in the male can also be visualized.

Medical Record

The information gathered by means of the physical examination (see Fig. 1.2) is compiled and correlated with the data obtained during the history (see Fig. 1.1). A problem list should be formulated through the physical examination and anamnesis, leading to the development of a differential diagnosis list, a specific diagnostic plan, and a proposed course of therapy (Fig. 1.6). Prognosis can also be assessed with the information now in the examiner's hands. Accurate recording of the abnormalities noted during the examination should become part of the medical record and can prove valuable in following the course of the case. In addition, with each complete and accurate physical examination performed, the practitioner becomes more skilled in the procedure, adapting it to fit his or her needs, and using his or her time more efficiently. With the number of diagnostic tests available to the profession today, the information gained from the physical examination will allow the examiner to pick the tests that are specific for those disorders suspected, which saves the practitioner time and the client money.

As has been noted earlier, temporal and economic constraints sometimes preclude the performance of a complete physical examination. This is especially true when called to investigate a population-based disease/disorder case. In these instances, the practitioner needs to use aspects of the physical examination procedure outlined previously in order to arrive at a reliable presumptive diagnosis that can then be investigated further via the diagnostic plan. The affected population can be observed for signs of disease as previously described. The practitioner can look for evidence of pain, condition of the hair coat, body condition score, and variations in height or size or even shape of the affected animals along with their normal counterparts. Increased respiratory effort or rate can be noted from a distance, as can be discharges from body orifices. Mentation status can also be assessed. An effort should be made to try and determine the course of the disease on the basis of the signs of pain and/or disease noted. For example, in the case of a neonatal calf disease problem, the veterinarian would begin with the newborn and look for evidence of the disease/disorder while progressively observing older calves. Doing the investigation in this order would allow for determination of the onset of the disease (i.e., at what age group do you begin to see signs of the disease?), would allow one to determine progression of the disease as the calves age, and would allow one to get an idea of resolution of the disease process and allow for determination of any aftereffects of the disease. This same principle can also be applied to older ruminants, as one can begin with the animals that have just recently been through parturition and end with those that are approaching the end of gestation. While doing this, the veterinarian can also observe the feed bunks, the pens, the water troughs, etc. and gain great insight that could lead one to conclude that the disease process is primarily one that is management induced rather that pathogen induced.

Diagnostic Tests That Can Be Applied in the Field

Laboratory procedures can be performed in the field, the results of which would prove beneficial in the development of a diagnostic plan. These include the CMT, partial urinalysis (dipsticks), ruminal pH determination, and milk or blood progesterone tests. In addition, some serum chemistries can be performed cowside with the use of the i-Stat Serum Chemistry Analyzer (i-Stat Corporation, Princeton, N.J.).

The CMT is a simple procedure that aids in the detection of clinical or subclinical mastitis (see Chapter 36). This procedure is done routinely during all physical examinations of lactating cows. Partial urinalysis is accomplished by collecting the urine and using any one of a number of urine dipsticks that can be commercially obtained. With a suspected case of lactic acidosis, a rumen sample can be collected through the stomach tube or via percutaneous needle puncture and rumen pH can be determined. Most drugstores carry pH paper that can be used for this procedure; however, confirm that the

paper has a standard range, because certain papers are specific for the acidic or alkaline range. A rumen pH below 4.5 would be indicative of lactic acidosis. Numerous cowside progesterone assays that use either milk or blood as substrate have recently been developed. These can be relatively easy to use and interpret or they can be difficult, so discretion should be used when making initial purchases. These ancillary diagnostic procedures are explained in greater detail later in this text.

Assessing the Welfare of the Individual Animal or the Herd

Health includes the mental and physical aspects of animals. The World Health Organization defined health as "a state of complete physical, mental and social well-being and not just the absence of disease or infirmity."[6] Animal welfare is characterized by lives that are worth living.[7] This begins with providing for the physiologic needs of animals (housing, nutrition, disease, and injury prevention) and includes their mental/emotional well-being. The emotional status of animals has been termed *affective state*[8] and involves how animals are coping with their environments. Mental states of animals can be positive (enjoyment, comfort) or negative (anxiety, fear, or discomfort).

Welfare, including both physical and mental (emotional) components, is usually assessed using a combination of physical signs, behavioral observations, and sometimes references to the natural state of an animal. A physical examination for the health of an animal assesses each organ system to determine if the organ system is within normal limits or if abnormalities are found. An animal, or group of animals, is considered to be in ill health or to have disease when an observation or sign is outside the normal function or physiologic norm for that organ system. The same approach is applied to examining the welfare of animals: Understand what normal welfare is and assess the animals systematically to determine if welfare is compromised.

In some situations both welfare and health are compromised. Heat stress seriously affects physiology and thus both welfare and health. Animals are lame, an obvious health problem, because they have pain, a welfare problem.

Mastitis is a clinical health disease and can, in many cases, be painful. Poor nutrition not only makes an animal hungry but can result in compromised immune functions and increased risk of infection.

Welfare assessments often determine whether the Five Freedoms of Animal Welfare (Box 1.1) are being met. The Five Freedoms[9,10] categorize the basic elements of animal welfare and therefore allow determination of the state of an animal in each area. An animal has poor or compromised welfare if any of the Five Freedoms is not being met.

As a general example, nutrition is a basic need (food and water). Hunger or thirst for extended periods would be a compromise in this area. Overcrowding a pen could result in animals being unable to eat when they are hungry or drink when they are thirsty. Animals can experience distress with overcrowding from hindered access to feed and water, lack of ability to lie down when tired, or inability to avoid dominant or aggressive pen mates.

Assessing Welfare

The tools used to assess welfare in the field are mainly observation of animals for physical outcomes and behaviors that indicate affective states. A basic tenet of welfare is that housing should be clean, dry, and comfortable. The animals will show if that is the case: if the housing and lying areas are clean, then the areas they lie in are clean. If the housing and resting areas are comfortable, the animals will not have skin or leg lesions or abrasions from hard surfaces. Behaviors associated with compromised welfare include aggression, cannibalism, depression, and stereotypies. Stereotypies are what animals display to compensate for inabilities to express innate behaviors or for boredom. They include biting other animals, excessive licking or chewing, tongue rolling, and banging on enclosures. Scoring systems[11,12] have been developed or adapted to quantitatively assess four aspects of welfare (Table 1.6): body condition score, hygiene score, leg lesion score, and locomotion score.

These scoring systems are used in formal welfare audits and evaluations of dairy cattle, and species-specific systems can be used for other animals. Body condition scoring of 1 to 5 is used to assess nutrition. Hygiene scoring (1 to 4) of animals is used to determine if housing and lying areas are clean and dry. In cattle, leg lesions on hocks and knees indicate comfort on lying areas and are scored 1 (no lesions), 2 (hair loss), or 3 (swelling). Locomotion scoring (1 to 5) is used to determine if the animal is lame and to what degree. These scoring systems can be used to determine the welfare of individual animals or applied to groups and herds as averages to assess the welfare of farms.

Some aspects of welfare are not readily assessed by observing animals. These encompass painful or distressing procedures such as dehorning, castration surgery, parturition, and treatments, including treatments for lameness. These procedures can affect welfare if not done humanely. Also included in this area are situations that are infrequent, such as handling disabled or nonambulatory animals and animals that require euthanasia. These areas are not often observed during a welfare assessment and are therefore evaluated by reviewing protocols and training for these tasks. Reviews of procedures that will cause pain must include assessment of pain management including postprocedure analgesia.

The behavioral aspects of welfare are assessed by understanding the species-specific behaviors of animals and determining

BOX 1.1

Five Freedoms of Animal Welfare

1. Freedom from hunger and thirst
2. Freedom from discomfort
3. Freedom from pain, injury, or disease
4. Freedom to express normal behavior
5. Freedom from fear and distress

TABLE 1.6

Animal Scoring Systems Used to Evaluate the Welfare of Dairy Cattle

Animal Observation	Score Range	Welfare Parameter	Conformance
Body condition score	1-5 (thin to fat)	Nutrition	2-4
Hygiene score	1-4 (clean to dirty)	Sanitation	1 and 2
Leg lesion score	1-3 (no lesion to swelling)	Comfort	1
Locomotion score	1-5 (sound to non–weight bearing)	Lameness	1 and 2

VetBooks.ir

if the animals observed have the ability to express the fundamental behaviors considered important. The abilities to move, associate with other animals when desired, and lie in comfortable positions are considered basic behaviors of livestock. Species have specific behavioral needs, such as cud-chewing in ruminants and rooting in pigs. Welfare evaluation of the housing and management of animals must consider the animals' ability to express normal behaviors.

Pain, anxiety, and distress are affective states that need to be minimized for animals to have good welfare. Signs of pain in animals include depression, vocalization, increased heart and respiratory rates, protection of body parts, lameness, and decreased activity. Signs of anxiety and distress include facial expressions (eyes open, ears up); restlessness; tail movements; feet stamping; and avoidance behavior. Recognition of negative affective states allows correct evaluation of the emotional aspects of animals' conditions and allows for appropriate medical and nursing care for sick or injured animals and management of animals in production systems.

In conclusion, evaluation or assessment of the welfare of an animal or a group of animals is similar. The most generic version of a welfare assessment is the FARM program (http://www.nationaldairyfarm.com/animal-care#standardsapp). It includes the FARM (Farmers Assuring Responsible Management) manual that details most of the points discussed. The practitioner must understand what normal, or good, welfare is, and then through systematic evaluation of each of the Five Freedoms determine if an animal's welfare is normal/acceptable for that species or is compromised.

Insurance, Interstate, and Prepurchase Health Examinations

The complete physical examination as described in the preceding sections is necessary for a proper prepurchase or insurance examination. For insurance purposes a more complete accounting of the examination must be done. This means that all findings, whether normal or abnormal, have to be recorded. A specific form is generally provided by the insuring agent, and this should be used. Potential for future legal action also exists whenever an animal is insured; therefore it is in the practitioner's best interest to complete the insurance form accurately.

The prepurchase examination is similar to the insurance examination. The physical examination form (see Fig. 1.2) can be used to record findings. The prepurchase examination could be performed on the highly pedigreed female that is being consigned to sale, but it is more often performed on the male scheduled for use as an artificial insemination stud. Occasionally one could be asked to examine an animal under consideration for purchase. Experience indicates that the veterinarian should be employed by the potential buyer in these cases. This arrangement avoids any potential accusations of conflict of interest on the part of the examining veterinarian. A complete blood count and a chemistry panel should be run. Generally it is prudent to certify that the animal is healthy and to test for tuberculosis, brucellosis, and bovine leukosis (using agar gel immunodiffusion). Additional laboratory tests for anaplasmosis and bluetongue may be indicated. Often an animal being consigned to sale or one going into artificial insemination service is required to meet federal regulations for interstate shipment. This information can be obtained from the federal veterinarian in charge in your area or from the office of the state veterinarian in the state of destination.

A problem arises when the number of animals submitted for interstate health examination is large. Economic and temporal constraints usually preclude complete examination of all the animals presented. At such times the visual examination described earlier can prove helpful in determining which animals are to be singled out for the more complete physical examination. The examination of individuals is less complete than for prepurchase or insurance examinations because such factors as fertility are not at issue when filling out an interstate health certificate. Choosing animals with abnormalities in behavior, physical condition, gait, or posture allows the practitioner to concentrate on those that have the most potential to be diseased. Also, one can be fairly confident that if all the animals appear normal on the general examination, they are healthy and would be suitable for interstate shipment as long as the results of the intradermal tuberculosis test and required serologic tests prove negative. To sign an interstate health certificate, a veterinarian must be accredited and licensed in a state. It is essential that a veterinarian signing an interstate health certificate has examined the livestock sufficiently and diligently enough to be confident that no infectious or contagious diseases are present in the consigned group. A call should be placed to the office of the state veterinarian in the state of destination to be sure that all current requirements are fulfilled before shipment is scheduled.

Equine History, Physical Examination, Records, and Recognizing Abuse or Neglect in Patients*

KATHLEEN CASEY GONDA, *Consulting Editor*

Section 1

The ideal purpose of the physical examination is to determine what or if a problem exists. The results should be used to establish a diagnostic plan, prepare a therapeutic approach, and develop a prognosis as rapidly and efficiently as possible.

The nature of an internal medicine problem does not always allow for each objective of the physical examination to spontaneously or quickly generate either a diagnosis or a prognosis. More realistically, the examination process dictates the specific laboratory tests or procedures to be performed that support the diagnostic or therapeutic effort. The clinician's self-discipline regarding the extent of the physical examination should be guided by experience, efficiency of time, and judicious selection of the ancillary diagnostic aids that are available. A complete and extensive examination of each patient may not always be practical, especially in busy private or academic practice situations. In these cases the clinician should provide for the client's concerns with an expedient history and a pertinent physical examination process that addresses the client's complaint (e.g., a rectal examination is not required for an evaluation of a pneumonia patient).

Physical Examination Record

Preparation for the initial contact time with the client and patient should begin with a system of record keeping. Ambulatory records are usually more flexible than "in-house" hospital admission forms. Both field and clinic forms should include designated spaces for the client or agent's address and phone number. An area for the complete signalment (name, sex, breed, color, age, reproductive status), including an estimated weight, should be provided. If the patient is unnamed, as with foals, it should be listed in the dam's name with the year of birth (e.g., Curious '06). The sire's name should not be used because more than one foal per year would be expected from a stallion's crop. Whenever surrogate mares produce multiple foals from a single embryo transfer dam, a new system of naming and identification will have to be incorporated. Additional identification of the patient may include a lip tattoo, freeze brand, or microchip number and, if available, should be noted in the horse's record. Thoroughbred racehorses are tattooed under the lip with a letter, denoting the year foaled, followed by four or five numbers. Thoroughbreds foaled in 1997 have "A" as the first character in their tattoo, followed by those foaled in 1998 with a "B" as the first letter, and so on. Once the end of the alphabet is reached, the process is repeated. Numbering and lettering schemes used for lip tattoos and freeze marks vary, depending on breed registry, so one should consider breed or discipline carefully when using the number for aging or identification purposes. As of 2013, horses competing in U.S. Equestrian Federation (USEF)–sanctioned events for the first time are required to have microchips as part of their passport identification. ISO 11784– and ISO 11785–compliant microchips (resQ, Bayer Healthcare, LLC, Shawnee Mission, Kan; HomeAgain, Merck Animal Health USA, Madison, NJ.), the same as those required by the U.S. Department of Agriculture's voluntary Animal Disease Traceability program (previously the National Animal Identification System), must be used.[1] Microchips should be located on the near side of the horse, in the nuchal ligament, approximately 3 to 4 cm below the crest, in the middle third of the neck.

Equine Insurance

If the animal is insured, this should be documented, preferably with the insurer's telephone number. In addition, the type of insurance should be noted (e.g., mortality and/or surgical and medical). It is the client's or his or her agent's responsibility to notify the insurance company representative whenever an animal insured for full mortality contracts an illness or sustains an insult, life-threatening or not, that requires a veterinary examination. If the patient is insured, it is considered a professional courtesy for the veterinarian to also communicate directly with the insurance company, especially in the case of a life-threatening illness. Also, permission from the insurance company is required whenever a general anesthetic, surgical procedure, or euthanasia is to be performed. Whenever euthanasia is requested, the insurance company may require a second opinion from an adjusting veterinarian. If a direct representative from the insurance company cannot be contacted immediately, the clinician must exercise professional judgment in assuming the responsibility for a humane or critical decision. The client or agent should agree with the decision, and all communications and pertinent data should be documented in

*The author acknowledges previous contributions to this chapter by T. Douglas Byars.

VetBooks.ir

the medical record, including a signed euthanasia consent form, if applicable. If a necropsy is to be performed, it should preferably be done in the presence of another veterinarian from a different practice. The American Association of Equine Practitioners (AAEP) provides an insurance pamphlet as a guide to veterinarians.[2]

History

The medical history should be directed to the clinical problem. The "herd health" of the stable or farm can be assessed briefly as depicted by the vaccination and parasite control program and visually by the condition of other horses residing on the premises. The patient's individual problems should be determined according to such factors as clinical history of onset, feed and water consumption, fevers, and decrease in performance. In essence, the clinician must effectively zero in on the problems at hand, which may affect multiple body systems.

The diet (e.g., supplements, grazing environment), stall or housing schedule, and medical problems concerning other animals on the premises, which may coincide with a group incidence of the client's complaint, should be determined. When contagious disease is a concern, travel history of the patient or stablemates, including recent additions to the farm, should also be considered.

When a veterinarian is dealing with neonates, the reproductive and foaling history of the mare may be important in establishing an early diagnosis. Any compromise during a mare's gestational period (e.g., systemic disease, general anesthesia, or administration of certain medications), foaling, or lactation; any placental abnormalities; and any problems that occurred during previous pregnancies should be questioned and considered to be important, pertinent historical data. In some circumstances, the foal's breed should be considered and the possibility of genetic disease transmission by the dam and/or sire should be investigated (e.g., combined immunodeficiency in Arabians).

A description of the types of medication used before hospitalization may aid in determining if "masking" agents have inadvertently been administered. Tranquilizers or sedatives, which can cause confounding clinical signs of hypotension, bradycardia, lethargy, weakness, and ataxia, are frequently given for the horse's safety during transport. In many instances a van driver or hauler is unaware of medications used or the patient's medical condition. Sedatives (e.g., xylazine) and analgesics such as flunixin meglumine, administered by owners or farm staff in the hours or days prior, may mask signs of pain or colic and alter interpretation of the severity of the horse's condition on arrival. Failure of such an analgesic to abolish clinical signs may necessitate hospital or clinic admission for further evaluation or surgical consultation. Conversely, the failure of other previous medical treatments can aid in the initial selection of more appropriate therapeutic planning. Knowledge of the quantity and interval of administered drugs is pertinent information as well, particularly in hypovolemic animals given drugs known to be nephrotoxic (e.g., phenylbutazone).

Physical Examination

The extent of the physical examination will be subject to the condition of the patient, the environment where the examination is conducted (field vs. hospital), the equipment at hand, and the ancillary personnel available for restraint and procedural purposes. In a hospital setting the clinician should have immediate access to most of the equipment and diagnostic instrumentation listed in Box 2.1. The physical examination sheet should provide a systematic list of the organ systems being evaluated. Vital signs (temperature, pulse, and respiratory rate) should be documented in the "calm" animal, if possible (Table 2.1).

TABLE 2.1

Heart rate (Beats/Min)	28-44	50-70
Respiration (Breaths/Min)	8-15	20-40

[a]Heart and respiratory rates vary depending on level of excitement and autonomic stimulation.

BOX 2.1

Recommended Examination Room Equipment and Ancillary Services

Examination Room Equipment

Records (examination sheet, request forms, and euthanasia forms)
Thermometer
Clock with second hand
Stethoscope
Twitch
Rectal sleeves, sterile examination gloves and lubricants
Nasogastric tubes in various diameters/lengths
Hand pump
Hoof knife and testers
Ophthalmoscope/Otoscope
Dental speculum
Endoscope (1-, 2-, and 3-meter lengths)
Electrocardiogram (ECG) machine
Ultrasound (linear or sector scanner)
Sphygmomanometer and Doppler (tail or limb)
High-volume fluid pump
Refrigerator
Incubator
Oxygen (O_2) tank and foal mask
Culture swabs, transport media, blood culture bottles
Video equipment

Ancillary Services

Radiology and imaging services
Ultrasound consultation
Laboratory services

Abnormal findings are described in an appropriate space provided, usually below the body systems checklist. Using the same numeral for each body system throughout the examination process and in problem identification is useful for future caseload recall, especially if a computer is used and codes can be applied to clinical findings and diagnosis. At the completion of the physical examination, the major problems identified are listed, and appropriate laboratory tests can be requested. The final diagnosis is seldom determined at the time of the initial examination; however, the final diagnosis represents the final assessment and should be filled in at the appropriate time (e.g., hospital discharge).

A general evaluation of the equine patient should be made from afar. This is particularly important for neonates at the side of their dams. The initial observations of body condition, posture, weakness, lethargy, incoordination, lameness, and musculoskeletal asymmetry are more easily observed at a slight distance from the patient. The integumentary system can usually be evaluated quickly as to the type, distribution, and number of lesions and site and layer of involvement. However, subtle lesions of petechia and ecchymosis cannot be visualized in the integument because the hair coat and pigment hide lesions that

VetBooks.ir

are obvious in other species, such as purpura of nonpigmented humans and pigs. In these instances the mucous membranes must be examined as an extension of the integumentary system. If obvious multiple lesions of the skin are present, documentation is usually expedited by photographing or drawing a picture of the horse and indicating the distribution of the lesions on both sides (see Chapter 11). Gross generalized distortions (e.g., anasarca) may be viewed as lesions of possibly more than one body system (integumentary and circulatory).

Abnormalities in demeanor and mentation can be assessed by watching the horse's initial response to the environment and again once the physical examination and interaction with the patient begins. Whatever the approach, the physical examination should be systematic and orderly, so as not to miss subtle features in the face of obvious abnormalities. In general, most examinations start at the head, so as not to startle the horse or foal and to prevent possible injury to the veterinarian who may be unfamiliar with the horse's temperament or previous handling experience. Evaluation of facial symmetry and cranial nerve function can be accomplished with minimal handling or manipulation. The eyes can be examined by a rapid visual assessment using a penlight. The cornea and cranial and caudal lens capsules can be evaluated by horizontally moving the penlight and noting the crossing light reflexes. Pupillary constriction to light and the "menace" response should be observed, although these reflexes may be significantly slower or absent in the neonate. An ophthalmoscope retinal examination should be performed whenever the eyes represent the primary complaint, and fluorescein dye should be used to detect corneal ulcers before the installation of other ophthalmic agents. Blindfolding one eye at a time may aid in the assessment of unilateral blindness and should be conducted in a safe area with "blunt" devices contrived as an obstacle course.

Evaluation of the circulatory system starts with assessment of heart rate, rhythm, and any presence of murmurs. Mucous membrane color, capillary refill time, scleral injection, palpable changes in the temperature of the ears and extremities, jugular pulsation, and pitting subcutaneous edema are the most common obvious circulatory physical examination parameters. The heart should be auscultated bilaterally, and murmurs should be graded according to intensity (I to VI or I to V), character, valve site, and phase of the cardiac cycle. Cardiac arrhythmias usually necessitate an electrocardiogram (ECG), except in the case of type II atrioventricular block, a normal finding commonly observed in clinically asymptomatic horses. Type II heart block in normal horses can usually be obliterated by exciting the horse with a threatening gesture or trotting the horse a few steps to increase the heart rate. In addition to electrocardiography, transcutaneous ultrasound examination of the heart and pericardium and transrectal evaluation of the caudal aorta and iliac arteries for intraabdominal thrombotic lesions can be used.[3] If procedural assessments of blood pressure are necessary, a manometer for central venous pressure or a sphygmomanometer with Doppler ultrasound is used on the base of the tail in foals[4] and adults.[5]

The respiratory system is similar to the circulatory system in that the breathing rate and mucous membrane color are important assessments. A quick visual assessment of the alar folds may identify conformational abnormalities or indicate severe compromise (e.g., nostril flaring). Respiratory effort and the phase of increased work should be assessed (e.g., increased expiratory effort with "heaves"). Nasal airflow can be determined by wetting the hands and holding them gently over the nostrils so that both intensity and equality of air movement can be assessed. The color (e.g., blood tinged), character, and amount of any nasal discharge should be noted and indicated whether it is present in one or both nostrils. A penlight can be used to visualize the internal nares (septal mucosa). Smelling the breath for fetid or necrotic odors (ozena) is similarly important, and endoscopic evaluation of the upper airways should be an adjunct to abnormal clinical findings. Percussion of the sinuses should be performed for detection of dullness, suggesting a possible mass (e.g., ethmoid hematoma), sinusitis, or the presence of fluid within the sinus cavity. In addition, the head should be carefully examined ventrally and caudally for the presence of lymphadenopathy. Auscultation should be of both the upper (larynx and trachea) and the lower airways. In horses with equivocal lower airway findings, a rebreathing bag can be used to accentuate abnormal sounds by increasing the respiratory rate and volume of inspired air. The interpretation of lung sounds has been described elsewhere,[6] and the clinician should try to auscultate dorsal and ventral regions of the thorax bilaterally and document findings as to the location or absence of sounds and the phase of respirations involved. Coughing in horses with upper and lower respiratory disease is variable.

Percussion of the thorax is a reliable clinical tool and should be performed in cases of suspected abscess, tumor, or pleural effusion. A pleximeter and tablespoon are the only tools required, although some clinicians are adept at direct finger percussion of the chest. In foals, percussion can be performed by placing a stethoscope on one side of the chest and reaching over the back of the foal to manually percuss the opposite side. Fractured ribs may be recognized in the neonatal foal as palpable asymmetry or a bony crepitus ("clicks"), often with edema of the sternum or elbow coinciding with the fractured side. Horses with pleuropneumonia may exhibit a reluctance to move (pleurodynia) similar to that seen in horses with laminitis, which is a possible sequela to endotoxemia caused by gram-negative bacterial pneumonia.[7]

Ultrasound has revolutionized the clinical evaluation of the thoracic cavity. Unfortunately, the familiarity of clinicians with thoracic interpretation is directly related to access to and frequency of ultrasound use. However, subtle pneumonia, abscess, and pleural effusion represent definitive objective findings and can be identified rapidly with little or no stress to the patient.[8] Because radiographic changes often lag behind clinical disease, serial examinations via ultrasound may be a more accurate way of monitoring response to treatment. In fact, ultrasound examinations may eliminate the need for chest radiographs in numerous cases, thereby increasing efficiency and decreasing client costs.

A systematic approach should always be used when examining the horse for gastrointestinal disease. Although most emergencies and referrals are related to colic or acute intestinal disease, the clinician should resist the temptation to focus only on the abdomen, so that important clinical signs relating to other problems (e.g., gastric ulceration, botulism) are not missed. If a clinical complaint involving the abdomen is present or in suspected cases of intestinal displacement, obstruction, or volvulus, the gastrointestinal system is initially examined with bilateral auscultation of intestinal sounds by dividing the abdomen into four quadrants. Intestinal borborygmi vary by location, and in the cecum and ascending colon propulsive contractions tend to occur in waves, with periods of quiescence, over several minutes. In general, small intestinal sounds are the least dramatic, heard in the area of the left flank. In addition, the abdomen should be auscultated ventrally for sounds similar to "ocean waves" or sand pouring on itself, indicative of the presence of sand within the gastrointestinal tract.[9] The presence of increased (hypermotile), reduced, or absent borborygmi (ileus) should be considered an important feature of the physical examination. It is helpful to document the activity or lack thereof in each of the four abdominal quadrants, especially in hospitalized patients where different clinicians may be monitoring the patient over several days. In cases in which the gastrointestinal tract is the site of the primary lesion, checking for gastric reflux and performing a rectal examination are required elements.

VetBooks.ir

Although only about 40% of the gastrointestinal tract can be reached by palpation, it is a valuable technique that can quickly identify surgical cases and affect survival.[10] Clinicians should strive to become adept at rectal palpation and regard the procedure as a premier diagnostic skill while also respecting the risks involved for the patient and veterinarian.

The patient should be observed for the presence of normal prehension, eating, and drinking whenever dysphagia is present or neurologic dysfunction is suspected. A subjective assessment of tongue strength and tone can be made by carefully grasping the tongue. Normal horses will pull against the hand and, once the tongue is released, replace it immediately in the mouth. The evaluation of the gastrointestinal system should also include a dental examination for the presence of malocclusion and dental abnormalities (e.g., missing or damaged teeth, tooth root abscess) that can affect prehension or mastication. Use of a dental speculum is required for safe and complete examination of the dental arcade and adjacent soft tissues. Accurate notation of affected teeth should be made in the medical record using a universally accepted identification system such as a numeric system in which the horse's head is divided into four quadrants, with each tooth described by its own number (e.g., two central upper incisors on horse's right and left would be 101 and 201, respectively). Clinicians should also become adept at dental age determinations, albeit with an awareness of its limitations and subjectivity.[11] Nasogastric intubation is useful in evaluating dysphagia and esophageal blockage (choke) and determining the presence or absence of gastric reflux. In addition, the volume and character (e.g., color, pH, presence of blood or toxic plant material) of reflux obtained can be rapidly evaluated and may aid in the diagnosis.

The use of long endoscopes (e.g., 2 to 3 m) is valuable in the visual assessment of the esophagus and stomach with lesions such as esophageal stricture and gastric ulceration. For a diagnostic endoscopic examination of the stomach, it is recommended that the patient be muzzled or held off feed for at least 10 hours to allow complete visualization of the stomach.[12]

Ultrasound evaluation of the abdomen in conjunction with aspiration and analysis of visualized abdominal fluid may quickly reveal peritonitis, uroperitoneum, hemorrhage, ascites, visceral rupture, or abdominal masses. In adults, palpable abdominal masses and enlarged lymph nodes can usually be scanned transrectally.

The urogenital system can be examined by manual palpation, rectal palpation, vaginoscopic (speculum examination) viewing, endoscopy, and ultrasound. The caudal portion of the left kidney is easily palpated in most horses. Uterine and catheterized samples (e.g., cultures, urinalysis) should be obtained before any contaminating invasive procedures (e.g., rectal palpation) are performed and before fluid therapy is initiated. Sphincter tone may be subjectively or objectively (urethral pressure profile) assessed in horses with urinary incontinence or stranguria. Horses with incontinence often demonstrate "scalding" of the perineum and hind legs, and foals with a patent urachus may dribble urine from a moist umbilical stump.

Examination of the neurologic system should involve a consistent procedure for all patients with nervous system disorders (see Chapters 8 and 35). The patient's attitude, posture, and head carriage should be assessed from afar. The cranial nerves should be evaluated, followed by examination of the spinal reflexes and tail tone. Sensory deficits should be noted at this time. Conscious proprioception and postural responses (e.g., placement, hemi-hopping, sway) can then be assessed before observing the patient in locomotion. Notes regarding symmetry, ambulation, paresis, muscle atrophy, and upper and lower motor neuron deficits should be documented to aid in determining the sites for any additional ancillary tests such as radiographs, cerebral spinal fluid collection, or myelogram. Blindfolding should be conducted in a safe area, especially for patients with vestibular disease. An area of incline is useful for evaluating the locomotor deficits, especially when the horse is led with the head elevated.

The lymphatic system is usually evaluated merely by recording any obvious lymphadenopathy. This can be regional or local (as in strangles) or generalized (cutaneous lymphosarcoma) and may be appreciated on rectal examination. Lymphangitis or the presence of edema should also be noted.

For the internist, evaluation of the musculoskeletal system usually involves a rudimentary examination of the site and appearance of the disease processes. Primary lameness is more commonly evaluated by clinicians familiar with diagnostic nerve blocks, arthrocentesis methods (e.g., septic arthritis in foals), and radiographic findings. It should be noted that acute (caused by fracture) or chronic lameness can coexist with primary neurologic disorders (e.g., equine protozoal myeloencephalitis). Therefore, when warranted, the patient should receive a cursory neurologic evaluation (see Chapter 8) in conjunction with the musculoskeletal examination. Conversely, all horses presenting with systemic illness (pneumonia, colitis) should also be evaluated for signs of laminitis in all four feet because this complication is often the limiting factor for the horse's survival. Visual inspection of the hoof wall and sole may indicate previous laminitic episodes and should be documented because this may increase the patient's risk and lower the threshold for repeat episodes. Careful palpation of the lower limbs may indicate increased intensity of digital pulses or changes in the coronary band that may be related to the "sinker" syndrome (distal phalangeal displacement).[13] If laminitis is present as a complicating factor, the clinician should be able to add to the clinical prognosis by using Obel grading (grades 1 to 4).

Once a patient has been admitted to the clinic or hospital, well-organized flow charts should be used for monitoring and assessing the patient.

Use of Ancillary Equipment in the Examination Procedure

Advancing technologies are allowing the practitioner or clinician to add to or replace many physical examination procedures with techniques capable of providing more rapid diagnostic information or direct therapeutic intervention. Ultrasound of the chest for the definitive diagnosis of a pleural effusion is an example of an objective procedure that may obviate many of the traditional physical examination procedures used for the clinical diagnosis of pleuropneumonia (e.g., auscultation, percussion). Though less commonly used by the internist, the advent of portable digital radiography has dramatically improved the efficiency of obtaining quality films without additional trips and repeated exposure of staff and patient.

The size of equipment is a determining factor in whether a diagnostic tool is suitable for the examination area. For example, equipment such as computerized axial tomography scanners, magnetic resonance imaging (MRI) units, and nuclear scintigraphy units do not currently fit in the spaces available in most hospital physical plants. Large, modular ultrasound machines can be cumbersome in small areas, although units for field reproductive use (linear or sector scanners) are appropriate for any area, including vehicle transport. The choice of ultrasound equipment is an individual decision based on need, budget, and availability. Security should also be a consideration in stocking an examination area with equipment and medications. The clinical examination areas of most facilities tend to be high-traffic regions; this may be a primary reason for not stocking certain pieces of equipment in both university practices and private facilities.

Medical Record

In 1968 Lawrence Weed published on the use of the problem-oriented medical record. This system of record keeping

VetBooks.ir

emphasizes the justifications for daily decision making during hospitalization. Problems are defined by the history, physical examination, and laboratory findings. Daily (or more frequently for intensive care unit patients) *s*ubjective findings (e.g., appetite, attitude) are documented, and *o*bjective data (e.g., heart rate, temperature) are recorded. This information (e.g., patient is febrile) is then *a*ssessed by the clinician, and a *p*lan (e.g., resubmit laboratory tests, change antibiotic medications) is derived based on the assessment. The abbreviated form of this type of medical record is SOAP, and this method is applied to each problem identified. Although the system encourages medical judgment and accountability, it more directly serves as a teaching tool within institutions by which the student's clinical thinking can be evaluated by the in-charge clinician. In private practices the method of record keeping is more flexible and tends to document vital information that primarily serves as an accounting of services and provides a medicolegal record. Unfortunately, many medical records function only as invoices and do not record medical information regarding the patient. This is more often true of ambulatory records but can be found in certain hospital practices. State veterinary regulatory bodies have strict requirements regarding the patient medical record, with particular regard to the administration and cross-documentation of controlled substances (e.g., ketamine, butorphanol) and euthanasia solutions. Whichever system is used, the responsibly prepared medical record should provide medical information, justification for charges, a protection from liability, and adherence to state and federal regulations. A thorough medical record further allows for the retrieval of retrospective information. The accumulation of data is beneficial to the communication of clinical caseload experiences to other clinicians for the benefit of their patients.

Medical Record Filing

Two major systems of medical record filing exist: numeric and name filing. Numeric systems offer consistency of the record and avoid the confusion of patients with similar names. The problem of name similarity is primarily confined to the nonregistered breeds of horses. Breed registration requires name approval to avoid duplication, among other undesirable designations. Again, for record-keeping purposes, clinic or ambulatory records for unnamed young horses are best designated by the dam's name and the foal's year of birth (e.g., Curious '06) and filed by month and year of examination. A "master" admission log should be maintained for record retrieval purposes, especially when a patient has been seen on multiple occasions. Color coding, along with numbering of the file folders, may be helpful in record retrieval. Computers offer the advantage that records can be retrieved through any one of several recall parameters (e.g., problem, client).

Computer-Generated Medical Records

Traditionally, patient medical records (PMRs) are maintained via a manual, paper-based, on-site system of data storage and retrieval as described previously. Before computerization and its acceptance by the medical community, all information regarding patient history, diagnostic testing, and treatment notes was handwritten and filed. Unfortunately, a number of problems coexist with a paper-based system, including illegible handwriting by practitioners or staff, poor integration of patient information (e.g., diagnostic test results and imaging studies filed separately from the PMR), and loss of or damage to files.[14] In addition, state veterinary boards require that all patient records and imaging studies be retained by a practice for a minimum period of time before they can legally be disposed of. Storage issues can be a problem for equine practices that do many prepurchase examinations, in which radiographs may be retained for 10 to 20 years. Although many veterinary facilities currently use computers for various tasks such as accounting and inventory, few have eliminated the paper-based PMR completely.

Computers offer the advantages of legibility, quick data retrieval, and immense archiving capacity. The need for rapid transfer of medical information from doctor to doctor or from doctor to referral facility is being met by advances in computer software and Internet access. Thus the current trend in human and veterinary medicine is the development and implementation of an electronic medical record (EMR) that is entirely computer generated. An EMR permits one or more individuals, simultaneously, to access laboratory results, imaging studies, and other pertinent patient information.[15] For the equine practitioner, the availability of real-time ultrasound imaging and digital radiography has revolutionized the production and transmission of high-quality diagnostic images, via computer, within moments after they have been taken. This has greatly increased the quality of medicine and efficiency of patient care, allowing general practitioners rapid access to the opinions of specialists at sites distant from the patient. Over time, acceptance of the EMR may result in the complete dissolution of the paper-based medical record.

Several software systems have been designed specifically for equine hospitals and include adaptations for ambulatory "off-site" data entry and retrieval (Henry Schein Veterinary Solutions, Piedmont, Mo.; Business Infusions, Calgary, Canada).

In addition to patient information, other applications such as client invoicing, inventory management, and payroll are included in certain software packages. Recently, voice recognition software has been adapted for use by veterinarians (Dragon Veterinary, Antigonish, Canada) and can be added to most software packages and implemented by using either a specialized microphone plugged into an in-house computer or a "cloud"-based mobile phone application. This system promises to improve efficiency and accuracy and save time by allowing ambulatory practitioners to enter data directly into the EMR through the app on their mobile phone at any time, either during the examination or while traveling between client locations.

Three basic types of systems are currently available to the equine practitioner: standalone and multiuser on-site systems; on-site systems with external synchronization; and Internet-based multiuser systems. The first and second types of systems are similar, but with the addition of external synchronization, patient information can be collected on handheld devices or laptop computers away from the main hospital (e.g., by ambulatory staff) and downloaded directly to an in-house computer. The third system is the most technologically advanced and offers not only greater efficiency but also the ability to continuously upgrade software. This system offers access to the Internet through either a hospital web page or a client Internet server and allows practitioners in the field the ability to transmit information such as digital radiographs immediately to other doctors, referral hospitals, or specialists throughout the world. These connections can be made via wireless (e.g., mobile phone) or direct Internet access (e.g., phone line, cable). Currently, IDEXX Laboratories in Westbrook, Maine, and VCA Antech, Inc. in Los Angeles can send test results directly to the PMR as soon as they are available. Another advantage of this system is that all information contained in the EMR can be stored on an off-site server and downloaded to the hard drives of in-house computers.

This technology can be a cost-effective, important tool in modern practice management that increases efficiency and quality of patient care and dramatically reduces storage requirements.

Record Keeping for Special Purposes

The U.S. Drug Enforcement Administration (DEA) requires veterinary practices to maintain detailed inventory records for scheduled drugs. Drug inventory and use must be recorded in a readily retrievable medical record. Requirements may vary

by state, so consultation with state regulatory agencies is prudent. Use should identify the patient, volume used/wasted, date, and authorized person who obtained the drug. The drug use should be further documented in the PMR to account for the volume having been depleted from the inventory. For scheduled drugs, states may vary as to the required timing and frequency of inventory accounting and/or inspection for veterinary practices, including ambulatory vehicles.

Occupational Safety and Health Administration (OSHA) records are comparable to the DEA ongoing inventory and use records and are stringent in terms of compliance with OSHA regulations.[16] Documentation regarding safety procedures (e.g., fire safety inspections) is required after an initial inspection for labeling and safety protocol. Upgrading of Material Safety Data Sheets (MSDSs) is a further requirement and should comply with current standards.

Section 2

Recognizing Abuse and Neglect in Equine Patients

According to the American Horse Council statistics from 2005, approximately 9.2 million horses live in the United States. During the past decade, equine welfare has come to the forefront as one of the most important issues facing the equine industry. It is a complicated and emotionally charged subject that includes moral, ethical, and financial considerations. Catastrophic breakdowns that occur during high-profile televised events are seen by millions of non-horse-owning but horse-loving viewers. Often what follows is a powerful groundswell of public opinion that places pressure on participants and sponsors of such events to enact changes that satisfy the public's real or perceived concerns for the horse's welfare. Sadly, these changes are often made not simply to protect the horse but primarily to limit the financial impact such negative press has on that sector of the horse industry. Similarly, the 2007 federal ban on horse slaughter in the United States was not initiated by veterinarians or horse owners but, again, by the American public and their disdain for horsemeat. It is clear from these examples that protecting the welfare of horses is important to owners, investors, and the horse-loving public, but the ultimate responsibility must rest with the equine veterinarian, who understands the needs of horses and is in the best position to identify neglect or abuse and educate owners, caretakers, and policy makers.

What *Is* Equine Welfare?

Defining what constitutes acceptable welfare practice continues to be an evolving process that has yet to be conclusively agreed on among investigators.[17] Previous to the past decade, the emphasis focused on food animal confinement systems, with the improvements in welfare correlating positively with increased production. The modern concept of welfare attempts to merge scientific knowledge with the emotional state or "experience," which has led to a greater emphasis on quality-of-life assessments.[18] Evaluating the health and welfare of horses can be a complex undertaking when one considers the number of contradictory ideas and opinions relating to husbandry and training practices. To circumvent these differences, surveys[19] and sophisticated methodologies[20] have been developed as tools to examine socioemotional issues such as welfare. Cruelty may be intentionally imposed or take the form of neglect due to ignorance, financial hardship, or poverty. Poor husbandry, unrecognized clinical and subclinical disease, improperly directed performance training, and work-related activities are examples of unintentional abuse and neglect that can also negatively affect a horse's quality of life.

As first responders, veterinarians are in the best position to not only recognize health issues that may be due to or affected by these practices but also educate clients who may be unaware of the harm they cause. To protect the welfare of horses, veterinarians must be equipped to recognize features that define abuse and neglect in patients. Unfortunately, social, moral, ethical, religious, and philosophical views affect how individuals, including veterinarians, approach the welfare of animals and ultimately react. Opinions vary widely as to exactly what constitutes "neglect" and "abuse," and the sheer complexity of defining and quantifying the less tangible elements that affect a horse's welfare, such as pain, depression, and anxiety, is immense when attempting to construct a "one-size-fits-all" paradigm. As a result, developing universally agreed-on guidelines that accurately identify welfare cases in a way that protects all horses is not straightforward. In acting as the "voice" for the horse, clinicians are placed in a precarious and challenging position by these issues. The veterinarian is obligated to put the best interests of horses front and center but, to do so, must reconcile in his or her own mind what parameters will be used to identify cases of neglect or abuse. Unfortunately, few veterinary school curricula include courses dedicated solely to issues of animal welfare and behavior, which can be particularly challenging for new graduates who will be expected to recognize differing degrees of abuse or neglect and respond appropriately.

Spotting Cruelty or Neglect

Millions of horses and donkeys around the world live in the poorest, most underdeveloped countries, where their primary use is work related—transporting goods or working in factories, on farms, or as the sole source of transportation for their owners. Veterinary care and education in animal husbandry practices are often lacking or nonexistent, and sources of quality forage in many areas further affect general health and survival. Signs of abuse and neglect are usually obvious to even the untrained eye, as evidenced by open wounds, chronic sores, overt lameness, and a skeletal appearance. In a study by Pritchard and colleagues,[21] which examined nearly 5000 working donkeys, horses, and mules residing in Afghanistan, Egypt, India, Jordan, and Pakistan, 70% had a body condition score of 2 or less (scale of 1 to 5), and nearly 90% of the 2071 horses examined had obvious lameness or gait abnormalities, associated with limb and/or hoof deformities.

In contrast, horses residing in modern, industrialized nations such as the United States are, for the most part, considered companion animals. Depending on the circumstance, individuals with little or no knowledge of horses can recognize cases of abuse or neglect, yet signs often may be vague or equivocal, enough to escape detection by experienced horsemen and equine veterinarians. At first glance, such horses may appear well fed, well groomed, properly housed, and cared for with no obvious signs; however, closer inspection may uncover evidence of behavioral (e.g., stereotypic behaviors) or physical mistreatment, such as healed pastern scars from a previous

VetBooks.ir

VetBooks.ir

"soring." Even on commercially successful or well-managed farms that provide high-quality feeds, pasture, grooming, and regular veterinary care, owners or trainers may employ psychologically damaging or physically painful or abusive procedures and training techniques aimed at enhancing the horse's performance. Veterinarians should be cognizant of subtle signs of inhumane treatment in these environments that may escalate over time to negatively affect the horse's health and quality of life.

UNEQUIVOCAL CRUELTY OR NEGLECT. All practicing veterinarians will likely be confronted with some form of cruelty or neglect during their careers. Aside from being exposed to these issues in their own practices, veterinarians may be invited to render second opinions or act as agents for humane organizations or local authorities investigating cases of welfare. In the latter case, a veterinarian may act as both caregiver and advocate for the horses in question. The decision regarding when to intervene with clients may be complicated by several obstacles, including the relationship with the owner or trainer, the veterinarian's employment status, and personal convictions. Depending on the magnitude of the abuse or neglect, sharing concerns with and providing a plan to owners must be carefully thought out to prevent embarrassment or alienation. After showing empathy for the horse and owner, most clients are willing to be compliant and eager to share the responsibility of improving the situation. To provide the best plan of action, it is imperative that practitioners show flexibility and understanding regarding the owner's particular situation. In cases where a veterinarian is merely an employee without ownership in the practice, a practice manager or owner may attempt to pressure a colleague against proceeding with a welfare claim for more practical reasons such as the loss of an influential client or one who may contribute significantly to the financial interests of the practice. In certain cases, state or local laws and ordinances may apply, and it is the veterinarian's responsibility to be aware of such statutes, to not only protect his or her own interests but also remain in compliance. The American Veterinary Medical Association Model Veterinary Practice Act[22] guarantees immunity from liability in welfare cases, and most state and local laws ensure the protection of veterinarians who report cases of neglect or cruelty in good faith. In either case, evidence including accurate medical records, diagnostic tests, and photographic documentation is necessary to support a case of abuse and protect the veterinarian against liability claims. This becomes particularly important when a case proceeds before a regulating body or progresses toward criminal indictment. It is of the utmost importance that veterinarians choosing to assist in welfare cases understand the legal process, are experienced in equine medicine, and are confident in their skills to collect and provide clear and "irrefutable evidence" to the courts.[23] Because considerable variation may be present within groups of equally neglected horses, practitioners should have in place organized methodology to approach cases of neglect or abuse so that subtle features are not missed. Observation of behavior and general condition should include careful physical palpation to determine the magnitude of muscle mass and identify the presence of scars or lacerations that may be obscured by profuse or matted coats. Photos of the animals and areas of concern may prove useful.

Beyond an intensive physical examination and body condition assessment, additional diagnostic tests may be warranted and serve to support claims of subclinical, clinical, chronic, or terminal diseases such as gastric ulceration, pituitary pars intermedia dysfunction (PPID), laminitis, and neoplasia, respectively. The minimum database includes a complete blood count, chemistry profile, and fecal analysis. Several body condition scoring systems have been developed to determine body condition in horses and donkeys.[23] All are comparatively similar for horses but vary enough in the scoring number and description that all clinicians in a practice should agree to use the same numeric system to avoid any ambiguity that may occur with an already subjective assessment. Box 2.2 illustrates an example of a nine-point scoring system for horses. Because donkeys accumulate fat preferentially over localized areas, scoring systems developed for horses should not be used to assess body condition in donkeys and mules.[24] The Donkey Sanctuary (www.thedonkeysanctuary.org.uk) has developed a body condition score chart specifically for donkeys.

BOX 2.2

Body Condition Scoring[a,b]

1—POOR. Extremely emaciated. Spinous processes, ribs, tailhead, hip joints, and lower pelvic bones project prominently; bone in withers, shoulders, and neck are easily noticed. No fatty tissue can be felt.

2—VERY THIN. Emaciated. Slight fat covers base of spinous processes; transverse processes of lumbar vertebrae feel rounded. Spinous processes, ribs, tailhead, hip joints, and lower pelvic bones are prominent. Withers, shoulders, and neck structure faintly discernable.

3—THIN. Fat buildup about halfway on spinous processes. Transverse processes cannot be felt. Slight fat covers ribs. Spinous processes and ribs easily discernable; tailhead prominent but individual vertebrae cannot be identified visually. Hip joints appear rounded but easily discernable; lower pelvic bones not distinguishable. Withers, shoulders, and neck accentuated.

4—MODERATELY THIN. Slight ridge along back. Faint outline of ribs discernable. Tailhead prominence depends on conformation, but fat can be felt around it. Hip joints not discernable. Withers, shoulders, and neck not obviously thin.

5—MODERATE. Back is flat; ribs easily felt but not visually distinguishable. Fat around tailhead feels a bit spongy. Withers round over spinous processes; shoulders and neck blend smoothly into body.

6—MODERATELY FLESHY. May have slight crease down back. Fat over ribs spongy; fat around tailhead soft. Small fat deposits behind shoulders and along sides of neck and withers.

7—FLESHY. Might have slight crease down back. Individual ribs can be felt, but noticeable filling between ribs with fat. Fat around tailhead soft; fat deposited along withers, behind shoulders, and along neck.

8—FAT. Crease down back. Difficult to feel ribs. Fat around tailhead very soft; area along withers filled with fat. Area behind shoulder filled with fat; noticeable thickening of neck. Fat deposited along inner thighs.

9—EXTREMELY FAT. Obvious crease down back. Patchy fat appears over ribs. Bulging fat around tailhead, along withers, behind shoulders, and along neck. Fat along inner thighs may rub together. Flank filled with fat.

[a]**Body condition scoring:** Body condition influences everything in your horse's life, from reproductive efficiency, to performance, to good health. By using Body Condition Scoring you can find out what kind of shape your horse is in and work to improve the score. Scoring focuses on critical areas of the body, based on palpable fat and visual appearance.

[b]**Ideal scores:** Most horses, including performance horses and growing horses, should be in a body score of 5 to 6. For optimum reproductive efficiency, broodmares should be a 5 to 7 and not allowed to lose condition such that they are below a 5 during breeding season. Horses over a condition score of 7 may be at greater risk for developing metabolic disorders such as insulin resistance.

IMPACT OF HUSBANDRY ON WELL-BEING AND BEHAVIOR. Regional (rural Western states vs. Eastern cities), cultural

VetBooks.ir

(Amish), political (animal rights activists), and religious differences strongly affect how societies and individuals view the treatment of horses and other animals. Husbandry practices vary widely and are also affected by location, property size, financial commitment, and an individual's personal background and exposure. Irregularities can affect the health and behavior of horses, leading to boredom, stall vices, training problems, and stereotypic behaviors. Problems usually result from misguided information or anthropomorphism, as most owners love their horses and do not set out to cause them harm. Paradoxically, veterinarians are often confronted with overzealous or ignorant owners who "over-care" for their horses and unnecessarily keep them covered in heavy blankets and hoods, ill-fitting tail sets, and tight leg bandages or with well-meaning owners who simply overfeed and oversupplement their horses. These benign-appearing practices may seem harmless but should be monitored by the veterinarian because they can affect the horse's behavior, health, and well-being and can lead to systemic disease such as laminitis secondary to obesity, localized disease (bacterial/fungal skin infections, blanket sores), and physical discomfort (overheating, pruritus).

The natural environment from which horses have evolved is one of vast, uninterrupted space, nearly continuous grazing or food-seeking behavior, and close affiliation and bonding with herdmates. As prey, they have learned to be acutely sensitive to changes in their environment and to respond quickly, usually with avoidance or flight. What owners may assume to be disobedience or spookiness is merely a form of self-preservation. Stereotypic behaviors such as wood chewing, cribbing, weaving, pawing, stall walking, and self-mutilation are seen most often when horses are kept in confinement, though once manifested, many horses will continue the behavior to some degree even when turned out in a paddock or pasture. Facial abrasions (weaving), open wounds (self-mutilation), worn teeth (cribbing), orthopedic injury (repetitive turning), and bleeding hooves (weaving)[25] can occur secondarily as a result of these stereotypies. Several causes for these behaviors have been cited, including a diet low in fiber or nutrients[26] and solitary confinement and stress.[27] Impediments (muzzles, cribbing straps, head ties) imposed to prevent these behaviors can be painful or injurious and lead to greater frustration and anxiety, further affecting the horse's welfare and mental well-being.[26,27] Many owners and trainers believe that other horses can "learn" these stereotypic behaviors from stablemates, so they will often sequester horses with these behaviors, further compounding their anxiety and stress. Often the horse is brought directly to the veterinarian from a stall or paddock for examination, so unless previously disclosed by the owner or witnessed by the clinician, the veterinarian may be unaware that the horse possesses an undesirable behavior. In fact, under certain circumstances (e.g., prepurchase inspection), such information may be intentionally withheld from the clinician in the fear that it will be passed on to potential buyers and affect the value or sale of the horse.

Modern feeding practices such as time grazing, forage and concentrate selection, quantities fed, and feeding intervals are not in line with the horse's natural behavioral and gastrointestinal requirements. Ideally, horses kept in confinement should have access to pasture or turnout for extended periods and be allowed to socially interact with other horses, as this has been shown to reduce stress[26-28] and behavioral problems,[26-31] improve musculoskeletal health,[30,32] reduce the occurrence of gastric ulceration[29] and certain types of colic,[31,33] and improve quality of life.[18]

Patients suffering from chronic diseases such as recurrent airway obstruction ("heaves"), advanced PPID, or uncontrolled laminitis should be closely monitored, and every effort should be made to maintain a continuing dialogue with the horse's owner/trainer regarding effects of treatment and quality-of-life issues and to discuss euthanasia when appropriate. Further, clients should be made aware of the costs involved in maintaining chronically ill horses and the likelihood that such costs may be necessary for an extended period or possibly for the life of the patient. The subject of euthanasia is never an easy one but is necessary to discuss under certain circumstances.

WELFARE AND TRAINING PRACTICES. Not every horse has the talent or mentality to excel at the discipline the owner has chosen, but many owners are unable to make this determination or refuse to accept such reality and will search for "shortcuts" designed to force the horse to succeed. Countless methods, training devices, and frightening contraptions have been developed over centuries to teach certain disciplines. Tying a horse's head in a fixed position for extended periods[34] and the use of severe bits, electric shock prods, and topical blisters are examples seen in modern training barns. In addition, surgical cosmetic alterations, systemic drugs or topical irritants, silicone injections, and alcohol tail blocks may be used in some breeds to enhance certain physical "breed" characteristics or change the horses' conformation to fit a show ring ideal. Physical and in some cases psychological effects resulting from such abusive practices can confound physical examination findings and delay diagnosis and timely intervention. This may be of particular concern for someone hired as an official horse show veterinarian who is inexperienced or unfamiliar with training practices related to a particular breed or discipline and is presented with an affected horse on emergency. For example, the ideal Western pleasure horse should carry the head and neck in a low, fixed, relaxed position while performing required gaits in the show ring. To maintain this unnatural head position[35] for the duration of the class, trainers suspend or "hang" the horse's head high above the withers for hours before the entered class. As a result, the neck muscles of these horses become fatigued and sore to the point that they will refuse to lift their heads above a horizontal plane, appearing compliant and well disciplined during the class. Clever pharmaceutical intervention is also used by some to affect the horse's vision, particularly in an indoor show ring. Ophthalmic atropine is used occasionally in English show horses to alter the gait, the head and neck carriage, and how they "look" through the bridle. The resulting mydriasis can last for days to weeks.[36] Depending on the presenting complaint, it is clear from only two isolated examples how secondary signs from undisclosed intervention may lead to confusion on initial physical examination.

Owners frequently seek the advice of veterinarians for problems related to training and behavior, and clinicians should recognize the responsibility of such recommendations and not make them unless confident in their abilities. Aside from previously discussed stereotypies, most problems manifest as fear[25] (avoidance) or aggression expressed as ear pinning, rearing, bucking, bolting, biting, and kicking. Fear and aggressive responses are unpredictable and of particular concern for the veterinarian or staff that may be inadvertently exposed to injury when the owner or handler is inexperienced or afraid of the horse. Conversely, accidental injury of the horse or owner as a result of a confrontation may lead to liability claims against the veterinarian. These actions by the horse can be a result of pain associated with disease or abuse, evasion of a painful impulse such as a misdirected snap of a shank chain, or a learned behavior. The owner's attempt at behavior modification often involves doing nothing, applying positive reinforcement for the behavior, or wielding some form of punishment, which tends to make the problems worse and the horse even more anxious and unpredictable. A veterinarian should gain a feel for the experience and competency of clients and become adept at determining when such behaviors result from poor management by owners or if a physical problem or injury exists and may be causing the response. If the practitioner is uncomfortable giving advice, suitable professionals should be recommended

VetBooks.ir

to the owner for help in determining the underlying motivation for the behavior.[25,26] If not remedied, the horse or owner may be exposed to serious injury and the horse may be exposed to escalated physical abuse by a frustrated or fearful owner or passed on to an innocent party that is unaware of the possible dangers.

Musculoskeletal disease and lameness are common client complaints in equine practice. Numerous elements can contribute to lameness, including misadventure, overexertion, inappropriate footing, poor conditioning, abusive or inappropriate training techniques, lunging, poor riding skills, poor hoof care, and improper shoeing. These elements should always be evaluated when attempting to determine the cause of an injury or change in temperament. Poorly fitting tack, unbalanced or heavy-handed riders, and inappropriate use of training aids (spurs or whips) can result in avoidance or physical damage to the horse. To make a complete assessment, it is often advantageous to observe the horse under tack to determine what factors may be causing or contributing to musculoskeletal or behavior issues. Unsuccessfully managed lameness can result in chronic pain, spread to other areas such as the back,[30] and limit the horse's value and potential welfare. Practitioners should stress the importance of rest and rehabilitation after injury and carefully monitor the client's use and potential abuse of antiinflammatory drugs, over-the-counter medications, and supplements.

Veterinarian's Responsibility to Patient Welfare

Concurrent with an increase in the number of nonprofit equine rescue organizations and politically powerful lobbying groups devoted to animal welfare, there has been a dramatic increase in the number of legal bills proposed and statutes imposed specific to the welfare of horses. The public's response after a series of high-profile breakdowns and abuses that occurred on Thoroughbred tracks and at other competitive horse events in the United States has placed veterinary practices engaged in servicing these sectors and others in the horse industry under intense scrutiny. As horse owners become more sensitive to these issues, veterinarians are expected to exercise careful handling of their patients so as not to cause undue pain or discomfort in the eyes of their owners or other onlookers.

Few veterinarians would challenge the idea that an abusive procedure such as "soring" of a Tennessee Walking Horse, used solely to improve show ring performance, is unacceptable. However, it could be argued that certain surgical and medical procedures performed with regularity in daily practice may be less obvious but equally suspect. Dispensing or administering steroidal and nonsteroidal medications locally or systemically to horses known to have underlying pathology, thereby enhancing the risk of further physical damage or catastrophic breakdown, could be viewed as a form of neglect of duty or malpractice. Castration in semiconscious horses without the use of local anesthetics[37] and postsurgical analgesics could also be looked upon critically. Surgical procedures such as distal limb neurectomies, done solely to remedy pain so that a horse may fulfill a career goal, can result in further bodily harm to the horse and affect the safety of current or future riders. The use or promotion of procedures such as internal blisters, injection of "off-label" or exotic substances (cobra venom), and electrocautery (pin firing), which not only lack the support of evidence-based medicine[38] but also may result in pain or long-term suffering for the patient, should be carefully evaluated. Requests for certain cosmetic procedures such as tail docking, which is currently illegal in several states, should be seriously justified. The American Association of Equine Practitioners (AAEP) has produced several guideline publications[39-44] specific to various breeds and disciplines to assist equine veterinarians in their management and care.

Veterinarians should strive to do the following:

- Achieve balance between protecting the health and welfare of their charges and satisfying the wishes of their clients
- Educate clients who may be unaware of the negative effects that husbandry or training practices impose on the horse's health and psychological well-being
- Direct owners to make informed decisions in the case of chronically ill animals, especially when financial constraints may affect appropriate treatment and quality of life

Horses are sensitive and incredibly compliant creatures. They are particularly vulnerable to many forms of continued physical and psychological abuse, whether done intentionally or unintentionally through ignorance or negligence. Equine veterinarians have a responsibility to protect horses and should make every effort to evaluate patients carefully for signs of inappropriate treatment or cruelty. Evidence of abuse or neglect may be blatantly obvious or less conspicuous initially, so constant surveillance is necessary to determine whether physical or behavioral problems challenge the horse's health and welfare.

Pain

SUZANNE T. MILLMAN and JOHANN (HANS) F. COETZEE, *Consulting Editors*

Introduction

Addressing pain is a key expectation for animal welfare, and large animal practitioners have an important role in educating clients to recognize and respond to livestock pain. Pain is a subjective experience for humans and nonhuman animals; hence, we cannot truly know how it is felt by other individuals. Subjective experiences are challenging in medicine but not unique to veterinary practice. Some techniques used in human medicine, particularly with respect to nonverbal and preverbal patients, can be applied to animals to inform diagnosis and treatment of pain.

Veterinarians have important influence on the attitudes and behavior of livestock producers in regard to pain recognition and pain management. Dairy producers that involve veterinarians in their management decision for disbudding and dehorning protocols are more likely to provide analgesia,[1] and veterinarians that rate pain levels as high are more likely to provide analgesia.[2,3] However, there is little consensus among veterinary practitioners about appropriate pain management, with several surveys indicating that caesarian section and claw amputation are believed to be the most painful conditions in cattle, but opinions differ for severity of castration pain.[4,5] Female[6] and younger[3-5] practitioners rate pain higher than their male and older colleagues. The decision to use analgesics for particular conditions appears to have a dichotomous distribution, with practitioners choosing to use analgesics for all cases or for none.[1,3]

Diagnosing Pain in Livestock

Pain processing includes sensation and perception. Sensation refers to the lower-level neurologic and biochemical components (nociception), whereas higher cognitive processing, such as interpretation, is associated with perception. A modification to the International Association for the Study of Pain definition of pain was suggested for application to animals: "an aversive sensory experience caused by actual or potential injury that elicits progressive motor and vegetative reactions, results in learned avoidance behavior, and may modify species-specific behavior, including social behavior."[7] Three functions of nociception include (1) warning the animal of actual damage to its tissues, (2) predicting when tissue damage is likely to occur, and (3) warning conspecifics of the presence of danger.

Sensory information is communicated from nociceptors at tissue levels and modulated through spinal and supraspinal mechanisms. Integration of sensory and emotional components results in varied responses relative to species, ontogeny, and type of insult. Basic motor responses, such as withdrawal, occur in response to acute pain stimuli and are associated with protection from further tissue damage. However, simple withdrawal responses can occur consciously or unconsciously, in awake and anesthetized animals. More organized behavioral responses involving higher cognitive processing include aggression or escape attempts.

Increased pulse, respiratory rate, and tidal volume, pupil dilation, and other physiologic responses occur during pain, but these responses are nonspecific indicators because they also occur during arousal, such as during fear and excitement. Conversely, pain behaviors occur when pain is present versus absent and are absent or decrease when animals are provided with appropriate analgesia treatments versus placebo treatments, such as saline. These pain behaviors can be measured objectively or subjectively. Subjective assessments traditionally have been the most practical for clinical application, but advances in technology provide opportunities for objective assessments outside the laboratory. Pain assessment should be measured across multiple domains, including resting, movement, hyperalgesia, function, and quality of life.[8] Blurring of these constructs within a subjective pain scoring system can result in poor sensitivity and specificity, especially when observers are unclear about which construct is driving an evaluation.

Clinical Scoring of Visual and Behavioral Indicators of Pain

Pain assessment in veterinary practice has typically relied on subjective global pain scales, with clinicians or animal caretakers providing proxy assessments for the animals in their care. Intangible measures, such as demeanor, attitude, or lethargy, are often cited for clinical scoring of pain but are poorly defined. Hence, challenges are likely to occur with interobserver and intraobserver reliability and interpretation. Subjective scoring systems may be improved when descriptions, photographic images (Fig. 3.1, *A* and *B*), or video clips of behaviors are provided for training clinicians and animal caretakers. A website developed by Dr. Joyce Kent and Dr. Vince Molony, Royal (Dick) School of Veterinary Studies, provides an excellent resource with photographic and video clips of pain responses in several livestock species to common clinical situations ("Guidelines for the Recognition & Assessment of Animal Pain", http://www.link.vet.ed.ac.uk/animalpain/Default.htm).

Validation of subjective scoring systems for animal subjects is emerging and is a positive step in the evolution of pain research. A standardized facial grimace scale has been validated for assessing pain in mice, including distinct five components of which three are also observed in the human facial pain grimace.[9] Livestock may display similar facial grimace components, such

FIG. 3.1 Humans report severe abdominal pain associated with infection with *Cryptosporidium parvum*. Similarly, when compared with healthy calves **(A),** calves infected with *C. parvum* **(B)** display a dull eye, ear rotation, lower head carriage, and back arch postures characteristic of abdominal pain. *(Courtesy Dr. Cynthia Todd, University of Guelph.)*

as orbital tightening and ear position (horse,[10] sheep,[11] pig[12]). Since changes in posture are subtle and often characteristic of particular types of pain, it is wise to standardize the visual assessment of the animal, scoring sequentially from head to tail (Table 3.1). Furthermore, changes in motivation and motor patterns are also characteristic of the type and location of pain and should be scored systematically (Table 3.2). Effective pain scoring protocols are critical for evaluating the effectiveness of interventions and determination of humane endpoints when alleviation of pain cannot be achieved. Scoring of affective states, such as depression, can be refined with transparency regarding the responses recorded and use of specific tests to evoke behavioral responses (Table 3.3). Subjective pain scoring is most refined in terms of lameness and locomotion scoring, with excellent training resources available for bovine and equine practitioners and caretakers. Locomotion scoring systems that provide detailed descriptions of the observable changes in gait and allow observers to score components of the gait separately have been validated for identifying cows with severe hoof lesions[13] and cows that have received a local anesthetic.[14]

Pain behavior responses can also be measured objectively, particularly in experimental applications where detailed observations are collected during live observations or more frequently from video recordings. In ethology, the science of animal behavior, a key component of research methodology is development of an appropriate ethogram, which consists of a list of definitions for mutually exclusive behaviors.[15] For transparency and to avoid inherent bias associated with interpretation, definitions that focus on motor patterns or movements that an animal performs are preferred over those described in terms of an underlying motivation. Pain behaviors can then be quantified in terms of frequency and duration of occurrence. For example, head-related behaviors, such as head shaking, rubbing, and scratching, occur at greater frequencies following disbudding surgery[16] and ocular injury.[17] Experiments can also be designed to provoke behavior and quantified in terms of latency to respond and thresholds of stimulus required for response. Although pain-specific behaviors are relatively straightforward to observe and quantify when detailed definitions are provided, manual collection of behavior data is labor intensive and difficult to record because these behaviors occur at low frequencies even when the animal is undisturbed by activity in the barn.

New technologies are emerging for automated data collection, such as accelerometers for frequency and duration of activity and resting behavior (Fig. 3.2), and show promise for detecting behavioral changes associated with lameness.[18] Accelerometers are increasingly being incorporated into dairy management software programs, with changes in activity flagged for further investigation by the stockperson. Lameness detection can be aided by kinematic analysis during locomotion[19,20] and pressure-sensing equipment incorporated in stalls to detect differences in weight

TABLE 3.1

Postures Associated With Different Acute, Visceral, Abdominal Pain and Chronic, Somatic Lameness Pain in Livestock

Location	Abdominal Pain	Lameness Pain
Head	Dull, sunken eye (chronic) Wild, distracted eye (acute) Lip curl Wrinkled muzzle/ grimace Contracted jaw tone Contracted ear position (acute) Drooped ear position (chronic)	
Neck/back	Lowered head carriage Neck extension Arched back	Arched back
Abdomen	Tucked abdomen Prolonged urination stance	
Limbs	Standing with hind limb extension Lying with hind limb extension Treading hind limbs	Uneven weight bearing Treading hind limbs Crossed forelimbs[a] Perching[b] Increased abduction/ adduction of limbs
Tail	Tail tuck Prolonged urination stance	

[a]Standing with crossed forelimbs results in weight transferred from the inner claw to the outer claw.

[b]Perching occurs in dairy stalls when weight is transferred to the rear hooves, which are placed in the gutter anterior to the stall while fore hooves are placed in the stall.

bearing during standing and locomotion.[20] During acutely painful procedures, livestock typically struggle or attempt to escape, and these behaviors can be quantified using exit velocity, latency for the animal to break an infrared beam, strain gauges to measure exertion forces on the restraint chute, or by software analysis of head movements captured with videoimages.[21]

TABLE 3.2

Behavior Changes Associated With Different Acute, Visceral, Abdominal Pain and Chronic, Somatic Lameness Pain in Livestock

Behavior	Abdominal Pain	Lameness Pain
Redirected and pain avoidance behaviors	Bruxism (teeth grinding) Wound licking Wound scratching Self-mutilation (equine) Rolling (equine) "Looking"—nose to flank Pawing, stamping (fore) Kicking, stamping (hind) Abnormal gait Crawling on knees Tail flicking	Abnormal gait Crawling on knees Difficulty turning
Activity	Statue standing[a] Increased lying Increased standing inactive Hyperactivity, restlessness Frequent standing/lying transitions Reduced grooming Reduced exploration	Increased standing inactive Increased lying Reduced standing/lying transitions Abnormal standing/lying transitions Reduced exploration
Feeding	Anorexia (acute) Reduced feeding duration Intermittent eating Intermittent drinking Playing with water Cessation of rumination	Reduced feeding duration
Social interactions	Aggression Social isolation Reduced play	Reduced play
Vocalizations	Distress calls Groaning Grunting Snorting Sneezing (goats)	

[a]Standing immobile in a fixed, rigid posture.

Similarly, in some livestock species distress calls are performed during painful procedures and can be discriminated from other vocalizations, such as contact calls, by the increase in rate, pitch, and volume.[22] Distress calls given during painful procedures are greater in intensity than other vocalizations, such as short calls at lower fundamental frequencies that are emitted from cattle when isolated.[23] However, vocalizations may not be a robust measure of pain for cattle, since they rarely vocalize, and propensity to vocalize is associated with breed, perhaps due to variations in excitability.[24] Conversely, goats are very expressive vocally, despite also being a prey species.

Nociceptive Threshold Tests

Several standard tests have been developed for assessing nociception in animal models for biomedical research, including von Frey filaments for mechanoreceptors and the Hargreaves' or plantar test for thermoreceptors. Increasingly, nociception tests are being modified or applied to livestock to ask about the sensory discriminatory perception of pain. To tease apart pain from other aversive experiences, such as fear or distress, attenuation of the response should occur when relevant analgesia is applied. Where possible, local anesthesia is preferable to opioids or sedatives due to confounding that results from direct impacts of the latter on animal behavior.

Pressure algometry is an example of a mechanical nociception test that has proven useful for assessing pain in livestock (Fig. 3.3). This tool measures the amount of force applied to a surface, and painful thresholds are determined using a withdrawal response. When applied around the horn buds, calves

FIG. 3.2 Accelerometers quantify activity when affixed to the limb and may provide useful data for identifying lame cows. The output includes duration and frequency of standing and lying bouts, as well as number of steps. For some devices, output is integrated into dairy management software to alert the stockperson when changes in activity patterns occur. *(Courtesy Dr. Janet Higginson Cutler, University of Guelph.)*

TABLE 3.3

Example of Clinical Scoring Form for Transparency and Consistency in Subjective Assessment of "Demeanor" or "Depression"

Parameter	Yes	No	N/A	Comments
Does the animal orient toward handler entering pen?				
Does the animal approach a novel object placed in its pen?				
Does the animal approach the feed bunk when fresh feed is provided?				
Does the animal require encouragement to consume daily ration?				
Does the animal require encouragement to walk to the milking parlor?

FIG. 3.3 Mechanical nociception threshold test using pressure algometry to test pain sensitivity at a sole ulcer lesion. Cattle tolerate less pressure before displaying an avoidance (hoof withdrawal) response when the pressure algometer tip is applied to the sole ulcer compared with normal sole. *(Courtesy Dr. Janet Higginson Cutler, University of Guelph.)*

FIG. 3.4 Thermal nociception threshold test using a radiant thermal stimulus to test pain sensitivity at the coronary band on a lame sow. Effective analgesia is evident by increased tolerance of the thermal stimulus and corresponding greater latency for an avoidance (leg withdrawal) response. *(Courtesy Ms. Kathleen Tapper, Iowa State University.)*

display significantly lower nociception thresholds following disbudding when compared with pressure tolerated on the day before surgery. Furthermore, calves display less pressure sensitivity when treated with nonsteroidal antiinflammatory drugs (NSAIDs), including meloxicam,[16] firocoxib,[25] and carprofen.[26] Pressure algometry data suggest that the duration of postsurgical pain is greater than estimates using neuroendocrine markers because significantly lower nociception thresholds are observed for 3 days following surgery relative to baseline values.[16] Differences in mechanical nociceptive thresholds can also be used to identify lameness, with responses mitigated by NSAIDs.[27] Pressure algometry appears to be a robust tool, with potential for clinical application because it is cheap and easy to use and differences in response are often large.

Thermal nociception threshold is quantified by the amount of time (latency) for an avoidance response to a radiant or laser thermal stimulus. A CO_2 laser thermal stimulator was found to provoke a foot lift or kicking withdrawal response when skin temperature reached 45°C to 55°C, and because CO_2 laser stimulators use a monochromatic, long-wavelength infrared source of radiation, absorption is not affected by pigmentation of the skin.[28] Standard operating procedures for all thermal nociception tests require the skin surface to be free of hair, manure, and moisture, and safety precautions, such as maximum duration of stimulus application, to avoid tissue damage on different skin surfaces.[29] A ceiling value of 20 seconds was successfully used as a safety precaution when a radiant thermal nociception stimulus (constant 80% beam intensity, 200C) was used during a lameness study in sows (Fig. 3.4).

Pain Aversion Tests

Classical pain tests that quantify reflexive nociceptive withdrawal responses to mechanical or thermal stimuli provide information about the sensory-discriminatory aspects of pain, but not the affective (emotional) components. There is some evidence that some species, such as chickens and sheep, choose to self-medicate to avoid painful conditions. Conditioned avoidance tests are based on an animal's ability to recall an association of a stimulus, such as a location or a person, with a previous aversive experience. Conditioned place avoidance is commonly observed where livestock have previously experienced painful interventions, such as branding, dehorning, or castration. Similarly, cattle may associate the appearance or odor of a veterinary practitioner with previous aversive experience, resulting in difficulties with handling. However, it is often difficult to tease apart aversion arising due to experiences associated with pain versus fear. This is especially problematic with extensively managed livestock that are unfamiliar with handlers and equipment. In several species, electrical stimulation results in startle and withdrawal reflexive behaviors, as well as higher pain processes associated with aggression and avoidance behaviors. However, it is used in livestock to facilitate movement (electric prods), for restraint (electroimmobilization), and for semen collection (electroejaculation). Aversiveness of electroimmobilization is evident by conditioned aversion responses by livestock, resulting in reluctance to move through handling chutes or avoidance of particular handlers.[30] These results have been used to advise against the practice of electroimmobilization, such as animal welfare policies of the American Veterinary Medical Association and Canadian Veterinary Medical Association.

Pharmacologic Interventions to Treat Livestock Pain

Negative public perception of pain associated with routine animal management practices such as dehorning and castration is mounting, with increasing call for the development of practices to relieve pain and suffering in livestock. Preemptive analgesia can be applied in advance of the painful stimulus, thereby reducing sensitization of the nervous system to subsequent stimuli that could amplify pain. Agents that could be used to provide preemptive analgesia include local anesthetics, NSAIDs, opioids, α2-agonists, and *N*-methyl *D*-aspartate receptor antagonists. However, less than 20% of U.S. veterinarians currently report using analgesia routinely at the time of dehorning and castration.[31]

The capacity to experience pain is considered to have a protective role by eliciting behavioral responses aimed at reducing further tissue damage and enhancing wound healing. However, persistent pain syndromes offer no biological advantage and are associated with suffering and distress. Pathologic pain states in cattle occur as a result of tissue damage, nerve damage, and inflammation and are frequently associated with pain hypersensitivity. Pain hypersensitivity manifests as hyperalgesia (exaggerated responses to painful stimuli) and allodynia (pain resulting from normally innocuous stimuli).

Hyperalgesia has been reported to persist in dairy cattle and lame sheep for at least 28 days after the causal lesion has resolved.[32,33] Consequently, chronic pain associated with lameness is considered one of the most significant welfare concerns in dairy cows. Inflammatory pain associated with lameness responds modestly to treatment with NSAIDs,[34,35] but neuropathic pain (due to nerve damage or neuronal dysfunction) is considered refractory to the effects of NSAIDs and many opioid

analgesics. Therefore there is a need to identify novel drugs and drug targets for alleviating chronic pain of neuropathic origin in animals.

Challenges Associated With Providing Analgesia in Food Animals

Several challenges are associated with providing effective analgesia in food animals in the United States. Firstly, before July 2017, there were no analgesic drugs specifically approved for the alleviation of pain in livestock. At the time of writing this chapter, only one compound (Banamine Transdermal, Merck Animal Health) is approved in the United States for the control of pain associated with foot rot. Administration of any drug to alleviate pain associated with other conditions therefore constitutes extralabel drug use (ELDU).[36] Under the Animal Medicinal Drug Use Clarification Act of 1994 (AMDUCA), ELDU is permitted for relief of suffering in cattle provided specific conditions are met. These conditions include that (1) ELDU is allowed only by or under the supervision of a veterinarian, (2) ELDU is allowed only for U.S. Food and Drug Administration (FDA)-approved animal and human drugs, (3) ELDU is only permitted when the health of the animal is threatened and not for production purposes, (4) ELDU in feed is prohibited, and (5) ELDU is not permitted if it results in a violative drug residue in food intended for human consumption. Therefore use of an analgesic to alleviate pain associated with castration in calves in the United States would be required by law to comply with these regulations.

A second challenge to providing effective analgesia in cattle is that there is often a delay between the time of drug administration and the onset of analgesic activity. For example, local anesthetics require 2 to 5 minutes before a maximal effect is achieved. This may slow animal processing, as producers must wait for local anesthesia to take effect. This delay may serve as a disincentive for them to provide routine preemptive analgesia. Furthermore, the requirement for large numbers of animals to be processed quickly may result in procedures being initiated before optimal analgesia is achieved. A third challenge is that the route or method of analgesic drug administration may require specialized training and expertise or may be hazardous to the operator. Therefore administration requires the animal to be adequately restrained and the operator to be proficient in intravenous administration. Similar issues are encountered with epidural analgesic drug administration and administration of local anesthesia into the scrotum. The latter procedure is also considered especially hazardous by many livestock handlers. In addition, the majority of analgesic drugs that are available in the United States have a short elimination half-life, necessitating frequent administration in order to be effective.[36] This increases the stress on the individual animal and increases labor and drug costs.

In addition to the regulatory considerations discussed previously, certain drug classes such as the opioid and NMDA receptor antagonists are designated as Schedule 3 drugs and are subject to regulation by the U.S. Drug Enforcement Administration (DEA). Therefore administration of these compounds to provide preemptive analgesia is restricted to use by licensed veterinarians. Finally, the cost associated with providing preemptive analgesia contributes to the reluctance of producers to adopt these measures, especially because there is no perceived economic benefit for doing so. It may also be difficult for producers and veterinarians to determine if analgesic compounds are effective because cattle may not show overt signs of pain and distress. Thus determining the need for analgesia and the dose, route, duration, and frequency of drug administration in cattle can be especially challenging.

Analgesic Compounds and Their Effect in Cattle

Pain perception involves the transduction of chemical signals at the site of injury into electrical energy (Fig. 3.5). This is followed by transmission of the electrical signal via nerve fibers up the spinothalamic tracts where modulation may occur in the dorsal

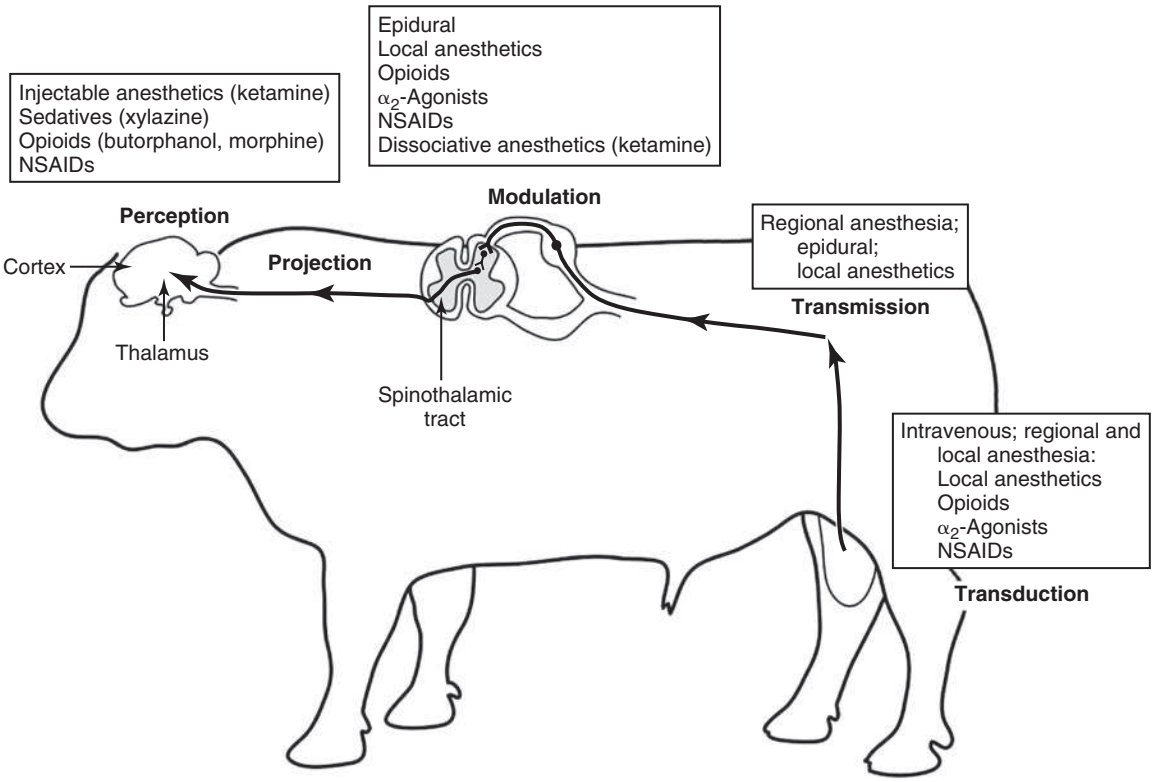

FIG. 3.5 Schematic representation of the nociceptive pathway in cattle indicating the anatomic location of target receptors for analgesic drug activity. *(Courtesy of Mal Hoover, Kansas State University.)*

VetBooks.ir

horn. Finally, the impulse is projected to the brain where pain perception occurs. The initial response to a noxious stimulus is typically brief, well localized, and somewhat proportional to the intensity of the insult. The second phase of the response is prolonged, diffuse, and often associated with hypersensitivity around the point where the initial stimulus was applied. This effect may lead to persistent postinjury changes in the central nervous system resulting in pain hypersensitivity or central sensitization ("wind-up"). These effects lead to hyperalgesia (increased pain from previously painful stimuli) and allodynia (a previously nonpainful stimulus now produces pain).

Surgery-induced pain and central sensitization consist of two phases: an immediate incisional phase and a prolonged inflammatory phase that arises primarily due to tissue damage. The goal of administering analgesic compounds before castration is to mitigate both the incisional and inflammatory phase of the pain response. Effective analgesia therefore requires a multimodal approach using compounds that act on different receptor targets along the nociceptive pathway (Fig. 3.1). This can be achieved through a combination of local anesthesia, NSAIDs, and sedative-analgesic combinations of opioids, α2-agonists, and *N*-methyl *D*-aspartate receptor antagonists.

Local Anesthesia

Local anesthetics are the most commonly prescribed preemptive analgesic drugs used in food animal practice.[37] These compounds produce reversible loss of sensation in a localized area without causing loss of consciousness. Local anesthetics enter and block open sodium channels of nerve cells and prevent generation and propagation of nerve impulses. Repeatedly stimulated nerve cells are therefore more susceptible to the effects of local anesthetics. Furthermore, unmyelinated nerve fibers that transmit pain signals are preferentially blocked by local anesthetics compared with myelinated fibers that are responsible for pressure sensation and motor activity. The quality of local anesthesia in an acidic environment, such as infected tissues, is often poor because these compounds are weak bases that must dissociate in an alkaline environment to exert their effect. Lidocaine has a fairly rapid onset of activity (2 to 5 minutes) and an intermediate duration of action (90 minutes). Local anesthetic administration into the epidural space has also been shown to provide regional analgesia of the perineal region commencing 5 minutes after administration of 0.2 mg/kg lidocaine and lasting 10 to 115 minutes.[37]

Compounds That Potentiate Local Anesthesia

MAGNESIUM SULFATE ($MGSO_4$). Magnesium sulfate has been combined with lidocaine to potentiate the local anesthetic effects.[38] Magnesium competitively antagonizes NMDA receptors and their associated ion channels in the same manner as ketamine, thus reducing central sensitization caused by peripheral nociceptive stimulation. It was recently reported that the combination of lidocaine with magnesium sulfate produced epidural analgesia of longer duration than lidocaine with distilled water. In this experiment, local anesthesia with 2% lidocaine solution administered at 0.22 mg/kg was potentiated with 1 mL of 10% magnesium sulfate solution. Magnesium also reportedly has antinociceptive effects in animals and humans after systemic administration.[39] These effects are considered to be associated with the inhibition of calcium influx into the cell and antagonism of NMDA receptors. Further studies with respect to the safety and efficacy of magnesium augmentation of local anesthesia are needed before this technique can be recommended.

SODIUM BICARBONATE. Commercial preparations of lidocaine are prepared as acidic solutions to promote solubility and stability. The addition of sodium bicarbonate before administration significantly reduces pain produced by infiltration of lidocaine in humans, probably due to the reduced acidity of the commercial formulation. The addition of sodium bicarbonate to lidocaine has also been found to reduce the time taken for the nerve block to take effect and enhance analgesia in humans. However, the addition of bicarbonate may decrease the duration of the block. A 10:1 ratio of 2% lidocaine with 8.4% sodium bicarbonate is recommended for optimal buffering of lidocaine. Thus 1 mL of commercially available 8.4% sodium bicarbonate solution can be added to 10 mL of 2% lidocaine immediately before administration in order to buffer the acidic effects of the formulation.

Alternatives to Local Anesthesia

Ethanol injection demyelinates nerve fibers and may be a promising long-acting local anesthetic for use at the time of disbudding.[40] When ethanol was administered as a corneal nerve block before disbudding, calves failed to display increased pain sensitivity in response to pressure algometry relative to their baseline values. Furthermore, ethanol-treated calves differed significantly from calves treated with the local anesthetic lidocaine at 1-hour post disbudding, when the lidocaine is assumed to be wearing off. Ethanol blocks appeared to desensitize the site of cautery dehorning for longer than 83 hours, at which time the experiment concluded. In this experiment, 2 mL of 100% ethanol were injected at the site of the corneal nerve block. However, more than half the calves subjected to ethanol anesthesia required a second injection to achieve complete loss of sensation in one or both horns. Further studies with respect to the safety and efficacy of ethanol blocks for local anesthesia are needed before this technique can be recommended.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS. NSAIDs produce analgesia and antiinflammatory effects by reducing prostaglandin (PG) synthesis through inhibition of the enzyme cyclo-oxygenase (COX) in the peripheral tissues and central nervous system. COX exists in two isoforms. COX-1 is constitutively expressed in both peripheral and central nervous systems, although expression is enhanced by pain and inflammatory mediators. COX-2 is ubiquitous in the CNS but only becomes the major enzyme for PG synthesis after induction by factors released during cell damage and death. It takes 2 to 8 hours for maximal COX-2 mRNA expression to occur in the peripheral tissues, therefore initial release of PG is primarily due to COX-1. PG in the peripheral tissues lowers the activation threshold of sensory neurons and may initiate nociceptive activity. PG also works in concert with substance P, histamine, calcitonin gene-related peptide (CGRP), and bradykinin to lower the firing threshold of sensory nerves and produce inflammation. Therefore NSAIDs that inhibit COX-1 may have a more immediate impact on pain by inhibiting PG production in the periphery than COX-2 selective compounds. However, NSAIDs that inhibit COX-1 may be associated with increased risk for adverse gastrointestinal and renal effects.

Spinal PG, notably PGE_2, is responsible for increased excitability of the dorsal root ganglia leading to centrally mediated hyperalgesia. Given that COX-2 is constitutively expressed in the CNS, inhibition of spinal PGE_2 production by NSAIDs that inhibit COX-2 may be an important mechanism in preventing the establishment of hyperalgesia. The effect of NSAIDs on both central and peripheral PG synthesis suggests that these compounds have an important role in multimodal analgesic protocols.

The dose and pharmacokinetic parameters of the commonly used NSAIDs in the United States are summarized in Table 3.4.

FLUNIXIN MEGLUMINE. Flunixin is a highly substituted derivative of nicotinic acid. Currently flunixin meglumine is the only NSAID approved for use in cattle in the United States.[37] The plasma elimination half-life of flunixin after IV administration is

VetBooks.ir

TABLE 3.4

Nonsteroidal Antiinflammatory Compounds Available for Use in Cattle

Drug	Approved Species	Indications	Dose (Cattle)	T½	Withhold Period
Flunixin meglumine	Cattle, horses, and pigs	NSAID—antipyretic, antiinflammatory	IV 2.2 mg/kg Topical 3.3 mg/kg	3-8 hours	IV Meat—4 days Milk—36 hours Topical Meat—8 days
Phenylbutazone	Horses and dogs	NSAID—anti-inflammatory	4 mg/kg IV ONLY!	40-55 hours	Not approved in cattle in the USA
Ketoprofen	Horses and dogs	NSAID—anti-inflammatory	3 mg/kg IV, IM	0.42 hours	Not approved in cattle in USA
Aspirin	No FDA approval Horses and cattle	NSAID—reduction of fever Relief of minor muscle aches and joint pain	50-100 mg/kg PO Oral F < 20%	0.5 hours (IV salicylate)	No formal FDA approval Not for use in lactating cattle
Carprofen	EU approval in cattle Dogs	NSAID—adjunctive therapy of acute respiratory disease and mastitis	1.4 mg/kg bodyweight IV or SC	Age Dependent <10 weeks: 49.7 ± 3.9 hours (R–) and 37.4 ± 2.4 hours (S+) Adult cows; 30.7 ± 2.3 hours	Not approved in cattle in USA
Meloxicam	EU and Canadian approval in cattle Dogs and cats	NSAID—adjunctive therapy of acute respiratory disease; diarrhea and acute mastitis (Europe)	0.5 IV, SC 0.5-1 mg/kg PO	27 hours (range: 19.97-43.29 hours)	Not approved in cattle in USA

IV, Intravenous; *PO,* per os/oral; *SC,* subcutaneous.

reported to be 3 to 8 hours. Following a single intravenous dose of 2.2 mg per kg of body weight (mg/kg), plasma concentrations decreased from 16.16 ± 5.28 μg/mL to 1.22 ± 0.16 μg/mL in 2 hours and reached 0.5 ± 0.02 μg/mL by 30 hours.[41] A peak concentration (Cmax) of 0.9 ± 0.05 μg/mL occurred at 3.5 ± 1.0 hours (T_{max}) after a single oral dose of 2.2 mg/kg with an estimated half-life of 6.2 hours and bioavailability of 60%. Therefore once-daily administration is likely required to maintain effective plasma drug concentrations. Although this drug class is recognized as having analgesic properties, IV flunixin is only indicated for control of fever associated with respiratory disease or mastitis and fever and inflammation associated with endotoxemia, rather than for control of pain. Studies demonstrating the analgesic effects of flunixin administered alone at the approved dose of 2.2 mg/kg IV are deficient in the published literature. Use of flunixin meglumine is further complicated by the requirement for intravenous administration, which is more stressful on the animal and involves more skill and training on the part of the operator. Several reports have suggested that the IM administration of flunixin may result in significant myonecrosis and tissue residues.[37]

In July 2017, a formulation of flunixin meglumine for systemic absorption following topical administration was granted FDA approval for the control of pain associated with foot rot in beef cattle. The mean bioavailability of topical flunixin is 48% (range: 34% to 61%).[42] It is noteworthy that the mean half-life for topical flunixin was 6.42 hours (range 5.22 to 9.76 hours) compared with 4.99 hours (range 4.37 to 5.82 hours) after IV administration. The C_{max} following topical application of flunixin was 1.17 μg/mL, and the time to maximum concentration was 2.14 hours. These data suggest that flunixin is rapidly absorbed and has longer plasma elimination half-life after topical administration compared with IV administration. It has also been reported that administration of flunixin meglumine significantly reduced PGE_2 concentrations in bovine exudate from 8 to 48 hours after treatment following an induced inflammation.[43]

Clinically, 6- to 8-week-old Holstein calves that were treated with topical flunixin meglumine without local anesthesia at the time of dehorning were found to tolerate more force applied to a site adjacent to the horn bud at 48 hours after treatment.[44] Furthermore, serum cortisol concentration was lower in treated calves compared with untreated dehorned calves at 90 minutes after the procedure. These data suggest that topical flunixin may be a convenient and effective analgesic when administered at the time of a painful procedure.

PHENYLBUTAZONE. Phenylbutazone is not approved for use in cattle in the United States, although it has been used in veterinary medicine for more than 50 years.[45] The pharmacokinetics of phenylbutazone is characterized by a slow clearance and longer terminal half-life compared with other NSAIDs. The oral bioavailability of phenylbutazone ranges from 54% to 69% with peak plasma concentrations achieved in 8.9 to 10.5 hours.[46] Phenylbutazone has been associated with rare but fatal blood dyscrasias, including aplastic anemia, leukopenia, agranulocytosis, thrombocytopenia, and deaths in humans. In light of these potential adverse effects associated with exposure to phenylbutazone, the FDA has issued an order prohibiting the extralabel use of phenylbutazone animal and human drugs in female dairy cattle 20 months of age or older. There is also a zero tolerance for phenylbutazone residues in edible tissues from any class of animal. Use of phenylbutazone as an analgesic in food animals is therefore strongly discouraged.[36]

KETOPROFEN. Ketoprofen is a member of the propionic acid class of NSAIDs. Ketoprofen has a short plasma elimination

half-life of 0.42 hours in adult cattle, making it less attractive for use as a preemptive analgesic.[47] Although it has been demonstrated that concentrations of ketoprofen are higher in inflammatory exudates than plasma, 80% of a parenteral dose is reportedly eliminated in the urine within 24 hours of administration.[48] Therefore multiple doses of ketoprofen will likely be required to maintain adequate analgesic concentrations.

Ketoprofen is approved in the European Union and Canada for the alleviation of inflammation and pain associated with arthritis and traumatic musculoskeletal injuries and as an adjunctive therapy for the alleviation of fever, pain, and inflammation associated with acute clinical mastitis.[48] The recommended dose in cattle is 3 mg per kg of body weight by intramuscular or intravenous injection, every 24 hours for up to 3 days. Ketoprofen is commonly used in small animal and equine medicine in the United States; however, there are currently no approved formulations for use in livestock.[36]

SALICYLIC ACID DERIVATIVES. Salicylic acid derivatives, including aspirin (acetylsalicylic acid) and sodium salicylate, were the first NSAIDs to be used in modern medicine and are still widely used for their analgesic, antipyretic, and anti-inflammatory properties. Although the veterinary forms of aspirin are extensively marketed with label indications for the treatment of fever, inflammation, and pain relief, these have never been approved by the FDA Center for Veterinary Medicine for such indications.[49] Therefore the legality of using salicylic acid derivatives in cattle is questionable because these are technically compounded products.

Aspirin elimination half-lives after oral administration range from approximately 4 hours after oral administration in cattle to approximately 38 hours in cats.[49] The slow absorption rate after oral administration demonstrated in adult dairy cows is evident in the difference between elimination half-times for IV sodium salicylate (0.54 ± 0.04 hours)[50] and oral acetylsalicylic acid (3.70 ± 0.44 hours).[51] The elimination half-life is longer after oral administration of aspirin because the rumen acts as a slow-release reservoir for aspirin absorption. The low volume of distribution (0.24 ± 0.02 L/kg) is indicative of limited distribution to tissues. It is noteworthy that salicylic acid derivatives are not associated with clotting deficits in cattle.

CARPROFEN. Carprofen is a member of the propionic acid class of NSAIDs.[52] The relative antiinflammatory, analgesic, and antipyretic activity of carprofen is reported to be greater than phenylbutazone or aspirin in calves.[53] Carprofen is approved in the European Union as an adjunct to antimicrobial therapy to reduce clinical signs in acute infectious respiratory disease and acute mastitis in cattle. The recommended dose for SC or IV administration is 1.4 mg/kg body weight. Carprofen is commonly used in small animal medicine in the United States, but there are currently no approved formulations for use in livestock.[36]

MELOXICAM. Meloxicam is an NSAID of the oxicam class that is approved in the European Union for adjunctive therapy of acute respiratory disease, diarrhea, and acute mastitis when administered at 0.5 mg/kg IM or SC.[54] It has been shown that 0.5 mg/kg meloxicam IM combined with a cornual nerve block reduced serum cortisol response for longer compared with calves receiving only local anesthesia before cautery dehorning.[16] Furthermore, calves receiving meloxicam had lower heart rates and respiratory rates than placebo-treated control calves over 24 hours post dehorning. It was recently reported that meloxicam administered IV at 0.5 mg/kg mitigated the onset of pain responses as measured by heart rate variability and eye temperature, compared with administration of a cornual nerve block alone.[55] We also observed that meloxicam administered at 0.5 mg/kg IV before dehorning in 16-week-old calves reduced plasma substance P concentrations and improved weight gain over 10 days compared with untreated controls.[56] These reports demonstrate that administration of meloxicam before dehorning at 0.5 mg/kg IV or IM may be effective at alleviating pain and distress associated with painful procedures in cattle.

Meloxicam (20 mg/mL) is approved for use in cattle in several European countries with a 15-day meat withdrawal time and a 5-day milk withdrawal time after administration of 0.5 mg/kg IM or SC.[54] An oral meloxicam suspension (1.5 mg/mL) and injectable formulation (5 mg/mL) are approved in the United States for the control of pain and inflammation associated with osteoarthritis in dogs. Furthermore, an injectable formulation (5 mg/mL) is approved for the control of postoperative pain and inflammation in cats. The pharmacokinetics of meloxicam after oral and IV administration to cattle have recently been described.[57] A mean peak plasma concentration (C_{max}) of 3.10 ug/mL (range: 2.64 to 3.79 ug/mL) was recorded at 11.64 hours (range: 10 to 12 hours) with a half-life ($T_{½ \lambda z}$) of 27.54 hours (range: 19.97 to 43.29 hours) after oral meloxicam administration. The bioavailability (F) of oral meloxicam corrected for dose was 1.00 (range: 0.64 to 1.66). These findings indicate that oral meloxicam administration could be an effective and convenient means of providing long-lasting analgesia to ruminant calves. Several inexpensive generic tablet formulations containing meloxicam (7.5 and 15 mg) have recently been approved for relief of signs and symptoms of osteoarthritis in human medicine. In the absence of specific FDA analgesic approvals for conditions other than foot rot in cattle, use of oral meloxicam tablets for alleviation of pain could be considered under AMDUCA.

SEDATIVE-ANALGESIC DRUGS. Opioids, α_2-adrenergic agonists, and *N*-methyl *D*-aspartate (NMDA) receptor antagonists are the most commonly used sedative analgesic compounds in veterinary medicine. These compounds may act synergistically and are therefore increasingly coadministered. A recent survey of Canadian veterinarians found that respondents who did use an analgesic at the time of castration used xylazine (>50% of respondents) more frequently than lidocaine (<30% of respondents).[3] Administration of local anesthetics into the testicles is considered by some to be dangerous and time consuming with unpredictable efficacy, especially when circumstances do not allow sufficient time for maximal anesthesia to take effect.[3] Sedative-analgesic compounds may replace the need for intratesticular anesthetic injection and thus enhance animal well-being and operator safety. A subanesthetic combination of xylazine, administered at 0.02 to 0.05 mg/kg and ketamine at 0.04 to 0.1 mg/kg given IV or IM ("Ketamine Stun") is reported to provide mild sedation without recumbency in cattle.[58,59] Butorphanol (0.01 mg/kg) or morphine (0.05 mg/kg) may be included for enhanced analgesic effects.[58]

OPIOID ANALGESICS. The analgesic effects of opioids are associated with binding to spinal and supraspinal mu (μ), kappa (κ), and sigma (δ) receptors. Drug binding decreases propagation of the nociceptive signal by activating receptor-linked potassium channels and inhibiting voltage-gated calcium channels. In addition to producing analgesia, μ receptor activation is associated with respiratory depression, decreased gastrointestinal motility, increased appetite, sedation, euphoria, and nausea. Therefore partial and mixed receptor opioids have been developed with fewer adverse effects and, in some cases, a lower abuse potential than pure μ agonists. There are currently no narcotic analgesics approved for use in cattle in the United States. Opioids are designated as Schedule 3 drugs in the United States and are subject to regulation by the DEA.

Butorphanol is a κ-opioid receptor agonist and either a partial μ agonist or antagonist. The potency of butorphanol is reported to be five to seven times that of morphine, although some authors dispute this. The efficacy of butorphanol is limited to mild and moderate pain, but it is one of the most common narcotic analgesics used in veterinary medicine. The half-life

VetBooks.ir

of butorphanol in dairy cows administered 0.25 mg/kg IV was 82 minutes.[60] Peak plasma concentration for butorphanol of 7.07 ± 0.55 ng/mL was observed at 9.5 ± 0.50 minutes after coadministration of 0.025 mg/kg butorphanol, 0.05 mg/kg xylazine, 0.1 mg/kg ketamine IM immediately before dehorning, and castration with a plasma elimination half-life of 71.28 ± 7.64 minutes.[61] In dogs a plasma concentration of 45 ng/mL is considered an effective analgesic concentration, but this has not been confirmed in cattle.

Nalbuphine is a synthetic opioid that is a κ-receptor agonist and a μ-receptor antagonist with similar pharmacologic effects as butorphanol. Nalbuphine has analgesic potency similar to morphine on a milligram basis. The onset of activity of nalbuphine reportedly occurs within 2 to 3 minutes after intravenous administration in humans with a plasma elimination half-life of 5 hours. Duration of activity of 3 to 6 hours has been reported after nalbuphine administration in human clinical studies. Nalbuphine injection may be associated with fewer adverse effects than morphine because κ agonists cause less respiratory depression compared with μ receptor agonists. Furthermore, κ agonists carry a significantly lower risk of dependency because opioid addiction is mediated primarily through activation of the μ receptor. As a result, nalbuphine is presently not scheduled as a controlled substance in most parts of the United States in accordance with the Controlled Substances Act (21 U.S.C. § 812) on the basis of the exclusion detailed in 21 C.F.R. § 1308.12. Therefore, special storage and record keeping are not necessary. The potential for fewer adverse effects and reduced regulatory restrictions may make nalbuphine an attractive narcotic analgesic option for use in cattle if clinical efficacy were demonstrated.

α_2-ADRENERGIC AGONISTS. α_2-Adrenergic agonists produce profound sedation, chemical restraint, and analgesia in cattle. Activation of α_2-adrenergic receptors inhibits the positive feedback mechanism for release of norepinephrine from the presynaptic nerve endings by reducing calcium conductance. Attenuation of norepinephrine release causes dose-dependent sedation and inhibits the afferent pain pathway. In addition, α_2-adrenergic agonists decrease cardiac output, cause a centrally mediated reduction in respiratory rate, produce muscle relaxation, and depress gastrointestinal motility. Epidural administration of α_2-adrenergic agonists can produce analgesia with minimal sedative and cardiovascular effects compared with IV administration.

Xylazine is the most commonly used α_2-adrenergic agonist used in cattle and is approved in the European Union for IM administration at 0.05 to 0.3 mg/kg. Administration of the lower dose is characterized by a slight decrease in muscle tone, but the ability to stand is maintained. Higher doses cause recumbency, deep sedation, and a degree of analgesia. It is recommended that cattle are fasted before systemic administration of higher doses of xylazine to reduce the risk of rumen tympany and aspiration of rumen contents.

Xylazine epidural has been shown to produce greater perineal analgesia than xylazine given intramuscularly.[62] Xylazine epidural has been proposed as a method of providing sedation and analgesia to facilitate castration in mature bulls.[63] The onset of analgesia following administration of xylazine alone was found to be significantly longer (11.7 ± 1 minute) than the combination of xylazine and lidocaine (5.1 ± 0.9 minutes) and lidocaine alone (4.8 ± 1.0 minutes).[64] The combination of lidocaine and xylazine produced analgesia of significantly longer duration (302.8 ± 11.0 minutes) than xylazine alone (252.9 ± 18.9 minutes) or lidocaine alone (81.8 ± 11.8 minutes). Xylazine induced mild to moderate sedation and ataxia. Ataxia was also noted in cattle receiving lidocaine alone.

N-METHYL D-ASPARTATE RECEPTOR ANTAGONISTS. Ketamine is an *N*-methyl *D*-aspartate (NMDA)-receptor antagonist that produces analgesia and dissociative anesthetic effects when administered at a dose of 2 to 4 mg/kg IV to calves.[65] Ketamine and its active metabolite, norketamine, also bind μ and κ opioid receptors producing analgesia. Data from rats suggest that norketamine contributes to the analgesic effect of ketamine, with a potency that is one third of the parent drug.

Subanesthetic ketamine administered at 0.1 to 1 mg/kg as an IV bolus is effective in managing acute postoperative pain in human medicine. In humans, plasma ketamine concentrations above 4 to 5 μmol/L (1000 ng/mL) are required to produce anesthetic effects, while analgesic effects are associated with plasma concentrations below 1 μmol/L (275 ng/mL) or $\frac{1}{10}$th to $\frac{1}{5}$th of the anesthetic dose. Plasma ketamine concentrations ranging from 40 to 150 ng/mL were associated with analgesia in humans. Our group previously demonstrated that mean plasma ketamine and norketamine concentrations in cattle decreased to below 40 ng/mL and 10 ng/mL after 30 and 60 minutes, respectively, after administration of a subanesthetic combination of xylazine (0.05 mg/kg) and ketamine (0.1 mg/kg).[66] NMDA receptor antagonists are designated as Schedule 3 drugs and are subject to regulation by the DEA.

Future Prospects for Treating Chronic Pain and Central Sensitization in Cattle

GABAPENTIN. Gabapentin (1-[aminomethyl] cyclohexane acetic acid) is a γ-aminobutyric acid (GABA) analog originally developed for the treatment of spastic disorders and epilepsy. Studies have reported that gabapentin is also effective for the management of chronic pain of inflammatory neuropathic origin. Although the mechanism of action of gabapentin is poorly understood, it is thought to bind to the α_2-δ subunit of voltage-gated calcium channels acting presynaptically to decrease the release of excitatory neurotransmitters. Efficacy of gabapentin in humans is associated with 2 μg/mL plasma drug concentrations. It has also been reported that gabapentin can interact synergistically with NSAIDs to produce antihyperalgesic effects. We report a mean peak plasma gabapentin concentration (C_{max}) of 3.40 μg/mL (range: 1.70 to 4.60 μg/mL) at 7.20 hours (range: 6 to 10 hours) after oral gabapentin administration to calves at 15 mg/kg.[67] An elimination half-life ($T_{½}$) of 7.9 hours (range: 6.9 to 12.4 hours) was recorded. Oral administration of gabapentin at 15 mg/kg may be associated with plasma concentrations of greater than 2 μg/mL for up to 15 hours. The pharmacokinetics of gabapentin suggests that this compound may be useful in mitigating chronic neuropathic and inflammatory pain in ruminant cattle.

Summary

The American Veterinary Medical Association veterinary oath was revised in 2011 to include emphasis in the protection of animal welfare and prevention and relief of animal suffering. In addition to diagnosis and treatment of pain discussed in this chapter, practitioners should explore opportunities to prevent and mitigate pain associated with routine surgical procedures through development of herd health protocols that include least painful techniques, training of stockpeople, and scheduling the surgeries to minimize stressors. In addition to pharmacologic interventions, thoughtful consideration of the hospital environment can aid convalescence by providing appropriate social groupings, a comfortable place to rest, and easy access to feed and water.

Alterations in Body Temperature

MARIE-EVE FECTEAU, *Consulting Editor*

■ MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Hyperthermia, 33 **Fever,** 36 **Hypothermia,** 42

Control of Body Temperature

In mammalian (homeotherm) species, the temperature of the deep tissues of the body—the *core*—remains within a narrow range (within ±1° F), even when exposed to extreme ambient temperature variations. In contrast, the *skin* temperature rises and falls with the temperature of the surroundings, giving it an important role in core temperature regulation. However, because the temperature regulatory mechanisms are not perfect, the core body temperature of even healthy animals can sometimes rise temporarily to as high as 104° F (40° C) when excessive body heat is produced (such as during a strenuous exercise) or, conversely, temporarily fall below 97° F (36° C) when the body is exposed to extreme cold. Maintenance of body temperature is under neuronal control in a negative feedback system. The first mechanism involves warm- and cold-sensitive neurons within the preoptic region of the anterior hypothalamus (POAH), which act similarly to a thermostat with a desired "set point."[1] Temperature sensors are also present in the skin and deep tissues of the body such as the abdominal viscera and around the great veins of the abdomen and thorax.[1] Most of the temperature-sensitive neurons in the skin respond to cold so that environmental temperature changes are detected before they threaten core temperature.[2] It is also for that reason that shivering occurs after exercise as the skin rapidly cools during sweat evaporation, despite the fact that core temperature may be normal or slightly elevated. Those temperature signals produced by the central and peripheral receptors are transmitted to the POAH, which then integrates them and initiates mechanisms to either increase or decrease heat loss or production (Fig. 4.1).[3] It is also important to note that the temperature "set point" varies between species and individuals and that fluctuations in body temperature occur normally throughout the day due to circadian rhythm.[1,4] For example, pigs have a higher temperature "set point" than do sheep, as the former lack hair or fiber. Conversely, dairy cattle that have a high milk production have a lower temperature "set point," as heat production increases with their increased metabolic demand. Temperature "set points" can also be affected by acclimatization to certain ambient temperatures. As such, with heat acclimatization, there is a lower body temperature threshold for sweating, and sweat gland sensitivity and capacity improve.[4]

Most of the heat produced in the body is generated in the skeletal muscles and deep organs. Muscle activity may range from inapparent contractions to generalized shivering and vary according to the need. Digestion of food also contributes significantly to heat production, and the amount of heat produced per gram of food differs between food categories (carbohydrates, fat, and proteins), with fat producing more than twice as much heat as carbohydrates and proteins.[1] Heat conservation occurs from adrenergic autonomic stimuli to decrease peripheral circulation (vasoconstriction) and cause piloerection. Behavioral means of heat conservation include adopting a "huddled" posture, group aggregation, and seeking a sheltered environment.

Heat loss occurs from conduction, convection, and radiation from body surfaces and by evaporation. Sympathetic vasodilation of cutaneous vessels contributes to surface cooling. As ambient temperature rises, evaporative heat loss becomes more important. In ruminants, evaporative heat loss is mostly confined to the respiratory system, and respiratory rate increases concurrently with temperature. In horses, sweat production and subsequent evaporation have the most important role in heat loss, followed by respiratory tract evaporation. Behavioral responses that contribute to heat loss include seeking shade and wind currents and wading into water.

Conditions of Increased Body Temperature (Hyperthermia)

Body temperature disorders in which the core body temperature set point is unaltered can occur from increased heat production, absorption of heat, or impairment of heat loss. Central nervous system (CNS) disorders that disturb the hypothalamic regulatory center, certain drugs, and metabolic disorders may also cause temperature changes. Regardless of the triggering cause, hyperthermia should be considered a medical emergency, and severely hyperthermic patients require immediate total body cooling, as temperatures above 107° F (41.6° C) may lead to permanent organ damage or death. Cooling options for the hyperthermic patient are discussed later in the "Heat Stroke" section.

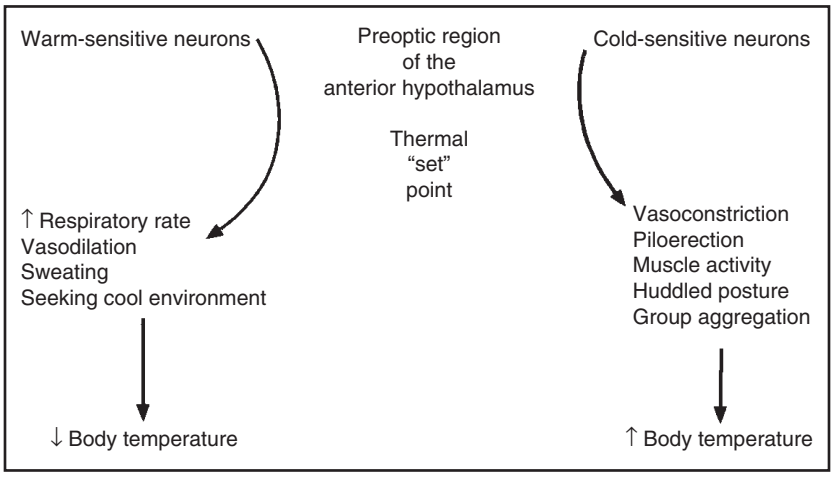

FIG. 4.1 Regulation of body temperature.

Malignant Hyperthermia

Malignant hyperthermia (MH) is a pharmacogenetic disorder of skeletal muscles that presents as a hypermetabolic response to potent volatile anesthetic gases such as halothane, sevoflurane, desflurane, and the depolarizing muscle relaxant succinylcholine and, rarely, in humans, to stresses such as vigorous exercise and heat.[5] The classical signs of MH include marked hyperthermia, tachycardia, tachypnea, increased end-expired carbon dioxide production, increased oxygen consumption, acidosis, hyperkalemia, and muscle rigidity.[5] The pathophysiology of MH involves an uncontrolled release of intracellular calcium from skeletal muscles' sarcoplasmic reticulum, resulting in sustained muscle contractions, increased oxygen consumption and carbon dioxide production, adenosine triphosphate (ATP) breakdown, and increased glycogen metabolism, which in turn generates heat.[5] Although MH is most common in humans and pigs, it has been reported in horses.[6-9] Of note, MH has also been reported in pot-bellied pigs.[10] A dominant mutation of the ryanodine receptor 1 gene (*RYR1*), which is essential in skeletal muscle excitation-contraction coupling, is the basis of MH in humans, pigs, and dogs.[11] The mutation has also been documented in Quarter Horses with MH and has an estimated prevalence of 1.3% in a random sample of 225 Quarter Horses.[12-13] In all species, MH typically leads to death if it is not recognized and treated early (see also Malignant Hyperthermia, Chapter 42).

Exercise

During sustained exercise, heat production may exceed the ability of heat loss mechanisms, leading to a stable increase in core body temperature proportional to the intensity and duration of exercise. The elevation in temperature often persists for several hours after exercise, but temperature returns to normal with rest as heat loss mechanisms remain activated. Body temperature increases of greater than 2° C (4° F) above normal during exercise, especially if reached early in exercise, are usually the result of severe environmental conditions and/or failure in heat loss mechanisms. In one study looking at the effect of age on thermoregulation during exercise, old horses reached higher body temperatures faster and had greater sweat losses when compared with young horses.[14] It is proposed that in horses, ageing affects the ability to handle the combined demand of exercise and thermoregulation in part due to a decrease in absolute preexercise plasma volume.[14] Peripheral cooling to augment heat loss should be used to lower body temperature because increases in temperature caused by exercise are unaffected by antipyretic drugs.[15-16]

The intense muscular activity associated with generalized tonic-clonic seizures may, like vigorous exercise, cause a rise in body temperature. If central heat regulatory systems are unaffected by the disease process, body temperatures return to normal no longer than 48 hours after the last seizure.[17] Elevated temperatures that persist for longer periods should prompt investigation into other causes for the increased temperature. Similarly, hyperkalemic periodic paralysis of horses has also been associated with episodes of hyperthermia.[18]

Heat Stroke

When animals are exposed to high ambient temperatures, intense solar radiation, and/or high humidity so that heat load increases at a rate faster than heat can be dissipated, heat stroke may develop.

Heat stroke is more common in ruminants because of their inability to sweat and thus their diminished evaporative ability for heat loss. Sheep with fleece and large dense cattle are especially prone to heat stroke when denied access to shade or adequate water and/or when physical activity is imposed on them. Rectal temperature will often exceed 107° F (41.5° C), and central body temperature may exceed 112° F (44.5° C). Heat stress is a recognized condition of llamas and alpacas that are exposed to high ambient temperature and high humidity.[19] Normal camelids dissipate heat through evaporation of water through the respiratory system and sweat. In camelids, sweat glands are concentrated in the fleece-free areas of the axillary and inguinal regions. Camelids exposed to extreme heat conditions will seek out cool areas, decrease unnecessary physical activities, and stand or lie in a more upright position to improve sweating efficiency.[20] They can also increase their respiratory rate and open-mouth breathe to help with heat loss through the respiratory system. Risk factors that can predispose animals to develop heat stroke include primary disorders that will render an animal weak or recumbent and obesity.[20] With the peracute form of heat stroke, clinical findings include hyperthermia (often >105° F); tachycardia and/or tachyarrhythmia; recumbency; edema of the ventrum, perineum, and legs; and signs of respiratory distress including open-mouth breathing.[20] Thoracic auscultation typically reveals increased bronchovesicular sounds and crackles suggestive of pulmonary edema.[20] A frothy, blood-tinged oral or nasal discharge can be observed secondary to diffuse vasculitis.[20] Affected animals are likely to die of multiple organ failure if rapid and aggressive treatment is not undertaken.[20] With the more common subacute form (heat stress), affected animals are bright and alert but refuse to stand or have difficulties standing for long periods of time.[20] With this form, the hyperthermia may be only present briefly or intermittently, and affected camelids typically maintain a normal appetite and organ function. A neurologic examination may be difficult to interpret, and clinicians may often rely on the results of ancillary tests to rule out CNS disorders. A

leukogram is typically nonspecific and reflective of stress response. Biochemistry will usually reveal increased muscle enzymes, azotemia, hypoproteinemia, hyperlactemia, and metabolic acidosis.[19-20]

Horses continuously exercised in high heat and humidity may also develop heat stroke. Evaporative heat loss from sweating is the most important means of heat loss as metabolic heat production increases during exercise, especially as ambient temperature and humidity increase.[21] Efficiency of evaporative heat loss diminishes when temperature and humidity are high and there is a significant radiation component resulting from strong sunshine.[22] Horses' susceptibility to heat stroke is enhanced if dehydration and electrolyte imbalances occur because of large losses of sweat (see also Exhaustion in Endurance Horses, Chapter 42). Adrenaline and noradrenaline may play a role in the adaptation of horses to thermal stress.[23]

As rectal temperature increases above 107° F (41.5° C), the homeostatic mechanisms of temperature regulation fail; peripheral vasoconstriction, decreased blood pressure, and decreased cardiac output occur. The animals are lethargic and have weak, flaccid muscles; prostration and shock occur rapidly. Disseminated intravascular coagulation, liver damage, renal failure, and myocardial necrosis are frequent complications.

The cornerstones of treatment of heat stroke are 1) to decrease the body temperature to normal levels and 2) to support the animal through its convalescent period.[20] First, the animal should be removed from the extreme condition and brought to a cool, shady, and well-ventilated environment. For animals with fleece or heavy hair coat, clipping away the fleece is helpful. Pools of water (such as down cow float tanks or water troughs) are useful in rapidly cooling down camelids and small ruminants. Topical alcohol and water (alcohol baths) are often ineffective at reducing body temperature as they may cause cutaneous vasoconstriction and can inhibit water evaporation from the skin. Administration of cool intravenous fluids may help with both decreasing body temperature and correcting hypovolemia and electrolyte losses. The rate of administration of intravenous fluids should be monitored closely, as animals with heat stroke (particularly camelids) can be prone to developing pulmonary edema. Other methods include administration of chilled water into the stomach or rectum and strategic placement of ice packs over areas with large vessels (neck, axilla, and inguinal regions). The administration of nonsteroidal antiinflammatory drugs is often useless at decreasing body temperature, as it is not a prostaglandin-mediated fever,[20] and may even be harmful to the kidneys of a severely dehydrated animal. Attempts should be made at diagnosing and treating primary disorders that may have predisposed the animal to developing heat stroke, such as a neurologic condition. It is not uncommon for camelids or small ruminants that have survived the acute phase of heat stroke to remain recumbent for an extended period of time following the acute stage of the disease. Basic supportive and nursing care is important for those animals in order to avoid pressure sores and limb contracture.

Anhidrosis

Up to 25% of horses in hot, humid environments lose their ability to sweat and subsequently suffer from hyperthermia as a result of impairment of heat loss.[24] In a more recent study that included more than 4500 horses from 500 Florida farms, the prevalence of anhidrosis was 11% at the farm level and 2% at the animal level.[25] Horses in training have been reported to have a higher frequency of anhidrosis, as are horses shipped to hot environments from more temperate regions; however, horses indigenous to hot, humid areas that perform less rigorously or not at all may also develop anhidrosis.[26-27] In addition to hyperthermia, clinical signs are poor performance, total or partial loss of ability to sweat, increased respiratory rates (three to five times normal), and dry, thin hair coats with areas of alopecia (see also Anhidrosis, Chapter 41).

Drugs and Toxins With Effect on Body Temperature

Phenothiazine tranquilizers are a recognized cause of loss of ability to control body temperature.[28] Conversely, α_2-adrenergic agonist sedatives (e.g., detomidine, xyalzine) have been shown to induce tachypnea and decrease body temperature in febrile horses.[29] The potential mechanism for the antipyrexic effect of α_2-adrenergic agonist drugs may be related to their ability to decrease prostaglandin E_2 production by the hypothalamus.[29-30] Erythromycin may induce hyperthermia during hot weather, particularly in foals.[31-32] This side effect has been attributed to a reaction to erythromycin itself or to an alteration of the foal's thermoregulatory system by mechanisms not yet described.[32] Other drugs that have been associated with increase in body temperature in large animals are summarized in Box 4.1. "Drug fever" should be a diagnosis of exclusion.[33] Helpful clues include the lack of fever pattern and the temporal association between initiation of a drug and the onset of fever or discontinuation of a suspected drug and resolution of fever.[33]

Certain toxins and drugs may act to increase body temperature by causing an increase in metabolic work (Boxes 4.2 and 4.3). For example, chlorophenols and nitrophenols, used as herbicides and wood preservatives, cause uncoupling of oxidative phosphorylation within mitochondria and lead to rapid extreme rises in body temperature.[34] Chronic and/or low-level exposure to these compounds may manifest clinically as hyperthermia.

Tall fescue infected with the endophyte *Neotyphodium coenophialum* contains vasoactive ergopeptine alkaloids that

cause vasoconstriction and reduced blood flow to the skin of ruminants.[35] These alkaloids also induce bronchoconstriction and pulmonary vasoconstriction, which further compromise ruminants' ability to lose heat, especially during hot environmental conditions.[35] Affected animals have a poor appetite and other indications of poor performance recognized as part of the syndrome of fescue toxicosis, or "summer slump."[35] A related endophyte infesting perennial ryegrass has been found to produce a similar hyperthermic condition in the western United States.[36] *Claviceps purpurea* infestations of annual or perennial ryegrass and of cereal grain heads have also been reported to produce a similar hyperthermic syndrome, which may lead to heat prostration and death when ambient temperatures are high.[37-39]

Cattle affected by any of these ergopeptine alkaloids have few to no clinical signs when environmental conditions are cool and heat loss mechanisms are not challenged. It is not yet known, however, if all of the effects of the alkaloids are peripheral or if they may also act within the CNS.[35]

Diseases of the Nervous System

CNS disorders that damage areas of the hypothalamus associated with temperature regulation may lead to either decreases or increases in body temperature, although hypothermia is most common. Hemorrhage, space-occupying masses (abscesses, tumors), infectious or inflammatory diseases, and degenerative disorders have all been implicated in hyperthermia. Hyperthermia is a common occurrence in humans with brain or spinal cord injury.[40] Central hyperthermia is usually characterized by lack of diurnal variation, absence of sweating, resistance to antipyretic drugs, and excessive response to external cooling.[3,28]

Fever

True fever differs from other hyperthermic states in that the desired core body temperature or set point is elevated.[1] This new, higher set point is vigorously defended by the same mechanisms that maintain body temperature in health. Initiation of the febrile state can occur by a variety of infectious, inflammatory, immunologic, neoplastic, or injurious conditions. In the classic model of fever, these stimuli cause the production of multifunctional pyrogenic cytokines by a wide variety of cells, but primarily by fixed or circulating monocytes and macrophages[37] (Fig. 4.2). Currently at least 11 cytokines have been shown to induce the febrile response in humans and animals. Of these cytokines, interleukin 1 (IL-1α, IL-1β) and tumor necrosis factor alpha (TNF-α) are the most potent. Pyrogenic cytokines reach the POAH via the circulation and induce the production of arachidonic acid and its metabolism to prostaglandin E_2 (PGE_2), by the cyclooxygenase (COX)-2 pathway. This process will eventually result in a higher "set point" within the hypothalamic thermoregulatory center[41-42] (see Fig. 4.2). COX inhibitors, specifically COX-2 inhibitors, effectively reduce the febrile temperature to normal but have no effect on normal body temperature.[3,42] In addition, pyrogenic cytokines stimulate the activation and proliferation of T lymphocytes and of antibody-producing B lymphocytes, which, in turn, produce additional cytokines that both enhance and inhibit further production of pyrogenic cytokines.[43-44] Finally, pyrogenic cytokines, particularly IL-1 and TNF-α, cause membrane perturbation in a variety of body tissues, with a resultant increase in phospholipases and the production of arachidonic acid. Subsequent production of mediators is dependent on the metabolic pathways for arachidonic acid in the target tissue. Prostaglandins induced by pyrogenic cytokines have been shown to stimulate the muscle catabolism associated with fever and to induce collagenase synthesis from synovial cells.[45] These processes contribute to the muscle and joint pain associated with fevers that are relieved by COX inhibitors.

Local tissue responses to IL-1β and TNF-α may stimulate afferent neural impulses that are responsible for many of the behavioral changes (increased sleep, decreased appetite, and loss of social behavior) associated with fever.

This model, however, does not fully explain the presence of fever, because specific blockade of IL-1 or TNF-α activity does not diminish the febrile response to lipopolysaccharide (LPS) or other microbial products in experimental studies or in patients with natural infections. Microbial products from a variety of agents bind to Toll-like receptors (TLRs) on the surface of cells. TLRs and IL-1 receptors share the same signaling areas and, along with other pyrogenic cytokines, a common pathway to activate nuclear factor (NF)-κB. Activated NF-κB in turn results in expression of COX-2 or COX-3 and PGE_2 synthesis. Mice deficient in COX-2 and injected with LPS, IL-1, TNF-α, or IL-6 either intravenously or within the CNS do not develop a fever.[42] Thus the induction of COX-2 and the subsequent production of PGE_2 provide a common pathway for divergent pyrogens to produce the febrile response (see Fig. 4.2).

There is also an apparent role for the vagal nerve in the production of the febrile response. Studies in laboratory animals in which the hepatic branch of the vagus nerve is severed have shown diminution of the febrile response to a relatively low dose of intraperitoneally injected LPS but not intramuscularly administered LPS or high-dose intraperitoneally injected LPS. Local production of cytokines may stimulate primary hepatic vagal receptors that, via vagal afferent fibers and A1/A2 noradrenergic cell groups in the brainstem, release noradrenaline, which subsequently induces the production of PGE_2 and fever.[46] Transection of the visceral vagal afferents has been shown to attenuate febrile behavioral responses, but not the associated temperature elevation, to high-dose intraperitoneal LPS injection in rats.[47]

In addition to a rise in body temperature, the febrile state is accompanied by a variety of metabolic, hematologic, and immunologic changes. IL-6 and IL-11, induced by IL-1α, IL-1β, and TNF-α, induce the synthesis of fibrinogen, C-reactive protein, haptoglobin, ceruloplasmin, and certain macroglobulins, known collectively as *acute phase proteins*, by hepatocytes.[42] In addition, these cytokines mediate the accompanying hypoferremia, hypozincemia, and hypercupremia of the acute-phase response.

Physiologic control of the febrile response is multifactorial and prevents extreme elevations in body temperature that are incompatible with life in most instances. TNF-α inhibits further production of itself. IL-1 and other inhibitory cytokines stimulate the production of IL-1 receptor agonist, which prevents further binding of IL-1. In addition, one of the receptors on cell surfaces for IL-1 (type II receptor) does not result in cell signaling and is thought to serve as a "decoy" receptor to decrease the concentration of IL-1.[48] IL-10, induced by pyrogenic cytokines, inhibits IL-1, TNF, and IL-6 production and suppresses the production of IL-2 and IFN-γ by T-helper cells.[48-49] Circulating pyrogenic cytokines may be bound to carrier molecules that reduce or prevent the interaction with receptors. For example, IL-1β has been shown to bind to α_2-macroglobulin, a protein increased during the acute phase response.[3] Glucocorticoids inhibit the transcription of numerous genes encoding the pyrogenic cytokines IL-1β, Il-6, and TNF-α. Within the brain, both arginine vasopressin (AVP) and alpha melanocyte stimulating hormone (αMSH) act as potent antipyretic agents. Receptors for AVP, which acts as a neurotransmitter within the brain, are found lateral to the POAH and decrease fever in both natural and experimentally induced fever, whereas injection of AVP receptor antagonist elevates fever and delays defervescence.[50-51] αMSH binds to local melanocortin receptors within the brain and on cell receptors of immune cells to decrease fever and inflammation. When administered systemically to humans, αMSH is 20,000 times more potent on a molar basis than acetaminophen in decreasing fever from endogenous pyrogens.[51]

In the brain, nitric oxide (NO) participates in regulation of body temperature by activating soluble guanylate cyclase and increasing cyclic guanosine monophosphate (cGMP) levels. Intracerebral ventricular injection of NO donors depresses fever in rats, whereas inhibition of NO synthesis within the CNS enhances fever.[48]

In summary, the occurrence of fever during disease results from a complex interaction of multiple cytokines and microbial products that act locally (site of tissue injury), systemically (in the circulation), and in the POAH of the brain and affect the immune, endocrine, and nervous systems.

Beneficial Effects of Fever

It should be emphasized that fever is not an illness but is, in fact, a physiologic mechanism that has beneficial effects in fighting infection. Body temperature elevation in pyrogenic-mediated fevers, in contrast to hyperthermic states, rarely exceeds 5° F (2.5° C) above normal. Although the severity of some viral infections is decreased at these temperatures, most pathogens are not affected by a modest rise in temperature. Studies on bacterial infections in fish, lizards, rabbits, and humans, however, have shown an increase in survival correlated with the presence of fever.[3,52-53] One well-studied effect of fever on bacterial proliferation is the effect of hypoferremia. Bacteria, which require iron for multiplication, are inhibited by the reduced availability of iron during the acute phase reaction. This response is augmented by the increased susceptibility of bacteria to low iron at higher temperatures.[54-55] Certain neoplastic cells are inhibited during fever, although it is likely that inhibition of neoplastic cell division results from augmentation of immune responses.[56]

Literature on the effect of fever is conflicting owing to the multiple variables present in in vivo studies and the application of heat in temperature ranges exceeding those of natural fevers in in vitro studies. Enhancement of host defenses, however, appears to be the primary beneficial effect of fever. Fever or heat applied in in vitro studies within the physiologic range of natural fevers has a beneficial effect on multiple processes of the adaptive immune response. Neutrophils and monocytes have increased motility and emigration, enhanced phagocytosis, increased oxygen radical production, and enhanced killing of intracellular bacteria. IFN production increases, and its antiviral, antitumor, antiproliferative, and natural killer (NK) cell–stimulating properties are enhanced. Increased T-cell proliferative responses to nonspecific mitogens IL-1 and IL-2 and enhanced T-helper cell activation, expression, recruitment, and cytotoxicity have all been correlated with fever. Enhancement of B cells, with a subsequent increase in production of antibodies, and enhanced expression of Fc receptors occur during fever.[57]

Activity of pyrogenic cytokines is also influenced by temperatures achieved during fever. For example, in a mouse-endotoxin model, fever enhanced the early expression of TNF-α but limited the duration of its expression. Production of IL-1β was delayed, whereas that of IL-6 (which downregulates production of TNF-α and IL-1β) was enhanced, preventing the simultaneous expression of TNF-α and IL-1β and the potential harmful effects of their simultaneous expression.[58] Other studies have demonstrated that the effect of fever on various cytokines is specific for each cytokine and specific to body compartments. Thus fever is an important component of the coordinated and specific cytokine response of the host to various inflammatory stimuli.[3,45,57]

Adverse Effects of Fever

The beneficial effects of fever during bacterial infections in rabbits have been shown to reverse at temperatures >5° F (3° C) above normal. Cytokine dysregulation may result in prolonged or extreme fevers with adverse effects on a variety of body functions in addition to the immune response. Catabolic metabolic processes during fever are markedly different from catabolism of starvation. Protein loss occurs four times as rapidly

in individuals with infectious or inflammatory diseases as compared with starvation-adapted individuals. Ketonemia is inhibited, resulting in the oxidation of large amounts of muscle-derived amino acids for energy. This cytokine-driven catabolism, combined with the decreased feeding behavior that accompanies fever, variable anorexia (even if feed is provided), and increased metabolic rate at higher temperatures, can result in rapid and severe muscle wasting, weakness, and atrophy. In humans, high fevers frequently cause seizures, especially in children,[59] but this is rare in animals unless temperatures reach 108° F (42° C) in neonates. Prolonged high fevers in debilitated animals may lead to failure of the cardiovascular system.

Fever is one of the earliest and most prominent manifestations of the acute phase reaction. Veterinarians have used the clinical thermometer to aid in diagnosis and to monitor the progress of illness in animals since 1770. With the increased knowledge of the pathogenesis of fever has come a better appreciation for the diverse causes of the febrile state. In ruminants and horses, however, infectious disease remains the most common reason for development of fever (Boxes 4.4 and 4.5). Careful evaluation for the presence of infectious disease is always indicated, especially when the onset of a fever is abrupt; the temperature is higher than 39.4° C (103° F); and the fever is accompanied by depression, variable loss of appetite, serous nasal exudate, epiphora, enlargement of lymph nodes, or diarrhea and a decreased or increased leukocyte count. Other causes of fever are neoplasia (Boxes 4.6 and 4.7), immune-mediated diseases (Boxes 4.8 and 4.9), noninfectious inflammation (Boxes 4.10 and 4.11), and certain drugs.

Fevers of Unknown Origin

Most febrile illnesses encountered in large animal practice are caused by infectious diseases that are readily diagnosed by careful evaluation of history and physical examination or are of short duration, run their course, and progress to complete recovery within 2 weeks without a specific etiologic diagnosis having been made. Some febrile conditions, however, continue for weeks or months, accompanied only by nonspecific signs of depression, variable anorexia, and weight loss, while the diagnosis remains obscure. Patients with prolonged febrile episodes of 3 weeks' duration or longer in which a diagnosis has not been made after a week of routine diagnostic efforts or after 3 days of hospitalization and diagnostic tests are considered to have fever of unknown origin (FUO). The majority of cases that meet the definition of FUO have infectious causes. Neoplastic diseases, immune-mediated vasculitides, and autoimmune diseases are the next most common causes. Adverse drug reactions and other miscellaneous diagnoses are the least common documented causes of FUO. Most cases of FUO are caused by common diseases with an unusual presentation; an ordered, problem-oriented approach to diagnosis will render a diagnosis in 90% of cases.[60-61] The following steps are suggested (Fig. 4.3).

Document Fever

A temperature chart consisting of at least twice-daily determination of rectal temperature should be completed to characterize the fever pattern. *Intermittent fevers* are characterized by diurnal variation in which a peak elevation of temperature of higher than 1.5° F (0.75° C) occurs, followed by a decline in temperature, which in some patients falls within the normal range. Most intermittent fevers peak in late afternoon or evening, with the lowest temperatures occurring in the morning, but approximately 10% of cases will have a reverse pattern. Intermittent fever is most commonly associated with pyrogenic infections, although it may occur in neoplasia, especially if tissue necrosis and inflammation are concurrent. *Remittent fevers* are characterized by a period of days in which elevated temperatures occur, followed by several days of normal temperature, only to have the cycle repeat again. Brucellosis in ruminants, equine infectious anemia (EIA) in horses, and blood-borne protozoal diseases such as babesiosis may exhibit this type of pattern. *Sustained fevers* are characterized by a consistently raised temperature without variation and appear as a "flat line" on a temperature chart. Fevers caused by drug administration and certain toxins may be of this type, especially if the patient does not exhibit any other signs of illness.[3] Any pharmacologic agents being administered to the patient should be discontinued. Defervescence of fever from drug administration should occur in 48 hours.

Consideration of Epidemiology

Repeated efforts to obtain a complete history in chronologic order of development of clinical signs may be necessary to

extract all the information pertaining to the individual animal. A knowledge of forage available, presence of nutrient deficiencies and excesses, toxic plants, and infectious organisms indigenous to the area, as well as the threat of exotic diseases, is necessary for the present and past geographic environment of the animal.

Physical Examination

A physical examination (see Chapters 1 and 2) should be carefully performed to evaluate all body systems as thoroughly as possible and repeated as often as practical, because it is unusual for a disease to cause a prolonged fever without the occurrence of some physical signs. Examination should include the following:

1. Horses
   a. Thorough auscultation of cardiopulmonary system at rest, with rebreathing bag, and following exercise; evaluation of peripheral perfusion before and after exercise
   b. Complete visual or manual oral examination; percussion of sinuses; endoscopic examination of upper airway structures (including the guttural pouches) and of the trachea and bronchi (if length of the endoscope allows)
   c. Palpation of external lymph nodes, ballottement, and deep palpation of external abdomen for pain
   d. Rectal examination
   e. Fecal odor, consistency, volume; frequency of defecation
   f. Complete ophthalmic examination
   g. Evaluation of external genitalia and mammary gland
   h. Evaluation of musculoskeletal conformation and gait analysis for lameness
2. Ruminants
   a. Complete visual or manual oral examination; percussion of sinuses; eye examination
   b. Check for abdominal pain by withers pinch or xiphoid pressure
   c. Thorough auscultation of cardiopulmonary system, evaluation of peripheral perfusion
   d. Palpation of all external lymph nodes
   e. Rate and quality of rumen contractions, abdominal ping, and ballottement for rumen fill and pain
   f. Complete udder examination and milk evaluation of lactating females

g. Testicular and penile palpation of males
h. Complete rectal examination (cattle) or external abdominal palpation (young cattle and small ruminants)
i. Fecal color, consistency, volume; frequency of defecation
j. Evaluation of musculoskeletal conformation and gait analysis for lameness, palpation of all joints

Diagnostic Aids (Table 4.1)

All cases of FUO should have a laboratory database consisting of a complete blood count (CBC), urinalysis, and biochemical profile. The CBC should include morphology of red blood cells and white blood cells (WBCs), WBC differential, and fibrinogen determination. Chronic inflammatory disease produces characteristic changes in the CBC (see Chapters 24 to 26), and morphologic evaluation of the blood smear may reveal blood-borne parasites.

Serum protein and albumin determinations characterize either hypoproteinemia or hyperproteinemia. Serum protein electrophoresis and immunoelectrophoresis further classify deficiencies or increased production of proteins. It is prudent to measure serum hepatocellular enzyme activities and serum bile acid concentration for evaluation of hepatocellular damage and function, respectively.

Because much of the abdomen is unavailable to rectal palpation, abdominocentesis and evaluation of peritoneal fluid for protein, cellularity, and cell morphology are justified. Peritoneal fluid is obtained more consistently in horses than in ruminants with abdominal disease because of the presence of the greater omentum and the rapid formation of fibrinous adhesions in ruminants with inflammatory abdominal disease. Peritoneal fluid evaluation is usually most helpful in inflammatory diseases, but it may be diagnostic in some cases of abdominal neoplasia. Bacterial culture and sensitivity of peritoneal fluid are indicated in inflammatory diseases when WBCs show degenerative or toxic changes but are rarely positive unless gross bowel contamination has occurred. Polymerase chain reaction (PCR) for *Streptococcus equi* and/or *R. equi* may be warranted in horses with evidence of chronic inflammation of the abdominal cavity.

Blood cultures are best used after characterization of a remittent fever and evidence of pyogenic inflammatory disease from the laboratory database. Any antimicrobial therapy should be discontinued 48 to 72 hours before sampling. Three to five samples should be collected at least 45 minutes apart and are best taken directly into culture media. Sampling just before and during a temperature rise is more likely to yield positive results than sampling at the temperature peak and decline.

Serologic evaluation for infectious diseases common in the geographic area and/or patient population should be performed. Single serologic determinations are usually of value only in those diseases in which one positive titer is significant and when the disease is characterized by persistent infection such as EIA, brucellosis, or Johne's disease. In many instances vaccination history and/or accompanying clinical signs must be correlated with titer determinations. Paired samples for toxoplasmosis, babesiosis, and various mycotic diseases (especially coccidioidomycosis) are indicated when the diagnosis remains obscure. Serologic determination of antibody titers to the SeM protein of *S. equi* can aid in the diagnosis of internal abscessation.[62] The synergistic hemolysis inhibition (SHI) test may be helpful in the diagnosis of *Corynebacterium pseudotuberculosis* infections in horses and small ruminants.[63-65] Virus isolation, PCR, and/or immunohistochemistry, particularly in persistent bovine viral diarrhea (BVD)-infected cattle, may be helpful.

Feces should be tested for the presence of occult blood. Suspicion of gastrointestinal blood or protein loss, intermittent/chronic diarrhea, and weight loss warrants fecal cultures and

TABLE 4.1

Fever of Unknown Origin: Diagnostic Procedures

Procedure	Indications
Abdominocentesis	Abdominal pain Abnormal rectal examination (e.g., mass) Fluid wave on ballottement Abnormal ultrasound finding (e.g., fluid, mass)
Biopsy	Enlarged lymph nodes or other mass found Abnormal renal or liver function test results Vesicular or ulcerative skin lesions
Blood culture	Intermittent fever, especially in a neonate with failure of passive transfer Neutropenia or neutrophilia ± bands Increased fibrinogen Cardiac murmurs (bacterial endocarditis)
Radiography	Any musculoskeletal pain, heat, swelling Thorax, see transtracheal aspirate Abdomen: traumatic reticuloperitonitis (cattle), enterolith (horse)
Synovial fluid aspirate	Joint effusion, heat, pain
Thoracocentesis	Abnormal percussion of chest Fluid line thoracic radiographs Fluid found on ultrasonography
Transtracheal aspirate	Persistent cough or nasal exudate with normal upper respiratory tract Abnormal auscultation or percussion of thorax Persistent increased respiratory rate
Bronchial alveolar lavage	Exercise intolerance with normal cardiovascular system
Immunodiagnostic screening	
Serum protein electrophoresis	Abnormal serum protein
Serum protein immunoelectrophoresis	Hypergammaglobulinemia Hypogammaglobulinemia (horses)
Direct Coombs test	Hemolytic anemia RBC autoagglutination
Skin biopsy direct immunofluorescence	Vasculitis, purpura Bullous or ulcerative skin lesions
Antinuclear antibody	Multiple noninfectious arthritis
ECG	Dysrhythmia, congestive heart failure
Bone marrow aspiration	Anemia Thrombocytopenia
Gastrointestinal absorptive tests (horse)	Hypoproteinemia with normal kidney, liver
Serology	Persistent undiagnosed disease
Exploratory laparotomy	Abnormal rectal examination, ultrasonography Chronic abdominal pain Abnormal peritoneal fluid
Ultrasonography	Cardiac murmurs, dysrhythmias Abnormal liver or kidney function tests Abdominal mass—suspect fluid in thorax, pericardium, abdomen

ECG, Electrocardiogram; *RBC*, red blood cell.

VetBooks.ir

rectal biopsy for ruling out salmonella or infiltrative bowel disease in horses, whereas such signs in adult dairy cattle warrant ruling out abomasal lymphosarcoma and Johne's disease as the cause.

Also helpful are biopsies of enlarged lymph nodes, accessible abdominal masses, and the liver and kidney when laboratory data indicate abnormalities. Liver biopsies should be cultured and evaluated histologically, because bacterial cholangiohepatitis can be a cause of FUO. Evaluation of biopsies for the presence of immunoglobulins, particularly if skin lesions are present, may add in diagnosis of immune-mediated disorders. Antinuclear antibody determinations and a Coombs test are also indicated in suspected immune-mediated diseases.

Radiographic evaluation, particularly of the thorax, should be performed in horses and small ruminants and is often possible in dairy cattle. In cattle, radiographic evaluation of the cranioventral abdomen can help diagnose traumatic reticuloperitonitis. Ultrasonographic examination of the heart may definitively diagnose cardiac abnormalities and may provide more complete scrutiny of other organs in the thorax and abdomen, as well as deep structures of the musculoskeletal system. Ultrasonographic examination also aids in percutaneous biopsy of internal structures and may help the practitioner make the decision for exploratory laparotomy.

In equine patients, exploratory laparotomy should be performed only in patients that are becoming progressively debilitated and in which all other avenues of diagnosis have been exhausted. Blind exploratory laparotomies usually do not contribute to diagnosis, are costly, and are not without risk. Standing laparotomy or laparoscopy can be a useful alternative to ventral midline exploratory celiotomy because each of them is less expensive and does not involve general anesthesia. In ruminants, especially adult cattle, exploratory laparotomy is inexpensive and low risk and should therefore be used more routinely as an aid in the diagnosis of an FUO.

Nuclear imaging and imaging using autologous WBCs labeled with technetium-99m or indium-111 are increasingly used in human and small animal medicine.[66] These procedures may be helpful in localizing abscesses, particularly osteoarticular infections. These modalities may prove to be of benefit for large animals as the modalities' availability increases. As a note, the use of nuclear imaging in food-producing animals is strongly discouraged.

The use of therapeutic trials of antimicrobials in FUO should be restricted to cases in which strong evidence of a bacterial infection exists. The therapeutic regimen should be as specific as possible and administered for a predetermined amount of time. Inappropriate use of broad-spectrum antimicrobials for all febrile diseases contributes to interference in accurate diagnosis.

Hypothermia

Decreases in body temperature may occur when environmental stresses (cold, wet, wind) overwhelm the body's capability of heat production (especially when the body is weakened from disease), when CNS disease has resulted in damage to the regulatory centers within the hypothalamus, or when adrenergic or sympathetic effector systems have been damaged. Newborns, cachexic, and aged animals are most susceptible to heat loss caused by cold exposure (see Neonatal Sepsis and Weak Calf Syndrome, Chapter 20). Concurrent signs of septic disease in hypothermic animals signify a guarded prognosis, because the body's defense mechanisms are often overwhelmed when core body temperature declines. Severely hypothermic animals (core body temperature >30° C) are profoundly depressed and have marked reduction in ventilation, absence of muscle activity, and decreased reflexes. Decreased intravascular volume and depressed cardiac function lead to hypoxia, acidemia, and cardiac dysrhythmias. Newborns are often hypoglycemic and have potassium imbalances. These animals should be warmed by protecting them from wind or drafts, drying them, and providing a microenvironment of high ambient temperature. Applying thermal blankets and housing them in an insulated stall, with or without supplemental heat, is superior to using direct external heat from heat lamps or other sources. Direct external heat without environmental control causes cutaneous vasodilation, often exacerbates central hypothermia, and contributes to cardiovascular compromise.

Animals with severe hypothermia should be warmed gradually over 24 hours, with careful monitoring of body temperature and the cardiovascular system. Maintenance of adequate systemic perfusion is the most important means of preventing cardiac failure.[67-68] Acidosis and potassium imbalances are common and may fluctuate rapidly. Consequently, repeated measurements, especially when a patient's clinical condition worsens in the process of warming, are often necessary. Appropriate crystalloid fluids, warmed to body temperature, are usually necessary throughout the warming process. Evaluation of blood glucose and concurrent dextrose therapy, especially in neonates, should also be performed.

Warmed humidified oxygen therapy both as an aid in treatment of hypoxia and as a means of warming is helpful. Gastric (rumen) or rectal lavage with warmed fluids may also be used. However, care should be taken in rapid rewarming, because an imbalance in the basal metabolic rate (which is temperature dependent) and systemic perfusion may result in life-threatening cardiac dysrhythmias and worsening of metabolic acidosis and hypoxia. Hypothermia attenuates the inflammatory response by a multiplicity of effects on cytokines and other key signaling mechanisms.[69] Thus the adverse metabolic effects of disease are slowed at low body temperatures, and as body temperature elevates, signs of systemic disease become apparent.[70] In hypothermic animals in shock, particularly neonates, severe anoxic changes in the bowel wall may result in severe diarrhea, sloughing of mucosa, or clostridial growth in the bowel.

Alterations in Respiratory Function

JEFFREY LAKRITZ, *Consulting Editor*

MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Cough, 43
Nasal discharge, 51
Epistaxis and hemoptysis, 57
Tachypnea, 60
Respiratory distress (dyspnea), 60
Cyanosis, 68
Abnormal respiratory noise (stridor), 71
Exercise intolerance and poor performance in horses, 75

Cough

W. David Wilson • Jeffrey Lakritz

Definition Coughing, an important and normal respiratory defense mechanism, is the sudden, forceful, noisy expulsion of air through the glottis to clear mucus, particles, and other material from the tracheobronchial tree and glottis.

Pathophysiology The mucociliary escalator and the cough reflex are the major protective mechanisms that function together to remove material from the respiratory tract.[1,2] Particles trapped in mucus are transported to the trachea by continuous waves of ciliary motion, starting at the level of the terminal bronchioles. Coughing is associated with development of increased intrathoracic pressure and generation of high-velocity airflow out of the respiratory system. This rapid expulsion of air removes secretions accumulating within the tracheobronchial tree proximal to the level of the segmental bronchi.[3] Coughing is thus a normal physiologic and protective response and a common clinical sign associated with a variety of cardiorespiratory disorders.

NEURAL PATHWAYS INVOLVED IN THE COUGH REFLEX. Coughing is an involuntary reflex; however, this reflex may be voluntarily initiated or suppressed.[2,3] The reflex pathways involve sensory receptors present within the airway epithelia, from the larynx to the respiratory bronchioles, with nerve fibers conducting afferent impulses within vagal, glossopharyngeal, trigeminal, and phrenic nerves.[1,3,4,5] The receptors, mainly irritant receptors, are particularly numerous within the proximal airways (trachea and bronchi), especially around the hilus of the lung and bifurcation of the bronchi.[1,4] Other receptors capable of activating the cough reflex are found within lung parenchyma, the pleura, and elsewhere. Brainstem neuronal pathways for the cough reflex in the horse are not well characterized; however, in other species, afferent signals to the medulla oblongata are received and efferent fibers pass back down to the respiratory system within the vagal, phrenic, intercostal, and lumbar nerves and motor portions of the trigeminal, facial, hypoglossal, and accessory nerves to supply striated and smooth muscles of the larynx, tracheobronchial tree, diaphragm, intercostal muscles, abdominal muscles, and secretory glands of the respiratory tract.[1,5-7]

Irritant receptors are stimulated by mechanical deformation induced by compressing the trachea; by bronchoconstriction, inert dusts such as carbon, irritant gases such as ammonia, and biological mediators such as histamine, prostaglandins, or bradykinins (Boxes 5.1 and 5.2).[2,4] Sensitivity to mechanical stimulation varies along the airway, and in horses the upper airway cough receptors appear to be less active than observed in many other species.[8] For example, a stomach tube inadvertently passed into the trachea frequently does not induce coughing until it reaches the carina. Similarly, endoscopic examinations often reveal large pools of exudate within the trachea of horses with limited history of coughing.[6] Foals with *Rhodococcus equi* pneumonia often develop a tracheal rattle, reflecting accumulation of exudates within the trachea, but may not cough. Repeated stimulation of irritant receptors over several hours does not appear to diminish sensitivity but may lead to changes in threshold.[4]

Bronchoconstriction is a consistent component of cough,[3,7,8] and stimuli resulting in a cough may also induce reflex bronchoconstriction through parasympathetic innervation.[4] However, cough and bronchoconstriction are separate airway reflexes.[7] Whereas stimulation of irritant receptors in large airways induces both cough and reflex bronchoconstriction independently, stimulation of nerve endings in smaller airways does not directly initiate coughing but does cause bronchoconstriction. Bronchoconstriction may then initiate coughing indirectly.[4] The role of bronchoconstriction in the induction of coughing is supported by studies in people demonstrating that administration of bronchodilators is associated with reduction in the frequency or severity of coughing in asthma.[9,10] These studies

BOX 5.1

Causes of Coughing in Horses

Common Causes

Equine influenza A2 virus (H3N8)
Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)
Bacterial pneumonia
Bacterial pleuropneumonia, pleuritis
Recurrent airway obstruction (RAO or chronic obstructive pulmonary disease)
Mechanical causes (e.g., nonspecific dust irritation)
Pharyngitis (acute or chronic pharyngeal lymphoid hyperplasia)
Postviral hyperreactive airways

Less Common Causes

Strangles (*Streptococcus equi* infection)
Equine viral arteritis
Other viruses (equine rhinitis A and equine rhinitis B)
Parascaris equorum migration
Pharyngeal paresis
Guttural pouch empyema
Guttural pouch mycosis
Pharyngeal, laryngeal trauma or surgery
Postsurgical aspiration (e.g., after laryngeal prosthesis surgery)
Epiglottal entrapment
Subepiglottal cyst or abscess
Chondritis, chondromas of the arytenoid cartilages
Retropharyngeal abscess
Tracheal collapse (including scabbard trachea in ponies)
Tracheal stenosis, stricture
Choke, esophageal obstruction
Aspiration pneumonia (foreign bodies, feed material)
Inhalation pneumonia (smoke, thermal injury, noxious gases)
Lungworm infection *(Dictyocaulus arnfieldi)*
Pulmonary abscessation
Exercise-induced pulmonary hemorrhage (EIPH)
Pulmonary edema (smoke inhalation, acute renal failure, overhydration, septicemia, anaphylaxis)
Summer pasture–associated obstructive airway disease (SPOAD)
Left-sided heart failure
Congestive cardiac failure
Neonatal septicemia

Uncommon Causes

Tuberculosis
Pneumoconiosis or silicosis; other interstitial pneumonias
Eosinophilic interstitial pneumonia
Nocardiosis
Coccidioidomycosis
Chlamydia psittaci pneumonia
Mycoplasma species pleuritis
Tularemia
Pulmonary hydatidosis
Tracheal perforation or rupture
Cryptococcosis
Dorsal displacement of the soft palate (laryngopalatal dislocation)
Rostral displacement of the palatopharyngeal arch
Idiopathic laryngeal hemiplegia
Guttural pouch neoplasia
Rectus capitis ventralis muscle rupture
Adenovirus infection
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia
Esophageal ectasia, dysfunction, stricture, perforation; esophagitis
Megaesophagus
Progressive ethmoidal hematoma
Nasal or paranasal sinus neoplasia
Fistula (pharyngeal, esophageal, esophagobronchial, esophagotracheal, bronchobiliary)
Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)
Infarctive lobar pneumonia
Bronchopleural fistula
Pleural mesothelioma
Pneumothorax
Pulmonary tumor, primary or metastatic
Lymphosarcoma, lymphoma, leukemia
Pulmonary aspergillosis
Phycomycosis, pythiosis
Plant awn stomatitis
Anaphylaxis or acute drug reaction
Atrial fibrillation
Tetralogy of Fallot
Cor pulmonale
Endocarditis
Ruptured mitral chordae tendineae
Melioidosis, *Pseudomonas pseudomallei* (exotic)
Glanders (exotic)
African horse sickness (exotic)

Toxic Causes

Crofton weed *(Eupatorium adenophorum)*
α-Naphthyl thiourea (ANTU)
Pentachlorophenol
Organophosphate
Carbamate

indicate that mediator release (blocked by cromolyn) causes bronchoconstriction (blocked by bronchodilators), which stimulates irritant receptors (blocked by local anesthetics) and causes coughing.[4] Much of the airflow obstruction in horses with recurrent airway obstruction (RAO) appears to be mediated through these pathways and is eliminated with atropine, a parasympatholytic bronchodilator.[4]

Mechanics of Coughing

The mechanical events that produce coughing occur during four phases: inspiration, compression, expression, and relaxation.[2-4] The first three phases are necessary to create the decreased airway cross-sectional area and high airflow rates needed for an effective cough. Coughing is a maximum expiratory flow maneuver that begins with deep inhalation to expand lung volume, increase elastic recoil, and dilate the airways through the tethering effect exerted by surrounding lung tissue.[11] Closure of the glottis is followed by forced expiratory efforts involving the rib cage, abdomen, and diaphragm, which increase pressure in the abdominal, pleural, and alveolar spaces to more than 500 mm Hg.[4] The glottis then opens suddenly, allowing the elevated alveolar pressure to rapidly accelerate gas flow from the respiratory tree.[2,4,11] This high-velocity gas stream shears exudate from the airway walls and lumen and carries it to the nasopharynx, from which point it exits the respiratory tract as nasal discharge or is swallowed.[11] Airflow stops before the animal has exhaled to residual volume because the glottis closes or the driving force provided by the muscles abates.[4] The characteristic sound of coughing is produced by vibration of laryngeal and pharyngeal tissues, narrowing and deformation of airways, vibration of surrounding lung tissues, and turbulent gas flow vibration in the airway.[4,7]

During forced expiration such as occurs with coughing, the increased pleural pressure is transmitted to the intrathoracic airways and alveoli. Intraalveolar pressure exceeds pleural pressure by an amount equal to the elastic recoil pressure of the lung.[4,11] A pressure gradient thus exists between the alveoli and atmospheric pressure at the nostrils and mouth. At a point in the airways known as the *equal pressure point* (EPP), the pressure in the airway lumen equals the pleural pressure because

BOX 5.2

Causes of Coughing in Ruminants

Common Causes

Mannheimia haemolytica or *Pasteurella multocida* pneumonia (includes shipping fever and enzootic calf pneumonia)
Histophilus somni pneumonia (B)
Lungworm infection, verminous pneumonia
Chronic bacterial pneumonia with abscessation or consolidation (*Arcanobacterium pyogenes* and other bacteria)
Infectious bovine rhinotracheitis (IBR; bovine herpesvirus type 1 [BHV-1]) (B, C)
Bovine respiratory syncytial virus (B)
Parainfluenza virus type 3
Mycoplasma species pneumonia
Caprine *Mycoplasma mycoides* subsp. *mycoides* infection (C)
Necrotic laryngitis, calf diphtheria (B, O)
Abscess (oral, lingual, retropharyngeal, pharyngeal, laryngeal)
Trauma (pharyngeal, laryngeal, tracheal, bronchial, chest wall)
Esophageal obstruction, foreign body choke
Septicemia (neonates)

Less Common Causes

Bovine rhinovirus (B)
Bovine adenovirus (B)
Bovine malignant catarrhal fever (B)
Bovine virus diarrhea (BVD-MD) (B)
Herpesvirus DN-599 (B)
Bovine herpesvirus type 4 (BHV-4) (B)
Bovine coronavirus (B)
Pulmonary adenomatosis (Jaagsiekte) (O)
Ovine adenovirus (O)
Ovine progressive pneumonia and arthritis, maedi (O)
Caprine respiratory syncytial virus (C)
Caprine arthritis-encephalomyelitis (CAE) pneumonia (C)
Aspiration, foreign body pneumonia
Foreign body (pharyngeal, laryngeal, tracheal, bronchial, pulmonary)
Inhalation pneumonia (smoke, noxious gases, thermal injury)
Pulmonary embolus from posterior vena cava thrombosis (B)
Anaphylaxis or adverse drug reaction
Reaction to death of parasites after anthelmintic treatment (B)
Milk allergy in cows (B)
Farmer's lung disease (hypersensitivity to *Faenia rectivirgula* and other mold spores) (B)
Atypical interstitial pneumonia (B)
Pleuritis, pleural effusion
Pneumothorax
Diffuse fibrosing alveolitis (B)
Left-sided heart failure (left atrioventricular [mitral] insufficiency, pericarditis, congenital cardiac defects, other causes)
High altitude disease (B)
Enzootic bovine leukosis (B)
Chlamydia psittaci pneumonia

Uncommon Causes

Diaphragmatic hernia
Pleural mesothelioma (B, C)
Sarcocystosis (B)
Sporadic bovine leukosis, thymic lymphosarcoma (B)
Tuberculosis
Tularemia (O)
Tracheal actinomycosis
Tracheal collapse, stricture, stenosis
Phycomycosis, pythiosis (B)
Pulmonary aspergillosis
Rhinosporidiosis
Zygomycosis, mucormycosis (B)
Pulmonary listeriosis (B)
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia
Cor pulmonale (C)
Neoplasia (nasopharyngeal, oropharyngeal, pulmonary)
Postpartum hemolytic-uremic syndrome (B)
Esophageal rupture, laceration, ulceration, megaesophagus, hiatal hernia
Neoplasia, skeletal (B, O)
Buss disease, chlamydial sporadic bovine encephalomyelitis (B)
Winter dysentery (B)
Ascaris suum migration in calves (B)
Rinderpest (exotic)
Theileriosis, East Coast fever (exotic)
Melioidosis, *Pseudomonas pseudomallei* (exotic)
Contagious bovine pleuropneumonia (exotic) (B)
African bovine malignant catarrhal fever (exotic) (B)
Virulent sheep and goat pox (exotic) (O, C)
Peste des petits ruminants (exotic) (O, C)
Contagious caprine pleuropneumonia (exotic) (C)
Viral dermatitis of goats (exotic) (C)
Ibaraki disease (exotic) (B)

Toxic Causes

Organophosphate, carbamate
Mercury (B)
Iodine (B, O)
Insect fogger (B)

the elastic recoil pressure has dissipated.[2-4,11] In the intrathoracic airways rostral to this point, the intraluminal pressure is lower than the pleural pressure; therefore a transmural pressure gradient exists, which causes dynamic compression or collapse of the more proximal airways.[2,4,11] The location of the EPP is determined by elastic recoil pressures, and thus indirectly by lung volumes and the frictional resistance to flow in the airways between the alveoli and the EPP.[4] At high lung volumes, elastic recoil pressure is high, resistance in peripheral airways is low, and the EPP is typically located in larger intrathoracic airways that resist collapse because they have cartilaginous support for their walls.[4] As lung volume decreases, elastic recoil forces decrease, airway resistance increases, and the EPP moves more peripherally, subjecting lower and less well-supported parts of the tracheobronchial tree to dynamic compression.[3,4,11] Dynamic compression reduces the cross-sectional area of intrathoracic airways and thus increases the velocity of airflow through the narrowed segment.[4] These spikes of accelerated airflow promote more effective shearing of mucus and debris from the airway wall and lumen during coughing.[11]

Dynamic compression also increases the resistance to airflow.[4] Once dynamic compression of peripheral (smaller) airways occurs, further increases in expiratory effort cause greater narrowing of the airway; thus the flow rate that can be generated at a given lung volume does not increase beyond a certain maximum point (maximum expiratory flow).[4] Maximum expiratory flow decreases progressively as the animal exhales because lung volume declines. Thus coughing beginning at high lung volumes achieves the highest airflows.[4] However, only the larger intrathoracic airways are compressed and subjected to these spikes of higher airflow velocity.[2,4,11] As lung volume falls or if cough is initiated at lower lung volumes, smaller airways

are dynamically compressed and cleared of mucus.[2,3,11] The effectiveness of coughing can thus be improved by repeating it several times in succession, either in a progression from high to low lung volume during the same breath or by inhaling between breaths.[4]

Because maximum airflows are lower in smaller airways, coughing is probably less effective in clearing material from the smaller airways than from the larger ones.[4] In the alveolar regions of the lung, gas flow is too slow for coughing to be an effective means of clearance.[11] Because only intrathoracic airways are dynamically compressed and subjected to these spikes of higher flow velocity during forced expiration, the extrathoracic trachea should be less effectively cleared by coughing.[4] However, horses and other animals with long necks do not seem to have great difficulty in clearing their airways, although they do lower their heads and straighten their airways during coughing to assist the clearance process.

In diseases such as RAO that cause narrowing of the airway lumen, the increased resistance to airflow, especially in peripheral airways, causes the EPP to move more peripherally toward the alveoli, resulting in a reduction in the maximum expiratory flow rate.[2,4] In this situation the effectiveness of coughing in clearing the airways is reduced. Thus administration of a bronchodilator may greatly improve the effectiveness of coughing in patients with RAO.[4]

COUGH STIMULI. Cough may be stimulated by bronchoconstriction; excessive mucous production; deposition of inhaled particles in the airways; release of inflammatory mediators; infectious diseases; exposure to hot or cold air; intramural or extramural pressure or tension on the airways (tumor, granuloma, abscess, or decreased pulmonary compliance caused by restrictive disease such as interstitial fibrosis or pleural effusion); sloughing of airway epithelial cells; and enhanced epithelial permeability (pulmonary edema).[12] Epithelial sloughing and enhanced epithelial permeability increase the accessibility of cough receptors to the mechanical or chemical agents that stimulate them. Loss of integrity of the epithelial lining of the respiratory tract is a common feature in many respiratory diseases associated with cough (infectious diseases); however, a cause-and-effect relationship between alterations in pulmonary epithelium and cough has not been established.[12] Diseases of the respiratory tract may alter the sensitivity of the cough reflex.[12] For example, viral infections may increase the responsiveness of cough receptors to stimuli.[7,12] Of the many causes of coughing in large animals, viral infections such as equine influenza and infectious bovine rhinotracheitis (IBR) are particularly important because they cause outbreaks of respiratory disease that have acute onset of coughing as a prominent feature and that are frequently associated with persistence of coughing for prolonged periods after signs of acute disease have abated. These features of viral infections reflect the decreased effectiveness of mucociliary clearance resulting from virus-induced injury to ciliated epithelial cells, together with exposure and sensitization of irritant airway receptors, which lead to persistent bronchial hyperreactivity.[4,13] Affected individuals show bronchoconstriction and coughing in response to mildly irritating stimuli such as dust, stable pollutants, cold air, dry air, and exercise that would not normally cause coughing. Coughing subsides only when the airway epithelium has healed, which may take up to 7 weeks.[4]

Although the role of mucus in coughing is not clear, normal amounts of mucus may have a protective effect by coating the epithelium with a layer that separates the receptors from irritants.[4] Conversely, excessive accumulation of mucus in the airways, such as occurs in horses with RAO, may mechanically stimulate irritant receptors and cause coughing.[4] Fluid flushed over the tracheobronchial epithelium stimulates irritant receptors, particularly if the fluid is hypertonic or hypotonic.[9,10,14] Coughing is also stimulated by fluid that lacks permeant anions (i.e., anions that have a hydrated size and membrane-penetrating characteristics similar to the chloride anion).[15]

Coughing is a prominent feature of cardiac disease in many species, although cardiac diseases are not often encountered in large domestic animals. Failure of the left side of the heart resulting from congenital defects, valvular stenosis or incompetence, conduction disturbances, myocardial disorders, or restrictive pericardial disease causes an increase in pressure in the pulmonary venous return from the lung. This results in transudation of fluid from the pulmonary capillaries into the pulmonary parenchyma and airspaces (cardiogenic pulmonary edema) and causes swelling of the mucosal lining of small airways.[2] These changes stimulate cough receptors and initiate the cough reflex. Coughing that occurs secondary to cardiac disease is usually chronic, although acute-onset coughing may be observed with ruptured mitral chordae tendineae and bacterial endocarditis.[16]

Approach to Diagnosis of Coughing

HISTORY. The history should include questioning relative to the patient, the cough, the environment, and management. The *age* of the affected animal is important because many conditions have a marked age incidence. For example, *R. equi* pneumonia occurs primarily in foals younger than 6 months of age, equine herpesvirus type 4 predominantly affects weanling and yearling horses, and RAO affects primarily mature stabled horses. The *use of the horse;* its state of fitness; the presence of vices such as crib biting; and any *history of contact with other horses* at shows, events, sales, racetracks, or breeding farms should be determined.

Recent stressors such as transportation, surgery, strenuous activity, or weaning should be determined because these are known risk factors for conditions such as pneumonia and pleuropneumonia. The duration of ownership of the animal, its previous health, and the geographic location of origin, if it was recently purchased, may help identify regional diseases not normally seen in the area (e.g., systemic mycosis, lungworms, or silicosis in horses) or indicate the degree of stress likely to have been experienced recently. For recently purchased feedlot cattle and sheep, it should be determined if the animals were preconditioned before sale, their place of origin, the number of sale yards through which they have passed, and the duration of transportation.

When evaluating the potential for contagious diseases or those related to common environmental conditions, the vaccination status of the affected animal and herdmates and the presence of similar clinical signs in other in-contact animals sharing common facilities or common airspaces should be determined. In nursing animals, the vaccination status of the dam is important. A history of other signs such as anorexia, nasal discharge, weight loss, exercise intolerance, stridor, lymphadenopathy, facial swelling, diarrhea, colic, and edema may provide important clues to the cause of the current problem. Weight loss occurs in many acute and chronic diseases, both infectious and noninfectious. Anorexia may indicate that eating is too painful for an animal, for example, because of a painful nasopharyngeal lesion or because the animal is devoting so much effort to breathing that it will not eat.

Environmental considerations such as the introduction of new animals into the environment or the return of animals from shows, sales, training centers, or breeding farms should increase the suspicion of infectious viral or bacterial diseases such as IBR in cattle or influenza in horses. For diseases such as *R. equi* pneumonia in foals, it is useful to know if similar cases have been seen on the premises in the past. The type of housing or pasturing facilities should be evaluated, particularly with regard to airspace, ventilation, sanitation, stocking density, dust, shade, and shelter. Equine stabling facilities that have enclosed barns, particularly when the stalls face a central arena or are located under a hay storage loft, promote the spread of contagious

agents and almost invariably increase the concentration of dust, mold spores, and noxious gases such as ammonia and tractor exhaust fumes in the environment. The type of feed and bedding, storage facilities, and feeding arrangements should be evaluated, especially in chronically coughing horses suspected of having allergic lung disease. Quantitative measures of ventilation and environmental quality can be made and can prove helpful in case management and in monitoring the effectiveness of measures to reduce environmental dust and other pollutants.[17] Similarly, the sampling of air in barns or paddocks using special devices allowing quantitation of bacterial pathogens such as *R. equi* may prove useful for assessing risk of infection.

The quality of the feed should be evaluated visually and by smell, particularly with regard to the presence of mold spores. General management, pasture management, and parasite control measures should also be evaluated, especially if lungworm infection is suspected. Horses with lungworm infection almost invariably have a history of current or previous co-grazing with donkeys. The season and seasonal incidence of recurrence of the coughing can provide useful clues (e.g., marked seasonal worsening of signs in the late autumn when horses are stabled suggests chronic allergic respiratory disease). Similar to the conditions mentioned for horses, cattle pastured during the warmer months of the year and housed during the colder months may demonstrate recurrent episodes of respiratory dysfunction and cough associated with allergies to dusts present in stored hay or bedding. The history should also include the nature of previous treatments and the response.

Important historical features of the cough include the time and speed of onset; frequency; duration (chronic if longer than 1 month); relation to feeding, housing, or weather; relation to exercise and timing during exercise; improvement, deterioration, or other change since onset; and the presence of and similarity to previous episodes of coughing or respiratory disease. Many coughs are exacerbated by exercise because exercise places greater stress on the respiratory tract. The resulting rapid airflow improves mobilization of secretions and irritates the airway directly. Coughs that occur during eating suggest specific or nonspecific sensitivity to molds, pollen, or other dusts in feed; inflammatory conditions of the larynx or pharyngeal region; laryngeal or pharyngeal problems, including complications of surgery, that interfere with swallowing or guarding of the lower airway; or esophageal obstruction (choke). The effort involved in coughing and associated pain may also give clues to the cause of the cough.

The character of the cough should be evaluated because certain features of a cough tend to point toward its origin and possible causes but are by no means pathognomonic for either. Coughs originating in the upper airway are usually of acute onset, loud, harsh, coarse, dry, hacking, and nonproductive in character. Painful upper airway conditions such as acute pharyngitis, strangles, or necrotizing laryngitis can make the cough more muted. Lower airway coughs are usually soft, deep, and productive (mucus, pus) and tend to be more persistent than coughs originating in the upper airway. However, chest pain frequently attenuates coughing in horses with pleuropneumonia. In horses the fixed position of the larynx within the nasopharynx usually precludes expectoration of sputum into the mouth; thus the productive nature of the cough is difficult to assess. Excess mucus or exudate that is coughed up into the pharynx is usually swallowed; thus a cough can be productive without evidence of a nasal discharge. Swallowing efforts that follow a cough generally indicate that the cough is productive.

PHYSICAL EXAMINATION. The physical examination should include both distant and close evaluation of the patient and the environment. In addition to a detailed examination of the respiratory and cardiovascular systems, a general physical examination should also be completed so that diseases in other systems can be detected and systemic manifestations of cardiopulmonary disease can be evaluated. The attitude of the animal, the respiratory rate and character, the presence of excessive intercostal or abdominal respiratory effort or of a "heave line" or "barrel chest," the presence and nature of respiratory distress or stridor at rest, and the presence and character of any nasal and ocular discharge should be noted before the animal is restrained. The following should then be determined: (1) rectal temperature, pulse rate, pulse rhythm and character, mucous membrane color, and capillary refill time; (2) symmetry of airflow from each nostril; (3) odor from the nostrils and mouth; (4) facial symmetry and swelling; (5) resonance or painful response on percussion of the maxillary and frontal sinuses; (6) enlargement of submandibular, parotid, retropharyngeal, prescapular, and other regional lymph nodes; (7) enlargement of the parotid salivary glands or thyroid gland; (8) swelling, pain, or palpable abnormalities in the retropharyngeal region; (9) palpable swelling or flattening of the cervical trachea; and (10) masses at the thoracic inlet and palpable turbulence such as a tracheal rattle in the extrathoracic airway. The oral cavity should also be examined. If spontaneous coughing is not heard during the physical examination, a cough should be induced after auscultation of the airways by pinching the larynx or trachea, and it should be ascertained whether the induced cough sounds like the animal's spontaneous cough. Pinching of the trachea generally causes normal animals to cough once or twice, whereas it often induces paroxysmal coughing in animals with lower airway disease. The laryngeal or tracheal cough reflexes show increased sensitivity in most infective and inflammatory airway diseases.[16]

The larynx, trachea, lungs, and heart should be carefully *auscultated*, as should both sides of the chest, in a quiet environment with the animal at rest and after the rate and depth of respiration have been increased by application of a rebreathing bag, by temporary occlusion of the nostrils, or by light exercise (see the Cyanosis section later). Auscultation of the trachea and larynx should be performed at an early point in the examination, before a rebreathing bag is applied, in order to assess the potential for upper airway obstruction during the examination of the thorax. Auscultation permits detection of turbulent airflow, increased or decreased bronchovesicular sounds, wheezes, crackles, pleural friction rubs, or pleural fluid splashes, all of which indicate disease of the airways, pulmonary parenchyma, or pleura. Wheezes and crackles reflect airway narrowing and dynamic airway collapse, respectively, and are both evidence of small airway disease.[16] A small (12 L) or medium-size (52 L) plastic trash bag makes an adequate rebreathing bag; a plastic rectal sleeve is satisfactory for foals or calves if the opening is stretched so that it does not occlude the nostrils. The response to application of a rebreathing bag should also be noted. Most horses tolerate this procedure well and breathe more deeply, whereas animals with chest pain often do not. Normal horses do not cough when the bag is applied unless they have been eating recently, whereas horses with airway irritation caused by pneumonia or other conditions often cough paroxysmally in response to application of a rebreathing bag. The time taken to regain the normal respiratory rate and character after removal of the bag provides a reasonable, qualitative indicator of ventilatory reserve. Normal animals recover quickly, within a few breaths, whereas respiration may be altered for several minutes in animals with significant lung disease. On removal of the rebreathing bag, the expired air in the bag can be smelled to determine if odors suggestive of necrotic tissue are present.

The chest wall should be *palpated* to detect pleural friction rubs or lesions such as rib fractures, and the symmetry of chest expansion should be determined. Young calves with chest deformation (unilateral or bilateral) and severe inspiratory and expiratory respiratory distress should be evaluated for fractured ribs that are causing tracheal compression/stenosis (see Chapter 31 for horses and more on ruminants). Temporary tracheostomy does not relieve this respiratory embarrassment. Unilateral chest

VetBooks.ir

pain (pleurodynia) often reduces chest excursion on the affected side. Both sides of the chest should be *percussed* systematically to detect changes in resonance and chest pain. The caudoventral percussion border in the normal horse traces from the level of the tuber coxae at the seventeenth intercostal space (the horse normally has 18 pairs of ribs) to the level of the tuber ischii at the fifteenth intercostal space to the midthorax at the thirteenth intercostal space to the level of the point of the shoulder at the eleventh intercostal space; it continues as a curving line to a point 1 to 3 inches above the olecranon. The normal caudoventral percussion boundary in cattle and small ruminants traces from the eleventh intercostal space at the level of the lateral edge of the epaxial musculature to the ninth rib at a level halfway between the costochondral junction and the lateral edge of the epaxial musculature to the fifth rib at the olecranon (cattle, goats, and sheep normally have 13 pairs of ribs). Percussion is an important diagnostic tool in all large animals, but it is most useful in foals, calves, and goats. The precise percussion boundaries, degree of resonance, and auscultation findings are influenced by age, size, body condition, fitness, and hair coat, as well as by disease processes; a gas-filled abdominal viscus can also confuse interpretation. Hyporesonance (dullness) may indicate pulmonary consolidation, large mass lesions, cardiomegaly, pleural effusion, or other pleural disease. Free pleural fluid usually causes an abrupt change from normal resonance above a horizontal fluid line to hyporesonance below this line. Hyperinflation or pneumothorax may cause hyperresonance with or without expansion of the normal percussion boundaries. A painful response to percussion may indicate pleuritis or some other inflammatory process involving the parietal pleura. Painful responses may be dramatic and potentially injurious to the examiner.

In cattle the presence of thoracic or cranial abdominal pain should be ascertained by application of upward pressure to the xiphoid area with the knee or by application of downward pressure with both hands just caudal to the withers. Animals with cranial abdominal or thoracic pain resist these maneuvers and may make an audible or auscultatable grunting noise. Signs such as jugular distention or pulsation (or both) and peripheral edema, which may indicate heart failure, should be noted. As well, the heart should be auscultated to detect murmurs, dysrhythmias, muffling of heart sounds, or other abnormalities that would indicate the need for further cardiovascular diagnostic procedures.

COMPLETE BLOOD COUNT. A complete blood count including fibrinogen concentration usually reveals nonspecific findings but may be useful in the evaluation of cases in which primary or secondary inflammatory conditions are suspected and in conditions such as pulmonary thromboembolism secondary to caudal vena cava thrombosis (CVCT) in cattle and guttural pouch mycosis in horses in which blood-loss anemia is likely to be a complicating problem. Acute viral infections often induce a transient anemia and leukopenia, predominantly lymphopenia, followed by a monocytosis during recovery. Neutrophilia and hyperfibrinogenemia are features of many inflammatory conditions but are usually most marked when bacterial infection is involved. Some parasitic diseases (e.g., lungworm infection in cattle) may induce eosinophilia, as may allergic conditions, but eosinophilia is not a common feature of either lungworm infection or allergic RAO in the horse.

NASAL OR NASOPHARYNGEAL SWABBING. Nasal or nasopharyngeal swabbing with direct cytologic examination and culture or molecular diagnostic testing are indicated for confirmation of viral or bacterial infections that involve the upper airway. Because a large number of bacteria normally inhabit the nasopharynx, only the presence of *Streptococcus equi* or some other pathogen not considered part of the resident flora can be considered significant in horses. When clinical signs suggest a viral respiratory infection, especially when an outbreak of coughing occurs in several animals, *molecular detection* by polymerase chain reaction (PCR), *antigen detection* by antigen-capture enzyme-linked immunosorbent assay (ELISA), or *virus isolation* from nasal or nasopharyngeal swabs, tracheal wash, and/or buffy coat (ethylenediaminetetraacetic acid [EDTA] blood) samples collected during the acute phase of the disease is indicated, as may be *viral serologic tests* on acute and convalescent serum samples.[18] Under these circumstances, sampling as many of the most severely affected, often younger, animals as early as possible in the disease course maximizes the chances of establishing an etiologic diagnosis. Nasal swabs are slightly easier to collect than nasopharyngeal swabs and yield similar results when sensitive PCR tests are used[19]; however, nasopharyngeal swabs are preferred for virus isolation by many diagnostic laboratories. Nasal swabs are best collected using 6-inch Dacron or rayon (not cotton) swabs, whereas nasopharyngeal swabs are best collected using longer, larger swabs (e.g., Fox 16-inch Procto Swabs, Allegiance Health Care, Hayward, Calif.). Swabs should be placed in capped tubes for submission for PCR testing or into viral transport medium for immediate submission to the laboratory if virus isolation will be requested. It is best to use the transport medium supplied by the respective laboratory to ensure compatibility with viral culture systems. Antigen-capture ELISA (e.g., influenza Directigen Flu A test, Becton-Dickinson, Franklin Lakes, N.J.) and PCR tests are available for testing of nasal or nasopharyngeal swabs and other samples to confirm a diagnosis of viral infection.[18] These rapid-screening tests are sensitive and less cumbersome to perform than virus isolation, do not require such stringent conditions for handling and transporting samples, and provide results sufficiently quickly that specific control measures can be implemented. However, they do not yield an isolate that can be used to monitor genetic and antigenic evolution of the viral agent. Serologic testing often provides only retrospective information, but it can prove helpful in the formulation of future control measures, including vaccination. The larger the number of animals tested, the more informative are the results of serologic testing in a herd or flock. Serologic testing is also indicated when pneumonia caused by *Coccidioides immitis* or other fungal agents is suspected.

ENDOSCOPIC EXAMINATION. Endoscopic examination of the nasal passages, conchae (turbinates), pharynx, larynx, and trachea allows the presence, nature, and source of exudates and the presence of anatomic or functional abnormalities or mass lesions to be noted. Endoscopic examination of the upper airway of the horse to evaluate for partial airway obstruction is best performed without the use of sedatives or tranquilizers if possible because these alter the tone and function of the muscles supporting laryngeal and pharyngeal anatomy and function and may confuse interpretation of endoscopic findings. In the horse the interior of the guttural pouches may be examined by advancing the endoscope through the pharyngeal openings of each guttural pouch using a guidewire such as a closed biopsy instrument passed through the biopsy channel of the endoscope and into the pouch. Most coughing horses have lower airway disease, which may be reflected in accumulation of endoscopically visible exudate in the horizontal trachea, particularly after exercise. Lungworm larvae may be grossly visible in the trachea of horses with lungworm infection. Deeper bronchoscopic examination is necessary to determine whether exudate reflects diffuse airway disease or it arises from a specific area of the lung, such as would occur with a pulmonary abscess or a foreign body lodged in a bronchus. Sedation may or may not be necessary to permit endoscopic examination of the extrathoracic airways in the standing horse; however, sedation with xylazine (1.1 mg/kg IV), detomidine (0.04 mg/kg IV), or romifidine (0.04 to 0.12 mg/kg IV) supplemented with butorphanol (0.1 to 0.2 mg/kg IV) is recommended to facilitate

VetBooks.ir

bronchoscopy and to dampen the cough reflex, as is spraying of the carina and bronchial branches with 2% lidocaine via the biopsy channel of the endoscope to reduce coughing during the procedure. Tracheobronchial aspiration and bronchoalveolar lavage (BAL) can be performed by introducing appropriate catheters via the biopsy channel of the endoscope.

TRACHEAL ASPIRATION. Tracheal aspiration with cytologic studies and quantitative or semiquantitative aerobic and anaerobic culture, or PCR testing, of collected samples is indicated in the evaluation of patients suspected of having disease of the lungs or pleura, particularly if an infectious cause is likely. Tracheal wash samples collected using the percutaneous transtracheal technique are preferred for bacterial culture because they are not contaminated by oropharyngeal organisms.[20,21] Collection of samples by introducing a sterile catheter through the biopsy channel of a presterilized endoscope inserted within a sterile sheath, or by introducing a double-sheathed catheter via the biopsy channel, is acceptable and less subject to complications than is the transtracheal technique, but samples obtained transendoscopically may be contaminated with *Pseudomonas* species and anaerobic bacteria despite the use of a guarded technique.[21] If tracheal aspiration will be performed percutaneously, the procedure should precede endoscopic examination of the lower airways to avoid contamination. Culture may fail to reveal the primary bacterial pathogen, especially in animals that have been treated with antibiotics. The diagnostic value of tracheal wash samples can be improved by discontinuing antibiotic therapy for at least 24 hours before collecting samples, rapidly processing samples, using antibiotic removal devices and selective culture media, and, if necessary, repeating sampling. Culture results should be evaluated in relation to the clinical signs, clinical experience (especially on the farm of origin of the patient), results of cytologic evaluation, and response to treatment. The trachea is not a sterile environment; therefore culture of small numbers of bacteria without cytologic evidence of infection is of questionable significance.

BRONCHOALVEOLAR LAVAGE. Samples collected by BAL are less useful than those collected by tracheal aspiration for evaluating infectious lower airway diseases and focal pulmonary conditions because the technique samples secretions from only a limited area of the caudodorsal lung on one side and is subject to contamination during introduction of the BAL tube through the nasopharynx. However, BAL yields better samples for cytologic assessment and is therefore preferred for evaluation of patients with generalized, noninfectious lower airway diseases such as RAO or silicosis.[18] BAL samples can be collected under endoscopic guidance by means of catheters introduced through the biopsy channel of a suitable endoscope (<9 mm in diameter and longer than 180 cm) or by using commercially available BAL tubes. The advantage of collection via endoscopy is that specific areas of the lung can be sampled, although gaining access to the cranial lung lobes is difficult with any method. Differential cell counts in BAL fluid of normal horses vary depending on age, environment, activity, and other factors. In young horses (<6 years of age), the distribution of macrophages, lymphocytes, neutrophils, mast cells, and eosinophils is on average 65%, 30%, 3%, 0.5%, and 0%, respectively.[22] In horses older than 6 years of age, the neutrophil population may reach 15% in normal horses, with a corresponding decrease in the proportion of lymphocytes and macrophages.[22] The percentage of neutrophils in normal calves is generally within the range of 5% to 20% depending on calf age, type, health status, and sampling method.[23,24]

Neutrophils are usually the predominant cell type in BAL fluid or tracheal washes of horses with RAO and in animals with bacterial infections. The neutrophils usually show degenerative changes when significant bacterial infection is present. Large numbers of eosinophils are a feature of parasitic infections such as lungworms, some allergic conditions, and infiltrative eosinophilic interstitial pneumonia. The presence of hemosiderin-laden macrophages is an indication of recent pulmonary hemorrhage, and finding refractile intracytoplasmic granules in macrophages or giant cells should raise the suspicion of silicosis, especially in animals showing radiographic evidence of marked pulmonary interstitial disease. Noting the presence, number, location (intracellular or extracellular), and Gram stain characteristics of bacteria permits rational selection of antibiotics for treatment while awaiting the results of culture and susceptibility tests.

ULTRASOUND EXAMINATION. Ultrasound examination is useful for examining externally visible lesions such as possible retropharyngeal abscesses impinging on the airway and causing the cough. Ultrasound examination of the chest is indicated to determine the presence and extent of pleural effusion, pleural roughening, pleural fluid with or without fibrin deposits, gas echoes in pleural fluid, pleural adhesions, and pulmonary lesions such as consolidation, atelectasis, or abscessation in animals with lesions in contact with the pleural surface or in animals in which sufficient pleural fluid has accumulated to allow evaluation of the underlying lung. The tissue-to-air interface at the visceral surface of the normal lung appears as a thin, smooth, bright echogenic line on ultrasound because it reflects the ultrasound beam, precluding visualization of deeper structures. Penetration of the ultrasound beam beyond the surface of the lung occurs only in the presence of lung pathology that extends to the visceral pleural surface of the lung in the area being scanned.

BLOOD GAS ANALYSIS. Blood gas analysis on arterial blood to determine oxygen (O_2) and carbon dioxide (CO_2) tensions is indicated in the evaluation and monitoring of patients in which a history or clinical signs of coughing are accompanied by signs of respiratory distress or cyanosis (see the Respiratory Distress [Dyspnea] and Cyanosis sections later).

THORACOCENTESIS. Thoracocentesis with culture and cytologic examination of collected samples is indicated in animals with clinical or ultrasonographic evidence of effusive pleural disease. Pleural fluid should be odorless, pale yellow to straw colored, and transparent and have a pH greater than 7.2, a protein concentration of less than 2.5 g/dL, and a total nucleated cell count of less than 10,000/μL cells, most of which should be mononuclear cells (macrophages and mesothelial cells).[18] Determination of the pH and concentrations of glucose, lactate, and lactate dehydrogenase (LDH) in pleural fluid collected into a heparinized tube or syringe helps differentiate septic from nonseptic effusions while awaiting culture results.[25] Septic effusions typically have a pH of less than 7.2, a low glucose concentration (<40 mg/dL), a high LDH concentration (>1000 IU/L), and a lactate concentration higher than that present in venous blood.[25-27] The best site for collecting pleural fluid can be confirmed by ultrasonography after auscultation and percussion of the chest. The sixth and seventh intercostal spaces at the level of the costochondral junction are commonly used sites in horses and cattle. The thorax should be penetrated in the part of the intercostal space immediately adjacent to the cranial border of the rib to avoid the intercostal vessels and nerves.

PLEUROSCOPY. Pleuroscopy is a more invasive procedure with limited indications that include investigation of chronic pleural diseases such as abscesses, pleural adhesions, and possible primary or metastatic pulmonary or pleural neoplasia such as lymphosarcoma, gastric squamous cell carcinoma, or mesothelioma. The procedure can be performed in a standing, sedated patient by using a sterile rigid or fiberoptic endoscope. This procedure is indicated for patients in which large intrathoracic masses and adhesions have been demonstrated by ultrasonography or thoracic radiology and when less invasive techniques have failed to provide the necessary diagnostic

VetBooks.ir

information. Pleuroscopy allows direct visualization of affected structures and provides an opportunity to biopsy masses or aspirate fluid. The pleuroscopy procedure is associated with complications (e.g., pneumothorax, lung laceration, infection) that should be anticipated in advance.

FECAL EXAMINATION. Fecal examination using the Baermann technique to detect lungworm larvae is indicated in ruminants suspected of having a lungworm infection. Because lungworm infection in the horse rarely becomes patent, larvae are not usually demonstrable by fecal examination. Pulmonary signs related to *Parascaris equorum* infection in foals occur during the prepatent (migratory) period; therefore the fecal flotation test for ascarid eggs often yields a negative result despite significant parasitic infection.

RADIOGRAPHIC EXAMINATION. Radiography of the chest is indicated in patients suspected of having lower airway disease to determine the presence, severity, and pattern of disease changes involving the lungs, pleura, and mediastinum. Four overlapping lateral projections are usually required to evaluate the whole lung field in an adult horse. Because ventrodorsal projections are possible only in young large animals, lateral projections from each side may be necessary to lateralize lesions within the chest. Radiographs of the lungs are particularly useful for determining the prognosis and for monitoring the response to therapy of pulmonary diseases such as bacterial pneumonia and lung abscesses. The cardiac silhouette and the pattern and caliber of the aorta, vena cava, pulmonary artery, pulmonary veins, and other vessels should be evaluated for evidence of cardiac failure and pulmonary vascular disease. Radiographs of the pharynx, retropharyngeal area (including guttural pouches in the horse), larynx, and proximal trachea are indicated in some cases to confirm problems not definitively diagnosed by clinical examination and endoscopy.

NUCLEAR SCINTIGRAPHY. Nuclear scintigraphy using aerosolized technetium-99m (^{99m}Tc)–labeled diethylenetriamine-pentaacetic acid (DPTA) and intravenously injected ^{99m}Tc-labeled microaggregated albumin particles has been used to determine patterns of pulmonary ventilation, perfusion, and ventilation/perfusion ratios.[20,28] This technique requires special equipment and personnel but provides an objective assessment of pulmonary function and gas exchange capability.[28]

BIOPSY. Biopsy, with histologic evaluation of samples, is indicated to diagnose certain mass lesions such as neoplasms, cysts, polyps, fungal granulomas, or foreign body granulomas in or surrounding the airway. Masses in the airway can be biopsied through the biopsy channel of an endoscope, but these samples inevitably are small. Biopsies can also be collected at the time of exploratory or corrective surgery from lesions in the upper airway. Lung biopsies can be collected blindly, using Tru-Cut, Biopty, or similar instruments, preferably from the peripheral areas of the lung to reduce the likelihood of serious hemorrhage (see Chapter 31). Focal lesions can be visualized ultrasonographically or radiographically during the percutaneous biopsy procedure to improve the likelihood of obtaining diagnostic specimens. Lung biopsy is most useful for diagnosing diffuse nonseptic conditions such as pneumoconiosis. The inherent risks associated with the procedure indicate that percutaneous lung biopsy should be reserved for circumstances in which the animal is not showing signs of marked respiratory distress, uncontrollable coughing, or bleeding disorders and a high likelihood exists that the procedure will yield significant diagnostic information. Open lung biopsy is possible, albeit rarely indicated.

IMMUNOGLOBULIN DETERMINATIONS. Quantitative immunoglobulin determinations and possibly other *immune function tests* may be indicated in animals, especially the young, with chronic or recurrent respiratory tract infections or other indications of immune compromise.

ALLERGEN TESTING. Intradermal testing (IDT) for allergens, a radioallergosorbent test (RAST), ELISA tests for immunoglobulin E (IgE) on serum, and inhaled challenge have been advocated to evaluate horses suspected of having allergic respiratory disease based on exacerbation of signs in certain environments or with certain feeding practices. Although there are anecdotal reports that horses with RAO have been hyposensitized successfully using allergens selected on the basis of these allergen tests, the authors are unaware of documentation in well-controlled studies. In addition, a recent study showed that compared with normal non-atopic horses, RAO-affected horses did not have a significantly greater number of positive reactions in IDT against any allergen group (molds, grasses, weeds, trees, and insects), leading the authors to conclude that reactions to individual allergens in IDT should not be used to determine that horses have clinically relevant hypersensitivity.[29] Many normal horses show sensitivity to individual mold spores and other allergens, and there is poor correlation between the dermal and pulmonary reactivities to mold antigens.[13] Furthermore, when compared with the results of IDT, RAST and ELISA serum allergy tests have been shown to have low sensitivity in detecting allergen sensitivity.[30] Although the use of recombinant allergens rather than crude mold extracts in ELISA tests substantially improves sensitivity in detecting levels of allergen-specific IgE,[31] and significantly more RAO-affected horses than normal horses have high allergen-specific IgE levels, the degree of overlap of results precludes its use for diagnostic purposes.[32] The crude trial-and-error approach of adding or removing potential allergens from the environment is sometimes helpful diagnostically and therapeutically in RAO cases in which an allergic cause is suspected. Feeding of pellets instead of hay and using shredded paper, peat moss, or wood shavings instead of straw bedding are common examples of this approach (see the RAO section in Chapter 31). Allergen testing or serologic evaluation of adult cattle with historical evidence of recurrent, seasonal, respiratory disease (extrinsic allergic alveolitis) have not proven diagnostic of specific allergen-induced disease; rather, results merely suggest prior exposure to molds (see Chapter 31).

PULMONARY FUNCTION TESTING. Except for measurement of pleural pressure using an esophageal balloon catheter attached to a pneumotachograph, pulmonary function testing and evaluation of airway dynamics during exercise have until recently been largely research techniques that were not readily applicable to clinical patients. Development of the minimally invasive techniques of oscillometry (forced oscillatory mechanics [FOM]), forced expiratory maneuvers, and flow metrics now permits physiologic assessment of lung function in clinical patients.[33,34] When coupled with histamine provocation tests to assess airway reactivity and bronchodilator response tests, pulmonary function tests can provide a considerable amount of information to guide therapy and prognosis. Indications for pulmonary function testing might include evaluating horses with a history of poor performance or exercise intolerance but no other detectable abnormalities; assessing the degree of functional impairment in horses with known evidence of respiratory disease; assessing the efficacy of therapeutic regimens; determining if a horse has recovered from a diagnosed respiratory disorder and can be returned to training; and ruling out functional pulmonary abnormalities in horses with upper airway conditions.

BRONCHODILATOR RESPONSE TESTING. Bronchodilator response testing involves determining the response of measured pulmonary functions and pleural pressures to rapidly acting

bronchodilator drugs such as albuterol (450 to 900 µg) or ipratropium bromide, administered by aerosol, or atropine administered parenterally.[33] Results are often helpful in determining the pathogenesis of RAO and the likely response to bronchodilator therapy. In the field setting, useful information can be gained by assessing the response of respiratory rate, respiratory character, and lung sounds to intravenous (IV) administration of a low dose of atropine (5 to 7 mg/450-kg horse). This test can be made more objective by measuring pleural pressures using a Ventigraph recorder (Boehringer Ingelheim Vetmedica, Inc., St Joseph, Mo.) attached to an esophageal catheter or flowmetric techniques.[13,33,35,36]

DIFFERENTIAL DIAGNOSIS OF COUGHING. The differential diagnosis of coughing can be enhanced by arbitrarily categorizing it on the basis of *duration of signs* into acute or chronic (>1 month) and by the *presence or absence of fever*.[37] It should be kept in mind that some acute coughs become chronic and that, conversely, conditions that cause chronic coughing may be seen early in the disease course. Conditions typically associated with *acute coughing* include viral, bacterial, and parasitic infections of the upper and lower respiratory tract; acute allergic reactions or acute toxic injury to the lung; foreign bodies; choke; injuries to the larynx, trachea, or chest; pharyngeal or laryngeal dysfunction secondary to neurologic disorders or surgery; aspiration of food material or foreign bodies; smoke inhalation; and compressive upper airway lesions such as retropharyngeal abscesses or necrotic laryngitis. In most instances, outbreaks of sudden-onset coughing in groups of animals are the result of viral infection involving the upper and lower respiratory tract.[8,16]

Conditions typically associated with *chronic coughing* include chronic bacterial pneumonia; pulmonary abscess; chronic pleuritis; chronic allergic pulmonary diseases such as RAO in horses and farmer's lung disease of cattle; postviral bronchial hyperreactivity; chronic viral respiratory disease such as ovine progressive pneumonia; irritant airway disease caused by environmental irritants such as dust; lungworm infections, particularly in horses and small ruminants; functional or anatomic problems in the pharynx or larynx that interfere with guarding of the airway, including postsurgical problems; heart failure resulting in pulmonary edema; tumors or polyps in the upper airway or lung; mycotic infections of the upper airway, lung, or pleura; chronic guttural pouch infections in horses; tracheal collapse, especially in ponies; chronic interstitial disease such as pneumoconiosis caused by inhalation of particulate material; and so-called nuisance coughs. Nuisance coughs are common in horses, especially at the beginning of exercise, which emphasizes the fact that coughing is a normal airway-protective mechanism and not always evidence of disease. Nuisance coughs tend to bother the owner more than the horse and can result from habit; vices such as crib biting, wind sucking, or greedy eating; and environmental factors such as dust, ammonia, and cold air. Some nuisance coughs resolve after modifying the stabling or work environment.

Cough with fever usually indicates a primary infectious cause or a secondary infection superimposed on a noninfectious cause.[37] Fever is a typical but not invariable feature of aspiration pneumonia, bacterial pneumonia, pulmonary abscess, viral respiratory tract infection, strangles, fungal pneumonia, pleuropneumonia (bacterial, viral, or mycoplasmal), acute bronchointerstitial pneumonia, and thoracic neoplasia.[37]

Cough without fever is typically found in RAO, abnormalities of the larynx or pharynx, parasitic pneumonia, exercise-induced pulmonary hemorrhage (EIPH), tracheobronchial foreign body, tracheal collapse, and airway-oriented neoplasia (e.g., bronchial carcinoma).[37] Horses with chronic interstitial pneumonia such as silicosis or granulomatous pneumonia are usually afebrile but may have mild to moderate fever.[1]

Nasal Discharge

W. David Wilson • Jeanne Lofstedt • Jeffrey Lakritz

Definition Nasal discharge, which is any nongaseous material that exits the respiratory tract through the external nares, is described according to its *physical characteristics* (serous, mucoid, purulent, hemorrhagic [sanguineous], or a combination of these types with or without feed material); *acuteness of onset* (sudden or insidious); *origin* (unilateral or bilateral); *volume* (profuse or scant); and *association with activity* (spontaneous or intermittent).[38-40]

Pathophysiology

NORMAL NASAL SECRETIONS. The ciliated, pseudostratified columnar epithelium lining the respiratory tract from the nasal passages to the level of the respiratory bronchioles contains serous, mucous, and mixed tubuloalveolar glands in its lamina propria.[38] Goblet cells are present in large numbers throughout the nasal cavity and are present in the airway mucosa to the level of secondary and tertiary bronchi.[38] The secretions of these glands and goblet cells and the fluid transudated from serum together serve to warm and humidify inspired air, trap particulate matter, protect the respiratory epithelium from desiccation and infection, and provide the seromucous bilayer necessary for effective ciliary function.[11,41] The tracheobronchial fluid that constitutes the mucous blanket in the lower parts of the respiratory tract contains exfoliated epithelial cells, alveolar macrophages, other mononuclear cells, glycoproteins, bacteriostatic proteins (primarily lysozyme), lactoferrin, secretory IgA, IgG, IgM, and serum proteins (primarily albumin).[11,41] The cilia lining the pseudostratified columnar epithelium beat in coordinated waves to carry mucus, trapped particles, and cells from the lower respiratory tract to the nasopharynx. Material cleared from the tracheobronchial tree is normally swallowed on reaching the pharynx but may appear at the external nares as nasal discharge.[41]

Serous nasal secretions in normal animals are responsible for the moist appearance of the ventral portion of the external nares. In cattle, normal nasal secretions are more voluminous and more mucoid compared with other large animal species. Healthy cattle keep their external nares clean through frequent and repeated licking. Cattle that are systemically ill or otherwise debilitated often neglect to do this, and as a result mucoid secretions accumulate and crust around the external nares. On the other hand, a buildup of nasal discharge in cattle with respiratory disease can be removed by frequent nose licking, masking the presence of disease.

Lacrimal secretions also drain into the nasal passages through the nasolacrimal ducts and may appear at the external nares as a thin, watery, clear, nonviscous discharge, particularly in animals with conjunctival irritation or ocular inflammatory diseases that stimulate excessive lacrimation.[39]

ABNORMAL NASAL SECRETIONS. Inflammatory conditions involving the nasal cavity stimulate increased production of glandular secretions.[41] These secretions initially are serous but later become mucoid and purulent as secondary bacterial invasion induces an influx of neutrophils.[38] Serous nasal discharge generally indicates disease conditions affecting the nasal passages or upper respiratory tract.

Inflammation, irritation, and other pathologic states affecting the trachea and bronchi increase the production of mucous and serous secretions in the tracheobronchial tree[41] (Boxes 5.3 and 5.4). Initially the accompanying nasal discharge is mucoid (clear, colorless, thin, and elastic in consistency), but with chronicity and secondary bacterial invasion, neutrophils and other inflammatory cells accumulate in the tracheobronchial secretions and the nasal discharge becomes purulent, progressing

BOX 5.3

Causes of Serous and Mucoid Nasal Discharge in Horses

Common Causes

Influenza
Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)
Other viruses (e.g., rhinitis A and B viruses, adenovirus, reovirus, EHV-2)
Pharyngitis, chronic pharyngeal lymphoid hyperplasia
Nasal or paranasal sinus infection, cysts, polyps, tumors
Early bacterial pneumonia or pleuritis
Early strangles (*Streptococcus equi* infection)
Guttural pouch infection, mycosis
Overflow of nasolacrimal ducts
Recurrent airway obstruction (RAO or chronic obstructive pulmonary disease)

Less Common Causes

Equine viral arteritis
Burn (thermal, chemical)
Anaphylaxis or acute drug reaction
Aspiration or foreign body pneumonia, smoke inhalation
Foreign body (nasal, pharyngeal, guttural pouch, tracheal, or bronchial)
Summer pasture–associated obstructive airway disease (SPOAD)

Uncommon Causes

Nasal fungal infection (rhinophycomycosis), aspergillosis
Nasal amyloidosis
Coccidioidomycosis
Restrictive pulmonary disease, pneumoconiosis
Trauma to the skull or upper airway
Tuberculosis
Tularemia
Guttural pouch neoplasia
Chlamydia psittaci pneumonia
Nocardiosis
Cryptococcosis
Fungal granuloma, maduromycosis, rhinosporidiosis, mycetoma, pythiosis
Lungworm infection *(Dictyocaulus arnfieldi)*
Ascarid migration
Cyst (pharyngeal, subepiglottal)
Progressive ethmoidal hematoma
Lymphosarcoma, lymphoma, leukemia
Halicephalobus (Micronema) deletrix granuloma
Pulmonary edema
Pulmonary aspergillosis
Stachybotryotoxicosis
Trichloroethylene-extracted feed toxicity
Pentachlorophenol toxicity
Organophosphate, carbamate toxicity
Ammonia toxicity
St. George disease (*Pimelea* species poisoning) (exotic)
Trypanosoma evansi, surra (exotic)
Trypanosoma equinum, mal de caderas (exotic)
Trypanosoma hippicum, murrina de caderas (exotic)
Besnoitiosis, globidiosis (exotic)
African horse sickness (exotic)
Getah virus (exotic)
Glanders (exotic)
Louping ill (exotic)

from cloudy to opaque and then to viscous with a whitish cream color (Boxes 5.5 and 5.6).

Conditions such as chronic bronchitis and RAO cause goblet cell hyperplasia and increased mucous production, which may be reflected as a discharge at the external nares, depending on the efficiency with which the animal swallows these secretions. In some cases nasal discharge is evident only early in the morning or after a period of recumbence because in these situations secretions accumulate in the trachea and pharynx, drain into the nasal passages, and exit from the nares.

Hemorrhagic (sanguineous) nasal discharge, or epistaxis, occurs secondary to trauma, coagulopathies, and erosive or invasive conditions that insult the richly vascular nasal mucosa or secondary to conditions that invade regional blood vessels such as occurs when the internal carotid artery is eroded by a mycotic plaque in horses with guttural pouch mycosis. Pulmonary disorders such as infarctive pneumonia in horses and pulmonary thromboembolism secondary to posterior vena cava thrombosis in cattle may also induce epistaxis (see the Epistaxis and Hemoptysis section later).[38-40]

Foul odor (ozena) accompanying nasal discharge suggests an anaerobic infection, a necrotizing condition (e.g., fungal infection, neoplasia, turbinate necrosis, or necrotizing pneumonia), foreign body, or communication between the oral and nasal cavities (e.g., maxillary sinusitis secondary to tooth root infection in the horse).[40]

Food or water may drain from the external nares when there is communication between the oral and nasal cavities (e.g., cleft palate), in association with swallowing disorders (e.g., pharyngeal paresis secondary to botulism, cranial nerve damage secondary to guttural pouch mycosis in the horse), or in cases of obstructive dysphagia (e.g., severe pharyngitis, guttural pouch enlargement in horses, retropharyngeal abscesses, esophageal obstruction, obstructions of the gastrointestinal tract that lead to regurgitation of food from the stomach).[38-40] The respiratory position of the epiglottis dorsal to the soft palate in the horse means that except in cases of dorsal displacement of the soft palate (laryngopalatal dislocation), food regurgitated from the digestive tract enters the nasopharynx and appears at the external nares rather than at the mouth (see Chapter 7).

Chronic nasal discharges often cause scalding in the area ventral to the external nares.[39] Mucoid and purulent nasal discharges tend to dry and crust as an admixture with environmental dust and dirt around the external nares. In all large animal species but particularly in sheep and goats, tenacious exudates may obstruct the nasal passages and induce a snuffling noise. Horses with profuse nasal discharge often rub the nose on the dorsum of the front fetlock and cannon regions. During the physical examination, these areas should be inspected for mucoid exudate, dried crusts, or swarms of flies.

ACUTENESS OF ONSET. Sudden-onset nasal discharge is usually associated with acute infection, trauma, or esophageal obstruction, whereas nasal discharge of insidious onset generally accompanies chronic infection, progressive neurologic disease that causes dysphagia, or neoplasia.[42]

ORIGIN OF NASAL SECRETIONS. Unilateral nasal discharge generally originates from structures located rostral to the caudal end of the nasal septum. Bilateral nasal discharge results from disease processes affecting structures caudal to the nasal septum or from conditions involving the nasal passages or paranasal sinuses bilaterally.[39,40] A discharge that appears from one nostril on some days and from the opposite nostril on others generally indicates a lesion or disease process caudal to the nasal septum.[40] The paired guttural pouches of the horse drain separately through ostia located dorsolaterally in the wall of the nasopharynx. Exudate draining from the guttural pouches may appear unilaterally at the ipsilateral nostril if the volume of drainage is small, but moderate to profuse guttural pouch drainage appears as a bilateral nasal discharge.[40]

VOLUME OF NASAL SECRETIONS. The volume of nasal discharge frequently increases when the head is lowered,

B, Bovine; *C*, caprine; *O*, ovine.

regardless of the source of the discharge, because of pooling of exudate in the trachea, pharynx, or nasal passages. However, the appearance of profuse, unilateral, purulent nasal discharge when the head is lowered generally indicates sinus empyema, and profuse bilateral nasal discharge under these circumstances suggests guttural pouch empyema.[21] This is attributed to accumulation of large volumes of exudate in the sinus cavities or guttural pouches when the head is elevated and to the fact that the ostia through which these structures drain are not located on the most dependent aspect of these cavities; thus

significant drainage can occur only when the head is lowered. Nasal discharge observed only after exercise suggests an origin in the lower respiratory tract.[43]

Approach to Diagnosis of Nasal Discharge

Because many conditions, particularly those involving the lower respiratory tract, are associated with both nasal discharge and cough, the diagnostic approach used for large animal patients presented for evaluation of nasal discharge is similar to that used for large animals presented for evaluation of cough (see the Cough section earlier). Only the components of the history and diagnostic evaluation that differ substantially from those used in patients with cough are described in depth in this section.

HISTORY. The patient history should include information about the rapidity of onset and duration of nasal discharge; whether the discharge is consistently unilateral, consistently bilateral, or intermittently bilateral; and the volume, color, consistency, and odor of the discharge.

The association of discharge with certain activities—such as initiation of exercise, when the animal is first disturbed in the morning, or when it is eating with its head lowered—can provide

VetBooks.ir

useful clues to the origin or cause. It should be determined if the animal is showing other signs of respiratory disease (e.g., cough, respiratory distress, or exercise intolerance), dental disease (e.g., quidding or slow eating), or systemic disease (e.g., weight loss, depression, anorexia, fever, or lymphadenopathy).

It should also be determined if in-contact animals have exhibited nasal discharge or other signs of respiratory disease. The vaccination status of affected and in-contact animals should be ascertained. Recent transportation, surgery, or weaning should be noted as supportive of stress, and a history of contact with other animals at sales, shows, or other events should be established. Environmental quality and the overall management of the affected animal and the herd should be assessed (see the Cough section earlier). Progression or improvement in the signs, attempted therapy, and response to current or previous treatments should also be ascertained.

PHYSICAL EXAMINATION. Physical examination of an animal showing nasal discharge should be complete and include inspection from a distance and close examination using *auscultation*, *palpation*, and *percussion* techniques (see Physical Examination in the Cough section earlier). The character and volume of the nasal discharge should be noted. Particular attention should be paid to whether:

- The nasal discharge is unilateral or bilateral
- The airflow from both nostrils is symmetric
- Odor emanates from the oral or nasal cavity
- Facial asymmetry is present
- Hyporesonance (dullness) or a painful response is elicited on percussion of the maxillary and frontal sinuses
- Enlargement of submandibular, parotid, retropharyngeal, or other regional lymph nodes is present
- Palpable turbulence such as a tracheal rattle is present

The depth and symmetry of chest expansion should be assessed, and the rostral end of both nasal passages should be illuminated with a penlight and examined carefully.

The roots of the third through the sixth maxillary cheek teeth (108 to 111 and 208 to 211) in the horse are contained within the maxillary sinus; therefore infection of these teeth frequently leads to sinus empyema with drainage from the nasomaxillary opening into the middle nasal meatus and ultimately to a unilateral nasal discharge. Disease involving the paranasal sinuses should be considered in horses with unilateral nasal discharge, particularly when ozena is present. Under these circumstances a thorough *oral examination*, which should include probing of the occlusal surfaces of the maxillary cheek teeth with a fine dental pick, is indicated. Particular attention should be paid to detecting erosive periodontal disease, fractured maxillary cheek teeth, open pulp chambers, and patent infundibula. In cattle the oral examination should include palpation of the base of the tongue, the oropharynx, and, if possible, the larynx to determine whether mass lesions or swelling of the tongue are present.

Further diagnostic evaluation of nasal discharge may include a complete blood count with determination of the fibrinogen concentration, a serum biochemistry profile, endoscopy of the upper and lower airways and the esophagus, nasal or nasopharyngeal swabbing for molecular diagnostic testing or virus isolation, virus serologic testing, tracheal aspiration, BAL, ultrasonography, thoracentesis, radiography, blood gas analysis, nuclear scintigraphy, fecal examination, pulmonary function testing, and lung biopsy. For further information on diagnostic procedures not discussed in the following sections, see the Cough section earlier.

ENDOSCOPIC EXAMINATION. Endoscopic examination of the upper and lower airways is a useful ancillary diagnostic procedure in all animals with nasal discharge. The nasal passages; the conchae (turbinates) including the ethmoidal conchae; the nasal septum; and the pharynx, larynx, and trachea should be examined through both nostrils. The presence, nature, and origin of exudates and the presence of anatomic or functional abnormalities or mass lesions should be noted. Although it is not possible to introduce standard, 8- to 12-mm–diameter endoscopes into the paranasal sinuses via the nasal passages, drainage from the sinuses may be detected by examining the middle meatus.[40] Examination of the middle meatus may also reveal turbinate necrosis or mass lesions (e.g., tumors, fungal granulomas, nasal foreign bodies). Lesions such as progressive hematomas (expanding mass lesions of variable size on the ethmoid turbinates) can be visualized by advancing the endoscope slightly, after deflecting its tip dorsally through the common meatus, from a position in the caudal part of the ventral meatus just rostral to the choanae. In the horse the pharyngeal openings of the guttural pouches, which are located dorsolaterally on the wall of the pharynx, should be inspected for drainage. The interior of both guttural pouches can be examined for exudate, blood, mycotic plaques, and other proliferative lesions by advancing the endoscope through the pharyngeal openings of each guttural pouch. This procedure is facilitated by first introducing a biopsy instrument or similar guidewire into the guttural pouch via the biopsy channel of the endoscope.

Bronchoscopic examination may prove useful for identifying the bronchus of origin of pulmonary exudates and for facilitating appropriate BAL. In horses with intermittent bilateral nasal discharge, it may be helpful to repeat the endoscopic examination after exercise, which often mobilizes secretions from the lower respiratory tract and causes them to pool in the horizontal trachea. Endoscopic examination of the esophagus is indicated in patients with a history of dysphagia or return of ingesta through the nose (Boxes 5.7 and 5.8).

RADIOGRAPHY. Radiography with lateral, dorsoventral, and oblique radiographic projections of the nasal passages, paranasal sinuses, pharynx, retropharyngeal area (including guttural pouches in the horse), larynx, and proximal trachea is indicated to confirm problems identified by clinical examination and endoscopy and to identify conditions not recognized by other diagnostic techniques. The demonstration of increases in tissue density, fluid lines, bony lysis or proliferation, distortion of normal architecture, or changes around tooth roots assists in the diagnosis and localization of disorders of the nasal passages, conchae, and paranasal sinuses. Space-occupying lesions in the oropharynx, nasopharynx, or larynx may also be demonstrated by radiographic examination of these areas. The presence of fluid lines, soft tissue densities, or thickening of the floor of the guttural pouches helps differentiate guttural pouch diseases (e.g., empyema) from other space-occupying lesions (e.g., abscesses) in the retropharyngeal region. Contrast radiographic studies such as barium swallows are indicated to evaluate aspiration during swallowing in horses suspected of having pharyngeal paresis. Carotid angiography under general anesthesia has been used to demonstrate aneurysms in the internal carotid artery of horses with guttural pouch mycosis.[44] Thoracic radiographs are indicated in patients suspected of having pulmonary, mediastinal, or pleural disease to determine the presence, pattern, and severity of radiographic changes.

COMPUTED TOMOGRAPHY SCANNING. When a definitive diagnosis is not achieved using plain radiographs, computed tomography (CT) scanning under general anesthesia has proven valuable for more accurately defining the location, nature, and extent of lesions involving the nasal passages, paranasal sinuses, and cheek teeth.[45,46] Intracarotid or IV injection of contrast material further enhances the diagnostic utility of CT for evaluation of mass lesions.

BOX 5.7

Causes of Ingesta in Nasal Discharge in Horses

Common Causes

Esophageal obstruction, choke
Cleft palate, palatal hypoplasia (neonate)
Pharyngitis
Strangles (*Streptococcus equi* infection)
Dorsal displacement of the soft palate
Guttural pouch infection, mycosis, neoplasia
Glossopharyngeal nerve damage
Botulism, shaker foal
Retropharyngeal abscess

Less Common Causes

Complications of laryngeal surgery
Laryngeal web defect
Epiglottal entrapment, subepiglottal abscess or cyst
Tetanus
Fistula (pharyngeal, esophageal, esophagobronchial, esophagotracheal)
Esophageal stricture, ectasia, diverticulum, megaesophagus, ulcer, rupture
Gastric, duodenal ulceration (foals)
Gastric dilation, rupture
Proximal enteritis, jejunitis
Small intestinal obstruction
Rabies
Other neurologic deficits affecting swallowing

Uncommon Causes

Persistent right aortic arch, vascular ring anomaly
Gastric tumor
Gastric stenosis
Rostral displacement of the palatopharyngeal arch
Hypoplasia of the soft palate
White muscle disease, nutritional myodegeneration
Rectus capitis ventralis muscle rupture
Lymphosarcoma, lymphoma, leukemia
Oleander poisoning
White snakeroot (tremetol) poisoning
Lead toxicity
Grass sickness (exotic)

BOX 5.8

Causes of Ingesta in Nasal Discharge in Ruminants

Common Causes

Esophageal obstruction, foreign body, choke
Pharyngeal, retropharyngeal abscess
Pharyngeal trauma, foreign body
Megaesophagus (B, C)

Less Common Causes

Rhododendron poisoning (O)
Diaphragmatic hernia
Water deprivation, salt toxicity (B, O)
Ruptured or lacerated esophagus
Tetanus
Cleft hard or soft palate
Glossopharyngeal nerve damage

Uncommon Causes

Neoplasia of the esophagus or rumen (B)
Persistent right aortic arch, vascular ring anomaly (B, O)
Listeriosis
Bronchobiliary fistula (yellow froth) (B)
Congenital defects of Kodiak Island calves (B)
Oleander poisoning
White snakeroot (tremetol) poisoning (B, O)
Crude oil toxicity (B)
Geigeria species poisoning
Sneezeweed (*Helenium* species) poisoning
Rubberweed (*Hymenoxys* species) poisoning

B, Bovine; *C*, caprine; *O*, ovine.

ULTRASOUND EXAMINATION. Ultrasound examination of externally visible lesions such as possible retropharyngeal abscesses or distended guttural pouches assists in characterization of lesions and collection of samples by aspiration or biopsy. Thoracic ultrasound is indicated when lower airway, pleural, or cardiac disease is the suspected cause of nasal discharge.

PERCUTANEOUS ASPIRATION. Percutaneous aspiration, performed either blindly or with the assistance of ultrasound, followed by cytology and culture of aspirated material, is useful in the evaluation of masses such as submandibular or retropharyngeal abscesses that are also causing a nasal discharge.

CENTESIS. Centesis of affected paranasal sinuses helps localize the source of exudates and provides samples for cytologic examination and culture in patients with chronic unilateral nasal discharge in which sinus percussion or radiographic examination (or both) suggests the presence of a sinus lesion. In the normal horse the rostral and caudal maxillary sinuses are separated by a thin osseous septum. This septum is often eroded in horses with septic sinusitis; therefore the caudal maxillary sinus is typically entered first. If no exudate can be aspirated, either directly or after lavage of the sinus, and if increased purulent drainage from the ipsilateral nostril is not accomplished during lavage, centesis of the rostral maxillary sinus is performed and the procedure is repeated. If the aspirated material is not malodorous and if there is no evidence of dental disease, there is a reasonable likelihood that primary (nondental) sinusitis is present. In the horse the rostral maxillary sinus can be entered at a site 2.5 cm dorsal and 2 to 3 cm caudal to the rostral end of the facial crest. The caudal maxillary sinus is entered at a point 2.5 cm dorsal to the facial crest and 2 cm rostral to the medial canthus of the eye. After shaving and surgical preparation of the skin and subcutaneous placement of a small volume of local anesthetic, a stab incision is created through the skin and extended down to the periosteum. A small hole is then drilled through the bone with a Steinmann pin in a handheld chuck or a 14-gauge needle. A 14-gauge cannula is introduced into the sinus and, if necessary, a 5-French catheter can be inserted through the cannula to facilitate sample collection and lavage (see the Diseases of the Paranasal Sinuses section in Chapter 31 for horses and the Diseases of the Sinuses section in Chapter 31 for ruminants).

CATHETERIZATION. Catheterization of the guttural pouches via the pharyngeal orifice, either blindly or under endoscopic guidance, followed by aspiration or lavage, culture, and cytologic examination of aspirated contents, is helpful in the evaluation of horses with chronic purulent nasal discharge in which guttural pouch empyema is suspected or has been confirmed by radiographic or endoscopic examination. In horses with large accumulations of fluid exudate, voluminous drainage of pus both through and around the catheter may occur when the pouch is first catheterized. In horses with chronic guttural pouch infection accompanied by tenacious or inspissated exudate, lavage with 250 to 400 mL of sterile saline or Ringer solution facilitates sample collection.

Epistaxis and Hemoptysis

W. David Wilson • Jeanne Lofstedt • Jeffrey Lakritz

Definition Epistaxis is defined as the presence of blood at the external nares[47]; the amount of blood at the nostrils can range from small flecks incorporated in serous nasal discharge to large volumes flowing freely from both nostrils. Hemoptysis is the coughing up of blood.[48]

Pathophysiology Blood at the external nares originates from one or more of the following structures: nasal cavity, paranasal sinuses, guttural pouch (auditory tube diverticulum), oral cavity, pharynx, larynx, trachea, or lungs.[47] These respiratory structures may be affected by a primary disease process or may be one of many mucosal surfaces involved in a bleeding diathesis (Boxes 5.9 and 5.10). The actual disease condition, the affected structure, and the large animal species involved determine whether epistaxis is profuse or scant, unilateral or bilateral, induced by exercise, accompanied by hemoptysis, and/or associated with concurrent abnormal nasal discharge.

NASAL CAVITY OR PARANASAL SINUS PATHOLOGIC CONDITIONS. Epistaxis associated with diseased respiratory tract structures rostral to the caudal border of the nasal septum (e.g., nasal cavity, paranasal sinuses) is usually unilateral and appears spontaneously (i.e., occurs without exertion or lowering of the head). However, with profuse hemorrhage from these sites, blood may drain caudally, accumulate in the pharynx, and exit from both nostrils.

Nasal cavity structures are highly vascular and prone to injury. Bleeding can be caused by foreign bodies, fungal granulomas, or neoplasms that invade the nasal cavity; epistaxis associated with these lesions is commonly unilateral, scant, and evident only intermittently. Trauma induced by passage of a nasogastric tube or endoscope is the most common cause of profuse hemorrhage of nasal origin in horses.[47] Erosive diseases that affect the paranasal sinuses of horses (e.g., progressive ethmoidal hematoma)[47] or sheep (endemic nasal adenocarcinoma)[49] commonly cause a unilateral, serosanguineous nasal discharge preceded or accompanied by mucopurulent discharge. In the case of sinusitis the exudate is often malodorous, particularly when these processes occur secondary to dental disease. Epistaxis resulting from fractures of the nasal bones or skull can be scant or profuse, depending on the extent of the fracture.

PATHOLOGIC CONDITIONS OF THE GUTTURAL POUCHES OF THE HORSE. Spontaneous epistaxis that occurs at rest in a mature horse warrants consideration of the guttural pouch as the source of hemorrhage.[50] In the case of guttural pouch mycosis, epistaxis is typically caused by fungal erosion of the internal carotid artery in the roof of the medial compartment of the guttural pouch.[50-52] The horse initially experiences several episodes of minor hemorrhage characterized by a small amount of fresh blood at the external nares; this may be preceded by a unilateral catarrhal nasal discharge and followed by a seromucous nasal discharge. Ultimately, massive arterial bleeding associated with erosion of the internal carotid artery manifests as large volumes of blood gushing from both nostrils.[51] Epistaxis caused by bleeding from the guttural pouch is typically most pronounced on the ipsilateral side, but nasal bleeding is usually bilateral in this condition, especially if hemorrhage is profuse, because the nasopharynx drains into both nasal passages.[52]

PULMONARY PATHOLOGIC CONDITIONS. In horses, pulmonary hemorrhage manifests as bilateral epistaxis, most often during or immediately after strenuous exercise.[47] In many cases of pulmonary hemorrhage, however, epistaxis is not observed because blood originating from the lungs is swallowed when it reaches the pharynx. Hemoptysis, the hallmark of pulmonary hemorrhage in cattle, is rarely observed in horses because the position of the epiglottis dorsal to the soft palate prevents blood flow from the nasopharynx to the oropharynx and mouth. In

BOX 5.9

Causes of Epistaxis in Horses

Common Causes
Exercise-induced pulmonary hemorrhage (EIPH)
Guttural pouch mycosis
Progressive ethmoidal hematoma
Nasal trauma
Pharyngeal or retropharyngeal trauma or abscess
Nasal polyps
Tumors (nose, paranasal sinuses)
Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)
Purpura hemorrhagica

Less Common Causes
Pleuropneumonia
Infarctive lobar pneumonia
Pulmonary neoplasia
Fungal granuloma (maduromycosis, aspergillosis, rhinosporidiosis, mycetoma)
Cryptococcal rhinitis
Coccidioidomycosis
Guttural pouch empyema
Guttural pouch neoplasia
Guttural pouch foreign body
Vesicular stomatitis
Atrial fibrillation
Idiopathic thrombocytopenic purpura
Immune-mediated thrombocytopenia
Lymphosarcoma
Myeloproliferative disease
Disseminated intravascular coagulation (DIC)
Toxic hepatic failure
Multiple clotting defects (foals)
Equine infectious anemia (EIA)
Skull fracture
Gunshot injury
Pharyngeal lymphoid hyperplasia

Uncommon Causes
Nasal amyloidosis
Rectus capitis ventralis rupture
Black disease *(Clostridium novyi)*
Snakebite
Retrobulbar neoplasia
Chronic hepatitis or cholangitis
Acute renal failure
Cardiac neoplasia
Laryngeal hemiplegia
Phycomycosis, pythiosis, zygomycosis
Thrombasthenia-like syndrome
Besnoitiosis, globidiosis (exotic)
Dacryohemorrhea (exotic)

Toxic Causes

BOX 5.11

Causes of Hemoptysis in Ruminants

Caudal vena cava thrombosis (CVCT)
Aspiration pneumonia
Pharyngeal or retropharyngeal abscess or trauma
Thoracic trauma (fractured ribs or sternum)
Foreign body (nasal, oropharyngeal, tracheal, bronchial)
Pulmonary aspergillosis

contrast to humans and other animal species, where foaming of blood exiting the nares suggests pulmonary hemorrhage, foaming of the blood is rarely encountered in horses with pulmonary hemorrhage because the horizontal position of the major bronchi allows blood to pool and flow freely without having to be coughed up.

EIPH, a syndrome experienced by 40% to 75% of Thoroughbred racehorses and by horses of other breeds engaged in strenuous activity, is characterized by hemorrhage into the tracheobronchial tree during competitive exercise.[47,53,54] Although pulmonary hemorrhage can be identified by endoscopic examination of the trachea immediately after exercise in these horses, EIPH manifests as frank epistaxis at the external nares in only a small percentage of cases.[53] Bleeding at the nares may range from a slight orange-tinged serous nasal discharge to a constant trickle of fresh blood that persists for several hours after exercise.[47,54] The exact source of hemorrhage in horses with EIPH has not been identified, but it is known that affected horses have proliferation of the bronchial arterial blood supply to the lungs.[55] Fatal massive epistaxis, an infrequent sequela to exercise, has been attributed to tearing of the lung in association with pleural adhesions or focal shear stress.[56] Other less common causes of postexercise pulmonary hemorrhage in horses include pulmonary abscesses or pleuropneumonia with pulmonary infarction; in these cases the odor of the breath may be fetid, and hemorrhage may occur spontaneously (without exercise), which aids in the differentiation of these conditions from EIPH.[47,57]

Caudal vena cava thrombosis (CVCT; also known as *pulmonary embolic aneurysm* or *pulmonary thromboembolism*) is the disease most likely to be associated with epistaxis and hemoptysis in cattle (Box 5.11).[58] This sporadic, fatal condition of feedlot cattle is the result of a four-step sequence of events that culminates with the rupture of a pulmonary artery aneurysm into a bronchus. Initially, affected cattle exhibit tachypnea, lethargy, painful cough, melena, and anemia. Terminally the disease is characterized by discharge of bright, foamy red blood from the nose and mouth, severe respiratory distress, and widespread pulmonary crackles.[58]

Pulmonary edema present in the terminal stages of left-sided heart failure may also be responsible for bilateral serosanguineous discharge at the external nares of large animals.[47]

PATHOLOGIC CONDITIONS OF THE ORAL CAVITY, PHARYNX, OR LARYNX. Less often, epistaxis can result from bleeding from lesions in the oral cavity, pharynx, or larynx. Examples include oral cavity erosions associated with infectious diseases (e.g., mucosal form of bovine virus diarrhea infection in cattle, bluetongue in sheep), erosions associated with epiglottic entrapment in horses, foreign bodies wedged in the mouth or pharynx of large animals, and pharyngeal or retropharyngeal trauma caused by a "balling gun."

BLEEDING DIATHESIS. Several inherited and acquired coagulation disorders of large animals manifest as epistaxis.[59] Inherited clotting factor deficiencies (usually deficiencies of

VetBooks.ir

factors VIII, IX, or XI) or acquired factor deficiencies (those caused by warfarin, sweet clover toxicosis, or advanced liver disease) cause bleeding from large vessels. In addition to epistaxis, subcutaneous hematomas, hemarthrosis, melena, hematuria, and prolonged bleeding from sites of injury may be observed. With conditions causing vasculitis (e.g., equine purpura hemorrhagica, equine viral arteritis), small vessel bleeding occurs. Vasculitis is characterized by mucous membrane petechiae and ecchymoses and demarcated areas of skin edema. Nasal mucous membrane petechiae associated with vasculitis may manifest as epistaxis. Similarly, thrombocytopenia (e.g., immune-mediated thrombocytopenia in horses, bracken fern toxicosis in cattle) is characterized by mucous membrane petechiae and occasionally epistaxis. In rare cases, disseminated intravascular coagulation (DIC) in large animals manifests as a consumptive coagulopathy with bleeding from mucous membranes and blood at the external nares.

Approach to Diagnosis of Epistaxis and Hemoptysis

HISTORY. History information collected should closely follow that described for animals with nasal discharge and should include duration of ownership, time of first appearance of blood at the nares, number of times the animal has bled, volume and color of blood, presence of blood at one or both nostrils, association of epistaxis with exercise, swallowing motions or cough after exercise, concurrent hemoptysis, other signs of respiratory tract disease (e.g., stridor, cough, nasal discharge, respiratory distress), evidence of involvement of cranial nerves (e.g., feed particles at the nares, drooping of the lip or ear), possibility of recent trauma (e.g., nasogastric intubation, head injury), and exposure to toxic plants (e.g., bracken fern, sweet clover).

PHYSICAL EXAMINATION. A complete physical examination should be performed to detect abnormalities indicative of systemic disease or disease affecting other body systems. This examination should include assessment of the attitude of the animal; determination of rectal temperature, pulse rate, and respiratory rate and character; evaluation of mucous membranes for color and petechiae; inspection of the animal to detect hematomas or prolonged bleeding from sites of injury or venipuncture; and neurologic examination to detect neurologic dysfunction (e.g., dysphagia, Horner's syndrome, facial paralysis, head tilt, nystagmus), which may accompany guttural pouch mycosis.

EVALUATION OF THE HEAD AND RESPIRATORY SYSTEM. A complete evaluation of the head and respiratory system should also be carried out. The nasal bones and flat bones overlying the maxillary and frontal sinuses should be examined for asymmetry or deformation; the eyes should be evaluated for exophthalmos or epiphora; the nasal mucosae should be inspected with a light source to demonstrate erosive, ulcerative, or mass lesions; and the sinuses should be percussed to detect altered resonance or pain. On continuing the examination, the following should be evaluated: symmetry and amount of airflow through the nostrils and the effect of occluding each nostril independently, odor at the nose or mouth, presence of stridor, and the effect of applying pressure to the larynx or trachea. The oral cavity should be carefully inspected in animals in which epistaxis is accompanied by a necrotic breath odor. Special attention should be paid to the maxillary cheek teeth of horses and the base of the tongue and the oropharynx of all large animals. Structures in the external pharyngeal region (mandibular lymph nodes, Viborg's triangle, retropharyngeal lymph nodes, parotid salivary gland) should be observed and palpated for swelling, heat, or pain, and the trachea should be observed and palpated where exposed to detect any abnormalities. The larynx, trachea, and lungs should be carefully auscultated at rest and after application of a rebreathing bag for abnormally loud breath sounds, crackles, or wheezes, which may implicate pulmonary disease as the cause of epistaxis. Careful cardiac auscultation should be carried out to detect murmurs or dysrhythmias, which may be associated with left-sided heart failure and pulmonary edema. The chest wall should be palpated to detect rib fractures or pleural friction rubs, and the thorax should be percussed bilaterally to demonstrate large mass lesions, pleural effusion, or pleurodynia.

COMPLETE BLOOD COUNT. A complete blood count and assessment of fibrinogen concentration can be useful in the evaluation of animals with primary or secondary inflammatory conditions or those that have developed blood loss anemia as a sequela to epistaxis (e.g., horses with guttural pouch mycosis or cattle with pulmonary thromboembolism secondary to CVCT). The degree of anemia may give an indication of the severity and chronicity of the bleeding or, in cases of bracken fern poisoning, of the degree of bone marrow suppression.

CLOTTING PROFILE. A clotting profile should be performed (platelet count, prothrombin time [PT], activated partial thromboplastin time [APTT], concentration of fibrin degradation products [FDPs], and plasma antithrombin III) if mucous membrane petechiae or a tendency to bleed was noted on the general physical examination or if the history suggests exposure to sweet clover, warfarin, or bracken fern.

BIOCHEMISTRY PROFILE. A biochemistry profile should be performed to detect disease processes in organ systems other than the lungs (e.g., increased liver enzyme activity in cattle with hemoptysis secondary to CVCT or animals with liver failure causing secondary clotting factor deficiency).

OCCULT BLOOD. Feces should be tested for occult blood. Positive results may suggest swallowing of blood originating from the lungs or pharynx or gastrointestinal bleeding.

ENDOSCOPIC EVALUATION. Endoscopic evaluation is a useful diagnostic aid in cases of epistaxis. The nasal passages, nasomaxillary aperture in the middle meatus, turbinates (conchae), nasal septum, pharynx, guttural pouches, larynx, and tracheobronchial tree should be systematically evaluated through both nostrils at rest and after exercise if indicated to determine the presence, nature, and source of blood and the anatomic or mass lesion responsible for the bleeding. Care should be taken when endoscopy is performed in horses with guttural pouch mycosis because dislodging a clot of blood in the affected guttural pouch may result in fatal hemorrhage.[60] Similarly, the stress of endoscopy may prove fatal to cattle with pulmonary thromboembolism secondary to CVCT. If EIPH is suspected, endoscopy should be performed 30 to 120 minutes after strenuous exercise to allow time for the mucociliary escalator to transport blood to where it can be visualized[53]; this blood may persist from 6 hours to 4 days after exercise, depending on the severity of pulmonary hemorrhage. It is important to remember that EIPH may not be repeatable. In one study only 33% of Thoroughbred racehorses tested positive for EIPH on all subsequent endoscopic examinations after breezing.[61] Biopsy (with histologic evaluation and possibly culture of samples) is indicated when granulomas, polyps, erosions, or mass lesions are visualized through the endoscope.

TRACHEAL ASPIRATION, BRONCHOALVEOLAR LAVAGE, AND THORACOCENTESIS. Percutaneous transtracheal aspiration or endoscopic tracheal aspiration, BAL, or thoracocentesis with cytologic studies and culture of collected samples is indicated when pulmonary or pleural diseases are thought to be

VetBooks.ir

responsible for hemorrhage into the respiratory tract[20,21,62-64] (see the Cough section earlier). The presence of hemosiderophages in tracheobronchial aspirates or BAL fluid is generally considered indicative of previous pulmonary hemorrhage[53]; however, mucopolysaccharides engulfed by alveolar macrophages can bind plasma iron in the absence of pulmonary hemorrhage to form an iron pigment resembling hemosiderin.[64]

RADIOGRAPHIC EXAMINATION. Radiographic examination of the nasal passages, paranasal sinuses, pharynx, retropharyngeal region (including the guttural pouches), larynx, and trachea is indicated if the source of nasal bleeding cannot be definitively diagnosed through physical examination and endoscopy. The nasal passages, turbinates, and paranasal sinuses should be evaluated for fluid lines, cystic structures, bony lysis or proliferation, distortion of normal architecture, or changes in the tooth roots. Space-occupying lesions in the pharynx and larynx may also be demonstrated by radiographic examination. Demonstration of a fluid-air interface in the guttural pouch may indicate guttural pouch hemorrhage or guttural pouch empyema.[47] New bone formation and sclerosis around the *temporohyoid articulation* (temporohyoid osteoarthropathy) may accompany mycotic infection of the guttural pouch but also occurs in the absence of mycotic infection.[47] CT examination may be indicated if the lesion in the head or neck causing hemorrhage cannot be defined adequately with plain radiographs. Thoracic radiographs using four overlapping lateral views in adult horses and cattle and lateral and ventrodorsal views in immature animals and small ruminants aid in identification and definition of diseases affecting the lungs, pleurae, and mediastinum.[20]

ULTRASOUND EXAMINATION. See the Cough section earlier.

PARACENTESIS. Paracentesis of the maxillary sinuses[20] can be performed if percussion and inspection indicate that a lesion in the maxillary sinus may be the cause of epistaxis (see the Nasal Discharge section earlier).

PLEUROSCOPIC EXAMINATION. Pleuroscopic examination[65] is rarely indicated in the evaluation of epistaxis and should be limited to cases in which a disease process involving the pleura (e.g., pleural neoplasia, pleuropneumonia with pulmonary infarctions) is strongly suspected based on the results of other diagnostic tests and a diagnosis cannot be reached by less invasive approaches (see the Cough section earlier).

Tachypnea

W. David Wilson • Jeanne Lofstedt • Jeffrey Lakritz

Definition *Tachypnea* is the term used to describe an increase in the respiratory rate; the term *hyperpnea* is used when both the rate and the depth of respiration have increased.

The respiratory rate, which is assessed by counting rib or nostril movements or by thoracic or tracheal auscultation, is best determined before the patient is disturbed or restrained. Under average conditions of temperature and humidity, acceptable ranges for the respiratory rate in normal adult animals are as follows: cattle, 24 (range 12 to 36) breaths/min; horses, 12 (range 8 to 15) breaths/min; sheep, 36 (range 12 to 72) breaths/min; and goats, 28 (range 15 to 40) breaths/min. Resting respiratory rates in young animals are higher than those in adults. A neonatal foal has a resting respiratory rate of 60 to 80 breaths/min during the first 30 minutes of life, a rate that later falls to 20 to 40 breaths/min. A young calf has a respiratory rate of 20 to 60 breaths/min by 30 minutes of age.

Pathophysiology Respiratory rate, depth, and rhythmicity are regulated by respiratory centers in the brainstem. Central chemoreceptors responding to increased levels of CO_2 (decreased cerebrospinal fluid pH) and peripheral chemoreceptors (carotid and aortic bodies) responding to hypoxemia (PaO_2 below 60 mm Hg), increases in $PaCO_2$, and decreases in pH initiate increases in the respiratory rate. Mechanoreceptors in the lungs and joints also influence ventilation. Lung inflation stimulates stretch receptors in the airways, which decreases the inspiratory effort, whereas mechanoreceptors in the joints are thought to be partly responsible for the increases in ventilation that occur during exercise. Pulmonary chemoreceptors that influence the respiratory cycle include irritant receptors in the airways, which are stimulated by dust and histamine, and J receptors, which apparently detect levels of interstitial fluid and are thought to be responsible for the respiratory pattern observed in animals with pulmonary edema.

Tachypnea is classified as physiologic when it occurs in the absence of underlying disease and as pathologic when it is a manifestation of respiratory distress. Physiologic tachypnea is associated with pain, exertion, heat, fever, anxiety, and other stresses (Boxes 5.12 and 5.13). Factors predisposing to pathologic tachypnea are the same as those that cause respiratory distress: inadequate oxygenation of the blood (i.e., a need for additional oxygen); compensation for metabolic acidosis; excessive environmental heat; disorders that damage the central nervous system respiratory centers in the medulla (e.g., head trauma, inflammation, mass lesions) if they disrupt the control of breathing; disorders that cause dysfunction of motor nerves and/or weakness of respiratory muscles (e.g., botulism, hypocalcemia); and painful conditions involving the respiratory sensory nerves, muscles, pleurae, and ribs (e.g., chest trauma, pleural infection, neoplasia)[66] (see the Respiratory Distress [Dyspnea] section later).

Approach to Diagnosis of Tachypnea

Because tachypnea is a manifestation of respiratory distress, the approach used for evaluating patients with tachypnea is the same as that used for evaluation of respiratory distress (see the Respiratory Distress [Dyspnea] section later).

Respiratory Distress (Dyspnea)

W. David Wilson • Jeanne Lofstedt • Jeffrey Lakritz

Definition Respiratory distress indicates an inappropriate degree of effort to breathe based on an assessment of respiratory rate, rhythm, and character.[11,67]

Respiratory distress is a clinical sign that implies labored breathing, whereas dyspnea is a symptom that describes the subjective feeling of difficult, uncomfortable, or unpleasant breathing (shortness of breath) in human patients.[1,11,67] As such, the term *dyspnea* is not strictly applicable to animal patients, although it is widely used by veterinarians to describe respiratory distress.

Manifestations of respiratory distress include elevated respiratory rate (see the Tachypnea section earlier), extended head and neck position, mouth breathing (ruminants), nostril flaring (horses, sheep, and goats), abnormal respiratory noise (stridor or stertor), exercise intolerance, exaggerated intercostal or abdominal effort (or both), a double expiratory lift and a "heave line" (expiratory respiratory distress), abducted elbows, anxious expression, and inactivity. Animals in severe respiratory distress may show cyanosis (see the Cyanosis section later) and (especially those with severe RAO) may exert so much effort to breathe that the whole body rocks, the anus pumps in and out, and the animal does not move or eat because this diverts its energies from respiration.[67]

Pathophysiology Normal respiratory rate and character are maintained by central and peripheral monitoring of blood gas and acid-base status, with resulting reflex adjustments that

VetBooks.ir

BOX 5.12

Causes of Tachypnea in Horses[a]

Common Respiratory Causes

Bacterial pneumonia
Pleuropneumonia, pleuritis
Pulmonary abscessation
Recurrent airway obstruction (RAO or chronic obstructive pulmonary disease)
Viral pneumonia (equine influenza, adenovirus, equine rhinitis A and B, equine viral arteritis, others)
Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)
Aspiration pneumonia
Prematurity, dysmaturity, or immaturity (foals)

Common Nonrespiratory Causes

Hyperthermia (fever, postexhaustion syndrome, heatstroke, anhidrosis, other)
Pain (abdominal crisis, laminitis, exertional myopathy, other)
Acidosis (acute enterocolitis, urinary bladder rupture, renal tubular acidosis, other)
Anaphylaxis
Blood transfusion reaction
Shock (hypovolemic, cardiac, septic)
Anemia (neonatal isoerythrolysis, blood loss, hemolytic anemia, iron deficiency, bone marrow suppression, ruptured middle uterine artery, other)
Cardiac disease (ruptured mitral chordae tendineae, ventricular septal defect, endocarditis, other)
Gastric dilation

Less Common Respiratory Causes

Smoke inhalation pneumonia
Parasitic pneumonia *(Dictyocaulus arnfieldi)*
Stenotic nares, choanal atresia
Nasal septum abnormalities
Neoplasia (nose, paranasal sinuses)
Fungal granuloma
Nasopharyngeal cicatrix
Paranasal sinus infection
Dorsal displacement of the soft palate
Pharyngeal or retropharyngeal abscess or trauma
Epiglottic entrapment
Chondroma of arytenoid cartilage
Guttural pouch empyema
Tracheal stenosis, collapse, stricture
Foreign body (nasal, nasopharyngeal, laryngeal, tracheal, bronchial)
Diaphragmatic hernia
Pneumothorax
Thoracic trauma

Less Common Nonrespiratory Causes

Anaphylaxis
Air embolism
Intracarotid injections
Fluid therapy complications
Tetanus *(Clostridium tetani)*
Malignant edema *(Clostridium septicum)*
Malignant hyperthermia
Meningoencephalitis
Anemia (piroplasmosis, iron deficiency, hemolytic blood loss, other)
Cardiovascular anomalies (tetralogy of Fallot, tricuspid insufficiency, atrial septal defect, hypoplastic left heart, transposition of great vessels, persistent right aortic arch, patent ductus arteriosus)
Cor pulmonale
Pericarditis
Atrial fibrillation
Ventricular tachycardia, fibrillation, flutter

Uncommon Respiratory Causes

Pulmonary lobar hypertrophy
Branchial or thyroglossal duct cyst
Tracheal rupture
Fracture of laryngeal cartilage
Fracture of hyoid bone
Cutaneous or nasal amyloidosis
Pulmonary tuberculosis
Pulmonary nocardiosis
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia

Uncommon Nonrespiratory Causes

Lactation tetany
Hydroallantois or hydrops
Nutritional myodegeneration (foals)
Methemoglobin reductase deficiency
Acute hepatic insufficiency
Electrocution
Cardiac neoplasia
Embryonal mediastinal cyst

Toxic Causes

α-Naphthyl thiourea (ANTU)
Arsenic
Bromide
Sodium fluoroacetate
Cantharidin (blister beetle)
Ammonia
Amitraz
Propylene glycol
Dioctyl sodium sulfosuccinate
Iron
Selenium
Metaldehyde
Organophosphate
Organochlorine, chlorinated hydrocarbon
Phenothiazine
Potassium
Larkspur (*Delphinium* species)
Japanese yew *(Taxus cuspidata)*
White snakeroot *(Eupatorium rugosum)*
Water hemlock (*Cicuta* species)
Jimson weed *(Datura stramonium)*
Potato *(Solanum tuberosum)*
Cyanogenic plants
Onion (*Allium* species)
Red maple *(Acer rubrum)*

[a]All causes of respiratory distress (see Box 5.14) are also causes of tachypnea.

maintain carbon dioxide (CO_2), oxygen (O_2), and the blood hydrogen ion concentration (pH) within a narrow range.[8] Respiratory distress may occur for the following reasons[66]:

- Inadequate oxygenation of blood (i.e., a need for additional oxygen)
- Compensation for metabolic acidosis
- Excessive environmental heat
- Disorders that damage the central nervous system respiratory centers in the medulla (e.g., head trauma, inflammation, mass lesions)
- Disorders that cause dysfunction of motor nerves or weakness of respiratory muscles (e.g., botulism, hypocalcemia)

BOX 5.13

Causes of Tachypnea in Ruminants

Common Respiratory Causes

Mannheimia haemolytica or *Pasteurella multocida* pneumonia (includes shipping fever and enzootic calf pneumonia)
Histophilus somni pneumonia (B)
Visceral caseous lymphadenitis *(Corynebacterium pseudotuberculosis)* (C, O)
Chronic bacterial pneumonia with consolidation or abscessation (*Arcanobacterium pyogenes* and other bacteria)
Necrotic laryngitis *(Fusobacterium necrophorum)* (B)
Pulmonary embolus from posterior vena cava thrombosis (B)
Respiratory syncytial virus
Parainfluenza type 3 virus
Adenovirus (B, O)
Infectious bovine rhinotracheitis virus (IBR; BHV-1) (B)
Ovine progressive pneumonia virus (O)
Mycoplasma species
Caprine *Mycoplasma mycoides* subsp. *mycoides* infection
Mycoplasma ovipneumoniae (O)
Parasitic pneumonia (*Dictyocaulus viviparus* [B]; *Dictyocaulus filaria* [O, C]; *Müllerius capillaris* [O, C]; *Protostrongylus rufescens* [O, C])
Bovine atypical interstitial pneumonia (B)
Acute pulmonary edema and emphysema (B)
Farmer's lung (*Faenia rectivirgula* hypersensitivity pneumonitis) (B)
Aspiration or foreign body pneumonia

Common Nonrespiratory Causes

Hyperthermia (fever, heatstroke, rapid rise in ambient temperature, other)
Pain (abdominal crisis, urethral calculi, traumatic reticuloperitonitis, musculoskeletal injury, other)
Acidosis (ruminal lactic acidosis, pregnancy toxemia, other)
Electrolyte aberrations (hypocalcemia, hypomagnesemia, other)
Shock (hypovolemic, cardiac, septic)
Anemia (iron deficiency, postparturient hemoglobinuria, blood loss, other)
Distended abdominal viscus (ruminal bloat, other)
Anaphylaxis
Blood transfusion reaction
White muscle disease

Less Common Respiratory Causes

Nasal trauma
Tumors of the nose and paranasal sinuses
Nasal granuloma (fungal granuloma, atopic rhinitis)
Congenital cystic nasal conchae
Laryngeal trauma, abscess
Tracheal stenosis, collapse, stricture
Bovine rhinovirus (B)
Bovine malignant catarrhal fever (B)
Ascaris suum migration (calves) (B)
Thoracic trauma, other causes of chest pain
Pneumothorax
Diaphragmatic hernia
Pleuritis or pleural effusion
Caprine arthritis-encephalitis (CAE) pneumonia (C)
Sheep pulmonary adenomatosis virus pneumonia (O)

Less Common Nonrespiratory Causes

Cardiac anomalies (ventricular septal defect, tetralogy of Fallot, other)
Endocarditis
Pericarditis
Central nervous system disease (meningoencephalitis, polioencephalomalacia, other)
Esophageal obstruction or foreign body
Clostridial diseases (Black disease, enterotoxemia, tetanus)
Anaphylaxis

Uncommon Respiratory Causes

Pleural mesothelioma
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia
Pulmonary aspergillosis
Pulmonary neoplasia
Cyst (branchial, cervical, thyroglossal duct) (B)
Bronchobiliary fistula
Contagious bovine pleuropneumonia (exotic) (B)
Endemic ethmoid carcinoma (exotic) (B)

Uncommon Nonrespiratory Causes

Bluetongue (B, O)
Thymic lymphosarcoma (B)
Retrobulbar neoplasia (B)
Calf lymphosarcoma (B)
Adult multicentric lymphosarcoma (B)
Embryonal mediastinal cyst
Dwarfism (B)
Anthrax

Toxic Causes

Sodium fluoroacetate
Strychnine
Sulfur
Propylene glycol
Urea or nonprotein nitrogen
Water deprivation or salt toxicity
Potassium
Nitrates
Bromide
Iron
Selenium
Organophosphate
Organochlorine or chlorinated hydrocarbon
Larkspur (*Delphinium* species)
Japanese yew *(Taxus cuspidata)*
Sneezeweed *(Helenium autumnale)*
Hairy vetch *(Vicia villosa)*
Whitehead *(Sphenosciadium capitellatum)*
White snakeroot *(Eupatorium rugosum)*

B, Bovine; *C*, caprine; *O*, ovine.

Note: Tachypnea is a rather nonspecific sign and is associated with toxicity caused by a large number of plant species; only a few are listed in this box. See also Box 5.15.

- Painful conditions involving the respiratory sensory nerves, muscles, pleura, and ribs (e.g., chest trauma, pleural infection, neoplasia)

Inadequate oxygenation of blood leads to arterial hypoxemia (low partial pressure of oxygen in arterial blood [PaO_2]). This can be caused by a low partial pressure of inspired oxygen (PiO_2), such as occurs at high altitude; by disorders that interrupt the transfer of oxygen from the environment to the blood (e.g., upper and lower airway obstruction, pulmonary disease associated with alveolar flooding or collapse, pulmonary or intracardiac right-to-left shunting of blood); or by a decrease

in the oxygen-carrying capacity of the blood, such as occurs in anemia, methemoglobinemia, and carboxyhemoglobinemia.[66] Primary or secondary disease conditions that affect the respiratory and cardiovascular systems induce arterial hypoxemia by causing alveolar hypoventilation, ventilation-perfusion mismatch, diffusion limitation, right-to-left shunting of blood, or combinations of these abnormalities (see the Cyanosis section later).[11,66]

Compensation for metabolic acidosis involves "blowing off" carbon dioxide, which may increase both the rate and the depth of respiration.[66] The resulting hyperventilation causes a decline in the partial pressure of arterial carbon dioxide ($PaCO_2$) in the face of clinical signs of respiratory distress.

Animals dissipate a considerable amount of heat through the respiratory tract. In ruminants, but not in horses, heat dissipation is further aided by the animals' ability to mouth breathe and pant to increase evaporative cooling of blood passing through the tongue and other structures in the oral cavity and oropharynx. The need to dissipate heat when exposed to high environmental temperatures induces labored breathing (Boxes 5.14 and 5.15). Apparent respiratory distress also occurs when the weather is not excessively hot but the temperature

BOX 5.14

Causes of Respiratory Distress in Horses

Common Respiratory Causes

Bacterial pneumonia
Pleuropneumonia or pleuritis
Pulmonary abscessation
Recurrent airway obstruction (housing or pasture associated)
Strangles (*Streptococcus equi* infection)
Viral pneumonia (influenza, equine viral arteritis, other viruses)
Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)
Aspiration pneumonia
Prematurity, dysmaturity, immaturity (foals)
Neonatal septicemia (foals)
Pharyngeal, retropharyngeal abscess or trauma

Common Nonrespiratory Causes

Cardiac disease (e.g., congestive cardiac failure, mitral insufficiency, other cardiac diseases)
Shock (septic, cardiogenic, hypovolemic, acute blood loss)
Endotoxemia
Anemia (e.g., neonatal isoerythrolysis, autoimmune hemolytic anemia, blood loss, other causes of acute anemia)
Pain (e.g., abdominal crisis, laminitis, myopathy, fracture, other lameness)
Hyperthermia (e.g., fever, postexhaustion syndrome, anhidrosis, heatstroke, erythromycin associated)

Less Common Respiratory Causes

Epiglottic entrapment with secondary infection or granulation
Arytenoid chondritis
Guttural pouch empyema, tympany, mycosis, neoplasia
Progressive ethmoid hematoma
Nasal polyps
Pharyngeal, subepiglottic cysts
Fungal rhinitis, cryptococcal rhinitis, equine nasal granuloma, nasal aspergillosis, rhinosporidiosis, rhinophycomycosis, maduromycosis, mycetoma
Cleft palate
Laryngeal or hyoid trauma, fractured laryngeal cartilages, laryngeal granuloma or scar
Paranasal sinus infection, cyst, trauma, tumor
Nasal trauma, nasal neoplasia
Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)
Exercise-induced pulmonary hemorrhage (EIPH)
Parasitic pneumonia (*Dictyocaulus arnfieldi*)
Coccidioidomycosis, cryptococcosis, mycotic pneumonia
Inhalation pneumonia, smoke inhalation, drowning, water inhalation
Hyaline membrane disease (foals)
Acute bronchointerstitial pneumonia
Peripartum asphyxia syndrome
Fractured ribs or sternum, thoracic trauma
Pneumothorax
Diaphragmatic hernia
Mediastinal abscess

Less Common Nonrespiratory Causes

Purpura hemorrhagica
Blood or plasma transfusion reaction
Complications of fluid therapy
Anaphylaxis
Intracarotid injection
Acidosis
Gastric distention (e.g., as in small intestinal obstruction)
Pulmonary edema
Malignant hyperthermia
Cardiovascular anomalies (ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot, common ventricle, other anomalies)
Endocarditis
Pericarditis
Cardiac dysrhythmias (atrial fibrillation, heart block, ventricular premature beats, ventricular tachycardia, ventricular fibrillation)
Ruptured mitral chordae tendineae
Mitral insufficiency or stenosis
Clostridial infections (e.g., tetanus, malignant edema, injection abscess)
Procaine penicillin G reaction or intravascular administration
Hyperkalemic periodic paralysis (HYPP)

Uncommon Respiratory Causes

Stenotic external nares
Cutaneous, nasal amyloidosis
Cutaneous, nasal habronemiasis (summer sore)
Failure of closure of the false nostril
Abnormalities of the nasal septum
Choanal (posterior nares) atresia or stenosis (foals)
Nasopharyngeal cicatrix
Laryngopalatal dislocation (dorsal displacement of soft palate), soft palate hypoplasia
Rostral displacement of the palatopharyngeal folds
Pharyngeal hematoma
Laryngeal paralysis
Fistula (pharyngeal, esophageal, esophagobronchial, esophagotracheal)
Chondroma of the arytenoid cartilage
Laryngeal spasm
Hypertrophic ossification of the laryngeal cartilages, laryngeal chondropathy
Neoplasia of the upper airway
Tracheal stenosis, stricture, collapse, rupture
Phycomycosis, pythiosis
Pneumoconiosis (e.g., silicosis)
Interstitial pneumonia (restrictive pulmonary disease)
Pulmonary thromboembolism
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia
Pulmonary lobar hypertrophy (foals)

Continued

VetBooks.ir

BOX 5.14

Causes of Respiratory Distress in Horses—cont'd

Infarctive lobar pneumonia
Chlamydia psittaci pneumonia
Pulmonary nocardiosis
Pulmonary tuberculosis
Pulmonary aspergillosis
Besnoitiosis *(Besnoitia besnoiti* and *Besnoitia jellisoni)*
Pulmonary neoplasia (primary or metastatic)
Pleural neoplasia (mesothelioma, lymphosarcoma)
Embryonic cyst (mediastinal, branchial, cervical, thyroglossal duct)
Hendra virus infection (exotic)

Uncommon Nonrespiratory Causes

Nutritional myodegeneration
Lactation tetany (eclampsia)
Hydroallantois or hydramnios
Methemoglobin reductase deficiency
Hemophilia A (factor VIII deficiency)
Acute hepatic insufficiency
Electrocution
Cor pulmonale
Neoplasia (all systems)
Snake or insect bite
Aortoiliofemoral thrombosis
Equine motor neuron disease
Cholesteremic granuloma

Toxic Causes

Vitamin D
Lead
Organophosphate-associated laryngeal paralysis
Monensin, lasalocid, salinomycin
Propylene glycol
Iron
Dinitrophenol
Selenium
Bromide
Sodium fluoroacetate
Strychnine
Ammonia
Theobromine, chocolate
Cantharidin (blister beetle)
α-Naphthyl thiourea (ANTU)
Red maple *(Acer rubrum)*
Water hemlock (*Cicuta* species)
Oleander *(Nerium oleander)*
Japanese yew *(Taxus cuspidata)*
Larkspur (*Delphinium* species)
Ryegrass (*Lolium* species)
White snakeroot *(Eupatorium rugosum)*
Crofton weed *(Eupatorium adenophorum)*
Pyrrolizidine alkaloid
Locoweeds (*Astragalus* species, *Oxytropis* species)
Avocado *(Persea americana)*
Hoary alyssum *(Berteroa incana)*
Coffee senna seed *(Cassia occidentalis)*
Rubber vine *(Cryptostegia grandiflora)*
Birdsville disease (*Indigofera* species) (exotic)
Trachyandra paralysis (exotic)

BOX 5.15

Causes of Respiratory Distress in Ruminants

Common Respiratory Causes

Mannheimia haemolytica or *Pasteurella multocida* pneumonia (includes shipping fever and enzootic calf pneumonia)
Bacterial pneumonia with consolidation or abscessation (*Arcanobacterium* and other bacteria)
Histophilus somni pneumonia (B)
Visceral caseous lymphadenitis *(Corynebacterium pseudotuberculosis)* (O, C)
Aspiration or foreign body pneumonia (especially after hypocalcemia)
Necrotic laryngitis *(Fusobacterium necrophorum)* (B, O)
Infectious bovine rhinotracheitis virus (IBR; BHV-1) (B)
Respiratory syncytial virus
Ovine progressive pneumonia virus (O)
Mycoplasma mycoides subsp. *mycoides, Mycoplasma agalactiae,* other *Mycoplasma* species (C)
Mycoplasma bovis (B)
Mycoplasma ovipneumoniae (O)
Parasitic pneumonia (*Dictyocaulus viviparus* [B], *Dictyocaulus filaria* [O, C], *Müllerius capillaris* [O, C], *Protostrongylus rufescens* [O, C])
Bovine atypical interstitial pneumonia (B)
Acute bovine pulmonary edema and emphysema (B)
Farmer's lung disease (*Faenia rectivirgula* hypersensitivity pneumonitis) (B)

Common Nonrespiratory Causes

Hyperthermia (fever, heatstroke, rapid rise in ambient temperature, other)
Pain (abdominal crisis, urethral calculi, traumatic reticuloperitonitis, other)
Distended abdominal viscus
Acidosis (ruminal lactic acidosis, pregnancy toxemia, other)
Electrolyte aberrations (hypocalcemia, hypomagnesemia, other)
Hypovolemic, cardiac, or septic shock
Fluid or electrolyte loss (acute diarrhea, gastrointestinal obstruction, other)
Endotoxemia (coliform mastitis, metritis, enteritis, salmonellosis, septicemia, other)
Neonatal septicemia
Anemia (iron deficiency, postparturient hemoglobinuria, hemolytic, anaplasmosis, eperythrozoonosis, other)
White muscle disease (nutritional myodegeneration)
Anaphylaxis or allergy, milk allergy

Less Common Respiratory Causes

Pulmonary embolus from posterior vena cava thrombosis (B)
Parainfluenza virus type 3
Adenovirus (B, O)
Nasal trauma
Tumors of the nose, paranasal sinuses, oral cavity
Nasal granulomas (fungal granuloma, atopic rhinitis)
Congenital cystic nasal conchae
Nose bots *(Oestrus ovis)*
Sinusitis (maxillary, frontal, postdehorning)
Laryngeal trauma or abscess
Trauma (oral, pharyngeal, retropharyngeal), abscess, hematoma
Tracheal stenosis, collapse, stricture
Bovine rhinovirus (B)
Bovine malignant catarrhal fever (B)
Bovine herpesvirus DN-599 (B)
Ascaris suum migration (calves) (B)
Thoracic trauma, rib fracture

BOX 5.15

Causes of Respiratory Distress in Ruminants—cont'd

Pneumothorax
Pleuritis or pleural effusion
Caprine arthritis-encephalitis (CAE) pneumonia (C)
Sheep pulmonary adenomatosis virus (Jaagsiekte) (O)
Smoke inhalation
Foreign body (nasal, oral, pharyngeal, laryngeal, tracheal, bronchial)
Caprine herpesvirus (C)
Bluetongue
Peste des petits ruminants (C, O) (exotic)
Congenital cardiac anomalies (ventricular septal defect, tetralogy of Fallot, patent ductus arteriosus, transposition of the great vessels, other anomalies)
Acquired cardiac failure (bacterial endocarditis, valvular incompetence, valvular stenosis, cardiomyopathy, pericarditis, other causes)
Central nervous system disease (trauma, meningoencephalitis, encephalomalacia, abscess, louping ill, pseudorabies, other causes)
Esophageal obstruction, foreign body, laceration, rupture, megaesophagus
Clostridial diseases (Black disease, enterotoxemia, tetanus, blackleg, bacillary hemoglobinuria, others)
Anthrax
Complications of fluid therapy (pulmonary edema)
Water deprivation (salt poisoning) (B)
Blood transfusion reaction
Anaphylaxis
Burn, thermal injury, electrocution
Systemic toxoplasmosis (C, O)
Tick paralysis (C, O)
Bladder rupture
Bee or wasp sting, snakebite
Photosensitization

Uncommon Respiratory Causes

Actinobacillosis (wooden tongue)
Actinomycosis (lumpy jaw)
Diaphragmatic hernia
Pleural mesothelioma
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia
Pulmonary aspergillosis
Pulmonary neoplasia
Pulmonary tuberculosis
Chlamydia psittaci pneumonia
Cyst (branchial, cervical, salivary, thyroglossal duct)
Bronchobiliary fistula
Contagious bovine pleuropneumonia (exotic) (B)
Endemic ethmoid carcinoma (exotic) (B)
Theileria annulata and *Theileria hirci* (exotic) (B)
Heartwater *(Cowdria ruminantium)* (exotic)

Uncommon Nonrespiratory Causes

Retrobulbar neoplasia (B)
Enzootic bovine leukosis (B)
Thymic lymphosarcoma or thymoma
Calf lymphosarcoma (B)
Adult multicentric lymphosarcoma (B)
Embryonal mediastinal cyst
Dwarfism (B)
Botulism
Vesicular stomatitis
High altitude (brisket) disease, cor pulmonale (B, C)
Procaine penicillin G reaction or intravascular administration
Liver disease (infectious, toxic, parasitic, other)
Border disease (hairy shaker) (C, O)

Toxic Causes

Sodium fluoroacetate
Strychnine
Sulfur (B, O)
Propylene glycol (B)
Oxalate, ethylene glycol (B, O)
Urea or nonprotein nitrogen
Potassium (B)
Nitrates
Bromide (B, C)
Lead
Mercury (C)
Iron (B, C)
Selenium
Arsenic
Organophosphate or carbamate
Organochlorine or chlorinated hydrocarbon
Permethrin
Gossypol
Ergot *(Claviceps purpurea)*
Phosphate fertilizer (B, O)
Vitamin D_3 (B)
Warfarin, dicumarol, diphacinone
Metaldehyde
Formaldehyde
Ammonia
Hydrogen sulfide
Monensin, salinomycin
Dinitrophenol (B, O)
Copper (acute oral toxicity)
Insect fogger pneumonitis (B)
Aflatoxicosis (C)
Levamisole (C, O)
Polychlorinated biphenyl (PCB) (B)
Xylazine-induced pulmonary edema (O)
Carbolic dips (O)
Cyanogenic plants (arrow grass, Johnson grass, common sorghum, Sudan grass, chokecherry, acacia, other plants)
Avocado *(Persea americana)*
Moldy sweet clover (*Melilotus* species)
Moldy sweet potato *(Ipomoea batatas)* (B)
Brassica species
Ryegrass (*Lolium* species) (B, O)

Sneezeweed *(Helenium autumnale)*
False hellebore (*Veratrum* species) (B, O)
Rhododendron (*Andromeda* species) (B, O)
Algae
Lupines (*Lupinus* species) (B, O)
Prickly paddy melon *(Cucumis myriocarpus)*

B, Bovine; *C*, caprine; *O*, ovine.

Note: Respiratory distress is a sign associated with toxicity caused by a large number of plant species. Not all have been listed here.

VetBooks.ir

VetBooks.ir

has risen rapidly, such as occurs when cattle in cold climates are brought indoors in the winter. When the environmental temperature has been consistently low, cattle in feedlots may also experience respiratory distress if the temperature suddenly rises from 4.4° to 10° C (40° to 50° F).

Observation of the nature of the respiratory distress may give important clues as to the functional characterization, and perhaps cause, of the underlying disease process. Obstructive diseases involving the intrathoracic airways (e.g., RAO in horses and farmer's lung in cattle) are more likely to cause flow limitation during expiration because of dynamic airway narrowing or collapse (see the Cough section earlier).[11,68,69] This results in expiratory respiratory distress and a pattern of respiration in which the expiratory phase occupies an increased proportion of the respiratory cycle as the patient attempts to expel air from the lungs.[68] In the extrathoracic airways, dynamic collapse occurs during inspiration because intraluminal pressures are subatmospheric at this time.[11,68,69] Therefore patients with upper airway obstructions, especially of the nonfixed type (e.g., laryngeal hemiplegia), generally show inspiratory respiratory distress and may have a prolonged inspiratory phase.[11,68] Fixed airway obstructions of either the upper or the lower airway (e.g., intraluminal mass, bronchoconstriction) are present during both phases of respiration and may lead to both inspiratory and expiratory distress.[11] However, the distress is likely to be accentuated during a particular phase of respiration, depending on the anatomic site of the obstruction (i.e., fixed upper airway obstructions cause more distress during inspiration, and fixed lower airway obstructions cause more distress during expiration). Restrictive diseases (e.g., pleural effusion, pneumoconiosis) inhibit expansion of the lungs and therefore generally lead to inspiratory respiratory distress.[11] Because an animal with restrictive disease has reduced compliance and must perform more respiratory work than normal to expand its lungs, a common strategy for maintaining adequate ventilation is to increase the respiratory rate and lower the tidal volume (i.e., rapid, shallow breathing).[11] Animals with obstructive diseases generally have a normal or even increased tidal volume.[11]

In many instances, respiratory distress is not apparent at rest but occurs in association with exercise. Under these circumstances the animal's capacity to exercise is impaired, and the owner may complain of exercise intolerance (see the Exercise Intolerance and Poor Performance in Horses section later).

Approach to Diagnosis of Respiratory Distress

HISTORY. After ruling out environmental causes of respiratory distress (e.g., heat stress, high humidity, moving from outside into a heated barn in the winter, handling stress, relocation to high altitude) and attending to the immediate needs of the patient, a careful history should be taken that includes the following factors: time and speed of onset of the clinical signs of respiratory distress; progression of clinical signs; whether this is the first episode of respiratory distress or the animal is subject to recurrent attacks; whether signs are present at rest or only after exercise; the relationship of signs to environmental conditions and the response to environmental change; recent administration of pharmacologic or biological agents; the presence of an audible respiratory noise; or other signs of respiratory tract, oropharyngeal, or neurologic disease (e.g., nasal discharge, cough, dysphagia, facial paralysis, retropharyngeal swelling). A history of recent trauma or exposure to potentially toxic substances such as lead-containing paints, nitrate-accumulating plants or urea (ruminants), or carbon monoxide should be elicited. The animal's appetite and attitude and signs of disease in other systems (e.g., diarrhea) should be determined. In neonates the circumstances surrounding gestation and parturition should be ascertained because prematurity, dysmaturity, congenital infection, birth trauma (e.g., rib fracture) related to dystocia, prolonged parturition, and aspiration of amniotic fluid and meconium are all important causes of respiratory distress. However, it should be noted that tachypnea, with respiratory rates of 60 to 80 breaths/min, is normal in foals during the first 30 minutes after birth as they "blow off" carbon dioxide.

PHYSICAL EXAMINATION. The physical examination should follow the same general approach as that described for cough. In particular, the following should be determined: rectal temperature, pulse rate, respiratory rate and character; regularity and pattern of breathing; presence of excessive intercostal or abdominal respiratory effort; synchrony and symmetry of chest excursion; presence of a "heave line"; presence of stridor at rest (the examiner listens at the nostrils); symmetry of airflow from each nostril; effect of occlusion of each nostril independently; odor from the nose or mouth (or both); presence and character of nasal discharge; swelling around the external nares, inside the nasal passages, or inside the false nostril; facial symmetry and swelling; ocular discharge; resonance or painful response on percussion of the maxillary and frontal sinuses; palpable abnormalities of the mandibles and hyoid apparatus; enlargement of submandibular, parotid, retropharyngeal, and other regional lymph nodes; enlargement of the parotid salivary glands or thyroid gland; swelling, pain, or palpable abnormalities in the retropharyngeal region; a palpable, left-sided pit on the dorsal surface of the larynx; accentuation of stridor, induction of a cough, or evidence of pain on application of pressure to the larynx and trachea; palpable swelling or flattening of the cervical trachea; masses at the thoracic inlet; and palpable turbulence in the extrathoracic airway.

The mucous membranes should be examined carefully for cyanosis, pallor, cherry red color, hemorrhages, congestion, or injection. The capillary refill time should be determined, and the peripheral pulse rate, rhythm, and character should be assessed. Other signs of heart failure (e.g., jugular distention or pulsation and peripheral edema) and signs of dehydration (e.g., delayed jugular filling, dry mucous membranes, altered skin turgor) should be noted. The larynx, trachea, and lungs should be carefully *auscultated* at rest and, after the rate and depth of respiration have been increased, if it is safe to do so, by application of a rebreathing bag, by occlusion of the nostrils, or by exercising the animal, so that turbulent airflow and abnormal lung sounds may be detected. The heart should be auscultated to detect murmurs, cardiac dysrhythmias, muffling of heart sounds, or other abnormalities. The chest wall should be carefully *palpated* to detect rib fractures and other lesions, and both sides of the chest should be *percussed* to detect large mass lesions, lung consolidation, pleural effusion, hyperinflation, pneumothorax, or a painful response, which may indicate pleuritis. A thorough oral examination is important, and in cattle this should include palpation of the base of the tongue, the oropharynx, and, if possible, the larynx (see the Nasal Discharge section earlier).

A general physical examination should be completed so that diseases in systems other than the cardiovascular and respiratory systems (e.g., respiratory distress in cattle secondary to ruminal bloat and respiratory distress secondary to central nervous system trauma or severe metabolic acidosis) can be detected. Attempts should also be made to identify conditions that may cause severe acid-base disturbances and hemoconcentration (e.g., diarrhea, renal disease), pain (e.g., laminitis, trauma), or hyperthermia (e.g., infectious conditions, heatstroke).

Further diagnostic evaluation of respiratory distress may include a complete blood count with fibrinogen concentration; blood gas analysis; serum biochemistry determinations; endoscopy of the upper and lower airways and esophagus; nasal or nasopharyngeal swabbing or scraping; virus identification, isolation, and serologic testing; bronchodilator response testing; tracheal aspiration; BAL; ultrasound examination of the chest

VetBooks.ir

and of suspected mass lesions that impinge on the upper airway; thoracocentesis; radiography of the nasal passages, paranasal sinuses, pharynx, guttural pouches, larynx, trachea, and chest; fecal examination for lungworms and other parasites; CT scanning of the upper airway; nuclear scintigraphy; pulmonary function testing; and biopsy of externally visible or palpable lesions or those identified by ultrasound, endoscopy, or radiography as described for the evaluation of cough and nasal discharge (see the Cough and Nasal Discharge sections earlier). The examiner should exercise discretion in the selection of diagnostic tests for animals with respiratory distress because procedures such as BAL or endoscopy may prove to be excessively stressful and exacerbate the distress, with potentially fatal consequences.

COMPLETE BLOOD COUNT. A complete blood count including fibrinogen and plasma protein concentrations helps evaluate the role of hemoconcentration, anemia, or leukocytosis and hyperfibrinogenemia, which may accompany pneumonia and other inflammatory conditions.

ENDOSCOPIC EXAMINATION. Endoscopic examination of the upper and lower airways is particularly helpful in evaluating patients suspected of having obstructive disease[70] (see the Cough and Nasal Discharge sections earlier and the Abnormal Respiratory Noise [Stridor] section later). Endoscopic examination of the esophagus is indicated in patients with a history of bloat, dysphagia, or return of ingesta through the nose in addition to respiratory distress (see the Nasal Discharge section earlier and the Abnormal Respiratory Noise [Stridor] section later).

BLOOD GAS ANALYSIS. Blood gas analysis and acid-base determinations should be performed on arterial blood to determine O_2 and CO_2 tensions so that the contribution of hypoxemia or acidosis to the signs of respiratory distress can be ascertained. In foals and calves, arterial samples are usually obtained from the great metatarsal artery or the brachial artery as it crosses the medial aspect of the foreleg.[71] The auricular artery is also convenient in calves. The femoral artery can be used in neonates but is less convenient because it tends to roll. The facial artery can be used in adult horses, and the auricular or coccygeal artery can be used in mature ruminants.[72] During the sampling process, the patient should be quiet and not struggling, which can decrease the $PaCO_2$.[73] Local subcutaneous infiltration of 2% lidocaine without epinephrine over the artery being sampled minimizes needless struggling and facilitates sample collection. A heparinized syringe and a 22- to 26-gauge needle can be used. Any air bubbles should be removed after sample collection and the needle properly sealed. If the sample is kept on ice, the pH will remain unchanged for 3.5 hours and the blood gases for 6 hours.[74] The animal's temperature should be recorded at the time of sample collection so that it can be used in the calculation of actual blood gas concentrations.

The normal PaO_2 for the horse is 83.6 ± 1.7 mm Hg, and the normal $PaCO_2$ is 42.2 ± 0.8 mm Hg.[75] Hypoxemia is defined as a PaO_2 below 80 mm Hg.[75] Cyanosis is usually not evident until the PaO_2 is much lower than this (usually below 40 mm Hg).[75] Hypercarbia, or hypercapnia, is a condition of increased $PaCO_2$ (above 44 mm Hg).[75] Because CO_2 diffuses readily, considerable ventilatory dysfunction can occur before the $PaCO_2$ rises; therefore severe hypoxemia can occur with a normal $PaCO_2$. An elevated $PaCO_2$ generally indicates that hypoventilation or a severe pulmonic pathologic condition is present. Because venous blood samples reflect tissue metabolism, they are not considered adequate for evaluating pulmonary function. However, a partial pressure of carbon dioxide in venous blood ($PvCO_2$) above 60 mm Hg usually reflects arterial hypercapnia, and a partial pressure of oxygen in venous blood (PvO_2) below 20 mm Hg usually indicates arterial hypoxemia.[74]

Venous admixture is the term used to denote the ways that blood can pass from the right side to the left side of the circulation without being properly oxygenated and represents the efficiency with which the lung oxygenates blood. The magnitude of venous admixture (efficiency of oxygenation) can be assessed by calculating the PaO_2/FiO_2 ratio or the alveolar-arterial PO_2 gradient. The PaO_2/FiO_2 ratio is normally 500. PaO_2/FiO_2 ratios between 300 and 400 reflect significant lung injury, values below 300 reflect profoundly inefficient lung function such as occurs with acute lung injury, and values below 200 reflect severe life-threatening lung disease typical of acute respiratory distress syndrome (ARDS). The alveolar-arterial (A-a) PO_2 gradient difference is the difference between calculated alveolar PO_2 and the measured arterial PO_2. Alveolar PO_2 = Inspired PO_2 – $PaCO_2$ (1.1), where inspired PO_2 = barometric pressure × 21% and 1.1 = 1/RQ, where RQ is the respiratory quotient and has an assumed value of 0.9. The A-a PO_2 difference is typically about 10 mm Hg in a normal horse breathing 21% oxygen (room air) at sea level and about 100 mm Hg when breathing 100% oxygen. The "120 rule" is a simplified version of the alveolar gas equation that can be applied to a patient breathing 21% oxygen at near sea level. The measured PaO_2 and $PaCO_2$ should add up to 140 ± 10. If the sum is less than 120, the patient has venous admixture; as well, the lower the value, the worse the admixture.

INSUFFLATION OF 100% OXYGEN. Insufflation of 100% oxygen causes a significant increase in PaO_2 if hypoxemia is caused by hypoventilation or ventilation-perfusion mismatch, whereas little or no improvement in PaO_2 occurs if hypoxemia is caused by anatomic or physiologic right-to-left shunting.[11] Therefore measuring PaO_2 5 minutes after insufflation of 100% oxygen can help in determining the pathophysiologic processes contributing to arterial hypoxemia. In full-term neonates and adults, the PaO_2 should exceed 200 mm Hg after 5 minutes of oxygen administration.[73] Continued cyanosis or inability to raise the PaO_2 above 100 mm Hg is highly suggestive of a right-to-left shunt.

DETECTION OF ABNORMAL HEMOGLOBIN. Blood samples should be evaluated for abnormal hemoglobin (e.g., methemoglobin) if exposure to nitrates or other intoxicants is suspected (see the Cyanosis section later).

RADIOGRAPHIC EXAMINATION. Radiographic examination of the nasal passages, pharynx, larynx, and trachea permits detection and evaluation of obstructive lesions in the upper airway, especially if tachypnea is accompanied by inspiratory stridor, asymmetric nasal airflow, or other evidence of upper airway obstruction.

Radiographic examination of the trachea and thorax should include end-inspiratory phase radiographs to facilitate identification of pulmonary lesions and disorders such as dynamic collapse of the trachea that are visible only on inspiratory-phase radiographs. Chest radiographs help detect evidence of pneumonia, pleural effusion, pneumothorax, cardiomegaly, and mediastinal lesions. The cardiac silhouette and the pattern and caliber of the aorta, vena cava, pulmonary artery, pulmonary veins, and other vessels should also be evaluated for evidence of cardiac failure and pulmonary vascular disease. *Contrast angiography* and other diagnostic procedures such as *echocardiography*, *electrocardiography*, and *hemodynamic (pressure and flow) studies* may be indicated in patients with respiratory distress that has occurred secondary to cardiovascular disease.

ULTRASOUND EXAMINATION. Ultrasound examination of the thorax is performed to detect pleural inflammation and effusion, pulmonary consolidation, pulmonary abscessation, and cardiac anomalies if the clinical examination suggests that

pulmonary, pleural, or cardiac disease is the cause of the signs of respiratory distress.

Cyanosis

Jeanne Lofstedt • W. David Wilson • Jeffrey Lakritz

Definition Cyanosis is the bluish discoloration of skin, conjunctivae, and visible mucous membranes that results from an increase in the absolute amount of reduced hemoglobin in the blood.[76]

Pathophysiology Oxygen is carried in blood in two forms, dissolved and in combination with hemoglobin (Hb). The amount of dissolved oxygen present in arterial blood is relatively small and is proportional to the Pa_{O_2}. Oxygen transport to tissues is facilitated by the ability of hemoglobin in erythrocytes to combine in a reversible manner with oxygen. When erythrocytes pass through the pulmonary circulation, oxygen binds to hemoglobin, forming oxyhemoglobin (HbO_2). As oxyhemoglobin passes through systemic capillaries, oxygen diffuses into tissues, and hemoglobin is once again formed.

The Bohr effect describes the ability of hemoglobin to bind to a number of different ligands (CO_2, H^+, and 2,3-diphosphoglycerate [2,3-DPG]), which results in modification of hemoglobin's affinity for oxygen. When tissue pH decreases, hemoglobin acts as a buffer and binds excess H^+, which decreases its affinity for oxygen. When the CO_2 concentration increases, some CO_2 is converted to bicarbonate and the remainder is bound to hemoglobin to form carbaminohemoglobin; this also decreases the affinity of hemoglobin for oxygen. Therefore the net effect of a decreased blood pH and increased blood CO_2 concentration is unloading of oxygen to the tissues. Conversely, as the CO_2 concentration in the pulmonary capillaries decreases and blood pH rises, the affinity of hemoglobin for oxygen increases; thus the net effect of elevated blood pH in pulmonary capillaries is increased uptake of oxygen by hemoglobin.

The affinity of hemoglobin for oxygen is also influenced by the concentration of 2,3-DPG, a metabolic intermediate of the Rapoport-Luebering shunt involved in erythrocyte glycolysis. An increase in the 2,3-DPG concentration may occur in association with chronic hypoxemia (high altitude, chronic lung disease), anemia, chronic alkalosis, phosphate retention, and red cell pyruvate kinase deficiency. When the 2,3-DPG concentration is increased, the affinity of hemoglobin for oxygen is decreased, resulting in improved unloading of oxygen to peripheral tissues. Conversely, a decreased 2,3-DPG level results in an increased affinity of hemoglobin for oxygen. A decrease in the 2,3-DPG concentration may occur in stored blood, in association with chronic acidosis, and with hypophosphatemia.

Cyanosis develops when the oxygen saturation of hemoglobin is below 80%. With a normal oxygen-hemoglobin dissociation curve, the Pa_{O_2} is usually below 40 mm Hg before cyanosis is noted in the patient.[77] The hemoglobin concentration of blood must be near normal for cyanosis to be clinically evident[78]; therefore patients with severe anemia and concomitant marked arterial oxygen desaturation may not show cyanosis. In contrast, patients with marked polycythemia may be cyanotic at higher arterial oxygen saturation than patients with normal hematocrit values.

Classification

Cyanosis can be classified as either *peripheral* or *central*.

PERIPHERAL CYANOSIS. Peripheral cyanosis is caused by slowing of blood flow to an area, resulting in abnormally increased extraction of oxygen from normally saturated arterial blood. Decreased blood flow through the peripheral capillary bed may be caused by vasoconstriction of superficial vessels, obstruction of arteries or veins, or low cardiac output. Peripheral cyanosis is observed in the extremities, nose, and ears and is not usually associated with cyanosis of mucous membranes. Peripheral cyanosis is rarely recognized in large domestic animals because of their skin pigmentation and hair cover.

TABLE 5.1

Pathophysiologic Classification of Central Cyanosis and Examples of Associated Conditions

Classification	Associated Condition
Decreased arterial oxygen saturation	Respiratory disease Ventilation-perfusion mismatch Alveolar hypoventilation Impaired oxygen diffusion Pulmonary arteriovenous shunting Cardiac disease Cardiac anomalies that cause right-to-left shunting (e.g., tetralogy of Fallot)
Abnormal hemoglobin derivative	Methemoglobinemia Sulfhemoglobinemia

CENTRAL CYANOSIS. Central cyanosis results from either inadequate oxygenation of arterial blood or the presence of an abnormal hemoglobin derivative and is characterized by cyanosis of mucous membranes (Table 5.1). Causes of inadequate oxygenation of arterial blood are respiratory disease or congenital cardiac anomalies causing right-to-left shunting (Boxes 5.16 and 5.17). Acquired abnormalities of hemoglobin function can be induced by a number of chemicals. Exposure to these chemicals results in the formation of methemoglobin or sulfhemoglobin, neither of which is capable of binding oxygen. Nitrites and nitrates are powerful reducing agents that produce methemoglobinemia by directly oxidizing hemoglobin to methemoglobin. Nitrate poisoning is most commonly associated with the incorporation of nitrate-accumulating plants (e.g., pigweed *[Amaranthus retroflexus]*, lamb's quarters *[Chenopodium album]*, and mintweed *[Salvia reflexa]*) in livestock forage. Nitrate intoxication is usually seen only in ruminants because rumen microorganisms reduce nitrate to the more toxic nitrite ion. Congenital defects in hemoglobin function have been reported in humans and may occur in large domestic animals. Examples of such defects are nicotinamide adenine dinucleotide methemoglobin reductase deficiency and familial methemoglobinemia.

Conditions That Predispose to Hypoxemia and Central Cyanosis

The remainder of this section is confined to a discussion of respiratory conditions and cardiovascular anomalies that predispose to hypoxemia and central cyanosis. Impaired pulmonary function may cause hypoxemia and, in some circumstances, cyanosis. Mechanisms by which hypoxemia of pulmonary origin can arise include alveolar hypoventilation, reduced gas transfer or diffusion across the blood-gas barrier, ventilation-perfusion mismatch, pulmonary arteriovenous shunt, or a combination of these factors.[76,78] An additional cause of hypoxemia is the decrease in the partial pressure of alveolar oxygen that occurs at high altitudes.

ALVEOLAR HYPOVENTILATION. Alveolar hypoventilation is defined as a reduced volume of inspired air reaching the alveoli per unit time. Alveolar hypoventilation is always associated with an increased Pa_{CO_2}. Conditions associated with alveolar hypoventilation are drug-induced respiratory depression (morphine, barbiturates), brainstem disease (encephalitis,

VetBooks.ir

BOX 5.16

Causes of Central Cyanosis in Horses

Common Causes

Bacterial pneumonia, pleuritis, pulmonary abscessation (*Rhodococcus equi, Streptococcus* species, other bacteria)
Recurrent airway obstruction (RAO or chronic obstructive pulmonary disease)
Aspiration pneumonia
Viral pneumonia (equine influenza, adenovirus, other viruses)
Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)
Acute bronchointerstitial pneumonia
Prematurity, dysmaturity, immaturity (foals)
Ventricular septal defect with pulmonary hypertension
Tetralogy of Fallot
Toxic methemoglobinemia
Anaphylaxis
Shock (hypovolemic, cardiac, septic)

Less Common Causes

Stenotic nares or choanal atresia
Neoplasia (nose, paranasal sinuses)
Nasal granuloma
Nasopharyngeal cicatrix
Tracheal stenosis, collapse, stricture
Tracheal rupture or perforation
Diaphragmatic hernia
Pneumothorax
Pulmonary edema
Smoke inhalation pneumonia
Interstitial pneumonia
Pneumoconiosis
Atrial septal defect with pulmonary hypertension

Uncommon Causes

Pulmonary lobar hypertrophy (foals)
Embryonal mediastinal cyst
Pulmonary tuberculosis, nocardiosis
Pneumocystis carinii (renamed *Pneumocystis jiroveci* in humans) pneumonia
Air embolism
Pulmonary neoplasia
Transposition of great vessels
Tricuspid atresia
Aortic, pulmonary artery rupture
Interruption of aortic arch
Common ventricle with separate pulmonary outflow chamber
Multiple cardiac anomalies
Methemoglobin reductase deficiency
Lactation tetany
Clostridial diseases
Malignant hyperthermia

Toxic Causes

Sulfur, hydrogen sulfide
α-Naphthyl thiourea (ANTU)
Chlorinated hydrocarbon
Organophosphate, carbamate
Red maple (*Acer rubrum*)[a]
Redroot pigweed (*Amaranthus retroflexus*)[a]
Sudan grass (*Sorghum vulgare var. sudanensis*)[a]
Mintweed (*Salvia reflexa*)[a]
Lamb's quarters (*Chenopodium album*)[a]
Variegated thistle (*Silybum marianum*)[a]
Winged thistle (*Carduus tenuiflorus*)[a]

[a]Nitrate accumulator, which causes methemoglobinemia.

trauma, hemorrhage, neoplasia), and transection of the cervical spinal cord. All these conditions prevent proper generation and transmission of signals from the respiratory center to respiratory muscles. Other possible causes of alveolar hypoventilation are abnormal respiratory muscle function (diaphragmatic hernia, botulism), thoracic cage abnormalities (rib fracture), increased airway resistance (e.g., stenotic nares, laryngeal stricture or paresis, foreign body obstruction, bronchitis, bronchiectasis), and pleural space disease (inflammatory or neoplastic effusions, pneumothorax, hydrothorax, chylothorax, pyothorax, hemothorax).

IMPAIRED DIFFUSION. Impaired diffusion, a second cause of hypoxemia, results from increased thickness of the blood-gas barrier. Equilibrium between alveolar oxygen and pulmonary blood oxygen is not reached because of increases in distance or resistance of barriers through which oxygen must pass to bind to hemoglobin. Because carbon dioxide diffuses more readily than oxygen, the $PaCO_2$ is not usually increased in conditions that cause impaired diffusion. In fact, $PaCO_2$ actually may be reduced because of compensatory hyperventilation stimulated by hypoxemia. Conditions that may result in impaired diffusion are pneumonia, pulmonary edema, atelectasis, pulmonary contusions, and pulmonary neoplasms.

VENTILATION-PERFUSION MISMATCH. Ventilation-perfusion mismatch occurs eventually in all generalized pulmonary diseases and is the predominant mechanism by which hypoxemia develops in respiratory conditions. Overall gas exchange is impaired by uneven ventilation and blood flow. Lung areas that are overperfused in relation to ventilation (low ventilation/perfusion ratio) contribute disproportionate amounts of blood with a low PaO_2 to the systemic circulation. Examples of respiratory diseases that can cause low ventilation/perfusion ratios include bronchitis, bronchoconstriction, airway closure, pulmonary atelectasis or consolidation, and local restriction of lung movement. In the case of pulmonary embolization or decreased pulmonary arterial pressure, ventilation may exceed perfusion (high ventilation/perfusion ratio) and result in pathologic dead space. Pulmonary mechanisms can partly compensate for ventilation-perfusion inequalities. Alveolar hypoxia may lead to reflex pulmonary arterial constriction, which redirects blood flow to alveoli that are adequately ventilated. Airway hypocapnia can stimulate bronchoconstriction, resulting in redirection of airflow to better-perfused alveoli.

SHUNTING. Shunting is defined as any mechanism by which blood that has not passed through ventilated areas of the lung is added to arteries of the systemic circulation. The term *venous admixture* is used to describe venous blood that passes through the lungs without proper oxygenation. Animals with venous admixture often hyperventilate and present with normocapnia or hypocapnia in association with hypoxemia. The most common cause of shunting is congenital heart disease, which allows unoxygenated blood from the right heart to pass directly into the left heart without passing through the pulmonary circulation. Intrapulmonary anatomic shunts can result from pulmonary artery to pulmonary venous fistulae, or from prior to severe lung consolidation that results in large portions of the lung being well perfused but poorly ventilated. Cyanosis or hypoxemia unresponsive to oxygen administration suggests the presence of such congenital cardiac anomalies or intrapulmonary shunts.[79] Examples of common cyanotic congenital cardiac defects are tetralogy of Fallot, truncus arteriosus, transposition of the great arteries, tricuspid atresia, and hypoplastic left heart syndrome.[77,79] Aside from congenital defects, reversion to fetal circulation should be considered in any critically ill neonatal animal with hypoxemia that is unresponsive to oxygen insufflation.[79]

BOX 5.17

Causes of Central Cyanosis in Ruminants

Common Causes

Bacterial pneumonia, pulmonary abscessation (*Mannheimia haemolytica* [B], *Arcanobacterium pyogenes* [B], *Pasteurella multocida* [B], *Corynebacterium pseudotuberculosis* [O, C], other bacteria)
Viral pneumonia (respiratory syncytial virus [B], ovine progressive pneumonia [O], caprine arthritis-encephalomyelitis [C], other viruses)
Parasitic pneumonia (*Dictyocaulus viviparus* [B], *Dictyocaulus filaria* [O, C])
Aspiration pneumonia
Acute bovine pulmonary edema and emphysema (B)
Pulmonary edema
Ventricular septal defect with pulmonary hypertension
Tetralogy of Fallot
Toxic methemoglobinemia
Anaphylaxis
Shock (hypovolemic, cardiac, septic)
Rumen bloat

Less Common Causes

Obstruction of nasal passages or paranasal sinuses (neoplasm, granuloma, abscess, other)
Laryngeal abscess
Tracheal stenosis, collapse, stricture
Tracheal rupture, perforation
Diaphragmatic hernia
Prematurity, dysmaturity, immaturity
Inhalation pneumonia (smoke)
Pneumothorax
Hemothorax
Pulmonary contusion
Ventricular septal defect with pulmonic stenosis
Postparturient hemoglobinuria
Clostridial diseases (e.g., malignant edema, blackleg, tetanus)
Bluetongue (O)
Obstructive urolithiasis, ruptured urethra

Uncommon Causes

Pleural mesothelioma (B)
Water inhalation (drowning)
Pulmonary adenomatosis (O)
Transposition of great vessels
Double-outlet right ventricle
Common ventricle with separate pulmonary outflow chamber
Acute anthrax
White liver disease (exotic) (O)
Sweating sickness (exotic) (B, O)

Toxic Causes

Strychnine
Arsenic
Metaldehyde
Hydrogen sulfide
Organochlorine, chlorinated hydrocarbon
Organophosphate, carbamate
Acute selenium toxicosis
Nitrate, nitrite
Perennial broomweed *(Gutierrezia microcephala)*
Oleander *(Nerium oleander)*
Whitehead *(Sphenosciadium capitellatum)*
Milkweed (*Asclepias* species) (O)
Rhododendron (*Andromeda* species)
Fireweed *(Kochia scoparia)*
Canary grass (*Phalaris* species)
Kikuyu poisoning (exotic) (B, O)
Albizia poisoning (exotic) (B, O)
Euphorbia, Sarcostemma poisoning (exotic) (B, O)
Acacia poisoning (exotic) (B, O)

Variegated thistle *(Silybum marianum)*[a]
Redroot pigweed *(Amaranthus retroflexus)*
Sudan grass *(Sorghum vulgare var. sudanensis)*[a]
Winged thistle *(Carduus tenuiflorus)*[a]
Mintweed *(Salvia reflexa)*[a]
Lamb's quarters *(Chenopodium album)*[a]
Many pasture grasses fed during optimum growth conditions[a]
Locoweeds (*Astragalus* species, *Oxytropis* species)[a]

[a]Nitrate accumulator, which causes methemoglobinemia.
B, Bovine; *C*, caprine; *O*, ovine.

Approach to Diagnosis of Cyanosis

HISTORY. The history should include questions about the duration of the cyanosis (e.g., cyanosis that has been present since birth or an early age may indicate congenital heart disease with right-to-left shunting); possible exposure to toxic plants or chemicals that may result in production of abnormal types of hemoglobin; evidence of an abnormal respiratory pattern (respiratory distress, inspiratory stridor, cough); and signs of episodic weakness or syncope that may be consistent with congenital cardiac anomalies or severe upper airway obstruction (e.g., tracheal collapse or severe laryngeal edema associated with necrotic laryngitis in calves).

PHYSICAL EXAMINATION. A thorough physical examination should include visual *inspection* to detect abnormalities in the respiratory pattern (e.g., tachypnea, respiratory distress, stridor) and careful *auscultation* of the larynx, trachea, and lungs to provide information that helps further define the cause of respiratory dysfunction. Rebreathing bags (12- to 52-L capacity for adult horses and cattle; 6- to 12-L capacity for calves, foals, and small ruminants) cause temporary buildup of CO_2, stimulating the respiratory center, prompting deep breathing immediately after the bag is removed and the animal is allowed to inspire room air. Loud breath sounds, pulmonary crackles and wheezes, or pleural friction rubs may suggest cyanosis in association with pathologic respiratory conditions. Loud cardiac murmurs accompanied by precordial thrills point to congenital heart disease as the cause of cyanosis.

Palpation and *percussion* of the thorax are important examination procedures in animals with cyanosis. Chest palpation may reveal pleural friction rubs or the pain and crepitus associated with rib fractures. Increased resonance on percussion may indicate pneumothorax, whereas decreased resonance suggests pulmonary congestion or consolidation, pleural effusion, or a space-occupying lesion in the thorax.

ENDOSCOPIC EXAMINATION. An endoscopic examination should be performed if upper airway obstruction or malformation is suspected (see the Cough, Nasal Discharge, and Respiratory Distress [Dyspnea] sections earlier).

VetBooks.ir

RADIOGRAPHIC EXAMINATION. Radiographs of the upper respiratory tract and thorax can be used to further characterize pathologic respiratory conditions. Abnormalities detected using these modalities include space-occupying lesions in the oropharynx, nasopharynx, or larynx; tracheal compression or collapse; enlargement or distortion of the cardiac silhouette; pulmonary consolidation; pneumothorax; pleural effusion; and pulmonary abscessation.

ULTRASOUND EXAMINATION. Ultrasound examination of the chest and heart is indicated to characterize cardiac anomalies and to detect the presence and determine the extent of pleural effusion, pulmonary consolidation, and pulmonary abscessation.

ARTERIAL BLOOD GAS ANALYSIS. Arterial blood gas analysis is indicated to determine O_2 and CO_2 tension (see the Respiratory Distress [Dyspnea] section earlier).

COMPLETE BLOOD COUNT. A complete blood count should be performed to determine if polycythemia or inflammatory alterations in the leukogram are present. Polycythemia may develop secondary to chronic hypoxemia associated with long-standing pulmonary disease or right-to-left shunting. An inflammatory leukogram is consistent with a diagnosis of bacterial or aspiration pneumonia or other inflammatory respiratory condition.

HEPARINIZED BLOOD. A sample of heparinized blood should be shaken gently in the air for 15 minutes. Reduced hemoglobin (cardiovascular or respiratory disease) turns red on exposure to air, whereas methemoglobin remains chocolate brown after shaking.

SPECTROSCOPIC EXAMINATION. Spectroscopic examination is necessary to determine if methemoglobin is present. Methemoglobin is stable in refrigerated heparinized blood for only a few hours. To preserve methemoglobin, 1 part of blood can be mixed with 20 parts of phosphate-buffered saline (pH 6.6) or diluted 1:20 in distilled water. These diluted samples can be refrigerated or frozen until they are analyzed.

Abnormal Respiratory Noise (Stridor)

W. David Wilson • Jeanne Lofstedt • Jeffrey Lakritz

Definition Stridor is an abnormal, intense respiratory sound (wheeze) that is audible without the use of a stethoscope. The sound is usually generated in the upper airway and is most often heard during inspiration.

Pathophysiology The extrathoracic airway of the horse consists of segments that are relatively rigid (e.g., nasal passages, extrathoracic trachea) and others (e.g., nostrils, soft palate, larynx) that not only are elastic but also have valve-like actions that are further capable of modifying the cross-sectional area and therefore resistance to airflow.[68,80] Pressures in the extrathoracic airways are subatmospheric during inspiration,[68,70,80] which causes the less rigidly supported parts of the upper airway to narrow (dynamic narrowing or collapse) during inspiration.[68-70,80,81] A major function of the upper airway muscles and other supporting structures is to prevent this dynamic narrowing or collapse during periods of high inspiratory gas flow.[68] Disease in these structures or a more rostral obstructing lesion that causes a greater negative pressure during inspiration may make them incapable of resisting axial displacement.[68,70] The increased resistance to flow induced by static or dynamic obstructions increases the driving pressure and therefore the work needed to move a given volume of air.[80]

Approximately 80% of the total airway resistance to gas flow at rest and during exercise is in the upper airway rostral to the thoracic inlet.[70] Nasal resistance, most of which is caused by resistance just within the external nares, comprises more than 50% of the total upper airway resistance in the horse.[69,82] In most species, including ruminants, this resistance can be bypassed by mouth breathing to accommodate the high airflow rates that accompany strenuous exercise. The horse, in contrast, is limited to nasal breathing even during exercise[69,70,82,83] because the larynx is firmly maintained in the nasopharynx by the tight seal formed around it by the muscular palatopharyngeal ring (intrapharyngeal osteum), except during swallowing.[83,84] Therefore mechanisms other than mouth breathing are necessary to reduce the energy cost of breathing in the horse.[68,81,83] These mechanisms include dilation of the distensible external nares by actively pulling the alar folds laterally, vasoconstriction in the erectile nasal vascular tissues to reduce congestion in the nasal mucosa, straightening of the respiratory tract, and dilation of the larynx by abduction of the vocal folds.[68,70,80-83,85,86]

The horse is capable of generating high respiratory rates during fast exercise. This is accomplished at the canter and gallop, but not at the trot, by locking respiration to locomotion so that the horse takes one breath for each stride.[84,87-89] Exhalation occurs each time the lead forelimb strikes the ground.[83,84,87] The horse can swallow during fast galloping exercise; the entire process is completed in exactly a two-stride sequence.[84,90]

At all levels of the respiratory tract, respiratory sounds are thought to result from vibrations in tissue and sudden changes in the pressure of gas moving in the airway lumen.[70,84] Airflow in the normal respiratory tract at rest occurs in a laminar fashion (i.e., the air closest to the wall of the airway is almost stationary, whereas succeeding layers toward the center of the lumen move progressively more rapidly).[84] Respiration in normal horses and in ruminants at rest does not generate easily audible sounds.

High rates of gas flow and airway narrowing increase both the tendency for dynamic collapse and the degree of turbulence and genesis of sounds. High peak flow rates of 125 mL/s/kg have been reported in galloping horses.[89] During exercise significant sound frequencies are generated and can be detected using sound spectrographs or radio stethoscopes, although most of these sounds are of frequencies and amplitudes not detectable by the human ear.[91,92] Deformities in the wall and masses in the lumen of the airway cause airway narrowing and further disturbances in laminar flow, resulting in more severe turbulence and sudden changes in the pressure of moving gas, which may generate audible sounds.[84] High airflow rates are necessary to induce audible stridor; therefore examination of the horse at exercise is an essential part of the physical examination.[83,84]

Stridor is best heard during inspiration in most cases because the usual source of origin, the upper airway, is subject to dynamic narrowing during the inspiratory phase of the respiratory cycle.[68,69,81] In particular, nonfixed obstructions such as the paretic vocal folds of horses with idiopathic laryngeal hemiplegia (ILH) cause obstruction to airflow and turbulence only when dynamically drawn into the airway by the high inspiratory airflow rates that accompany fast exercise. Other obstructions such as arytenoid chondritis are fixed and obstruct airflow during both inspiration and expiration, which frequently result in audible stridor during both phases of respiration.

The pharynx is the site of greatest airway angulation because of flexion of the atlanto-occipital joint. At rest the horse's head is usually held at about 50 degrees to the horizontal plane.[84] At gallop the horse extends its head and neck and thus straightens the pharyngeal airway.[84] This maneuver also stretches and straightens the trachea, making it less compliant and less subject to dynamic narrowing during inspiration.[81] When ridden at a collected canter, the horse is forced to flex its poll so that its face is nearly vertical, thereby increasing the angulation of the pharyngeal airway and the obstruction to gas flow at this point.[84] Therefore abnormal respiratory sounds originating in the

VetBooks.ir

pharyngeal region are often more easily heard when the horse is ridden at a collected canter than when it is exercised at a full, extended gallop.[83,84]

Because food animals are not normally expected to perform fast exercise, signs of stridor are usually present at rest when the animals are presented to veterinarians for examination. Stridor in resting animals usually indicates moderate to severe upper airway obstruction of a fixed nature. In ruminants the epiglottis is relatively short and blunt, and the palatopharyngeal ring allows the laryngopalatal dislocation necessary for mouth breathing. In conditions that give rise to respiratory distress and mouth breathing, the turbulence produced is often sufficient to induce abnormal (grunting) expiratory sounds, which may be classified as expiratory stridor. The external nares of cattle are much less compliant than those of sheep, goats, and horses, which prevents dynamic collapse during inspiration; thus conditions such as paresis of the nares that cause stridor in sheep, goats, and horses do not cause stridor in cattle (Boxes 5.18 and 5.19).

Approach to Diagnosis of Stridor

HISTORY. The procedure for taking a history should follow that used in the evaluation of cough and nasal discharge (see the Cough and Nasal Discharge sections earlier). The history should also include the duration of ownership; time of onset of the clinical signs of stridor; progression of clinical signs; presence or absence of the noise at rest; relation of noise to fitness; relation of noise to speed, duration, and direction of work; relation of noise to head position during work; association of noise with poor performance or exercise intolerance; and other signs of respiratory tract, oropharyngeal, or neurologic disease (e.g., nasal discharge, cough, dysphagia, retropharyngeal swelling).

PHYSICAL EXAMINATION. A physical examination of the entire respiratory tract at rest should be performed as described for cough and respiratory distress. In addition, the presence or absence of stridor at rest should be ascertained by listening

BOX 5.18

Causes of Stridor in Horses

Common Causes

Idiopathic laryngeal hemiplegia (ILH, roaring)
Dorsal displacement of the soft palate (laryngopalatal dislocation)
Epiglottic entrapment
Retropharyngeal abscess
Strangles (*Streptococcus equi* infection)
Guttural pouch empyema
Chronic pharyngeal lymphoid hyperplasia
Arytenoid chondritis
Guttural pouch mycosis
Laxity of the alar cartilage

Less Common Causes

Arytenoid chondroma, chondropathy
Pharyngeal paresis
Botulism, shaker foal
Dynamic collapse of the pharynx
Subepiglottal, pharyngeal cyst
Subepiglottal abscess
Epiglottal retroversion
Guttural pouch tympany
Guttural pouch neoplasia
Rostral displacement of the palatopharyngeal arch
Nasal fungal infection (e.g., aspergillosis, rhinophycomycosis)
Nasal polyp
Nasal foreign body
Nasal trauma
Nasal tumor
Nasopharyngeal cicatrix
Progressive ethmoidal hematoma
Sinusitis (sinus empyema)
Sinus cyst
Sinus tumor
Atheroma
Laryngeal trauma
Tracheal collapse (scabbard trachea)
Tracheal stricture, stenosis
Tracheal chondroma
Tracheal rupture, perforation
Stenotic nares
Laryngeal edema
Purpura hemorrhagica
Anaphylaxis or acute drug reaction
Chronic lead poisoning
Choanal (posterior nares) atresia, hypoplasia (foals)
Fracture of laryngeal cartilages
Laryngeal granuloma, scar tissue
Equine influenza
Exercise-induced pulmonary hemorrhage (EIPH)
Jugular thrombosis
Hyperkalemic periodic paralysis (HYPP)

Uncommon Causes

Amyloidosis (cutaneous, nasal)
Lymphosarcoma, lymphoma
Bee or wasp sting
Snakebite
Thyroid adenoma, adenocarcinoma
Vesicular stomatitis
Retrobulbar neoplasia
Dystrophic myodegeneration (white muscle disease)
Neoplasia (oral, mandibular, maxillary, laryngeal, pharyngeal, tracheal)
Coccidioidomycosis
Inhalation pneumonia, smoke inhalation
Burns (thermal, chemical)
Congestive cardiac failure
Cutaneous habronemiasis
Unilateral ventral displacement of the roof of the nasopharynx
Epiglottiditis
Hyoid bone injuries
Fungal granuloma, maduromycosis, rhinosporidiosis, mycetoma, cryptococcal rhinitis, equine nasal granuloma
Goiter
Hypertrophic ossification of the laryngeal cartilages
Abnormalities of the nasal septum
Intramural esophageal cyst
Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)
Hyperparathyroidism
Phycomycosis, pythiosis
Anaerobic abscesses (e.g., *Clostridium perfringens*)
Besnoitiosis, globidiosis (exotic)
Glanders (exotic)

Toxic Causes

Organophosphate-induced laryngeal paralysis
Lead-induced laryngeal paresis
Reserpine

VetBooks.ir

BOX 5.19

Causes of Stridor in Ruminants

Common Causes

Necrotic laryngitis (calf diphtheria) (B, O)
Abscess (pharyngeal, laryngeal, retropharyngeal, oral)
Nose bots *(Oestrus ovis)* (C, O)
Caseous lymphadenitis *(Corynebacterium pseudotuberculosis)* (C, O)
Actinobacillosis (wooden tongue, nasal actinobacillosis)
Nasal adenocarcinoma, adenoma, adenopapilloma, polyp (C, O)
Trauma (oral, nasal, pharyngeal, laryngeal, tracheal)
Anaphylaxis or drug reaction
Sinusitis
Foreign body (nasal, oral, pharyngeal, laryngeal, tracheal, bronchial)

Less Common Causes

Actinomycosis (lumpy jaw)
Tracheal stenosis, collapse, stricture
Bovine leukosis (enzootic adult lymphosarcoma) (B)
Sporadic bovine leukosis (adult multicentric lymphosarcoma) (B)
Thymic lymphosarcoma (juvenile) (B)
Mannheimia haemolytica or *Pasteurella multocida* pneumonia (includes shipping fever and enzootic calf pneumonia) (B)
Infectious bovine rhinotracheitis (IBR; BHV-1) (B)
Atypical interstitial pneumonia (B)
Malignant catarrhal fever (B)
Vesicular stomatitis
Clostridial infection of the head (O)
Pulmonary embolism from posterior vena cava thrombosis (B)
Snakebite
Bee or wasp sting
Bovine nasal granuloma, atopic rhinitis (summer snuffles) (B)
Honker syndrome in feedlot cattle (B)
Neoplasia (nasal, paranasal sinus, oral, pharyngeal, laryngeal, tracheal, maxillary, mandibular, retrobulbar)
Congenital abnormalities
Inhalation pneumonia, smoke inhalation

Uncommon Causes

Tuberculosis (B)
Congenital cystic nasal conchae (B)
Choanal atresia (O)
Salivary cyst, mucocele, ranula, trauma (C)
Photosensitization in Southdown and Corriedale sheep (O)
Fungal granuloma, maduromycosis, rhinosporidiosis, mycetoma (B, C)
Phycomycosis, pythiosis (B)

at the nostrils, and digital pressure should be applied to the retropharyngeal region and to the larynx during palpation of these areas to evaluate whether stridor or pain (or both) can be induced easily or exacerbated. The dorsal surface of the larynx should be palpated with the fingertips with the horse relaxed and its head and neck in an extended position. This permits comparison of the prominence of the muscular process of the arytenoid cartilages and the thickness of the cricoarytenoideus dorsalis (CAD) muscle, both of which are affected in horses with atrophy of the CAD muscle in association with ILH. Air turbulence, flattening, swelling, and pain should be assessed during palpation of the extrathoracic airway. The larynx, trachea, and lungs should be carefully auscultated, and the chest should be percussed. A thorough oral examination should be completed, particularly in ruminants; in cattle this should include palpation of the base of the tongue, the oropharynx, and, if possible, the larynx through the oral cavity.

FIELD EXERCISE TESTING.[84] In performance horses most examinations are carried out because the horse makes a noise only when worked, because of exercise intolerance or poor performance, or as part of a prepurchase examination. Unless a high-speed treadmill is available, the exercise testing should be completed under saddle with a competent rider, preferably with an intensity of work that matches the horse's normal activity.[70,83] It is less satisfactory but often necessary to work the horse on a lunge line, in which case it should be lunged in both directions.[83]

The horse should be worked in a circle about 30 yards in diameter so that it passes close to the observer on each circuit.[84] The observer should first identify the expiratory sound by its association with locomotion and then try to fit abnormal sounds into this base rhythm. At fast speeds, respiration is rapid; thus the observer should not stand too far away from the horse because the slow speed at which sound is transmitted confuses interpretation of whether the sound is inspiratory or expiratory.[84,90] In cold weather the visibility of exhaled breath aids interpretation. It is important to ride the horse in both directions because an abnormal sound is frequently heard more clearly when the horse is exercising in one direction than in the other.[83] If the presence or character of a respiratory noise remains in doubt after the horse has been exercised in a circle at a collected canter, the horse should be galloped until it is blowing hard and then ridden past the observer at a fast gallop.[83]

A satisfactory exercise test should include at least 5 minutes of work at the canter, after which the horse should immediately be brought over to the observer so that the character and sequence of abnormal sounds that persist can be determined. All horses that have been worked adequately make a loud expiratory blowing sound at this time. Turbulence of airflow in the larynx may be audible with a stethoscope.[84] Inducing adduction of the vocal fold, particularly on the right side, by applying gentle pressure in a rostromedial direction to the muscular process of the arytenoid cartilage often accentuates an inspiratory noise in horses with laryngeal hemiplegia. Noises originating from unilateral lesions in the nasal passages are easily localized because the sound can be eliminated by alternately blocking off airflow through each nostril with the hand. Temporary occlusion of both nostrils simultaneously may provoke laryngopalatal dislocation and a loud gurgling sound in a susceptible horse.[83,84] The presence of nasal discharge or blood at the nostrils should be noted, and the time required for the heart and respiratory rates to return to preexercise values should be interpreted in light of the severity of the exercise test.[83]

INTERPRETATION OF ABNORMAL SOUNDS. A normal horse makes no audible respiratory sound at rest and when exercised at a canter or slow gallop makes only a blowing expiratory sound.[70,83,84] In unfit horses, particularly overweight ones, an inspiratory sound is also frequently audible. This sound can be quite loud, and it may be difficult to differentiate from sounds caused by abnormalities of the respiratory tract.[82,83] Thus evaluation of the horse's "wind" is best carried out when the horse is in fit condition for its intended use. It takes at least 1 month for an older horse that has been turned out to

VetBooks.ir

pasture to regain a satisfactory level of fitness to perform a meaningful wind examination. Many normal horses produce a harsh expiratory "high blowing sound" of variable pitch, which results from resonance in the cavity of the false nostril during expiration.[83,84,90] If the source of the stridor remains in doubt, temporary suturing of the alar fold dorsal to the nostril can help localize noises suspected of being caused by vibration of the alar fold.

Horses with ILH make a rather characteristic biphasic sound, the inspiratory sound occurring between successive expiratory sounds. The pitch of the sound can vary from a whistle to a deep roar, the lower-pitched note giving rise to the so-called sawing wood sounds.[84] Sonographic and spectrographic analysis of the sounds produced by "roarers" indicates that the range of sound frequencies generated by these horses is the same as that produced by normal horses.[91,92] However, horses that make an audible whistle generate an intense band of frequencies centered on 1.9 kHz that are thought to result from amplification by the still-patent lateral ventricle of the frequency generated by vibration of the incompletely abducted left vocal fold.[92] In a normal horse the left vocal fold is fully abducted, and the cavity of the lateral ventricle is thus obliterated during strenuous exercise.[86]

The sounds generated by horses with laryngeal chondritis, severe proliferative pharyngeal lymphoid hyperplasia, epiglottic entrapment, and tracheal stenosis can be similar to those caused by ILH.[83,84] Laryngopalatal dislocation (dorsal displacement of the soft palate) gives rise to a transient, vibrant, gurgling sound.[69,83,84] In many instances a severe exercise test is required to induce this condition; thus this sound may be heard only during a race.[70,83,84] It is thought that the condition may occur when pharyngeal stimulation causes swallowing during fast exercise.[84] Instead of the horse completing the process and regaining the laryngopalatal seal consistent with the respiratory position of the larynx in the nasopharynx, the tip of the epiglottis disengages from the rostroventral aspect of the palatopharyngeal ring (the caudal free border of the soft palate), resulting in the entire epiglottis slipping ventral to the soft palate. At the subsequent inspiration the palatopharyngeal arch tends to be drawn into the rima glottis, and at expiration it is driven toward the roof of the pharynx by the airstream. The palatopharyngeal arch acts as an airway obstruction, and the tissue vibration and resulting turbulence generate a sound of varying pitch and intensity, often described as gurgling followed by swallowing.[84] The horse often slows suddenly or stops when this event occurs, and the jockey often reports that the horse stopped after "choking" or "swallowing its tongue." If repeated swallowing is successful in relocating the normal laryngopalatal respiratory arrangement, the horse often continues to race after slowing or stopping.[70]

Gross obstruction of the airway by pressure from pus-filled guttural pouches, retropharyngeal abscesses, large subepiglottal cysts or abscesses, or large proliferative lesions (e.g., laryngeal tumors) produces loud, stertorous breathing (snoring) often heard at rest and readily so with exercise; both inspiratory and expiratory sounds are clearly audible.[84]

In a normal horse the pattern of respiratory sounds is regular and synchronized with the pace of the exercise. Laryngeal irritation caused by exudate from the upper or lower airway, pharyngeal lymphoid hyperplasia, or other inflammatory or space-occupying conditions causes the horse to swallow more frequently during exercise, which generates an irregular pattern of respiratory sounds characterized at the canter and gallop by a respiratory cycle of double the normal length.[84,90]

Interpretation of stridor in yearlings presented for sale is difficult because these animals are rarely fit and it is usually possible to exercise them only at a canter on a lunge line. It has been shown that resentment of restraint under such circumstances can significantly alter the linking of locomotion and respiration, which complicates recognition of the respiratory phasing of noise production.[86] In addition, there is not always a close correlation between noise production, endoscopically visible abnormalities, and signs of exercise intolerance even in fit adult horses.[70, 83]

ENDOSCOPIC EXAMINATION. Endoscopic examination of the upper airway is the most useful diagnostic procedure for investigating stridor. The examination should be performed at rest and, if possible, repeated during exercise in the field or on a high-speed treadmill. Endoscopic examination immediately after cessation of exercise is less satisfactory than endoscopy during exercise because dynamic collapse of the rima glottis terminates rapidly on cessation of exercise. The availability of self-contained portable videoendoscopy equipment allows visualization of the pharynx and larynx during over-the-ground exercise and permits digital video-image capture and analysis. Over-the-ground videoendoscopy has the distinct advantage of allowing the horse to be examined under the exact conditions under which the stridor occurs.

Because sedatives and tranquilizers may alter the tone and function of the muscles supporting laryngeal and pharyngeal anatomy, endoscopic examination should be performed without chemical restraint whenever possible.[70] The nasal passages, conchae (turbinates) (including the ethmoidal concha), nasal septum, pharynx, guttural pouches, larynx, and trachea should be examined through both nostrils so that the presence, nature, and source of exudates and the presence of anatomic or functional abnormalities or mass lesions can be determined. Because the nasal passages are not positioned on the midline, the larynx is viewed slightly obliquely when examined from the left or the right ventral meatus and may appear slightly asymmetric. Thus visually apparent asymmetry of the larynx should be confirmed by examining these structures through both nostrils.[70,83]

Interpretation of the findings of the endoscopic examination of the pharynx and larynx is by no means straightforward. The results can be influenced by the day the examination was done, the use of sedation, the side through which the endoscope was passed, and the observer's interpretation. The appearance of laryngeal symmetry or asymmetry in resting horses varies considerably and therefore is of limited clinical usefulness unless complete hemiparalysis is present. Many horses have asynchronous or asymmetric laryngeal movement at rest but not during exercise, whereas other horses have a normal-appearing larynx at rest but suffer dynamic collapse during exercise. Interpretation of findings is improved by use of an objective grading system, which includes assessment of the ratio of the areas of the left and right half of the rima glottis, and by correlating findings at rest with those observed on videoendoscopy performed during maximal exercise.[93] For evaluation of the larynx at rest, full abduction of the vocal folds should be induced by exercise or by temporary occlusion of the nostrils.[83] Contralateral adductory laryngeal movement should be stimulated by slapping the horse just behind the withers (slap test).[94] To induce the horse to swallow, the tip of the epiglottis should be touched with the endoscope, or water should be flushed through the endoscope. These maneuvers help to establish whether movement of the arytenoid cartilages is synchronous and symmetric and increase the predictive value of endoscopic observations, allowing laryngeal function to be graded as follows.[93]

- Grade 1: Synchronous, full adduction and abduction of the left and right arytenoid cartilages (considered normal).
- Grade 2: Asynchronous movement such as hesitation, fluttering, or adductor weakness of the left arytenoid cartilage during inspiration, expiration, or both, but full abduction of the left arytenoid cartilage, inducible by nasal occlusion or swallowing. Grade 2 findings are considered a normal

variation and are not usually associated with dynamic airway collapse during exercise.
- Grade 3: Asynchronous movement of the left arytenoid cartilage during inspiration, expiration, or both, but full abduction is not inducible by nasal occlusion or induction of swallowing. The true functional significance of grade 3 findings can be determined only by performing endoscopic examination during maximal exercise, a procedure that has led to subclassification of grade 3 findings.[95] Some grade 3 horses (grade 3A) are able to achieve full abduction during exercise, whereas others maintain a partly abducted position similar to the resting position (grade 3B) or experience dynamic collapse (grade 3C).[95]
- Grade 4: Marked asymmetry of the larynx at rest and no substantial movement of the left arytenoid cartilage during any phase of respiration. These horses have complete left laryngeal hemiplegia, are true "roarers," and consistently experience dynamic collapse on inspiration during strenuous exercise.[93]

Performing an endoscopic examination during exercise over ground or on a high-speed treadmill makes it possible for a stationary observer to gain a good dynamic appreciation of the significance of upper airway abnormalities (i.e., dynamic endoscopy)[95-99] (see the Exercise Intolerance and Poor Performance in Horses section later). Dynamic changes in airway lumen diameter occur quickly during treadmill endoscopy and may be difficult to visualize; therefore the endoscopic examination should be videotaped for later playback in slow motion and freeze frame.[99] Racehorses should be exercised maximally and to exhaustion because some abnormalities are apparent only at maximal exercise toward the end of a race when pharyngeal or laryngeal muscles become fatigued and are no longer able to resist the transmural pressure gradient, which tends to induce dynamic collapse of the upper airway during inspiration.[95-99] Endoscopic identification of an upper respiratory tract abnormality in a resting horse does not necessarily mean that it is inducing a problem during exercise, and, conversely, the absence of an upper respiratory tract abnormality at rest does not rule out the possibility of intermittent airway obstruction during strenuous exercise. For example, dorsal displacement of the soft palate, epiglottic entrapment, dorsal displacement of the epiglottis, dynamic collapse of the left arytenoid cartilage or vocal fold (or both), and unilateral or bilateral ventral displacement of the roof of the pharynx (dynamic pharyngeal collapse) have been observed during treadmill exercise in horses with an endoscopically normal upper airway at rest.[95-99]

RADIOGRAPHIC EXAMINATION. Radiographic examination of the nasal passages, paranasal sinuses, pharynx, retropharyngeal area (including guttural pouches), larynx, and proximal trachea is indicated to confirm anatomic or functional problems or space-occupying lesions not definitively diagnosed by clinical examination and endoscopy (see the Nasal Discharge and Respiratory Distress [Dyspnea] sections earlier). Radiography is particularly useful for visualizing subepiglottic masses such as cysts or abscesses and for evaluating the epiglottis of the horse when it is obscured from endoscopic view by dorsal displacement of the soft palate or other space-occupying lesions. An accurate assessment of epiglottic length can also be made from standardized true lateral radiographs of the larynx by measuring the distance from the body of the thyroid cartilage to the tip of the epiglottis (thyroepiglottic length).[100] The mean ± SD (standard deviation) thyroepiglottic length in normal Thoroughbreds is reported to be 8.76 ± 0.44 cm.[100] Significantly shortened thyroepiglottic lengths have been recorded in Thoroughbreds with dorsal displacement of the soft palate (laryngopalatal dislocation) and in those with entrapment of the epiglottis in the aryepiglottic folds.[100] Tracheal diseases such as chondroma or dynamic collapse may be visualized on radiographs of the trachea, particularly those made during the inspiratory phase.

ULTRASOUND EXAMINATION. Ultrasound examination of externally visible lesions, such as possible retropharyngeal abscesses that may be impinging on the airway, helps to characterize lesions and assist in the collection of samples by aspiration or biopsy. Transcutaneous ultrasound examination of the larynx may also provide useful information.

BIOPSY. Biopsy and histologic evaluation of samples are indicated to diagnose certain mass lesions such as neoplasms, cysts, polyps, fungal granulomas, or foreign body granulomas in or surrounding the airway. Masses in the airway can be biopsied through the biopsy channel of an endoscope, but these samples inevitably are small. Larger samples can be collected from lesions in the nares, nasal diverticulum, and nasal passages using uterine biopsy forceps, laparoscopy forceps, or curettes. Hemorrhage usually accompanies such procedures and should be anticipated before the procedure. Biopsies can also be collected at the time of exploratory or corrective surgery from lesions in the nasal passages, pharynx, larynx, and guttural pouches. Lesions such as habronemiasis involving the external nares and lesions in other accessible areas such as the parotid salivary gland can be biopsied percutaneously using Tru-Cut or similar instruments.

ASPIRATION. Aspiration, performed either blindly or with the assistance of ultrasound, followed by cytologic examination and culture of aspirated material is useful in the evaluation of masses such as retropharyngeal abscesses that are causing stridor by impinging on the upper airway.

SWABBING OR SCRAPING. Nasal or nasopharyngeal swabbing or scraping followed by direct cytologic examination and culture is indicated for confirmation of nasal fungal infection and bacterial infections of the upper airway (e.g., strangles).

COMPLETE BLOOD COUNT. A complete blood count including fibrinogen concentration can be useful in evaluating patients suspected of having a primary or secondary inflammatory condition or conditions such as ethmoidal hematoma and guttural pouch mycosis in which blood-loss anemia is likely to be a complicating problem.

Exercise Intolerance and Poor Performance in Horses

Stephanie J. Valberg • W. David Wilson

The popularity of performance horses has broadened our perspective on health beyond the conventional diagnosis of health or disease in a horse at rest. Sports medicine defines equine health as the optimum function of all body systems during the expected level of performance. Because many body systems function at only a small fraction of their maximum capacity in a resting athlete, a clearer understanding of exercise responses in the horse and new methods of evaluating horses during exercise are necessary.

Exercise Responses

As horses accelerate during exercise, motor units within active muscles fire in a coordinated fashion to produce the power necessary to drive the animal forward. Initially, slow-twitch type 1 muscle fibers are recruited, followed at increasing speed by recruitment of oxidative fast-twitch type 2A fibers and finally the fastest and most powerful muscle fibers, type 2X. The

VetBooks.ir

increased demand for adenosine triphosphate (ATP) to support muscle contractions during exercise can be met initially by small intracellular stores of creatine phosphate, but within seconds oxidative or glycolytic metabolism (or both) is activated. At submaximal speeds the major factors contributing to fatigue are motivation, total depletion of fuel reserves (glycogen), fluid and electrolyte losses, and hyperthermia.[101] Nociceptive input from muscle receptors to the brain may be a primary motivator to discontinue exercise in many horses, as in people.[102] Training increases the oxidative and endurance capacity of skeletal muscle by increasing the volume of mitochondria and the capillary density surrounding muscle fibers.[103] This delays the onset of fatigue by increasing the availability and metabolism of plasma free fatty acids and glucose, thus sparing muscle glycogen. Training also fine-tunes the motor unit recruitment pattern to provide the most efficient and coordinated pattern of movement.

When a horse accelerates toward a maximum speed, a peak in the total amount of oxygen consumed is realized ($\dot{V}O_{2max}$). Additional energy to produce speeds beyond $\dot{V}O_{2max}$ must be supplied by anaerobic glycolysis with lactic acidosis as a consequence. The term *anaerobic threshold* has been used to describe the speed at which this exponential rise in lactate begins to occur. This inflection point is usually at a velocity producing a blood lactate of 4 mM (VLA_4). Fatigue with maximum (fast) exercise occurs when muscle pH falls so low that glycolysis and excitation contraction coupling are inhibited and muscle ATP concentrations fall.[104,105] Muscle (ATP) begins to decrease after muscle lactate exceeds 40 to 80 mmol/kg of dry muscle and muscle pH falls below 6.8. Overall muscle glycogen stores are not a limiting factor with maximum exercise.[106] Training over time increases the mitochondrial volume and the ratio of type 2A to type 2X muscle fibers.[103,107] As a result, the onset of anaerobic metabolism is delayed until a higher speed is reached and horses are able to maintain a higher speed over a given distance.

The cardiovascular system plays a central role in the oxygenation of blood by the lungs, the delivery of oxygen and other energy substrates to exercising muscles, and the removal of metabolic products from those muscles. Cardiac output increases with exercise in horses, largely as a function of an increase in heart rate.[108] As exercise begins, the heart rate quickly increases and then reaches a steady state within minutes at a submaximal speed. With increasing exercise intensity the heart rate shows a linear relationship with speed up to a maximum rate of 210 to 230 beats/min. The mean systemic arterial pressure does not change with submaximal exercise but rises with maximum exercise. Mean pulmonary arterial pressures increase with speed as the heart rate increases, reaching remarkably high levels that are four times resting values.[109] The oxygen-carrying capacity of the blood also rises with increasing speed through splenic contraction and a more than 50% increase in blood hemoglobin.[110] The increase in blood viscosity that occurs with splenic contraction is believed to contribute to the increase in blood pressure with exercise. Among the adaptive cardiovascular responses to training are a lowered heart rate and blood pressure at the same exercise intensity[111]; increased red cell volume[92]; and increased capillarization of muscle.[103]

After an initial abrupt rise, the respiratory rate increases linearly with the speed of trotting until, at a canter or gallop, respiration is linked to stride frequency on a 1:1 basis.[87,89] This leaves less time available for completing a respiratory cycle at faster speeds. To counter this, inspiratory and expiratory airflow velocities must increase to maintain or increase minute volume. As airflow rates increase, increased turbulence and an increased tendency for dynamic narrowing of the airways causes an increased resistance to flow and increases the work (energy cost) of breathing.[70,81] A finite maximum flow rate is eventually achieved, beyond which the expiratory muscles and the physical characteristics of the respiratory tract do not permit further increases in flow rate.[81] In addition, a maximum stride frequency is reached, restricting the maximum respiratory rate to 140 to 150 breaths/min.[87,89] It has been suggested that beyond the finite maximum flow rate, the animal is forced to hypoventilate, which may result in arterial hypoxemia during maximal fast exercise.[112] The limitation placed on oxygen diffusion by blood hyperviscosity and the short transit time of blood through the pulmonary capillary bed at rapid heart rates also likely contribute to arterial hypoxemia.[113] The arterial hypoxemia and incomplete saturation of hemoglobin that occur during strenuous exercise do not necessarily limit delivery of oxygen to the tissues, however, because the decline in blood oxygen tension is offset by the increase in the total blood hemoglobin oxygen content resulting from splenic contraction. This fact and the horse's ability to sustain at least a sixfold increase in cardiac output between rest and the point of maximum oxygen uptake ($\dot{V}O_{2max}$)[114] are the major factors that contribute to the enormous aerobic capacity of the horse.

In contrast to the muscular and cardiovascular systems, the respiratory system shows little adaptation to training. Whether the apparent inability of the equine respiratory system either to adjust to training[115] or to compensate fully for the increased flow demands of heavy exercise limits athletic performance remains to be proven. However, it is likely that the maximally exercising horse is operating near the upper limit of ventilation and that even slight degrees of respiratory disease profoundly affect oxygen uptake and performance.[116] Any condition that causes increased resistance to airflow, decreased minute volume, decreased diffusion of gases, ventilation-perfusion mismatch, shunt, or increased oxygen cost of breathing constitutes a respiratory cause of exercise intolerance.

Approach to Diagnosis of Exercise Intolerance and Poor Performance

Top athletes arise from both a genetic background that emphasizes athletic ability and environmental influences that capitalize on this inherent potential. A coordinated, energy-efficient gait, muscular power and endurance, a large capacity for oxygen transport, and several intangible factors such as the horse's mental toughness and competitive spirit and the rider's skill all contribute to successful performance. *Poor performance* most often results from inadequate training, a lack of genetic potential, or both, or from a congenital or acquired dysfunction of the locomotor, cardiovascular, or respiratory systems. The term *exercise intolerance* is often used to describe this inability to perform to an expected or previously attained intensity of exercise.

HISTORY. An accurate history is a fundamental part of the evaluation of exercise intolerance and should include the age, breed, and use of the horse and the training and feeding programs. The onset (time and rapidity) of the problem, previous performance history, activity level at which signs are observed, whether the horse performs well at first and then suffers tailing off of performance (no stamina), or whether performance is poor throughout the work period should be ascertained. If performance drops off during work, it should be established whether the drop-off is associated with the onset of other signs such as stridor. The presence of coughing, respiratory distress, stridor, excessive or lack of sweating associated with stress or exercise, or muscle stiffness should be noted. It should be ascertained whether the affected horse or in-contact horses have recently shown signs of respiratory disease, especially viral infections, and whether other horses are perceived to be performing poorly. It should be determined if the horse has shown lameness, gait abnormalities, or biting problems. Any medications or other treatments that have been used and their effects should be noted.

VetBooks.ir

In particular, it is important from the history to distinguish between horses that have never been able to perform satisfactorily and horses that suddenly or gradually show a reduction in the level of performance after a background of satisfactory performance. The first scenario suggests a lack of genetic potential, congenital abnormalities, or inadequate training. Some horses do not have the genetic background to perform the expected work (e.g., racing Quarter Horses rarely make good endurance horses, and Thoroughbreds from sprinting families rarely excel at distances of more than 1¼ miles).

CLINICAL EXAMINATION. Overt clinical diseases that cause exercise intolerance at moderate speeds usually can be diagnosed with a good history, physical examination, and selected ancillary diagnostic techniques. The diagnostic procedures and specific diseases that can be identified at rest are detailed in subsequent chapters in this book (particularly Chapters 30, 31, 37, 38, 41, and 42). Problems that are subclinical at rest provide a greater diagnostic challenge. When testing procedures at rest fail to identify the cause of exercise intolerance, various types of ancillary diagnostic procedures including exercise tests may be used to further define the problem. Because the respiratory, cardiovascular, musculoskeletal, and hematopoietic systems are all important for competitive performance and because diseases in these systems are the most likely causes of exercise intolerance, these systems should receive particular attention in the detailed clinical examination of the horse at rest.

HEMATOLOGIC ASSESSMENT. Hematologic tests have historically been popular in the evaluation of fitness and performance because they are easy to perform and because of the important role of hemoglobin in oxygen transport.[117,118] Routine hematologic evaluation may be useful in monitoring the general health status and perhaps fitness of horses if the conditions of collection, particularly in relation to time of day and exercise, can be carefully controlled and if attention is paid to horses that become excited before or during sample collection.

Anemia can result in a decreased oxygen-carrying capacity during exercise. Veterinarians traditionally have regarded resting hematocrits below 35% as abnormal and likely to cause suboptimal racing performance, but values lower than this have been found in normal Thoroughbred racehorses.[119] Endurance horses and eventing horses usually have resting hematocrit values that are lower than those of racehorses.[119] However, the fact that a significant proportion of equine red blood cells and hemoglobin is contained in the splenic reserve makes interpretation of resting values for these parameters difficult (inaccurate). There is no correlation between the resting level of hemoglobin and the total body hemoglobin or red cell mass.[110,119] Consequently, even though total body hemoglobin does increase in response to training and may correlate with performance, this cannot be determined from a resting blood sample. Measurement of the total hemoglobin or total red cell mass requires collection of a blood sample after strenuous exercise or after administration of epinephrine to mobilize the red cell reserve and the determination of plasma volume using a technique such as Evans blue dye dilution.[110] These techniques have been used to document red cell hypervolemia in poorly performing, overtrained Standardbreds.[110]

Some veterinarians use the resting leukocyte count to monitor fitness, and particularly overtraining, in performance horses.[119] Decreases in the neutrophil/lymphocyte (N/L) ratio have been used to indicate overtraining (training off or adrenal exhaustion). However, the N/L ratio varies in individual horses, depending on when it is determined in relation to the timing and type of exercise and on factors such as age, stress, and disease. Reliable evidence indicates that the N/L ratio is not a good predictor of adrenal status.[120] Indeed, adrenal function in horses with "adrenal exhaustion syndrome" remains to be accurately characterized based on reproducible function tests.

SERUM BIOCHEMICAL PROFILES. Biochemistry profiles are commonly used to monitor performance horses and to evaluate those with performance problems. These profiles are useful, but interpretation must take into account that when many measurements are performed, there is a high statistical probability that one or two results will be outside the normal range (95% confidence).[119] If only one or two results on a profile are slightly abnormal, the tests are best repeated on a second sample before the true significance of the result is ascribed. Biochemistry profiles are most useful in detecting horses with subclinical muscle problems (either primary exertional rhabdomyolysis or muscular strain secondary to skeletal problems), liver diseases, renal diseases, and gross disturbances in electrolyte and acid-base regulation. Biochemical profiles usually include aspartate aminotransferase (AST), creatine kinase (CK), LDH, alkaline phosphatase (AP), γ-glutamyltransferase (GGT), sorbitol dehydrogenase (SDH), blood urea nitrogen (BUN), creatinine, sodium (Na), potassium (K), chloride (Cl), bicarbonate, phosphate, calcium (Ca), magnesium (Mg), glucose, and other parameters that are of variable clinical relevance. Studies of horses during training have failed to show any correlation between resting or exercising values for these parameters and fitness.[119] In endurance horses, evaluation of renal fractional excretions of electrolytes may provide better information regarding the horse's electrolyte balance than serum chemistry measurements alone.[121]

EVALUATION OF THE RESPIRATORY TRACT. Standard parameters of a routine examination, including rectal temperature, respiratory rate, respiratory character, mucous membrane color, and capillary refill time, should be carefully evaluated at rest. The presence of nasal discharge, cough, edema, jugular distention or pulsation, or other signs suggesting local or systemic disease should be noted. The larynx, muscular process of the arytenoid cartilages, retropharyngeal area, and trachea should be palpated for size and symmetry. The heart and lungs should be carefully auscultated and percussed at rest, and auscultation of the lungs should be repeated as the horse is induced to breathe more deeply by application of a rebreathing bag. When stridor is part of the history, the upper respiratory tract should receive particular attention in the diagnostic evaluation. Not only must the character of the noise be determined, but the extent of work the patient can tolerate before exhibiting diminished performance must be established, because this helps in the interpretation of abnormalities seen on the endoscopic examination (see the Abnormal Respiratory Noise [Stridor] section earlier). Often the onset and intensity of the stridor coincide with a decrease in work capacity that is typical of certain obstructive airway diseases. Endoscopy, including treadmill endoscopy if facilities permit or over-the-ground videoendoscopy, and radiography form an important part of the diagnostic evaluation of horses with upper airway abnormalities[122] (see the Respiratory Distress [Dyspnea] and Abnormal Respiratory Noise [Stridor] sections earlier). The most common abnormalities of the upper airway that cause poor performance include dorsal displacement of the soft palate, dynamic pharyngeal collapse, dynamic collapse of the left arytenoid cartilage in association with ILH, epiglottic entrapment, pharyngitis, and collapse of the alar folds.[97,99] Diminished performance in horses with mild or subclinical viral infection is probably mediated at least partly by abnormalities in the respiratory tract.[123] If no abnormalities are detected at rest, functional disturbances of airflow may occur during maximum exercise, and these disorders can best be identified by examining the upper airway using videoendoscopy on a treadmill during exercise or using over-the-ground videoendoscopy units. Slow-motion playback

VetBooks.ir

must be used because many abnormalities occur rapidly with each respiratory cycle. In particular, dorsal displacement of the soft palate and the extent of dynamic laryngeal obstruction with ILH can be more fully evaluated with videoendoscopy during exercise.[97,99,122,124] Over-the-ground videoendoscopy has the distinct advantage of allowing the horses to be examined under the exact conditions in which the problem occurs. The presence of inspiratory or expiratory obstruction can be further evaluated during treadmill exercise by introducing transducers via the nostrils to measure airway pressures at the level of the pharynx and trachea.[99,122] During a treadmill exercise test, samples for blood gas analysis can be drawn from extension tubing connected to an 18-gauge, 2-inch catheter inserted into the transverse facial artery.

Further diagnostic evaluation of the lower airways is indicated in horses with an abnormal respiratory rate or character, cough, nasal discharge, abnormal lung sounds, prolonged recovery after application of a rebreathing bag, or with a history of EIPH, cough, or respiratory distress with exercise. Horses in which excess mucus or exudate can be demonstrated in the trachea during endoscopy performed after exercise are also candidates for further evaluation. Applicable tests include a complete blood count, tracheal wash or BAL, endoscopy, radiography, and ultrasound examination (see the Cough and Abnormal Respiratory Noise [Stridor] sections earlier). Tracheal wash samples collected after exercise are more likely to identify lower airway disease than those collected before exercise.[125] Respiratory viral infection, EIPH, bronchiolitis, hyperreactive airways, and RAO are all conditions that may not be apparent at rest but that constitute significant causes of exercise intolerance.

EVALUATION OF THE CARDIOVASCULAR SYSTEM. A full evaluation of the mucous membranes, capillary refill time, pulse rate, pulse character and rhythm, heart rate and rhythm, and auscultatory findings is an important part of the evaluation of the performance horse. Failure to maintain cardiac output because of an inability to regulate either heart rate or stroke volume is the mechanism through which cardiac diseases induce exercise intolerance. Many cardiac dysrhythmias and valvular dysfunctions are apparent on auscultation of the resting horse. However, the contribution of mild abnormalities to exercise intolerance may require exercise testing. In addition, some arrhythmias and valvular or myocardial dysfunctions can be detected only during or shortly after exercise. Thus resting and exercising electrocardiography and echocardiography before and immediately after exercise are indicated.[99,122] The heart rate can be monitored during exercise using either telemetric electrocardiography or commercial heart rate monitors. Electrocardiograms (ECGs) provide the additional benefit of evaluating both heart rate and rhythm. Supraventricular tachyarrhythmias, the most important of which is atrial fibrillation (AF) in horses, can lead to heart rates exceeding 240 beats/min at submaximal exercise.[126] Under these circumstances, cardiac output may be limited by the decreased time available for diastolic perfusion of the myocardium; the absence of atrial contraction; and the reduced time for passive ventricular filling, leading to reduced stroke volume. Many horses with AF maintain efficient circulation at rest and during light exercise but are intolerant to strenuous exercise because they are unable to increase cardiac output sufficiently at rapid heart rates.[127] Some horses show transient paroxysmal AF during exercise but not at rest.[127] These are often easiest to observe in ECG tracings obtained within 60 seconds after an exercise test. Conversion to sinus rhythm, either spontaneously with quinidine sulfate or with electroconversion,[128] usually leads to a return to normal performance in horses with AF.[129,130] The ability to maintain cardiac output can be compromised by other cardiac arrhythmias such as ventricular tachycardia and ventricular premature depolarization.[99,131] The frequency of premature depolarization can increase with exercise, and the timing of resultant abnormal extra systoles can reduce cardiac output even at submaximal heart rates.[131] Intraatrial block, second-degree atrioventricular (AV) block, and intraventricular block have also been documented in exercise-intolerant, poorly performing horses.[132,133] Horses with cardiac arrhythmias may show abnormal elevations in lactate concentration in response to exercise, indicating a lowered anaerobic threshold, which contributes to exercise intolerance.[111]

Electrocardiography is believed by some veterinarians to be of value in identifying myocarditis. T wave abnormalities (positive and peaked T waves, in contrast to the normal diphasic T waves) in multiple leads on resting ECG traces have been found in a high percentage of horses with a history of fading during the final portion of a race.[132] T waves are highly labile, affected by training status, and the mechanism by which abnormal T waves are generated is uncertain. However, T wave changes have been identified in some horses with myocarditis confirmed at necropsy.[119,133,134] Myocarditis may be more definitively documented by evaluating cardiac troponin I.[135] A positive correlation has been demonstrated between heart size and racing performance.[133] Electrocardiography has been used to assess performance potential by heart score measurement. The heart score represents the mean QRS duration in leads 1, 2, and 3 expressed in milliseconds and has been strongly correlated with heart weight and prize money won by racehorses.[119,133] The physiologic basis for heart score remains in dispute, and expertise is required to standardize leads and measure QRS complexes.

An *echocardiogram* provides essential information in many cases in which clinical evidence of valvular or myocardial dysfunction is present. The pericardium, the size of the heart chambers, the presence of congenital defects, the function of valvular leaflets, and myocardial contractility all can be assessed (see Chapter 30). Decreased myocardial contractility, regurgitant leaks caused by valvular incompetence, left-to-right shunts, and increases in afterload such as occur in aortic stenosis result in systolic dysfunction and a drop in cardiac output.[136] A pulsed, continuous, or color flow Doppler technique may be necessary to determine the size and significance of any disturbances to flow. Cardiac conditions such as effusive pericarditis and myocardial fibrosis and peripheral vascular conditions that inhibit venous return may interfere with ventricular filling during diastole, resulting in decreased end-diastolic volume, stroke volume, and cardiac output.[136] Measurement of fractional shortening before and immediately after treadmill exercise, when pulse rates are above 100 beats/min, permits documentation of resting and exercise-induced myocardial dysfunction.[99] Contrast angiographic studies may be indicated if congenital or acquired cardiac outflow problems are suspected. Nuclear angiocardiography is also useful for evaluating myocardial contractility, cardiac chamber enlargement, outflow problems, and other abnormalities. Hemodynamic studies, which measure pulmonary capillary wedge pressure, pulmonary driving pressure, and pressure in the right side of the heart and pulmonary artery, have proven useful in detecting early cardiac and pulmonary failure in poorly performing trotting horses. These studies involve the introduction of flow directional balloon-tipped catheters through the jugular vein into awake horses.[137]

EVALUATION OF THE SKELETAL SYSTEM. A lameness examination including appropriate flexion tests and other stress tests should be completed to help rule out musculoskeletal problems. If lameness is observed, appropriate diagnostic nerve blocks, radiographs, scintigraphy, rectal examination of the bony pelvis and aortoiliofemoral arterial pulses, or ultrasound examinations are indicated to help localize the lameness and

VetBooks.ir

determine its cause, significance, and prognosis. Some lameness problems that are evident only at high speed may best be evaluated using treadmill exercise. For example, aortoiliofemoral thrombosis reduces peripheral perfusion but often causes only progressive hindlimb lameness with exercise. Foot balance should be carefully assessed at rest and, if possible, during exercise, because gait changes and subtle lameness related to foot imbalance can adversely affect performance. Dynamic evaluation of hoof balance can be accomplished by examining videotapes recorded from behind the horse while it is exercising on a high-speed treadmill or by trotting the horse over force plates embedded in a firm level surface.[138]

Subtle lameness can increase the metabolic cost of locomotion by inducing changes in gait and coordination, which accelerate the onset of fatigue. In the same fashion, some horses may have an inefficient gait that reduces their performance capacity. Video imaging systems and gait analysis may play an increasingly important role in identifying these individuals in the future.

EVALUATION OF THE MUSCULAR SYSTEM. Primary skeletal muscular limitations on performance may occur as the result of painful conditions such as exertional rhabdomyolysis or weakness due to defects in energy generation or loss of muscle mass. In resting samples, high serum AST may indicate chronic rhabdomyolysis. Measurement of serum CK 4 to 6 hours after an exercise test is most useful in detecting horses with chronic or subclinical forms of exertional rhabdomyolysis. Serum muscle enzyme concentrations measured in blood samples collected immediately after exercise are often normal, but in horses with chronic exertional rhabdomyolysis significant abnormal elevations may be seen when CK peaks at 4 to 6 hours after completion of exercise. In the past it has been recommended that the exercise test be conducted at a speed and duration of exercise similar to that expected of the horse in competition. However, it has been shown that a 15- to 30-minute test at a slow trot more frequently produces abnormal elevations in serum CK (more than twofold to threefold) in susceptible horses.[139] Standardbreds and Thoroughbreds with histories of recent episodes of recurrent exertional rhabdomyolysis and horses with type 1 polysaccharide storage myopathy (PSSM) often show a greater than twofold increase over normal resting values in response to an exercise test.[139] Horses with type 2 PSSM may show exercise intolerance after 10 to 15 minutes under saddle, reluctance to pick up and maintain a canter, or inability to collect and maintain self-carriage under saddle without abnormal elevations in serum CK. Subtle loss of muscle mass and performance decline can occur with deficiencies in vitamin E, warranting assessment of serum alpha-tocopherol concentrations.

Muscle biopsy is a relatively simple procedure that can prove useful for characterizing the nature of an identified exertional myopathy. However, the procedure is not widely used in the diagnostic assessment of poor performance because the evaluation of samples requires considerable histochemical expertise. Percutaneous techniques using a 6-mm–diameter needle (Bergstrom biopsy needle, Mortenson, Copenhagen, Denmark) and local anesthetic are routinely used. The middle gluteal muscle is most often sampled because it is relatively accessible and active at all intensities of exercise.[103,107,140] In adult horses a biopsy is collected at a depth of 2½ to 3 inches from a site 8 inches from the tuber coxae along a straight line connecting the point of the tuber coxae with the base of the tail. Open surgical biopsies are most easily obtained from the semimembranosus or semitendinosus muscle at a site approximately 3 inches below the tuber ischii. After the skin has been shaved and aseptically prepared, lidocaine is injected under the skin. A 2-inch–long incision is made through the skin and fascia, and two parallel incisions, 1 inch long and ½ inch apart, are made vertically in the muscle. The muscle is grasped in one place, to prevent handling artifacts, and the biopsy is first transected proximally, freed to a depth of ¼ inch, and then transected distally. The disadvantage of open surgical biopsies is that a recovery period of 1 week is often required, whereas horses can immediately begin to exercise when a needle biopsy is used. Muscle samples should be sent to a laboratory, where they will be frozen in isopentane that has first been chilled in liquid nitrogen. Commonly used histologic and histochemical stains include adenosine triphosphatase (ATPase) after alkaline and acid preincubations, nicotinamide dinucleotide diaphorase (NADH), periodic acid–Schiff (PAS), and hematoxylin and eosin.

An estimate of the state of training can be made by determining the percentage of type 1, type 2A, and type 2X muscle fibers, as well as the oxidative capacity of skeletal muscle in these small muscle samples. In general, horses suited for short-distance, fast exercise have a greater proportion of fast-twitch fibers in the middle gluteal muscles than horses suited for longer distance events, which have a higher proportion of slow-twitch type 1 fibers.[140] However, there are many successful athletes that do not follow this pattern. The proportion of type 1 relative to type 2 fibers is thought to be genetically based and cannot be manipulated to a great extent by training, whereas age and training increase the proportion of oxidative fast-twitch type 2A fibers relative to type 2X fibers.[103,107,139] Histochemical assessment of NADH staining or quantitative measurement of enzymes such as citrate synthase in biopsy samples frozen rapidly in liquid nitrogen may provide a guide to the state of aerobic fitness.[136] The use of muscle biopsies in horses with poor performance has also aided in the identification of oxidative enzyme defects in Arabian horses and glycogen storage disorders in Quarter Horses that can markedly affect performance.[140,141]

Standardized Exercise Testing

Exercise intolerance is ultimately a neuromuscular phenomenon resulting from extreme metabolic stress at the level of the muscle fibers.[104] Under many circumstances premature muscle fatigue occurs secondary to disorders that affect oxygen transport (cardiopulmonary systems) or mechanical efficiency (lameness) (Box 5.20). Standardized treadmill exercise tests are often required to assess the function of these systems at high speeds to determine the primary cause of poor performance and to measure the metabolic response of skeletal muscle relative to work intensity. In a substantial number of cases, poor performance results from related or unrelated disorders in more than one body system, such as dynamic airway obstruction and cardiac dysrhythmia in the same horse.[99]

TREADMILL TESTS. Horses often need to be acclimated to a treadmill before representative exercise testing can be performed. Standardbred horses are typically exercised while wearing their usual racing tack, whereas horses of other breeds are typically exercised in a halter or bridle with a lead rope attached to each side. Most horses exercise comfortably on a treadmill after two to four training sessions at speeds that include all gaits to be tested. Breaking into a canter is an important skill to train horses to perform on the treadmill. During one of the training sessions, endoscopy of the upper airway can be performed to evaluate upper airway function during maximal speeds. Two types of standardized exercise tests can be used: a high-speed test, in which horses are accelerated to maximal speed for their normal racing distance, or an incremental test, in which speed is increased every 1 or 2 minutes until fatigue is reached. The incremental exercise test is used most commonly because it includes both submaximal and maximal intensities and is readily reproducible. Many exercise tests are performed with the treadmill set at a 6% to

BOX 5.20

Causes of Exercise Intolerance That Are Inapparent at Rest

Respiratory Causes

Obstructive Upper Airway Diseases

Common Causes

Laryngopalatal dislocation (dorsal displacement of the soft palate)
Dynamic pharyngeal collapse
Dynamic collapse of the left arytenoid cartilage in association with idiopathic laryngeal hemiplegia
Chronic pharyngeal lymphoid hyperplasia
Epiglottic entrapment
Axial deviation of the aryepiglottic folds
Arytenoid chondritis
Paranasal sinus empyema
Paranasal sinus cysts
Guttural pouch infection

Uncommon Causes

Dynamic collapse of the alar folds
Nasal polyps
Progressive ethmoid hematoma
Subepiglottic cysts
Epiglottic retroversion
Chondroma of the arytenoid cartilages
Fractured laryngeal cartilages
Nasopharyngeal cicatrix

Congenital

Choanal (posterior nares) atresia or stenosis
Excessive alar folds
Stenotic nares
Abnormalities of the nasal septum
Rostral displacement of the palatopharyngeal arch
Tracheal stenosis, stricture, collapse

Lower Airway Diseases

Common Causes

Inflammatory lower airway disease
Exercise-induced pulmonary hemorrhage (EIPH)
Recurrent airway obstruction (RAO or chronic obstructive pulmonary disease)
Equine herpesvirus types 1 and 4 (EHV-1 and EHV-4)
Other viral infections (influenza, rhinitis A and B viruses, adenovirus, reovirus)
Bacterial pneumonia
Pleuropneumonia, pleuritis

Uncommon Causes

Pulmonary abscess
Pneumoconiosis (e.g., silicosis)
Interstitial pneumonia
Diaphragmatic hernia

Cardiovascular Causes

Common Causes

Atrial fibrillation
Ventricular premature contractions
Ventricular tachycardia
Mitral insufficiency
Aortic insufficiency
Resting or exercise-induced myocardial dysfunction and reduced fractional shortening
Pericarditis
Aortoiliofemoral arteriosclerosis or thrombosis

Uncommon Causes

Ventricular septal defects
Monensin toxicity
Heart block (intraatrial, second- and third-degree atrioventricular and intraventricular)
Endocarditis
Congestive cardiac failure
Ruptured chordae tendineae
Cor pulmonale
Congenital defects

Musculoskeletal Causes

Exertional rhabdomyolysis
Lameness involving limbs, sacroiliac joint, back
Focal muscle strain

Metabolic and Systemic Causes

Anemia
Fluid and electrolyte imbalances
Anhidrosis
Heat exhaustion
Neoplasia
Liver disease (pyrrolizidine alkaloid)

General Causes

Obesity
Poorly trained horse
Poor genetic potential
Administration of illicit medications (doping)

10% slope to minimize the possibility of injury at top speeds and to ensure that maximum exercise intensity is reached.

Several measurements are possible during treadmill exercise testing. In its simplest form, the heart rate can be monitored after 1 minute at each intensity of exercise using a heart rate monitor, although recording of an ECG during exercise provides additional information about exercise-associated dysrhythmias.[99] Blood samples can also be drawn from a jugular catheter during the final 15 seconds at each speed. A linear relationship between heart rate and speed is expected, with a plateau forming at the maximum heart rate. The maximum heart rate does not change with training, but the speed at which the maximum heart rate is reached should increase with training. As an alternative, a linear regression can be used to determine the horse's speed at a heart rate of 200 beats/min (V_{200}). V_{200} is close to the anaerobic threshold, may predict aerobic capacity, increases with increasing fitness, and has a high individual predictability that allows for early and valid detection of clinical disorders that limit performance.[111,119,142] The speed at which horses reach a maximum heart rate has been proposed as a better measure than V_{200} because it is an absolute rather than a relative measure; however, measurement of maximum heart rate requires a more strenuous exercise test. Parameters such as the velocity at which the whole blood lactate value reaches 4 mmol/L (V_{LA4}) and the heart rate at which blood lactate reaches 4 mmol/L (HR_{LA4}) can be calculated to evaluate the anaerobic threshold.[111,142] The rate of lactate accumulation may also provide valuable information.

Lactate concentrations can be determined in either whole blood or plasma. Recent studies suggest whole blood lactate may provide a more accurate reflection of lactate accumulation than plasma lactate[143] because red blood cells actively take up

lactate and buffer it, and the type and number of red blood cell lactate transporters differ markedly among horses.

The value of V_{200}, V_{LA4}, HR_{LA4}, and other parameters is that they provide standards against which improvement or deterioration in fitness can be assessed, and individual horses can be objectively compared.[111,119,142] Hematocrit can also be easily determined from blood samples obtained at each speed to provide a rough estimate of the number of circulating red blood cells. Blood samples drawn before and 4 hours after exercise for measurement of CK activity can be used to screen for subclinical exertional rhabdomyolysis.

Further evaluation of the oxygen transport system can be obtained in laboratories where the sophisticated open-flow gas-collection system necessary to measure oxygen consumption ($\dot{V}O_2$) is available. During the incremental exercise test, a plateau in oxygen consumption eventually is reached, representing maximum oxygen uptake. $\dot{V}O_2$ can be used at submaximal speeds to calculate the oxygen cost of locomotion, and $\dot{V}O_{2max}$, a key indicator of aerobic capacity, can be determined. The cardiopulmonary system can be further evaluated during exercise by measuring arterial blood gases from the transverse facial artery using an 18-gauge indwelling catheter.[142] An accurate measure of the total red blood cell volume in a horse can be determined using an Evans blue dye dilution technique immediately after maximal exercise.

FIELD TESTS. Standardization of field exercise tests is difficult because weather, track conditions, and other factors influence the amount of work performed. The simplest form of exercise test involves timing a horse exercising maximally over a fixed distance and evaluating heart rate recovery rates at specific time points after exercise. Additional information can be obtained by measuring heart rate during exercise using a heart rate monitor or telemetric ECG.[119] As fitness improves, the heart rate for a given speed of exercise should be lower. Incremental field exercise tests have been used most successfully in Standardbred horses in which the heart rate and blood lactates were measured after several heats at predetermined increases in pace. At speeds above 450 m/min, lactate begins to accumulate in the blood during exercise; the precise kinetics of accumulation depends on the horse's fitness and exercise capacity. V_{LA4} has been used in field exercise tests to monitor responses to training. Fitness responses include a lower heart rate and lactate concentration for the same exercise speed. The value of these measurements is only as good as the standardization of the testing procedures used.

Alterations in Cardiovascular and Hemolymphatic Systems*

VIRGINIA B. REEF and JOANN SLACK, *Consulting Editors*

MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Peripheral edema, pleural effusion, and ascites, 82
Cardiac arrhythmias, 84
Cardiac murmurs, 87
Muffled heart sounds, 88
Cardiovascular exercise intolerance, weakness, and syncope, 89
Venous distention and pulsations, 90
Painful peripheral swellings, 92
Enlarged lymph nodes, 92
Abnormal peripheral pulse, 93

Peripheral Edema, Pleural Effusion, and Ascites

Edema is an abnormal accumulation of extracellular fluid in the interstitial spaces of the tissues or in body cavities that can be generalized or localized. If the fluid accumulation occurs in the pleural cavity, it is referred to as *pleural effusion* or *hydrothorax;* if the fluid accumulation is in the abdominal cavity, it is referred to as *peritoneal effusion* or *ascites*.

Fluid accumulates more easily in those parts of the body where the connective tissue structure is relatively loose. The accumulated fluid tends to gravitate to the dependent areas of the body. In the cow, generalized edema is detected externally by swelling of the submandibular tissue, the brisket, the ventral abdomen, and occasionally the limbs (Fig. 6.1). External manifestation of generalized edema in the horse is frequently in the pectoral region between the front limbs, along the ventral abdomen, in the prepuce in stallions and geldings (Fig. 6.2), in the limbs, and sometimes in the head. Stocking up, or limb edema restricted to the lower limbs, is commonly detected in stabled horses with no underlying disease. Large amounts of fluid may accumulate before clinical signs become evident. External evidence of pulmonary edema (i.e., a frothy, possibly blood-tinged fluid in the nares or expectorated) is rarely detected in large animals (Fig. 6.3). Edema has numerous causes including congestive heart failure (CHF) (Boxes 6.1 and 6.2). Edema is a late sign of CHF; other subtle signs of failure may be present before edema appears.

Mechanisms of Edema

Edema is caused by an alteration in the equilibrium between capillary permeability and the forces that govern fluid movements at the capillary level. These forces are as follows:

1. Intravascular hydrostatic pressure
2. Interstitial fluid hydrostatic pressure, which exerts counterpressure to keep fluid within the capillary
3. Intravascular colloid oncotic pressure exerted by plasma proteins, which favors the resorption of interstitial fluid; the major determinant of colloid osmotic pressure in the capillary is albumin
4. Interstitial fluid colloid osmotic pressure exerted by some proteins in the interstitial fluid, which resists resorption of fluid from the interstitial space
5. Vascular surface area capable of fluid transport
6. Vascular permeability to proteins and water

Activation of complement and liberation of cytotoxic agents such as oxygen radicals, leukotrienes, hydrogen peroxide, platelet-activating factor, and lysosomal enzymes contribute to the endothelial and epithelial damage, causing permeability edema. Subsequent increase in colloid osmotic pressure causes fluid accumulation in the interstitial space. The most common causes of increased capillary permeability are trauma, infection, endotoxemia, and hypersensitivity (allergic) vasculitis. Topical administration of counterirritants can also cause local increase in capillary permeability. Equine purpura hemorrhagica, the most common vasculitic disease in horses, may in its mildest form have symptoms of mucosal petechiae and plaques of edema or, in severe cases, serum exudation from and necrosis of skin surfaces.

Increased hydrostatic pressure can cause either localized or generalized edema. In horses and ruminants the most common causes of increased hydrostatic pressure are CHF, venous thrombosis, liver disease causing obstruction of the portal venous system, lymphadenopathy, a cranial mediastinal mass, compression bandages, limb immobilization, and topical administration of counterirritants. CHF occurs when there is concomitant pulmonary and systemic vascular congestion. The compensatory salt and water retention increases ventricular diastolic, venous, and capillary pressures, which can result in the formation of generalized edema. Arteriolar vasodilation, caused by release of tissue mediators of inflammation or increased venous pressure resulting from obstruction to venous outflow, can also elevate capillary hydrostatic pressure and result in edema formation.

When the plasma protein concentration decreases from normal to values <5 g/dL or albumin concentration is <1.5 g/dL,

*The authors would like to thank Dr. Sheila McGuirk for her original contributions to this article.

VetBooks.ir

FIG. 6.1 Cow with brisket, ventral, and udder edema.

FIG. 6.2 Gelding with ventral and preputial edema.

FIG. 6.3 Gelding with acute fulminant pulmonary edema.

generalized edema may occur. Hypoproteinemia can result from 1) decreased production of plasma proteins with starvation, liver disease, or severe heart failure or 2) augmented loss of plasma proteins resulting from kidney disease, protein-losing enteropathies (Johne's disease, chronic inflammatory bowel disease), peritonitis, or pleuritis. Hemodilution as a result of overzealous administration of fluids or decreased elimination of fluid can cause edema. Failure to excrete adequate water to maintain fluid balance can result from decreased glomerular filtration as a result of kidney disease or heart failure.

Increased tissue colloid osmotic pressure is rarely a cause of edema in horses and ruminants. Interstitial fluid has a lower plasma protein concentration than plasma. When capillary permeability is increased or when abnormal protein-like material is present in the interstitial space, edema can develop by this mechanism. The latter may occur with infection or after administration of topical counterirritants.

Lymphedema occurs when lymphatics are absent or obstructed. Congenital absence of lymphatics is extremely rare. Obstruction to lymphatic drainage can be caused by tumor, local inflammation (lymphangitis or lymphadenitis), or elevated central venous pressure as in heart failure.

Approach to Diagnosis of Peripheral Edema, Pleural Effusion, and Ascites

1. Take history. Note especially history of deworming program, diet, and vitamin or mineral supplements. Determine onset, progression, and duration of the problem and whether other animals are affected. Ask about history of fever, signs of respiratory disease or difficulty, appetite, consistency of feces, and previous medications. Establish the function of the animal and whether there have been changes in performance capability. Compare growth and activity level with that of peers.
2. Perform a physical examination and record vital signs. Determine whether edema is localized or generalized. Palpate external lymph nodes. Palpate edematous areas to determine whether there is heat, pain, or fluid exudation. Edema is typically cool, nonpainful, and pitting, leaving an indentation when a finger is pushed against it. Carefully auscultate heart and lungs. Note abnormalities in cardiac rhythm, murmurs, or other sounds associated with the cardiac cycle. Palpate a peripheral pulse; observe mucous membranes for color, capillary refill time, and petechiae. Observe the jugular vein for distention and pulsations. Evaluate peripheral veins, including the mammary vein, for distention and pulsations. Perform a rectal examination to determine whether internal lymph nodes are enlarged. Palpate the aorta and iliac arteries for pulse strength and fremitus.
3. Obtain whole blood for the following:
   a. Complete blood count (CBC) (includes fibrinogen, serum amyloid A [SAA], and plasma protein concentration)
   b. Selenium concentrations if cardiomyopathy is suspected
   c. *Anaplasma phagocytophilum* (formerly *Anaplasma equi* or *Ehrlichia equi*) morula in granulocytes or *Anaplasma* DNA by polymerase chain reaction if edema, petechial hemorrhages, fever, icterus, or muscle stiffness is present
4. Test serum or plasma for the following:
   a. Total protein and albumin concentrations; measure or calculate globulin fraction
   b. Test for kidney function as follows: serum urea nitrogen (SUN) and creatinine concentrations, serum electrolyte

VetBooks.ir

BOX 6.1

Causes of Peripheral Edema, Pleural Effusion, and Ascites in Horses

Common Causes

Chronic right-sided or biventricular heart failure
Pericarditis
Pleuritis/Pleuropneumonia
Peritonitis
Pregnancy
Neoplasia: lymphosarcoma
Cranial mediastinal mass
Hypoproteinemia
Liver disease
Gastrointestinal malabsorption: inflammatory bowel disease, neoplasia, parasitism
Vasculitis
Equine infectious anemia
Purpura hemorrhagica
Equine granulocytic ehrlichiosis (*Anaplasma phagocytophilum*)
Equine viral arteritis
Thrombophlebitis
Lymphatic obstruction
Ulcerative lymphangitis
Lymphadenitis (*Corynebacterium pseudotuberculosis* abscesses)
Trauma

Uncommon Causes

Aortic cardiac fistula
Aortopulmonary fistula
Heart base tumor other than lymphosarcoma
Neoplasia: mesothelioma, melanoma, plasma cell myeloma, squamous cell carcinoma, fibrosarcoma
Starvation
Kidney disease: glomerulonephritis, amyloidosis
Ionophore toxicity
Copper deficiency
Counterirritant application
Hemodilution
Ruptured bladder
Cassia occidentalis toxicity

BOX 6.2

Causes of Peripheral Edema, Pleural Effusion, and Ascites in Ruminants

Common Causes

Chronic right-sided or biventricular heart failure due to mitral or tricuspid regurgitation, vegetative endocarditis, or congenital heart defects
High-altitude disease (brisket disease)
Cor pulmonale
Pericarditis (traumatic reticulopericarditis)
Pleuritis
Pregnancy (udder edema in heifers)
Cranial mediastinal mass: lymphosarcoma
Hypoproteinemia
Liver disease
Kidney disease: amyloidosis, glomerulonephritis
Gastrointestinal malabsorption: lymphosarcoma, Johne's disease, parasitism
Lymphatic obstruction (*Corynebacterium pseudotuberculosis*, lymphosarcoma)
Thrombophlebitis
Urolithiasis: ruptured urethra or bladder

Uncommon Causes

Mycoplasma (formerly Eperythrozoon) wenyoni (B)
Idiopathic hemorrhagic pericardial effusion
Chronic right-sided or biventricular heart failure due to cardiomyopathy, infectious myocarditis, ionophore toxicity
Starvation
Hemodilution
Copper deficiency
Vasculitis
Trauma
Caudal vena caval thrombosis
Anaplasmosis
Gossypol toxicity
Cassia occidentalis
Phalaris species toxicity
Oxytropis (locoweed) toxicity

B, Bovine.

(Ca, P, Na, K, Cl) concentrations, fractional excretion of electrolytes (see Chapter 34 for method), complete urinalysis; serum concentrations of Na may be decreased, and SUN may also be elevated in chronic heart failure
   c. Liver enzyme concentrations and liver function (aspartate aminotransferase [AST], sorbitol dehydrogenase [SDH], alkaline phosphatase, γ-glutamyltransferase [GGT], bilirubin, and bile acid concentrations); values may be elevated in CHF
   d. Check for antibodies to equine infectious anemia virus by agar gel immunodiffusion (AGID) or Coggins test
   e. Check for antibodies against *Streptococcus equi* M protein if signs are compatible with purpura hemorrhagica
   f. Determine titers to equine viral arteritis by serum neutralization if there is ocular inflammation, nasal discharge, abortion, or fever with edema
   g. *A. phagocytophilum* antibodies as demonstrated by immunofluorescence if physical examination reveals icterus and fever with edema
   h. Vitamin E levels if cardiomyopathy suspected
5. Perform two-dimensional (2D), M-mode, and Doppler echocardiography if there is a cardiac murmur that is not localized to the left heart base, that radiates, is greater than 2/6 intensity, or is of significant duration.
6. Analyze fluid to rule out peritonitis, pleuritis, and pericarditis; if physical examination and CBC findings are compatible, examine:
   a. Pleural fluid
   b. Pericardial fluid
   c. Peritoneal fluid
7. Isolate virus from nasopharyngeal swabs, buffy coat, or semen for equine viral arteritis if clinical signs are compatible.
8. Oral D-xylose or glucose absorption test should be done in horses if there is hypoproteinemia and if starvation, renal disease, hepatic disease, pleuritis, peritonitis, infectious gastrointestinal disease, and hemodilution have been ruled out; these tests are not useful in ruminants unless intraabomasal instillation of D-xylose or glucose is accomplished.

Cardiac Arrhythmias

Cardiac arrhythmias are abnormalities in the normal heart rate, rhythm, or conduction pattern. Arrhythmias result from abnormalities of impulse generation or impulse conduction or a combination of both. In the normal heart the impulse is generated in the sinus node because it has the highest rate of spontaneous depolarization. Atrial depolarization is followed shortly by ventricular depolarization. There is variability in

VetBooks.ir

reported normal ranges for heart rate in the large adult animal species, but there is general acceptance of the following ranges:
- Horses: 26 to 50 beats/min; 60 to 80 beats/min in foals
- Cattle: 49 to 84 beats/min
- Sheep and goats: 70 to 90 beats/min

Arrhythmias are more common in horses than in other domestic animal species. Up to 25% of horses that have no other signs of heart disease have cardiac arrhythmias during routine examination or electrocardiography.[1] During continuous 24-hour electrocardiography, 44% of normal horses had second-degree atrioventricular (AV) block, 10% had sinus arrhythmia, 3% had sinoatrial (SA) block, 27% had occasional supraventricular extrasystoles, and 15% had occasional ventricular arrhythmias.[2] Cardiac arrhythmias may be present in 40% of horses that have other signs of cardiac disease.[1] The horse may have arrhythmias at rest that are considered benign or functional. Benign, physiologic, or functional arrhythmias are usually bradyarrhythmias and are thought to be the result of increased vagal tone. These arrhythmias disappear at high heart rates (exercise or excitement) or with the administration of atropine 0.01 mg/kg intravenously (IV) or 0.02 mg/kg intramuscularly (IM) or glycopyrrolate (0.003 to 0.006 mg/kg SC or IM). Some examples of benign or functional arrhythmias are as follows:
- Second-degree AV block
- Sinus arrhythmia
- Sinus bradycardia
- SA block
- SA arrest

Other arrhythmias are usually considered to be pathologic, even if there are no other overt signs of cardiac disease. Some examples of pathologic arrhythmias are:
- Atrial fibrillation/atrial flutter
- Frequent atrial and ventricular premature depolarizations
- Supraventricular or ventricular tachycardia
- Advanced second-degree or third-degree (complete) AV block

The most effective method of identifying the specific arrhythmia is by performing an electrocardiogram (ECG). Resting electrocardiography may not detect arrhythmias that are transient or intermittent. Continuous ECG recordings (Holter or telemetry) are useful for identifying transient arrhythmias and for characterizing the type, frequency, and severity of arrhythmias. Exercising electrocardiography may identify arrhythmias that are absent or clinically insignificant at rest but that may impair performance or affect safety of a rider or driver.

In general, cattle do not have benign arrhythmias like horses, but they are frequently found to have sinus bradycardia and sinus arrhythmia associated with lack of feed intake. These arrhythmias were previously thought to be abnormal and associated with vagal indigestion but have been shown to occur in normal cattle held off feed for 12 to 48 hours.[3] Cattle with gastrointestinal disease seem to have increased susceptibility to cardiac arrhythmias, especially atrial premature depolarizations and atrial fibrillation. Although the reason for the susceptibility is not established, abnormal electrolyte concentrations, acid-base disturbances, and aberrations in autonomic nervous system function have been proposed.[4,5] Sinus arrhythmia in goats is considered to be a benign arrhythmia and is present in many normal animals. Normal camelids also frequently have sinus arrhythmia.

Mechanisms of Cardiac Arrhythmias

Arrhythmias result from abnormalities of impulse generation or impulse conduction or a combination of both. A variety of mechanisms can cause abnormal impulse generation or conduction (Boxes 6.3 and 6.4). Abnormal impulse generation occurs because of localized changes in ionic currents that flow across the membranes of single cells or groups of cells. Abnormal impulse generation can be seen as automaticity (normal and abnormal) or triggered activity.

BOX 6.3

Causes of Cardiac Arrhythmias in Horses

Common Causes

Excitement
Autonomic imbalance
Fever
Sepsis
Toxemia
Hypoxemia
Colic
Disorders of acid-base or electrolyte homeostasis
Congenital defects
Myocarditis
Valvular disease
Idiopathic (presumptive myocardial fibrosis or fibrofatty infiltrate)

Uncommon Causes

Ionophore toxicity
Zilpaterol toxicity
Anesthesia
Other drugs
Pericarditis
Cardiomyopathy
Cardiac or heart base tumor
Aortic root rupture
Aortopulmonary rupture
Atypical myopathy
Aortic regurgitation
Severe hemorrhage
Dynamic upper airway obstruction
Rattlesnake envenomation
Cardiotoxic plants
Hyperthyroidism (iatrogenic)

BOX 6.4

Causes of Cardiac Arrhythmias in Ruminants

Common Causes

Gastrointestinal disease
Lymphosarcoma
Valvular heart disease
Myocardial diseases
Brisket disease
Pericarditis
Cor pulmonale
Excitement
Foot rot
Fever
Sepsis
Toxemia
Disorders of acid-base or electrolyte homeostasis
Myocarditis

Uncommon Causes

Ionophore toxicity
β-adrenergic agonist (zilpaterol) toxicity
Anesthesia
Hypoxemia
Cardiomyopathy
Autonomic imbalance
Cardiotoxic plants (*Rhododendron* and *Taxus* spp.)

VetBooks.ir

Automaticity, the ability to initiate action potentials spontaneously, is a property of cells in the sinus node, some parts of the atria, AV junction, and His-Purkinje system. Cardiac disease can be responsible for the development of automaticity in cells that normally do not have this property. Normal automaticity develops when the membrane potential slowly falls (i.e., becomes less negative) during diastole. When the membrane reaches its threshold potential, an impulse is initiated. The most common clinical arrhythmias caused by the automaticity mechanism are sinus tachycardia and sinus bradycardia, which are the result of alterations in autonomic nervous system tone. Enhanced automaticity in another area of the heart that is capable of automaticity (spontaneous depolarization) may be responsible for atrial or ventricular premature beats. Atrial fibrillation is thought to be triggered by rapid firing from one or more foci (in humans, the foci are usually in the pulmonary vein region).

Under certain circumstances, conduction abnormalities allow a propagating impulse, which has already excited the heart, to persist and reexcite the atria or ventricles after the end of the refractory period. This can occur in an ordered or random fashion. Random reentry occurs over reentrant pathways that continuously change in size and location with time, whereas ordered reentry occurs over a relatively fixed reentrant pathway. Impulse propagation may be slow enough that reentrant circuits can be established in small areas of myocardium. In large animals the size of the myocardial circuit is large enough that relatively mild alterations in impulse propagation may make reentry feasible and may account for the relatively greater frequency of arrhythmias in these species. Both reentry and focal triggers are likely involved in the maintenance of atrial fibrillation. Atrial remodeling (electrical and structural) occurs with atrial fibrillation, which then perpetuates the arrhythmia. The mechanism of ventricular fibrillation is unknown, but reentry circuits are thought to be involved.

Under clinical conditions, cardiac arrhythmias may be associated with disturbances in electrolyte concentrations, especially potassium and calcium; in acid-base balance; and in autonomic nervous system function. These conditions can precipitate cellular changes conducive to the development of arrhythmias by any of the previously mentioned mechanisms.

Approach to Diagnosis of Cardiac Arrhythmias

It is important to distinguish between abnormal arrhythmias that are primary and those that are secondary. Most abnormal arrhythmias of horses and cattle are tachyarrhythmias. Primary arrhythmias are caused by pathologic conditions of the heart (myocarditis, valvular disease, conduction system abnormalities, and pericarditis). Secondary arrhythmias develop in the absence of heart disease and can be caused by excitement, fever, sepsis, hypoxemia, acid-base disorders, electrolyte homeostasis, gastrointestinal disturbances, anemia, severe hemorrhage, anesthesia, ionophores, other drugs, or toxemia. The treatment and prognosis for the two types of arrhythmias can be very different, and examination and laboratory tests are used to assist in making the distinction.

1. Take history. Determine the diet, feed additives, or medication (including thyroid hormone, furosemide, bicarbonate, or other prerace medications); note whether there has been exercise intolerance, syncope, fever, coughing, or edema; inquire about gastrointestinal problems, diarrhea, or colic; inquire about access to cattle feed (containing ionophores or beta adrenergic agonists), poultry feed (containing ionophores), or feed supplements (containing kelp) and about previous respiratory tract infections in this animal or stablemates.
2. Perform a physical examination to determine whether there is primary cardiac disease. Record the animal's vital signs. Determine whether this is a bradyarrhythmia or tachyarrhythmia. Careful auscultation should note which heart sounds are present and should characterize the arrhythmia. There may be irregularities in the basic rhythm, added sounds, or long pauses; classification of heart rate by regularity of rhythm can distinguish one arrhythmia from another (see Chapter 30). Note whether a pulse deficit is present by simultaneous auscultation and palpation of the peripheral arterial pulse; note the strength of the peripheral arterial pulse; observe the jugular vein for pulsations and distention; examine peripheral veins for distention; and examine mucous membrane color and capillary refill time. Careful auscultation of the lungs with and without a rebreathing bag should be performed.
3. Record an ECG. The base-apex lead can be used to screen for arrhythmias; it is attached using positive, negative, and ground leads as follows:
   a. Positive lead is attached to skin over the left fifth intercostal space at the point of maximal intensity (PMI) of the apex beat; using lead I, this is the left arm electrode; using lead II or lead III, it is the left leg electrode.
   b. Negative lead is attached to the skin of the right jugular furrow two thirds of the distance from the ramus of the mandible to the thoracic inlet; using lead I or lead II, this is the right arm; using lead III, it is the left arm. ECG interpretation is discussed in Chapter 30.
4. If there is a cardiac murmur, perform an echocardiogram (including 2D, M-mode, and Doppler). Look for evidence of ventricular dysfunction, myocardial failure, chamber dilation, valvular abnormalities (such as prolapse, thickening, ruptured chordae tendineae, or endocarditis), congenital defects, aortocardiac fistula, aortopulmonary fistula (Friesian horse), pericardial effusion, and tumor.
5. Obtain feed for analysis if ionophore (monensin, lasalocid, salinomycin) or β-adrenergic agonist (zilpaterol) exposure is suspected.
6. Determine if horse is grazing on pasture containing seeds of *Acer pseudoplatanus* or *Acer negundo* species in the late fall or early spring[6] or other cardiotoxic plants.
7. Obtain whole blood for the following:
   a. CBC
   b. Selenium and vitamin E concentrations if cardiomyopathy suspected
   c. Blood gas determinations and acid-base status
7. Test serum or plasma for the following:
   a. Electrolyte (Na, K, Cl, Ca, Mg, P) concentrations
   b. Vitamin E (α-tocopherol) concentration
   c. Cardiac troponin-I (cTnI) or cTnT[7] if myocardial inflammation, injury, or necrosis is suspected
8. Test urine for the following:
   a. Electrolyte (Na, K, Cl) concentrations
   b. Creatinine determination for fractional clearance calculations
   c. Myoglobin and hemoglobin
9. Calculate fractional excretion of potassium in the urine. This will be variable, depending on the diet, but a low value indicates the need for supplementation.
10. Treat the arrhythmia if:
   a. Patient is hemodynamically unstable (e.g., poor cardiac output, weak peripheral pulses, cold extremities, syncopal)
   b. There is ventricular tachycardia with a rapid rate (heart rate >120 beats/min)
   c. There are multifocal ventricular ectopic beats
   d. A QRS is detected in the preceding T wave (R on T)
   e. There is advanced second-degree or complete (third-degree) AV block
   f. The primary problem is cured or the condition is stabilized, and the patient is symptomatic with the cardiac arrhythmia
   g. If the arrhythmia is performance limiting, such as atrial fibrillation in horses performing high-intensity exercise

Cardiac Murmurs

Throughout the cardiovascular system, blood has a laminar or streamlined flow, except in the heart and sometimes in the aorta. Occasionally conditions occur that cause turbulent flow that is sufficient to cause resonance in adjacent structures. This resonance may be heard as a murmur when a critical level of turbulence is reached (Boxes 6.5 and 6.6). The factors that determine whether blood flow is laminar or turbulent are related by the Reynolds number, which is the ratio of the inertial to viscous forces. When the Reynolds number exceeds a critical value (about 2000 in large vessels), turbulence occurs. Increased flow velocity or reduced blood viscosity (e.g., anemia) predisposes to murmur development. The characteristics of the murmur depend on the velocity of the blood flow and the nature of the structures that vibrate.

It is useful to characterize murmurs with regard to timing in the cardiac cycle (systolic, diastolic, or continuous); duration in the cardiac cycle (early, mid, late, holo-, pan-); intensity (loudness); shape and quality or frequency; PMI; and radiation of the murmur. Systolic murmurs occur any time between the first and second heart sound. Diastolic murmurs occur between the second and first heart sounds. Continuous murmurs occur throughout the cardiac cycle (Fig. 6.4). The intensity of murmurs is frequently graded on a scale of 1 to 6[8]:

- *Grade 1* is a soft murmur heard only after minutes of careful listening.
- *Grade 2* is a soft murmur heard immediately on auscultation.
- *Grade 3* is a murmur of moderate intensity.
- *Grade 4* is a loud murmur associated with a faint palpable thrill.
- *Grade 5* is a loud murmur with a palpable thrill but is not heard when the stethoscope is removed from the chest wall.
- *Grade 6* is a loud murmur with a palpable thrill and is audible with the entire stethoscope chest piece held away from the chest wall.

The PMI of a murmur usually corresponds to the location of one of the heart valves. Murmurs associated with the mitral valve will frequently be heard best in the left fifth intercostal space just dorsal to the level of the elbow. These murmurs usually radiate dorsally or toward the aortic valve area. Pulmonic valve and aortic valve murmurs are best heard at the base of the heart. For this area to be accessed, the hand is moved under the left triceps muscle to the third (pulmonic) and fourth (aortic) intercostal spaces just below the level of the shoulder. Murmurs associated with the tricuspid valve are frequently located in the right third or fourth intercostal space between the shoulder and elbow.

Most systolic murmurs fall into one of two categories: ejection or regurgitant (see Fig. 6.4). Systolic ejection murmurs are caused by obstructed, increased, or turbulent blood flow across normal or damaged semilunar valves. Valvular obstruction is rare in large animals, but functional ejection murmurs are commonly found in healthy horses. The diagnostic considerations for systolic ejection murmurs are given in Box 6.7. The PMI of the innocent or functional murmur is typically at the pulmonic or aortic valve or just dorsal to them over the great vessels. It is a crescendo-decrescendo murmur that is audible in early to mid systole. The functional murmur may be distinguished from a pathologic murmur by being of lower and variable intensity,

peaking in early to mid systole, ending well before the second heart sound, and having no radiation. The physiologic systolic ejection murmur may disappear or become louder after exercise. Diagnostic considerations for systolic regurgitant murmurs are listed in Box 6.7.

Regurgitant murmurs can be variable in duration and may occur in early, mid, or late systole or can be pansystolic or holosystolic. Location of the PMI and the direction of radiation of the systolic murmur distinguish mitral or tricuspid regurgitation from a ventricular septal defect (VSD). Systolic clicks are rare in horses and cattle but may indicate abnormalities of the chordae tendineae, AV valve prolapse, or dilation of the aorta. The presence of a musical murmur indicates vibration of a cardiac structure such as rupture of one of the chordae tendineae or a torn valve leaflet.

Diastolic murmurs can occur between S_4 and S_1 (atrial systolic murmurs), between S_2 and S_3 (ventricular filling murmurs), or from S_2 to S_1 (aortic regurgitation or, rarely, pulmonic regurgitation). Both the atrial systolic and ventricular filling murmurs are usually functional, can be heard over the left or right hemithorax, and can vary in intensity. They may have a musical or "squeaky" quality. The aortic regurgitation murmur is typically a decrescendo murmur with its PMI over the aortic valve that begins immediately after S_2 (see Fig. 6.4). Some aortic regurgitation murmurs can be harsh or musical, associated with high-frequency vibrations of an aortic valve leaflet, and they are often audible over the right thorax, although with lesser intensity.

Continuous murmurs are uncommon in horses and ruminants. Patent ductus arteriosus, a finding in normal foals for a short time after delivery, can be heard in the left third intercostal space. This murmur can be continuous, but more frequently only a residual systolic murmur is audible.[9] Continuous machinery murmurs are most frequently reported in adult horses with an aortic cardiac fistula secondary to rupture of the aortic root or of a sinus of Valsalva aneurysm. If both a systolic and diastolic murmur or a continuous murmur are heard in the aortic to pulmonic valve area in a Friesian horse, an aorticopulmonary fistula should be considered.[10] Most acquired systolic and diastolic murmurs in adult horses or cattle are usually the result of separate murmurs but can sometimes be confused. A continuous "washing machine" murmur/rub, which is most easily heard over the left cardiac area, is associated with traumatic pericarditis in cattle and is caused by the accumulation of fluid, gas, and fibrin within the pericardium.

Approach to Diagnosis of Cardiac Murmurs

1. Take a history. Note the age, onset, duration, and progression of the condition. Determine exercise capability, growth, and attitude; inquire about previous fever, illness, or medications.
2. Perform a physical examination. Record the animal's vital signs. Determine timing, duration, intensity, location of PMI, shape, and radiation of murmur. Palpate peripheral arterial pulse and observe the jugular vein for distention and pulsations. Carefully auscultate the lungs at rest and during deep inspiration.
3. Obtain blood for CBC (includes fibrinogen, SAA, and total plasma protein concentration).
4. Test serum or plasma for the following:
   a. Electrolyte concentrations
   b. Bovine leukosis virus (BLV), AGID status (cows)
   c. Cardiac troponin I or cTnT if myocardial inflammation, injury, or necrosis is suspected[7]
5. Record an ECG.
6. Perform an echocardiogram to look for valve abnormalities, abnormalities of the aortic root, congenital defects, chamber enlargement, and wall motion abnormalities; use pulsed wave and color flow Doppler echocardiography to localize the shunt, regurgitant blood flow, or stenosis (rare); use color flow and continuous wave Doppler echocardiography to estimate the severity of the jet associated with a shunt, valvular regurgitation, or stenosis (rare); estimate pulmonary artery pressure by applying the Bernoulli equation to tricuspid or pulmonic regurgitant jet velocities, if present. Contrast echocardiography can also be used for examination of congenital defects and detection of an aortic cardiac fistula and some valvular insufficiency. Tissue Doppler imaging and speckle tracking can be used to further assess myocardial function.[11]
7. Take radiographs or perform thoracic ultrasonography to find evidence of pulmonary edema or pleural effusion.
8. Catheterize the right heart to determine pulmonary artery and wedge pressures, which may complement data obtained noninvasively with Doppler echocardiography.

Muffled Heart Sounds

Auscultation of heart sounds requires that the vibrations generated by the heart be transmitted through the tissues of the thorax to the outer chest wall with sufficient amplitude to be heard. Blood transmits sound well, whereas lung tissue strongly attenuates sound waves. The chest wall itself causes attenuation of the sound that is most significant at the interface between bone and muscle. Therefore physical factors in a normal patient, such as a large, thick chest or obesity, can cause heart sounds to be muffled. If the environment for auscultation is conducive to hearing heart sounds, other factors such as stethoscope quality may cause muffling of heart sounds in a normal patient. One should strive to have a stethoscope with comfortably fitting earpieces; thicker and shorter tubing; a rigid diaphragm to hear S_1, S_2, and higher-frequency sounds; and a bell piece for auscultation of S_3, S_4, low-frequency sounds, and murmurs. If the overlying hair coat is thick, clipping the hair may be necessary for optimal contact of the stethoscope to the skin.

Heart sounds are muffled primarily because of displacement of the heart from the thoracic wall by fluid (pericardial effusion), a soft tissue mass (abscess or tumor), or air (pneumothorax, pneumomediastinum, or emphysema) (Boxes 6.8 and 6.9). Rarely is muffling of heart sounds attributed to weak cardiac contractions alone, although this may be a finding in recumbent, hypocalcemic cows.

Approach to Diagnosis of Muffled Heart Sounds

1. Take a history. Inquire about any change in attitude, appetite, diet, or posture; determine whether a magnet has been administered to cattle; note any history of fever, weight loss, respiratory disease, colic, or diseases of other body systems and the deworming history; determine whether cattle are known to be BLV positive. Determine whether the horse had possible exposure to Eastern Tent caterpillars.[12]

Uncommon Causes

Pulmonary emphysema
Pneumothorax
Neoplasia: mesothelioma, squamous cell carcinoma, fibrosarcoma

BOX 6.9

Causes of Muffled Heart Sounds in Ruminants

Common Causes

Obesity
Large or thick chest wall
Pericarditis (traumatic reticulopericarditis)
Neoplasia: lymphosarcoma
Pleural abscess
Chronic heart failure
Emphysema

Uncommon Causes

Pneumothorax
Idiopathic hemorrhagic pericardial effusion

2. Perform a physical examination and determine vital signs. Carefully auscultate the lungs to establish whether there is ventral dullness or evidence of increased or added sounds from pulmonary parenchymal compression; carefully auscultate the heart for pericardial friction rubs; determine whether there are signs of CHF (jugular venous distention, peripheral edema); percuss the thorax to determine whether there is emphysema, pleural fluid, or pneumothorax; note that pleural fluid in the absence of pericardial effusion causes radiating heart sounds but absence of airway sounds; determine whether there is thoracic and/or abdominal pain; and in cattle, check for the presence of a reticular magnet using a compass or stud finder.
3. Obtain blood for the following:
   a. CBC
   b. Fibrinogen concentration
   c. SAA concentration
   d. Plasma or serum protein concentration
   e. Liver enzymes and tests for liver function (AST, SDH, alkaline phosphatase, GGT, bilirubin, and bile acid concentration)
   f. Tests for kidney function (urinalysis, creatinine, blood urea nitrogen [BUN], Na, K, Cl, P concentrations, and fractional excretion of Na, Cl, P)
4. Test serum for BLV serology and for equine influenza, viral arteritis, and herpes virus.
5. Take radiographs of the thorax to determine whether there is pulmonary parenchymal and/or pleural or pericardial disease.
6. Perform an ECG.
7. Perform a thoracic ultrasound examination/echocardiogram to determine if there is pericardial or pleural fluid, a cardiac mass, or a mass in the cranial mediastinum compressing the heart. Determine the location and type of fluid present.

8. Analyze pericardial or pleural fluid, and perform culture and sensitivity testing if indicated.

Cardiovascular Exercise Intolerance, Weakness, and Syncope

Exercise intolerance, weakness, or syncope can be a clinical sign associated with disease in many body systems. Exercise intolerance can be manifested as sudden deceleration or stopping, failure to perform at an expected level, a sudden change in the level of performance or production, lowered enthusiasm for work, cough on exertion, evidence of respiratory distress, or excessive sweating. Weakness can be manifested as recumbency, difficulty in rising from recumbency, muscle tremors or fasciculations, reluctance to move, or toe dragging. Syncope is a sudden collapse and loss of consciousness (fainting).

Mechanisms of Cardiovascular Exercise Intolerance, Weakness, and Collapse

The clinical signs of exercise intolerance, weakness, or collapse can be caused by cardiovascular disease (Boxes 6.10 and 6.11). They are the result of failure to maintain cardiac output, caused by inability to regulate either heart rate or stroke volume. A normal horse increases cardiac output at submaximal heart rates (<210 beats/min) primarily by tachycardia. At maximum heart rates (≈210 to 240 beats/min in horses), subsequent increments in cardiac output occur by increased stroke volume.[13] The maximum heart rate for cattle and small ruminants has not been published.

Supraventricular arrhythmias, primarily atrial fibrillation in horses, can lead to heart rates greater than 240 beats/min with submaximal exercise.[14,15] Heart rates exceeding the maximum rate may limit cardiac output by decreasing the time for diastolic perfusion of the myocardium or by limiting stroke volume because the short diastolic intervals leave inadequate time for ventricular filling. The ability to maintain cardiac output can also be compromised by other cardiac arrhythmias such as ventricular premature systoles. The frequency of extrasystoles can increase with exercise, and the timing of the

VetBooks.ir

abnormal beats can reduce cardiac output even at submaximal heart rates.[16] Horses with cardiac arrhythmias can have abnormal elevations in lactate concentration in response to exercise, indicating a lower anaerobic threshold and leading to exercise intolerance.[17,18] Bradyarrhythmias cause exercise intolerance and/or collapse via failure to maintain an adequate heart rate at rest or by failing to adequately increase heart rate to meet the increased cardiac output demands during exercise. Complete heart block and advanced second-degree heart block are the most common bradyarrhythmias to cause clinical signs.

Cardiac output maintenance may also be compromised in animals by diseases affecting myocardial contractility or diseases that result in increased end-systolic volume despite a submaximal heart rate.[19] Diseases that result in decreased venous return (peripheral vascular disease) can also reduce cardiac output and cause signs of exercise intolerance, weakness, or collapse.

Exercise intolerance or weakness can also be caused by painful peripheral vascular conditions or conditions causing peripheral hypoxia or lactic acid accumulation. In horses, such conditions may exist with aortoiliac thrombosis. Sudden episodes of weakness and collapse without change in consciousness are associated with hyperkalemic period paralysis in horses (see Chapter 42).

Collapse may be associated with epilepsy, narcolepsy, or other central nervous system (CNS) disturbance. If cardiovascular and pulmonary function appear normal, the nervous system should be examined in detail (see Chapter 8). Collapse at rest may also be caused by sleep disorders or poorly defined mechanisms such as girth tightening. Collapse during exercise is most commonly caused by cardiovascular disease, whereas collapse at rest is usually associated with neurologic disease.

Approach to Diagnosis of Exercise Intolerance, Weakness, and Collapse

1. Note signalment and take history. Establish onset of problem, previous performance history, activity level, and whether there is loss of consciousness when clinical signs are observed. Determine whether there is coughing, dyspnea, or excessive sweating associated with stress or exercise. Determining whether the weakness or collapse primarily occurs with exercise or at rest will direct further workup.
2. Perform a physical examination and record vital signs. Of particular importance are heart rate at rest, peripheral arterial pulse characteristics, presence of pulse deficits, mucous membrane color, and appearance of jugular venous pulses. Lungs should be auscultated for evidence of pulmonary edema or pleural effusion. The chest should be percussed. Rectal examination should be performed to evaluate aortic and iliac arterial pulses; metatarsal artery pulses and saphenous vein refill should be evaluated.
3. Perform neurologic and lameness evaluations. Perform a rectal ultrasound examination if aortoiliac thrombosis is suspected, to document the disease and assess its severity.
4. Perform an echocardiogram (2D, M-mode, and Doppler) to evaluate the size of heart chambers; to look for congenital defects, acquired valvular heart disease, and pericardial disease; and to evaluate myocardial contractility and ventricular wall motion. Tissue Doppler imaging and speckle tracking can also be used to further evaluate atrial and ventricular wall motion.[11]
5. Record an ECG at rest. Record a continuous 24-hour ECG to determine the frequency of arrhythmias detected on the resting ECG or to look for infrequent or paroxysmal arrhythmias not detected at rest.
6. Simultaneous video monitoring and continuous ECG recording can help determine if episodes of collapse are associated with cardiac rhythm disturbances. Video surveillance can also help characterize the nature of the collapse episodes and aid in differentiation of seizure activity from sleep disorders.[20]
7. If collapse is associated with exercise and a definitive diagnosis cannot be made with resting diagnostics, an exercising stress test should be performed. Diagnostics may include resting and exercising upper airway endoscopy, an exercising ECG (preferably with real-time monitoring), stress echocardiogram before and immediately after exercise, resting and exercising lactic acid and arterial blood gas concentrations, resting and postexercise creatine kinase, and cTnI or cTnT concentrations and a postexercise bronchoalveolar lavage. Clinicians should be prepared to discontinue the test, treat life-threatening arrhythmias, and/or establish a patent airway (tracheostomy) in horses with a history suggestive of ventricular arrhythmias or upper airway obstruction, particularly pharyngeal collapse or laryngeal dysfunction.

Venous Distention and Pulsations

The jugular venous pulsations observed in the neck are primarily a reflection of right atrial and right ventricular activity. There may be some small contribution from carotid arterial impact.[21] The jugular venous pulse reflects the right atrial or central venous pressure, which is influenced by blood volume, right ventricular cardiac output, and right atrial contractility (Boxes 6.12 and 6.13). Jugular venous pulsations are observed in normal animals, but the pulse seldom radiates more than one third of the distance from the thoracic inlet to the ramus of the mandible when the head is held in a normal, upright position.

Mechanisms of Venous Distention and Pulsations

The normal jugular venous pulse consists of three positive and two negative deflections (Fig. 6.5). The first and dominant positive wave is the A wave, produced by atrial contraction. During atrial relaxation the pressure declines until ventricular systole. The second positive deflection is the C wave, which is produced by the bulging of the tricuspid valve leaflets into the right atrium during early (isovolumetric) right ventricular systole. Carotid arterial impact on the jugular vein may also contribute to the C wave.[21] As the ventricle contracts, the plane of the tricuspid valve is pulled toward the apex of the

heart and the atrial pressure declines, producing the X descent. The X descent is terminated by the V wave, which is associated with venous return, subsequent atrial filling, and a closed tricuspid valve. At the end of ventricular systole, the atrial pressure falls again as a result of tricuspid valve opening and rapid right ventricular filling. This is the Y descent. The Y descent is terminated as the pressure gradually rises with right-sided heart filling.

Abnormal pulsations occur with increased resistance to right ventricular filling, regardless of the cause. Distention and pulsations in the jugular vein are usually associated with an elevated right ventricular pressure such as occurs in right-sided heart failure, constrictive pericarditis, or, more rarely, cardiomyopathy. Prominent jugular pulsations are noted with tricuspid regurgitation and certain cardiac arrhythmias, especially those arrhythmias associated with atrial contraction against a closed AV valve. The carotid arterial pulse can mimic jugular venous pulsations. To distinguish among the causes of jugular venous pulsations, lightly compress but do not occlude the jugular vein at the thoracic inlet. The jugular vein will distend enough to eliminate carotid arterial pulsations. If pulsations are still present, tricuspid regurgitation, atrial arrhythmias, or right-sided heart failure should be considered. If the jugular vein is compressed near the ramus of the mandible and massaged toward the thoracic inlet, refilling is indicative of tricuspid regurgitation. Jugular venous distention without pulsations can occur with compression of the cranial vena cava from a cranial thoracic or mediastinal mass or from occlusion of the jugular vein with a thrombus.

Approach to Diagnosis of Venous Distention and Pulsations

1. Take history. Note especially history of respiratory disease, exposure to high altitude and locoweed, or ingestion of potential cardiotoxins. Determine whether other animals have been similarly affected, whether the BLV status of affected cattle is known, and whether a magnet has been administered.
2. Perform a physical examination. Determine whether there is tachypnea or tachycardia. Carefully auscultate for abnormal heart sounds, rhythm, or intensity of sounds; note whether jugular veins are patent. Look for jugular venous pulsations as described previously.
3. Obtain blood for the following:
   a. CBC
   b. Fibrinogen concentration
   c. SAA concentration
   d. Total protein concentration
   e. BLV status (bovine) and serology for equine influenza, viral arteritis, and herpes virus
   f. Vitamin E (serum) and selenium concentrations if cardiomyopathy suspected
4. Take radiographs of the thorax and abdomen to establish whether there is respiratory disease, a magnet, or a penetrating foreign body.
5. Record an ECG when there is an arrhythmia to look for atrial premature depolarizations.
6. Perform an echocardiogram to examine the following:
   a. Right ventricular size and function
   b. Right atrium, for abnormal size or structures
   c. Tricuspid valve
   d. Pulmonary artery diameter looking for evidence of pulmonary hypertension
   e. Left atrial size
   f. Left ventricular size and function
   g. Pericardium
   h. Interventricular septal thickness and motion
7. Perform Doppler echocardiogram to look for:
   a. Tricuspid regurgitation
   b. Pulmonic regurgitation
   c. If tricuspid or pulmonic regurgitation is detected, check for concurrent mitral and aortic regurgitation. Use velocity of tricuspid and/or pulmonic regurgitation to calculate/estimate pulmonary artery pressure.

Septic tenosynovitis
Bursitis

8. Perform ultrasound examination of the cranial thorax and cranial mediastinum.
9. Performing jugular venous catheterization may be useful to determine right atrial (central venous), right ventricular, and pulmonary arterial pressures.

Painful Peripheral Swellings

Close inspection of the skin and extremities of patients can reveal evidence of peripheral vascular or lymphatic system disease. These diseases can be manifested by diffuse swelling; localized swelling (papules, nodules, macules, or wheals); or subcutaneous edema of the extremities. Frequently there is necrosis, ulceration of the skin, and exudation as the disease progresses. Animals may be lame, have heat in the involved area, or exhibit a painful response to palpation of the area (Boxes 6.14 and 6.15), which helps to differentiate these conditions from nonpainful peripheral edema. Swellings in the neck may cause dyspnea or abnormal carriage of the head. In light of the zoonotic potential of certain infectious agents (e.g., glanders, sporotrichosis), donning of appropriate personal protective equipment should be considered.

Approach to Diagnosis of Painful Peripheral Swellings

1. Take history. Establish whether there is a history of a wound or trauma to the area or previous drainage; inquire about previous infections, particularly those referable to the respiratory system, in this animal or others; determine vaccination, deworming, and drug administration history.
2. Perform a physical examination. Determine vital signs. Note whether the animal is febrile; examine extremities for wounds, dilated lymphatic channels, ulcers, focal swellings, and edema; determine the temperature and sensitivity of the swollen area; examine mucous membranes for color and presence of hemorrhages; perform a rectal examination and palpate aortic quadrifurcation in horses for vessel size, firmness, pain, fremitus, and strength of pulse; evaluate these vessels before and after exercise, if indicated; test saphenous refill by holding off the saphenous vein distally over the hock, stripping the vein proximally, and releasing the pressure over the vein at the level of the hock.
3. Obtain blood for the following:
   a. CBC (includes examination of red blood cells, neutrophils, and eosinophils for inclusion bodies or morula and determination of platelet count)
   b. Fibrinogen concentration
   c. SAA concentration
   d. Total protein concentration
   e. Coombs or direct immunofluorescence test
   f. Appropriate tests for equine ehrlichiosis (immunofluorescence assay), piroplasmosis (complement fixation), or viral arteritis (serum neutralization), if indicated
4. Take radiographs of swollen extremities, if appropriate.
5. Perform an ultrasound examination of the swelling, if appropriate. Perform transrectal ultrasound examination of terminal aorta and iliac arteries of horse if palpation or physical examination findings suggest thrombus.
6. Obtain Gram stain and bacterial and fungal culture of ulcerated area or exudate.
7. Perform a biopsy of granulomas and submit for histopathology and culture and sensitivity testing, if appropriate.
8. Analyze and culture fluid obtained from dilated lymphatic channels or localized edematous areas.
9. Analyze urine to look for hemoglobinuria or hematuria.
10. Test feces for fecal occult blood.

Enlarged Lymph Nodes

Diffuse or single lymph node enlargement occurs with infectious (bacterial, viral, fungal) conditions, neoplasia, and, rarely, immune-mediated causes in large animals (Boxes 6.16 and 6.17).

VetBooks.ir

BOX 6.16

Causes of Enlarged Lymph Nodes in Horses

Common Causes

Strangles
Lymphosarcoma
Upper respiratory infection
Corynebacterium pseudotuberculosis lymphadenitis

Uncommon Causes

Ulcerative lymphangitis
Epizootic lymphangitis
Sporadic lymphangitis
Glanders
Melioidosis
Granulomatous lymphadenitis
Plasma cell myeloma
Tuberculosis
Hemolytic uremic-like syndrome

BOX 6.17

Causes of Enlarged Lymph Nodes in Ruminants

Common Causes

Caseous lymphadenitis (*Corynebacterium pseudotuberculosis*)
Lymphosarcoma (including bovine leukosis virus)
Abscess or cellulitis of area drained

Uncommon Causes

Tuberculosis
Sporadic bovine encephalomyelitis
Malignant catarrhal fever

Lymphadenopathy may cause obstruction to lymphatic drainage, leading to peripheral edema, pleural effusion, or ascites. The peripheral lymph nodes that are most readily accessible for examination are the submandibular (horses), superficial cervical (ruminants), and superficial inguinal (ruminants) lymph nodes. When there is generalized lymphadenopathy, internal lymph nodes may be enlarged, causing clinical signs such as dyspnea, esophageal obstruction, diarrhea, or other signs of organ dysfunction.

Approach to Diagnosis of Enlarged Lymph Nodes

1. Take history. Note especially history of weight loss, inappetence, depression, lethargy, or lymph node enlargement; inquire about previous illness or wounds; for cattle, determine whether there is a history of lymphosarcoma in the family or herd and whether the cow has a positive BLV test result; for sheep and goats, determine whether there is a history of *Corynebacterium pseudotuberculosis* abscesses in the flock or herd.
2. Perform a physical examination. Determine vital signs. Examine peripheral lymph nodes or other swellings, perform a rectal examination to palpate accessible internal lymph nodes, and, when appropriate, examine the uterus in cattle; carefully inspect the skin over the area drained by the lymph node for pain, swelling, or exudate; check mucous membranes for pallor or icterus; determine whether there is jugular venous distention or pulsations or whether there is evidence of pleural or pericardial effusion or ascites.
3. Obtain blood for the following:
   a. CBC to examine for anemia or leukemic changes; note inclusions, morula, or abnormal appearance of cells
   b. Serum chemistry profile to determine if there are signs of other organ dysfunction (e.g., gastrointestinal [hypoproteinemia], liver, or kidney)
4. Test feces for occult blood, if indicated.
5. Perform ultrasonographic examination of the lymph node or swelling.
6. Obtain lymph node or swelling aspirate and biopsy sample for culture and histopathologic examination.
7. Obtain a bone marrow sample for cytologic examination.

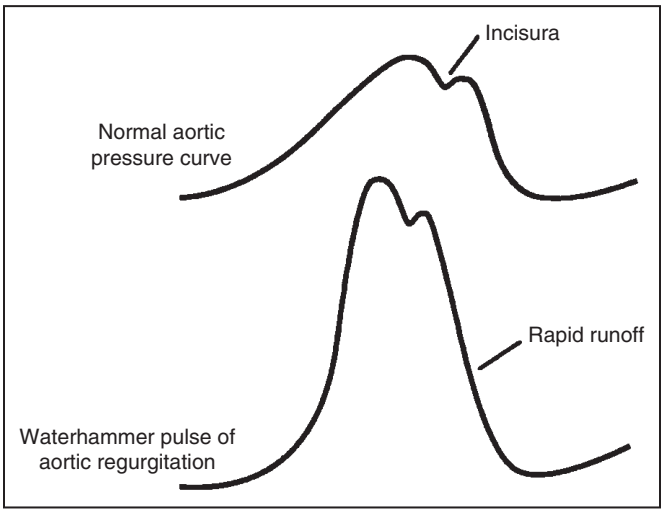

FIG. 6.6 Schematic illustration of the normal arterial pressure pulse. The incisura that occurs during the descending limb is caused by a transient reversal in flow during isovolumic relaxation. Compared with the normal arterial pressure pulse, the waterhammer pulse of aortic regurgitation builds rapidly and has a rapid runoff.

Abnormal Peripheral Pulse

Palpation of the arterial pulse is an important aspect of the examination of the patient with cardiovascular disease. Arterial pulse strength and contour (how fast pressure rises and falls) are the objectives of the examination and are determined by the cardiac output, heart rate, and vascular impedance. The arterial pressure pulse begins with the opening of the aortic valve and ventricular ejection and rises rapidly in early systole. The pulse pressure reaches a peak and then declines as ventricular ejection slows. During isovolumic relaxation (before AV valve opening), there is a transient reversal of flow in the arterial system, and an incisura or dicrotic notch (Fig. 6.6) is inscribed on the descending limb of the pressure curve. Following the incisura, there is a small positive wave that is attributed to elastic recoil of the aorta and the aortic valve and the summation of reflected waves from more distal arteries.[19] After the positive wave, the pulse pressure declines because there is peripheral runoff of blood in diastole. The incisura and secondary positive wave are not usually palpable. Palpation of peripheral arteries (facial, transverse facial, and digital arteries in the horse and median and coccygeal arteries in ruminants) normally reveals a smooth, rapid upstroke, a dome-shaped summit, and a downstroke that is slightly more prolonged than the upstroke.

Pressure values and pulse wave configurations are altered as the pressure waves are transmitted through the peripheral arterial tree. With increasing distance from the heart, the dicrotic notch and second positive wave disappear, the systolic pressure gets higher (loss of distensibility in the distal arteries and summation of reflected pulse waves from the distal vascular bed), and the diastolic pressure gets lower. The difference between the systolic and diastolic pressure determines pulse pressure and can be evaluated by an impression of pulse strength.

Toxemia
Congestive heart failure
Electrolyte imbalances
Acid-base disorders
Fever
Cardiac arrhythmias

Uncommon Causes

Patent ductus arteriosus
Aortic regurgitation
Peripheral arteriovenous shunt

Pulse pressure increases as one moves to more peripheral arterial sites. The mean arterial pressure changes little but decreases slightly as one moves downstream in the arterial system from the pressure source. Systolic blood pressure, as measured indirectly at the tail or on a limb, is higher than that measured in the ascending aorta. In smaller arterial beds (e.g., arteries of the ear), the pulse wave is gradually dampened and pulsatile characteristics are lost on the capillaries and small veins.

Mechanisms of Abnormal Peripheral Pulse

Hyperkinetic arterial pulses occur in patients with increased cardiac output (e.g., fever, exercise, excitement), increased stroke volume, or bradycardia (Boxes 6.18 and 6.19). They may also occur when there is rapid runoff of blood in the arterial system, as occurs with aortic valve regurgitation, patent ductus arteriosus, aortic cardiac fistulas, or aortopulmonary fistulas. In aortic valve regurgitation the rapidly rising, hyperdynamic pulse is caused by increased stroke volume (regurgitated blood in the left ventricle), followed by a rapid runoff of pressure later in systole as a result of regurgitation (see Fig. 6.6).

Hypokinetic pulses are present in patients with diminished stroke volume caused by hypovolemia, left ventricular failure, or, rarely in large animals, mitral or aortic valve stenosis.

Abnormal peripheral pulses are detected in patients with cardiac arrhythmias. With premature ventricular complexes (PVCs), the compensatory pause that occurs after the PVC allows a longer period of time for ventricular filling, which results in a greater end-diastolic volume, increased contractile force, and a stronger pulse in the beat that follows the PVC. The strength of the peripheral pulse is variable in arrhythmias such as atrial fibrillation because the irregular rhythm is associated with variable time for ventricular filling. Certain arrhythmias, particularly tachyarrhythmias, allow inadequate ventricular filling to generate a peripheral arterial pulse, and a pulse deficit is palpated. This is particularly likely with ventricular tachycardia at high heart rates.

Approach to Diagnosis of Abnormal Peripheral Pulse

1. Take history. Note changes in appetite, attitude, milk production, or ability to exercise; determine whether there have been signs of previous illness and duration and progression of the problem.
2. Perform a physical examination. Determine vital signs. Note whether there is a cardiac arrhythmia, murmur, or other evidence of heart disease (e.g., jugular venous distention or pulsation, edema). Palpate the pulse in multiple sites and bilaterally to rule out occlusive arterial disease; check patient's hydration. Evaluate for potential causes of hypovolemia (e.g., diarrhea, blood loss) and sepsis/toxemia.
3. Obtain blood for the following:
   a. CBC; look for evidence of toxemia or anemia
   b. Blood gases to determine acid-base balance
   c. Electrolyte concentration, especially Ca and K
4. Record an ECG to characterize any arrhythmia.
5. Determine blood pressure. The site for indirect blood pressure measurement in the standing animal is the tail over the coccygeal artery; a limb can be used in a recumbent animal. Take the mean of several (minimum of three) readings in which the blood pressure cuff is gradually inflated and deflated at approximately 2 to 4 mm Hg/sec; values obtained should be corrected for the difference in height between the site measured and the heart, which is considered to be at the level of the shoulder; the difference in height (centimeters) between the heart and the site of pressure measurement is multiplied by 0.77 (constant used to convert centimeters of blood to millimeters of mercury). In standing horses, approximately 27 mm Hg is added to the indirectly measured coccygeal artery pressure to give the corrected value[22]; no correction factor is necessary if the measurement is made in a recumbent animal. An appropriately sized blood pressure cuff is considered to be one fourth of the tail circumference[23]; in horses a 4.5- to 5.6-cm cuff has been recommended for electronic oscillometric devices, and a 10.6-cm cuff is used for ultrasonic flowmeters.[22] Values for normal horses by blood flow detection methods are 79/49 to 145/106 mm Hg (uncorrected for the height of the tail).[21] Mean arterial blood pressure (MAP) obtained noninvasively (NIBP) correlates well with invasive blood pressure (IBP) measurements in normotensive horses but not in hypotensive or hypertensive horses.[24,25]
6. Blood pressure can be evaluated by Doppler scan, or measurements can be recorded by direct cardiac catheterization (see Chapter 30).
7. Perform an echocardiogram to evaluate size of chambers, myocardial function, presence of valvular or pericardial disease, or congenital defects.

Diarrhea

K. Gary Magdesian • Bradford P. Smith

Diarrhea is an increase in the frequency, fluidity, or volume of feces. Diarrhea may be a sign of a primary gastrointestinal (GI) disease or a nonspecific response to sepsis, toxemia, or disease of another organ system.

Under normal circumstances a large volume of essentially isotonic fluid enters the proximal GI tract daily. Most of this fluid is resorbed, and only a small percentage is ultimately passed with the feces. The fluid comes from dietary intake and from endogenous secretions of the upper digestive tract. The total daily volume exchanged exceeds that of the animal's total extracellular fluid volume. Normally absorption just exceeds secretion; therefore small changes in rate of absorption or secretion can result in diarrhea. In the horse most water resorption occurs in the cecum and large colon, and diarrhea in the horse (other than neonates) usually involves some abnormality in the lumen or wall of the large intestine.

Normal fecal color is tan, brown, or greenish, depending on diet. The adult horse normally produces 11 to 13 kg of fecal material per day (24 to 29 lbs of body weight per day) while on a diet of grass hay and 3 lb of oats.[1] Fecal output is as high as 20 kg/day (44 lbs/day) in horses fed a mixture of alfalfa and orchard grass ad libitum.[2] Horses with chronic watery diarrhea can produce up to 214 g/kg of body weight per day,[1] which is >90 L of diarrhea in a 450-kg horse.

Cattle normally produce 15 to 28 kg of feces per day with a water content of about 75% to 85% on a diet of grass hay.[3] Fluidity of cattle feces can increase markedly in animals on lush green feed. Sheep and goat feces contain only 50% to 60% water.[3] Fluid feces in the cow and unformed feces in the horse, goat, and sheep are nonspecific signs that often accompany sepsis or illness other than a primary gastrointestinal disease.

Animals with chronic diarrhea rarely develop severe dehydration because they compensate for increased fecal water losses by increasing water consumption by an equivalent amount. Normal water consumption in the horse on a hay diet in a mild ambient temperature environment is about 24 to 30 L/day, whereas cattle consume 30 to 60 L/day based on 10 kg of dry matter feed intake. Water and feed intake do not increase linearly with increasing body size, but by multiplying body weight in kilograms to the 0.75th power (BW $kg^{0.75}$) by a base factor (≈200 mL for water). Thus a 500-kg horse requires 21 L of water. The effect of temperature on water intake is dramatic and not linear; as ambient temperatures rise close to 37° C (98° F), water intake per kilogram of dry matter increases much more rapidly than at lower temperatures. Exercise and loss through sweat, particularly in the horse, can dramatically increase salt and water requirements.

Mechanisms of Diarrhea

The following six major mechanisms produce diarrhea (Box 7.1):

- Decreased or damaged absorptive surface area (malabsorption)
- Increased numbers of osmotically active particles within the intestinal lumen
- Increased volume of secretion of solutes and water
- Abnormal intestinal motility resulting in decreased transit time, as with systemic inflammatory response syndrome (SIRS)
- Increased blood-to-lumen pressure as in heart failure or acute or chronic inflammatory bowel diseases
- Gastrointestinal inflammation, as occurs with peritonitis

The common net result is an increase in fecal water.

Decreased surface area is mainly a result of villous blunting (atrophy) and/or microvillous damage in the small intestine, which lead to malabsorption. Both occur to some degree with most enteric diseases, and regeneration of surface area from crypt cells with healing is accompanied by a gradual decrease in the volume of diarrhea. Diseases in which this is a major

BOX 7.2

Causes of Diarrhea in Horses[a]

Common Causes

Colitis or typhlitis
Salmonellosis
Enteritis, unknown cause
Potomac horse fever (equine monocytic ehrlichiosis)
Endotoxemia or gram-negative sepsis
Overfeeding or sudden change in diet
Clostridium difficile
Clostridium perfringens
Parasites (ascarids, large and small strongyles)

Less Common Causes

Eosinophilic gastroenteritis
Renal failure, uremia
Necrotizing enterocolitis
Heart failure
Enterotoxemia (*C. perfringens,* mainly type A)
Lawsonia intracellularis (mainly foals and weanlings), proliferative enteropathy
Intestinal lymphosarcoma
Cathartics or laxatives
Parasympathomimetics
Chronic granulomatous bowel disease
Proximal enteritis
Peritonitis
Intussusception
Sand, gravel, or enterolith in gut lumen
Gut stenosis
Antibiotic use
Gastroduodenal ulcers
Rhodococcus equi, gut infection (mainly foals)
Cryptosporidiosis (mainly foals)
Giardiasis (mainly foals)
Toxins or poisonous plants (see Box 7.3)

Uncommon Causes

Hepatic failure
Cholelithiasis
Vascular aneurysm
Combined immunodeficiency
Agammaglobulinemia
Lactose intolerance (mainly foals)
Campylobacter jejuni (mainly foals)
Colorectal polyps
Anaphylaxis
Vitamin A deficiency
Tularemia
Snake bite, insect or spider sting or bite
Histoplasmosis
Hydroallantois
Hyperlipidemia
Internal abdominal abscess
Pheochromocytoma
Viral arteritis
Sarcoidosis
Addison disease
Malignancy
Grass sickness (exotic)
Glanders (exotic)
Besnoitiosis (globidiosis) (exotic)

[a]See Chapter 17 for information on neonates.

mechanism include neonatal diseases such as rotavirus and coronavirus enteritis,[4] cryptosporidiosis, acute inflammatory disease such as salmonellosis, and chronic diseases such as Johne's disease and other granulomatous bowel diseases. The finding of villous atrophy is so nonspecific that it is not diagnostic in itself. It can also occur in advanced cases of secondary copper deficiency (molybdenosis) with diarrhea. Loss of villous epithelial cells can result in maldigestion because these cells produce important enzymes such as lactase. Many neonates with enteritis develop temporary lactose intolerance as a result, especially with rotaviral and clostridial infections. Damaged surface area occurs in such diseases as salmonellosis, where the mucosa of the large colon and cecum may be severely disrupted.

Inflammation can be accompanied by increased mucous production and increases in size of membrane pores, through which tissue fluids and serum proteins leak into the lumen. This is associated with increased capillary and lymphatic hydraulic pressures. Both acute (salmonellosis) and chronic (Johne's) inflammatory bowel diseases are protein-losing enteropathies. Low plasma protein concentrations, particularly low albumin, are often found (unless hypovolemia and hemoconcentration are present). Bowel inflammation often results in transudation and exudation of serum proteins, blood, and/or mucus, resulting in dysentery (bloody diarrhea). In addition to salmonellosis, dysentery may also commonly be seen with enterotoxemia caused by *Clostridium perfringens*, types A, B, or C; *Clostridium difficile; Lawsonia intracellularis*[5]; attaching effacing *Escherichia coli; Campylobacter jejuni;* coccidiosis; malignant catarrhal fever (MCF); arsenic toxicity; and oak toxicity. Inflammation results in malabsorption, maldigestion, osmotic effects, and, in acute disease, changes in intestinal motility. Because most water absorption in the horse occurs in the cecum and colon, inflammatory typhlitis and colitis are the major causes of diarrhea in the adult horse (Boxes 7.2 and 7.3). The neonatal foal commonly develops small intestinal enteritis.

Irritation of the bowel with a foreign body such as sand may result in either low-grade recurrent colic or diarrhea or both. Weight loss may also be evident with a large amount of sand. Sand accumulation in the large bowel of the horse may be suspected when there is evidence of a significant amount of sand in the feces or when sand can be auscultated with a stethoscope or detected via ultrasound over the ventral abdomen. Irritation probably causes diarrhea through creation of an inflammatory response and altered motility.

Osmotic diarrhea results from any disease causing maldigestion and/or malabsorption. Any osmotically active solute can produce diarrhea in normal animals if given in quantities sufficient to surpass the intestinal capacity for digestion or absorption. Disaccharides are natural examples. Osmotic cathartics such as dioctyl sodium sulfosuccinate (DSS) hold water in the intestine and act as fecal softeners. Magnesium phosphates and sulfates and other divalent and trivalent cations and anions are poorly absorbed and thus are effective laxatives and cathartics.

Osmotic diarrhea can be associated with ingestion of osmotically active and poorly absorbed solutes, overloading of the intestine with carbohydrates or lipids beyond the amount that can be digested and absorbed, sudden dietary changes resulting in marked shifts in gut flora and resulting bacterial action on ingested substrate (e.g., grain overload), or bowel disease in which surface area is diminished or digestion interfered with in some manner. Lactase deficiency, secondary to rotavirus or *C.*

difficile infections, may result in osmotic diarrhea in foals[6] and probably also in neonatal ruminants. This results in increased concentration of undigested and/or unabsorbed nutrients entering the lower bowel, increased bacterial fermentation, and an increase in the concentration of osmotically active particles. Unfavorable electrochemical gradients prevent resorption of water. Mucosal digestive enzyme levels are often decreased with any disease involving the small intestine, resulting in maldigestion. When osmotic diarrhea is suspected in mature animals, dietary modification to basic roughage should be tried as part of the nonspecific therapy. Sodium and potassium are normally present in roughly equal amounts in feces and (with small concentrations of ammonium) make up the vast majority of cations in the feces. Concentrations of sodium and potassium in feces and osmotically active nonelectrolytes influence fecal water. In general, osmotic diarrheas diminish when the animal is fasted. When the offending substance is reintroduced, diarrhea occurs.

Secretory diarrheas are most important in neonates[4] (e.g., enteropathogenic *E. coli*), but many strains of *Salmonella* that are associated with colitis in large animals may also produce enterotoxins that stimulate secretion. Enterotoxins act by stimulating cyclic adenosine monophosphate (AMP) or other intracellular messengers to promote secretion of chloride, sodium, and other electrolytes into the gut lumen. Water is carried with these electrolytes and osmotically retained. The hallmark of secretory diarrheas is the large volume of feces produced.

Examples of secretory diarrheas are enterotoxigenic *E. coli*, many strains of *Salmonella*, and *C. perfringens*. *Salmonella* and other invasive microorganisms produce inflammation that may induce prostaglandin-mediated secretion as well. *Salmonella typhimurium* translocates Salmonella effector proteins into epithelial cells and causes diarrhea.[7] Secretion may occur with viral diarrhea by a different mechanism, as damaged mature (absorbing) villous cells are replaced by immature (secreting) crypt cells.[8] An example of viral secretory enteritis is rotavirus.

Decreased intestinal transit time, associated with increased peristalsis and/or decreased segmentation, appears to occur in many bowel diseases because of bowel irritation. Peritonitis is a major cause of bowel inflammation and should always be explored as a contributing cause of diarrhea, especially when fecal output volume is scant. Abnormal motor patterns have been demonstrated to occur with many infectious diarrheas and may be a bowel response to irritation and/or increased intraluminal volume. Elimination of gut contents thus appears to be a normal gut defense mechanism against infection and should not be pharmacologically alleviated in acute infectious diarrheas. Primary motility disorders of animals are not well recognized; diarrhea associated with nervous or excited animals may be the best example of this type. In general, fecal volume associated with motility disorders is not great.

Increased hydraulic or hydrostatic pressure, from the blood to the intestinal lumen, also decreases net fluid absorption. These can result from decreased oncotic pressure (hypoalbuminemia), increased capillary hydrostatic pressure (heart failure or portal hypertension as with liver disease), or decreased lymphatic drainage associated with inflamed or blocked lymph vessels or nodes (lymphosarcoma). These mechanisms are most commonly associated with chronic diarrhea, but acute inflammation can also result in diarrhea associated with this mechanism.

Two or more of these mechanisms are probably at work in most diarrheal diseases. Therapy of diarrhea is therefore nonspecific and supportive, except when the actual causative agent can be identified and is treatable. Diagnosis of a specific causative agent is most important when diarrhea is caused by an infectious agent so that appropriate therapeutic steps can be taken before chronicity develops, spread of disease can be prevented, and an accurate prognosis can be made.

In mature horses, small intestinal diseases such as granulomatous bowel disease or duodenitis/proximal jejunitis (anterior enteritis) may not be associated with diarrhea, and diseases of the stomach almost never cause diarrhea. Most significant diarrheal disease in adult horses involves the large colon because this is the principal site of water absorption. The exception to this is the neonatal foal, in which primarily small intestinal diseases such as rotavirus infection and cryptosporidiosis may cause severe diarrhea.

The frequency of defecation is usually increased when diarrhea is present, and defecation frequency is highest when the colon or rectum is irritated. When these areas are involved, tenesmus (straining) may result. Tenesmus can also occur with hepatic failure in ruminants and in horses and ruminants with rectal tears or strictures, vaginitis, retained placenta, dystocia, intussusception, urolithiasis, perirectal abscesses, rabies, and diseases involving the nervous system when there is retention of feces or urine. Severe rectal irritation can lead to straining and rectal prolapse.

In **ruminants,** abnormalities such as grain overload (toxic indigestion) resulting in ruminal osmotic changes can produce diarrhea, as can changes in abomasal pH such as occur with type II ostertagiasis. Diarrhea in ruminants is frequently caused by forestomach problems (Boxes 7.4 and 7.5). The colon and

BOX 7.4

Causes of Diarrhea in Ruminants (Except Neonates; See Chapter 20 for Neonates)

Common Causes

Parasitism, worms
Coccidiosis
Salmonellosis
Colitis or typhlitis
Enteritis, unknown cause
Indigestion (spoiled feed, overfeeding, or sudden change)
Displaced abomasum (B)
Abomasal torsion (B)
Peritonitis
Intussusception
Sepsis or toxemia
Johne's disease
Enterotoxemia
Grain overload (rumen acidosis)
Bovine viral diarrhea (B)
Winter dysentery (B)
Liver failure
Malignant catarrhal fever (B)
Molybdenosis or copper deficiency
Heart failure
Uremia, renal failure
Xylazine, following large doses
Cathartics or laxatives
Parasympathomimetics
Toxins or poisonous plants (see Box 7.5)

Less Common Causes

Amyloidosis
Giardiasis (mainly calves)
Intestinal obstruction, partial
Intestinal neoplasia
Traumatic reticuloperitonitis (hardware)
Vagal indigestion
Selenium deficiency (white muscle disease)
Cecal dilation (B)
Liver abscess
Brisket disease (high-altitude disease) (B)
Sarcocystosis (B)
Bluetongue (O)
Bovine leukosis (BLV) (B)
Hemorrhagic bowel syndrome (B)

Uncommon Causes

Fat necrosis (B)
Abomasal impaction
Duodenal ulcers
Systemic candidiasis
Vitamin A deficiency
Volvulus, root of mesentery
Water intoxication (B)
Cholelithiasis
Cobalt deficiency
Zinc deficiency (baldy calf) (B)
Hydrops allantois (B)
Lethal trait A 46, keratogenesis imperfecta (parakeratosis) (B)
Zygomycosis, mucormycosis
Pregnancy toxemia
Bacillary hemoglobinuria
Rumen flukes, paramphistomosis
Pancreatic adenocarcinoma
Bee or wasp sting
Pseudorabies
Hemochromatosis of Salers cattle (B)
Rift Valley fever (exotic)
Rinderpest (exotic)[a]
Schistosomiasis (exotic)
Theileriosis (East Coast fever) (exotic)
Wesselsbron disease (exotic) (B, O)
Heartwater (exotic)

[a]Rinderpest was a cause of diarrhea in ruminants until 2011, when it was eradicated worldwide.
B, Bovine; *O*, ovine.

remainder of the distal bowel are involved in diseases such as salmonellosis. Gram-negative infections and resulting endotoxemia, found in conditions such as coliform mastitis and septic metritis, are relatively common causes of nonspecific diarrhea.

Foals with septicemia also commonly develop nonspecific diarrhea associated with SIRS.

Diarrhea may be 1) a manifestation of a primary disease (bovine viral diarrhea [BVD]; Johne's disease; *C. difficile*, salmonellosis); 2) one of the signs of a generalized disease (MCF, uremia); or 3) secondary to toxemia (coliform mastitis, septic metritis, septicemia, salmonellosis).

Nonspecific Fluid Therapy for Diarrhea

Dehydration, electrolyte losses, and acid-base abnormalities can occur rapidly when diarrhea is present. Treatment to correct these problems is an important component of nonspecific therapy in animals with diarrhea. Often the cause of diarrhea remains undetermined, yet correction of hypovolemia, dehydration, and acid-base and electrolyte abnormalities can result in a return to normal systemic function, particularly if the diarrhea is acute and severe. Fluids and electrolytes can be given orally or parenterally. Oral fluids can be given rapidly and inexpensively but only if dysmotility is not present. Oral fluids should be isotonic or hypotonic. The degree of dehydration should be estimated as a percentage of body weight. Mild dehydration is usually considered less than 5%; moderate, 5% to 8%; and severe, over 8%. Thus a severely dehydrated 450-kg patient with an estimated 10% dehydration (weakness, cold extremities, sunken eyes, decreased urine output, decreased elastic skin rebound, weak pulse, rapid heart rate) may require up to 45 L of fluids over time. Boluses of 10 to 20 mL/kg of isotonic crystalloid can be administered IV until signs of shock abate or plateau.

The optimal means of determining electrolyte status is to analyze a plasma or serum sample before initiating fluid therapy. Electrolyte requirements can be estimated; with diarrhea, mixed water and electrolyte losses occur, so sodium-containing fluids are usually required to replace lost sodium and improve blood volume (see also Critical Care and Fluid Therapy, Chapter 44). Unless the acid-base status can be measured, the safest sodium-containing fluids are balanced polyionic fluids such as PlasmaLyte A, PlasmaLyte 148, Hartmann's solution, or lactated Ringer's solution. Normal saline is a satisfactory alternative in many cases, but the relatively high concentration of chloride ions in saline can aggravate a preexisting metabolic acidosis through raising chloride concentration, producing a hyperchloremic metabolic acidosis (HCMA), and therefore saline should be used sparingly. In calves with severe metabolic acidosis, use of fluids containing sodium bicarbonate is indicated. In horses, it is best not to include large quantities of sodium bicarbonate in fluids unless there is laboratory evidence that a significant strong ion metabolic acidosis exists (such as hyperchloremia). Flow rates for administering isotonic

VetBooks.ir

BOX 7.5

Toxic Causes of Diarrhea in Ruminants[a]

Arsenic poisoning
Sulfur poisoning
Salt poisoning
Propylene glycol
Levamisole
Monensin, salinomycin, lasalocid (ionophores)
Polybrominated biphenyl
Sodium bicarbonate
Aflatoxin
Herbicide
Zinc
Lead
Phosphorus toxicity
Nicotine (Black Leaf 40) toxicity
Copper
Chlorpyrifos (Dursban)
Organophosphates
Phosphate fertilizer
Lincomycin
Trichothecene (T-2 toxin)
Plant toxins
Oak (acorn poisoning)
Senna occidentalis (coffee weed)
Selenium accumulators
Slaframine (blackpatch-diseased legumes, slobber factor)
Mycotoxicoses
Helenium (sneezeweed, bitterweed)
Solanum (nightshade)
Pyrrolizidine alkaloid (*Senecio, Crotalaria, Amsinckia* species)
Brassica (mustards, crucifers, cress)
Oleander poisoning
Japanese yew (*Taxuscuspidata*) poisoning
Whitehead (*Sphenosciadium capitellatum*)
Pokeweed (*Phytolaccaamericana*)
Mushroom
Inkweed (*Drymariapachyphylla*)
Tung tree (aleurites)
Chinese tallow tree
Kalanchoe (crassulaceae)
Fungal toxicity
Sesbania (rattlebox)
Gutierrezia (broomweed, snakeweed)
Hypericum (St. John's wort; Klamath weed) poisoning
Agrostemma githago (corn cockle) poisoning
Monkshood
Buttercup
Castor bean (ricin)
Foxglove (digitalis)
Larkspur

[a]See additional lists at www.vet.cornell.edu/consultant.

intravenous fluids should be monitored, with close attention to perfusion parameters, in order to avoid fluid overload, pulmonary edema, and excessive diuresis. When the patient is shocky, flow rates close to 20 mL/kg/h or faster may be required for the initial administration of isotonic crystalloid fluids, but in general rates below 5 to 10 mL/kg/h are desirable, especially once hypovolemic shock has been addressed. Fluid overload is detrimental, and therefore frequent reassessment of the patient should be made. Hypertonic saline (7% NaCl) may be given rapidly intravenously at a dose of 4 to 5 mL/kg once. When a colloid fluid is required to combat low plasma protein concentrations, hetastarch or plasma can be used. Hetastarch is available as 6% hetastarch in a balanced electrolyte or normal saline solution. A dose of 10 mL/kg should not be exceeded for hetastarch because of development of dose-dependent coagulopathies. The use of hetastarch in human critical care has recently been questioned. A meta-analysis has suggested an increase in renal disease and mortality in patients treated with hetastarch.[9] How this applies to large animals is unknown, but creatinine should be monitored closely. See Neonatal Diarrhea, Chapters 17 (section on Neonatal Foals) and 20 (section on Neonatal Ruminants); Fluid and Electrolyte Balance, Chapter 22; and Fluid Therapy, Chapter 44 for more details on fluids and acid-base balance.

Approach to Diagnosis of Diarrhea in the Horse
(for Neonates, See Chapter 17)

1. Take history. Especially note change in diet, deworming program, housing and management, and whether diarrhea is acute or chronic. Note appetite, whether animal is drinking an adequate volume of water, and whether salt is available. Note whether it is a single or multiple case, if there are concurrent diseases, or if other medications or exposure to toxins are involved. Most antimicrobials have been associated with diarrhea in horses at times, but especially lincomycin and erythromycin. Antimicrobials should be discontinued if diarrhea develops during administration. Most pathogenic bacterial and protozoal agents rely on altered intestinal microflora to proliferate in the gut and cause diarrhea. Note whether nonsteroidal anti-inflammatory drugs such as phenylbutazone were used before the development of diarrhea. Many causes of diarrhea can be eliminated from consideration on the basis of history. Find out about housing and whether animals have access to pasture or natural water sources or are stall confined. For example, Potomac horse fever would be considered in horses with access to or living near water sources in endemic areas.
2. Perform physical examination. Take vital signs (these are often normal in chronic cases). Perform rectal examination unless an infectious contagious agent is suspected, especially if diarrhea is scant in volume. Note body condition score (see Chapter 9). Systemic signs of endotoxemia, SIRS, hypovolemia, and dehydration often accompany acute colitis, including salmonellosis, equine monocytic ehrlichiosis (Potomac horse fever), clostridiosis, and many other acute diseases.
3. Examine feces. Perform gross inspection; note whether blood or fibrin is present (see list of causes of dysentery).
   a. Gram stain of feces. A predominance of gram-positive rods may indicate an anaerobic overgrowth such as occurs with *C. difficile* infections, although this is not highly sensitive or specific. Perform microscopic examination for ova and protozoa, especially for chronic cases.
   b. Perform multiple cultures for *Salmonella*, *C. difficile*,[10] and *C. perfringens* if onset is acute, if animal is febrile, or if feces contain fibrin and mucus. A commercial polymerase chain reaction (PCR) test can be used as an aid to evaluate for the presence of salmonellosis.[11] Cultures for *C. difficile* should be performed on selective media (cycloserine-cefoxitin-fructose agar). Recently *Brachyspira pilosicoli* has been isolated from the feces of weanlings with chronic diarrhea.[12] This agent warrants further investigation as a cause of diarrhea and failure to thrive in young horses. Fecal PCR and serology for *Lawsonia intracellularis* should be performed on young

VetBooks.ir

horses (including young adults) with hypoproteinemia, unthriftiness, and variable diarrhea.

c. An evaluation for *C. difficile* and *C. perfringens* toxins (with fecal enzyme-linked immunosorbent assays [ELISAs] or a stool cytotoxin assay for *C. difficile*) should be made if the diarrhea is temporally associated with antibiotic administration. Several ELISA kits are available for identification of toxins A (enterotoxin) and B (cytotoxin) of *C. difficile* in feces. A stool cytotoxin cell culture is available for toxin B.[13,14] Toxin B cell culture testing is considered the gold standard.[15]

d. Isolates of *C. perfringens* should be examined for the ability to produce alpha, beta, epsilon, and beta 2–toxins because certain strains may be associated with gastrointestinal disease.[16,17] Type C *C. perfringens* isolates have been associated with the most severe disease in horses and foals and elaborate both alpha and beta toxin. Gene sequences for these toxins are found by PCR once the isolates are cultured. Commercial veterinary diagnostic laboratories now offer PCR for the *C. perfringens* gene sequences directly in horse feces as part of diarrhea PCR panels. In addition, a commercial fecal ELISA is available for detection of alpha-toxin, beta-toxin, and epsilon-toxin in feces directly at the California Animal Health and Food Safety Laboratory (San Bernardino). This allows diagnosis of *C. perfringens*, types A (alpha toxin) and C (alpha and beta toxins). Recently, NetFtoxin-producing type A *C. perfringens* isolates have been linked to severe, necrotizing enterocolitis in foals.[18]

e. Fecal occult *blood* (if positive, see list of causes of melena and blood in feces).

f. Fecal osmolality, sodium, and potassium concentrations (optional). Electrolyte concentration in feces is roughly twice the sodium plus potassium. When this value is much lower than the measured osmolality of the feces, the difference is an osmolar gap caused by osmotically active nonelectrolytes such as lactose, and osmotic diarrhea is confirmed.

g. Check for sand by placing some feces in a bucket of water or rectal palpation sleeve, mixing thoroughly, and decanting the water or inspecting the bottom for sedimentation of sand. If a radiographic unit with the appropriate power capability is available, abdominal radiographs should be taken to detect the presence and amount of sand. Ultrasound of the ventral abdomen can be used to diagnose the presence of sand, although this requires considerable expertise.

A PCR test for feces is available at University of Minnesota Diagnostic Laboratory at www.vdl.umn.edu and the University of California Molecular Laboratory at www.vetmed.ucdavis.edu/vme/taqmanservice/ (see Chapter 29 for complete list) for detection of *L. intracellularis*, organisms in weanlings and yearlings with diarrhea, weight loss, general malaise, and hypoalbuminemia.[19] Also see serum test described later. Young adult horses can also develop disease from *Lawsonia*.[20]

h. *Rhodococcusequi* can cause diarrhea in 3-week to 6-month-old foals. Diagnostic tests include cultures of transtracheal aspirates, abdominal fluid cytology and culture, abdominal ultrasonography, and ruling out other etiologies of diarrhea. Fecal PCR should also be performed.[21]

i. If all other cultures are negative and an infectious cause of diarrhea is suspected, the feces should be cultured for *Aeromonas* species and *C. perfringens* (see earlier).[22,23]

4. Obtain blood for the following database:

a. Complete blood count (CBC; includes fibrinogen and plasma protein concentrations). Increased fibrinogen concentration indicates inflammation. Decreased protein concentrations indicate protein-losing enteropathy. Thrombocytopenia may indicate a coagulopathy. Neutropenia with or without a toxic, left shift (immature neutrophilia) is often present with infectious and inflammatory causes of acute colitis, indicating SIRS. Increases in packed cell volume (PCV) and red cell mass are often present, indicating hemoconcentration and/or splenic contraction in horses.

b. Acid-base analysis should be performed if the condition is acute and the horse is dehydrated or toxic. Although acid-base values are not useful diagnostically in terms of specific etiology, they allow for initiation of proper acid base and electrolyte supportive therapy.

5. Test serum for the following:

a. Electrolyte (Na, K, Cl, Mg, Ca, HCO_3) concentrations, including ionized calcium.

b. Serum creatinine and blood urea nitrogen (BUN) concentrations—prerenal azotemia is common as a result of dehydration; check again after rehydration. Acute kidney injury is also common. Serum chemistries should be evaluated for liver and other organ disease. Liver enzymes are frequently elevated during and for a period following acute toxic diarrhea.

c. Albumin and globulin concentrations; hypoalbuminemia is seen with chronic protein-losing enteropathies such as inflammatory bowel disease (e.g., granulomatous enteritis), phenylbutazone toxicity (right dorsal colitis), hypobiotic cyathostomiasis, *Lawsonia intracellularis* infection, and acute colitis conditions (such as salmonellosis).

d. Specific immunoglobulin (Ig) A, IgM, and IgG concentrations; immunodeficient individuals may have chronic diarrhea. Specific immunoglobulin concentrations may be altered with lymphoma or multiple myeloma. Elevated globulins may indicate the presence of chronic disease.

e. PCR for *Neorickettsia risticii* (Potomac horse fever) in whole blood and feces samples. Both blood and feces should be tested, in order to increase the sensitivity of detection. Paired sera for *Neorickettsia risticii* titer following acute diarrhea with fever can also be performed, but this is rarely performed since availability of PCR testing.

f. Clotting times (prothrombin time [PT] and partial thromboplastin time [PTT] or activated clotting time [ACT]) should be monitored as indicators of coagulopathies such as disseminated intravascular coagulation (DIC) in horses with acute typhlocolitis. Antithrombin concentrations can be monitored for the risk of thromboses, particularly in horses with hypoproteinemia.

6. Perform abdominocentesis, especially if signs of colic are present. Evaluate cytology, protein, and fibrinogen values in chronic cases to rule out peritonitis, tumors, and mesenteric abscess.

7. Perform function and absorption tests in chronic diarrhea cases, especially when weight loss is present.

a. Oral glucose or xylose small intestine absorption tests (see Chapter 32) for chronic cases, particularly if a high index of suspicion of malabsorption exists because of hypoalbuminemia. If tests indicate malabsorption, either biopsy the gut (duodenum through duodenoscopy) or rectum or assess the response to treatment following larvicidal anthelmintic treatment.

b. Perform liver function tests such as measurement of serum bile acid concentrations if liver involvement is suspected as a result of increased liver enzyme concentrations and/or hypoalbuminemia. Liver enzymes are increased in many cases of enterocolitis and in these cases do not necessarily indicate primary liver disease (see Chapter 33). Secondary liver disease may occur secondary to endotoxemia or altered hemodynamics, as well as cholangiohepatitis.

8. Examine tissue.
   a. Rectal or intestinal (duodenal) biopsy for microscopic examination and fluorescent antibody for immune-mediated diseases (also culture for *Salmonella*). Rectal mucosal histopathology is particularly useful in horses with hypoalbuminemia or weight loss.[24]
   b. Detection of *C. perfringens* beta 2–toxin from type A or beta toxin from type C isolates can be performed by immunohistochemistry of gut mucosa and is diagnostic on biopsy or postmortem specimens.[25] NetF toxin is a recently recognized virulence factor in some type A isolates[18].
   c. Liver biopsy if indication of significant or persistent liver disease, especially in chronic cases.
9. Toxicology.
   a. Blood lead, liver lead, and liver arsenic concentrations can be measured if toxicity is suspected.[26]
   b. High-pressure liquid chromatography or gas chromatography-mass spectrometry can be used to detect cantharidin (blister beetle toxin) in urine or gastrointestinal contents in endemic areas or when hay is imported from those areas.[23,27]
   c. Urine, serum, and gastrointestinal contents can be evaluated for the presence of oleandrin toxins using thin-layer chromatography. Oleander toxicity should be suspected in animals with diarrhea, colic, arrhythmias, and renal disease.[28]
10. Evaluate response to treatment with undiagnosed chronic diarrhea.
   a. Alter diet to simple grass hay. Alternatively, a complete pelleted diet can be tried, especially if right dorsal colitis or maldigestion/malabsorption is suspected, as well as in horses that are normal clinically and have normal clinicopathologic results, but that have increased fecal water. Psyllium mucilloid (4 oz), and 1 to 2 cups of corn oil can be added to the daily diets of horses with right dorsal colitis.[29,30]
   b. Stop nonsteroidal drugs such as phenylbutazone if right dorsal colitis is a possible cause of loose feces.
   c. Transfaunation with fecal (or colon or cecum if available) contents from a healthy animal that has been tested negative for Salmonella and other fecal pathogens can be tried, especially when dysbiosis of the microbiome is suspected.
   d. Attempt to classify by rectal biopsy; many changes are nonspecific.

      If lymphocytic, lymphoplasmacytic, or granulomatous enteritis is diagnosed: Administer 0.04 to 0.06 mg/kg IM or IV dexamethasone per day, tapering down to 0.02 mg/kg in 5 to 7 days; if response is favorable, continue with 1 to 1.5 mg/kg prednisolone PO per day, taper over 2 months.

      Eosinophilic infiltrate: Administer larvicidal anthelmintic dose of fenbendazole plus corticosteroids.
   e. Transfusion with plasma (1 to 2 mL/kg) in young horses 2 to 12 months of age that may need some additional proteins, antithrombin, or immunoglobulin. Synthetic colloids such as hetastarch can be used in animals with reduced colloid osmotic pressure (hypoalbuminemia); check especially if edema is present. Hetastarch (6%) has been used at 10 mL/kg, and this dose should not be exceeded daily because of risks of dose-dependent coagulopathies.[31] Hetastarch has been associated with adverse effects in human patients, including renal injury and mortality in some studies.[9]
   f. Horses with Potomac horse fever often respond favorably to systemic treatment with tetracycline.
   g. Metronidazole (15 mg/kg PO q 8 h) can be used empirically, especially if an anaerobic overgrowth is suspected, *C. difficile* or *perfringens* has been diagnosed, or when the diarrhea is secondary to antibiotic use.[32] Metronidazole can be administered intravenously in horses with reflux.

Approach to Diagnosis of Diarrhea in Ruminants
(for Neonates, See Chapter 20)

1. Take history. Especially note diet, appetite, previous deworming and vaccinations, and whether it is an individual or herd problem. In animals younger than 1 year of age, *Coccidia*, *Ostertagia*, or other helminths should be strongly considered. Determine if onset is acute or chronic. If chronic, first consider diseases such as parasitism, Johne's disease, copper deficiency (molybdenosis), selenium deficiency, liver failure, and other diseases of individual cows such as bovine leukosis virus (BLV), amyloidosis, heart failure, or uremia.
2. Perform physical examination. Especially note weight loss, fever, systemic signs, rumen activity, and oral lesions. Perform rectal examination. In most acute-onset diseases, vital signs are abnormal and systemic involvement or oral lesions (especially with BVD) may be obvious.
3. Examine feces.
   a. Gross inspection
   b. Microscopic examination for ova and parasites
   c. Culture for *Salmonella* if animal is febrile or feces appear inflammatory (fibrin or mucus)
   d. Check for fecal occult blood
   e. Culture or other diagnostic test for *Mycobacterium avium* subsp. paratuberculosis, if weight loss is a problem (especially if a herd problem in animals older than 2 years of age)
4. Take rectal scrapings of mucous if weight loss and chronic diarrhea are present.
   a. Make thin smear on glass slide for acid-fast staining for *M. avium* subsp. paratuberculosis. Examine under oil immersion lens
5. Test for BVD if any oral lesions or other relevant clinical signs. See Chapter 32 for available tests.
6. Obtain blood for the following:
   a. Plasma proteins
   b. Fibrinogen
   c. In acute cases, electrolytes and acid-base status
   d. If a herd problem, copper and selenium status
7. Test serum for the following:
   a. BUN
   b. Liver enzymes (γ-glutamyltransferase [GGT] and sorbitol dehydrogenase [SDH])
   c. Albumin and globulin values
   d. Agar gel immunodiffusion (AGID) for BLV (single animals); request gp51 and p24 antibody status (see Chapter 37).
   e. If Johne's disease is suspected, perform ELISA test or other relevant test (see Chapter 32).
8. Perform paracentesis. Paracentesis rules out gross peritonitis, but many false-negatives are possible as a result of focal or fibrinous peritonitis.
9. Perform urinalysis for protein to rule out consideration of amyloidosis or other multisystemic immune-mediated disease. Because ruminants normally have a urine pH of 8 or higher, most dipstick tests will give a trace or a 1+ positive reading for urine protein even when the animal's urine is normal.
10. Examine tissue. Perform rectal, intestinal, or mesenteric lymph node biopsy for acid-fast stain for Johne's disease, for culture for *Salmonella*, BVD, and for presence of lymphosarcoma.
11. Perform feed analysis (herd problem only); check copper, molybdenum, and selenium levels.
   a. Toxins suspected (e.g., mercury, arsenic)

VetBooks.ir

12. Tap abomasum for increased pH; rule out type II ostertagiasis.
13. Perform necropsy (herd problem only).
    a. Pick severely affected individual to examine thoroughly.

VetBooks.ir

Colic

K. Gary Magdesian • Bradford P. Smith

Colic is defined as the manifestation of visceral abdominal pain. Colic may be the result of nongastrointestinal pain such as urinary tract obstruction (Boxes 7.6 and 7.7). This section discusses colic of gastrointestinal origin. Pain may be acute, chronic, or recurrent. Gas distention or recognizable organic problems such as displacements are most frequently associated with acute colic. Five basic causes of colic in large animals are as follows:

- Distention of gut with fluid, gas, or ingesta
- Pulling on the root of the mesentery (mesenteric tension)
- Ischemia or infarction
- Deep ulcers in the stomach or bowel
- Peritoneal pain (peritonitis)

Signs of colic in the horse include restlessness, lying down and getting up, groaning, grunting, rolling, sweating, kicking at the abdomen, or suddenly dropping to the ground in pain. Anorexia and depression often accompany these signs. Horses may develop hypovolemic or endotoxic shock characterized by tachycardia with weak pulse quality and prolonged capillary refill time, cold extremities, and bright red (vasodilatory phase) followed by dark or pale (vasoconstrictive phase or low cardiac output state) mucous membranes if the problem is severe and affects cardiovascular integrity.

Evidence of shock is usually present only when the disease condition is severe and involves ischemic or infarctive disease (volvulus, torsion, thromboembolism) or advanced visceral distention (extreme flatulence, impaction, or dilation). Foreign bodies such as sand or enteroliths in the large colon may result in low-grade recurrent colic. When an enterolith is passed into the transverse colon where it obstructs the bowel, signs of complete obstruction and acute colic ensue. These signs are manifestations of visceral pain, mediated by the sympathetic nervous system. External palpation and pushing on the abdomen of adult horses do not usually elicit pain unless the affected inflamed or dilated viscus is contacted.

In contrast, parietal pain associated with peritonitis is sometimes responsive to external palpation. Whereas the animal with visceral pain shows active signs of colic, the animal with parietal pain is usually reluctant to move and has a splinted abdomen. Acute peritonitis occurs within minutes after rupture of the stomach or perforation of an ulcer as a result of immediate irritation of serosal surfaces by the acid contents, whereas with rupture of the colon or rectum it may take several hours or more before peritonitis is clinically apparent.

Ruminants exhibit colic less frequently than horses, probably because of a higher threshold for pain and because dietary shifts principally affect the rumen; thus intestinal gas pains occur less frequently. Colic with visceral pain (including urinary tract) is manifested by grinding the teeth (odontoprisis or bruxism), grunting or groaning, treading with the hind feet, kicking at the abdomen, restlessness, repeatedly lying down and getting up, anorexia, and depression. With parietal pain caused by peritonitis, ruminants demonstrate abdominal pain by arching the back, splinting, and exhibiting pain on deep palpation of the area. These signs are seen most commonly with traumatic reticuloperitonitis and perforating abomasal ulcers; rarely are these diseases associated with the colic signs described previously.

BOX 7.6

Gastrointestinal Causes of Colic in Horses[a]

Common Causes

Accumulation of intestinal, cecal, or colonic gas
Hypermotility and intestinal spasms
Feed impaction, constipation
Meconium impaction (newborn)
Gastric ulcers (foal)

Less Common Causes

Thromboembolism
Intestinal foreign body (sand; enterolith; phytobezoar)
Volvulus of small intestine
Pedunculated lipoma with bowel strangulation
Hernia, inguinal, epiploic, umbilical, diaphragmatic
Nephrosplenic ligament bowel entrapment
Ascarid impaction
Massive strongyle infection
Gastric dilation
Anterior enteritis (duodenitis or proximal jejunitis)
Enteritis, impending or active
Peritonitis
Parasympathomimetic drugs
Irritant cathartics
Necrotizing enterocolitis
Psychogenic colic
Rectal tear
Volvulus or displacement of large bowel
Rupture of stomach or intestine
Ileus
Intussusception

Uncommon Causes

Abdominal adhesions
Intramural hematomas of stomach or intestine
Stenosis or stricture of bowel lumen
Botulism
Tetanus
Potomac fever
Exhaustion
Anaphylaxis
Rhodococcus equi, gut abscesses
Cribbing or wind sucking
Abdominal fibroma
Segmental ischemic necrosis following mesocolic tearing
Equine viral arteritis
Anthrax with bleeding
Malignant edema (*Clostridium* species)
Malignant mesothelioma
Gastric or intestinal tumor
Atropine
Vitamin K3 deficiency (moldy sweet clover)

Toxins

(See also toxins listed under Diarrhea)
Cantharidin toxicity
Dioxin
Trichloroethylene-extracted feed toxicity
Warfarin (dicumarol)
Herbicides
Lead
Nitrophenyl urea (vacor)
Phenylbutazone or other nonsteroidal antiinflammatory drugs
Poison plants (many of those that produce diarrhea also produce colic; see plant toxins listed under Diarrhea)
African horse sickness (exotic)
Grass sickness (exotic)

[a]See additional lists at www.vet.cornell.edu/consultant.

VetBooks.ir

BOX 7.7

Causes of Colic in Ruminants[a]

Common Causes

Increased intestinal gas
Intussusception
Torsion or volvulus of the mesenteric root
Peritonitis
Intestinal foreign body or obstruction
Urolithiasis
Ruptured bladder
Acute pyelonephritis
Abomasal torsion
Abomasal ulcer
Cecal dilation or volvulus
Severe bloat

Less Common Causes

Cystitis or urinary tract disease
Abomasal bloat (neonates)
Uterine torsion or rupture
Hernia
Parturition, impending
Hypermotility and spasms of gut
Feed impaction
Right displaced abomasum
Acute traumatic reticulitis, abomasitis, or duodenitis
Acute liver disease
Vagal indigestion
Hemorrhagic bowel syndrome
Atresia coli (neonates)

Uncommon Causes

Rabies
Rectal tear
Rectal prolapse
Diaphragmatic hernia
Grain overload
Water intoxication
Winter dysentery
Ovarian abscess
Fat necrosis
Cholelithiasis
Intestinal adhesions
Enterotoxemia
Ileus
Intestinal strangulation
Inversion of uterine horn
Malignant edema
Malignant mesothelioma
Ruptured uterine artery
Intestinal neoplasia
Aortic, iliac, or femoral thrombosis
Anaphylaxis
Renal cysts
Ruptured prepubic tendon
Vaginal laceration
Torsion of descending colon
Rinderpest (exotic)[b]

Toxins

Plant poisonings (many of those that cause diarrhea also produce colic; see plant toxins listed under Diarrhea)

[a]See additional lists at www.vet.cornell.edu/consultant.

[b]Rinderpest was a cause of colic in ruminants until 2011, when it was eradicated worldwide.

BOX 7.8

Extraintestinal Causes of Colic in Horses

Common Causes

Mesenteric abscess
Ovarian tumor, abscess, or hematoma
Parturition
Acute hepatitis (massive necrosis) or hepatic lipidosis
Diaphragmatic hernia
Ruptured bladder (foal)
Uterine torsion

Less Common Causes

Urinary tract or renal disease, including urolithiasis
Pleuritis or pericarditis (referred pain)
Retained placenta
Uterine rupture or retroflexion
Spermatic cord thrombosis or torsion
Hypocalcemia

Uncommon Causes

Perirectal abscess
Pheochromocytoma
Purpura hemorrhagica
Biliary atresia
Vaginal or vulvar tear
Cholelithiasis
White muscle disease
Atypical myopathy
Rabies
Rupture of prepubic tendon
Splenitis, splenic abscess, splenomegaly
Cauda equina neuritis with retention of feces or urine

Diagnosis and Management of Colic in the Horse

(for Neonates, See Chapter 17)

1. Take history. Because colic is a common problem in horses, mild to moderate degrees of abdominal pain are often initially treated symptomatically with analgesics and/or laxatives before major diagnostic efforts are undertaken. Most colic of mild to moderate severity responds favorably to symptomatic treatment. In general, severe pain or pain that is unresponsive to analgesics indicates a more serious condition for which more aggressive medical management or surgical correction may be indicated. Recurrent mild-to-moderate colic may be an indication of a more serious problem such as bowel entrapment or displacement, thromboembolism, internal abscess, enterolith, sand or other foreign body, tumor, gastric ulcers, hypobiotic cyathostomiasis, *Strongylus vulgaris* larval migration, heavy burden of ascarids, abdominal adhesions, cholangiohepatitis, biliary stones, strictured bowel, or urinary tract disease.
2. Perform physical examination. Intestinal causes of colic can often be differentiated from colic associated with other organ systems (Box 7.8) by physical examination findings and laboratory data. Although extraintestinal origins of acute colic are relatively uncommon in the horse, they include abdominal abscesses, tumors, cholelithiasis or cholestatic disease, and genitourinary tract disease and can be recurrent. It is important to note the presence or absence of normal intestinal borborygmi and whether or not feces are being passed in determining whether the problem is extraintestinal. Careful auscultation of the thorax should be performed to evaluate for the presence of diaphragmatic hernias or pleural disease. The testicles should be palpated on all stallions to screen for scrotal hernias or testicular torsions. Rectal examination findings often help to determine anatomic location within gut or other site. Abdominal tumors, abscesses, and other masses may be

VetBooks.ir

palpable. Although mild to moderate chronic intermittent colic may be of extraintestinal or intestinal origin, most cases of severe, unremitting colic indicate gut involvement, often with anatomic displacement or ischemia.

3. Ultrasound and radiology. Ultrasound may help in locating masses, adhesions, or enlarged liver (see Abdominal Ultrasonography, Chapter 32). It may also be helpful in the diagnosis of gastrointestinal disease including nephrosplenic entrapment of the large colon, right dorsal displacement, and small intestinal distention. Detection of sand from the ventral abdomen may be possible. Ultrasound can be particularly useful in foals and small ruminants because of their size. Radiology can also be useful in detecting enteroliths or sand in adult horses and in some gastrointestinal conditions of foals, such as meconium impaction or sand enteropathy, provided powerful units are available. Rarely is radiology useful in diagnosing the cause of colic in ruminants, except for urethrographs in sheep and goats to locate a urethral stone.
4. Examine feces. Gross examination of feces should be performed. The presence of sand can often be detected by mixing feces with water in a bucket, then pouring off the water and looking for sediment. If no feces are passed, a more serious condition is usually indicated, particularly if intestinal sounds are absent.
5. Use laboratory aids. Laboratory aids of immediate benefit in diagnosis and management include measurement of PCV and plasma protein concentration to aid in assessing hydration and vascular integrity, as well as an abdominal paracentesis to evaluate abdominal fluid grossly and microscopically. Pain and excitement alone can increase the PCV in horses, but some studies indicate that there is a correlation of increased PCV (>55%) and nonsurvival in colic cases. Plasma proteins are not increased acutely unless blood volume is decreased through shifts in compartmental distribution of body fluids. In colic cases these fluid shifts usually mean that an increased and abnormal amount of extracellular fluid is in the gut lumen, a "third space" where it is not available for maintaining blood volume. Blood lactate concentration measurement has become routine in evaluation of horses with acute abdominal disease. It is useful in monitoring as an end point to fluid therapy, as well as of systemic inflammation and cell metabolic health. Some studies have suggested a prognostic role of lactate in horses with colic, although there is marked overlap between survivors and nonsurvivors. An increase in peritoneal lactate concentration over time has been predictive of strangulating lesions in horses with colic.[33]
6. Abdominal fluid is normally present in small volume (a few drops to 50 mL); is clear and colorless to yellow; and has a total protein concentration below 2.5 g/dL, specific gravity less than 1.015, little or no fibrinogen (<100 mg/dL), and fewer than 5000 white blood cells (WBCs) per microliter. Increases in these parameters often indicate inflammation on serosal surfaces (including colitis), strangulating lesions or ischemic compromise in colic cases. Comparisons of abdominal fluid glucose with serum glucose (>50 mg/dL difference is abnormal) and evaluation of abdominal fluid pH, lactate (as compared with blood lactate), and lactate dehydrogenase (LDH) concentrations can aid in the diagnosis of septic peritonitis.[34] Grossly, fluid changes to cloudy yellow, then to blood-tinged with fibrin clots, and finally to black in color as bowel necrosis and hemolysis of extravasated red blood cells (RBCs) occur. Increased levels of peritoneal fluid protein concentrations are consistently found in anterior enteritis (duodenitis and proximal jejunitis) and often disproportionate to the increase in white blood cell concentration; in these cases it therefore provides a useful differential aid, although this finding is nonspecific and observed with other conditions, such as in cantharidin poisoning. Increased protein levels are present in peritonitis but are accompanied by increased numbers of neutrophils as well. If peritoneal fluid is grossly contaminated with feed material, rupture of a viscus should be considered. Another peritoneal tap in a different location should be undertaken if the possibility of bowel penetration during paracentesis cannot be ruled out. It is not necessary to have abnormal peritoneal fluid before consideration of surgical correction of colic is contemplated. Recently, abdominal fluid lactate has been shown to be predictive of intestinal ischemia secondary to strangulating obstruction in colic cases and may aid in early detection of intestinal strangulation, rupture, and septic peritonitis.[35]
7. Plasma fibrinogen, as well as peripheral leukocyte counts, can aid in the differentiation of enterocolitis or anterior enteritis from strangulating lesions. Serum electrolyte concentrations and acid-base status are important from a therapeutic standpoint. Serum biochemistries including liver enzymes, creatinine, and BUN are important in evaluating for liver and renal compromise. Hyperglobulinemia may be indicative of chronic disease.
8. Evaluate response to treatment. The approach to diagnosis of colic signs is often tied in with management because if the animal's pain cannot be alleviated, surgical intervention and specific diagnosis of displacements, torsions or volvulus, internal hernias, masses, and adhesions are the next steps. The initial diagnosis considers the history of deworming and feeding. The findings of the physical examination including rectal examination and evaluation of the degree of pain determine whether additional laboratory workup is indicated. In many cases with mild to moderate pain and no evidence of shock, standard treatment includes parenteral administration of an analgesic agent such as flunixin meglumine (as long as the patient is hydrated) or butylscopolamine (see Chapter 3) and oral administration of a mild laxative such as mineral oil (4 to 8 mL/kg). When a nasogastric tube is passed, the stomach should be checked for reflux and decompressed as needed. The pH of the gastric reflux may indicate primary gastric dilation if acidic, or small intestinal blockage or ileus if alkaline. Dark brown, foul-smelling, and alkaline reflux is often associated with anterior enteritis (duodenitis and proximal jejunitis). If a significant amount of reflux is present, oral medications should be withheld. If cardiovascular function is impaired (poor mucous membrane color and capillary refill, weak pulse, cold extremities, impending shock), balanced, polyionic, and isotonic crystalloid fluids should be given intravenously at a rate of 10 to 20 mL/kg boluses until signs of shock abate or plateau. In addition, 4 mL/kg hypertonic saline can be administered as a rapid but transient treatment of shock. Large amounts of apparently painful gas that is auscultable in the right flank can be tapped and drawn off with cecal trocharization, although the risk for peritonitis should be considered and this technique should be reserved for when surgical exploration is not an option or is delayed. The principles of colic management include 1) control of pain, 2) relief of distention, 3) relief of obstruction, and 4) treatment of shock.
9. Perform exploratory surgery. In making a decision concerning management of colic, it is important to separate impending enteritis and peritonitis from bowel disease requiring surgical intervention. Anterior or proximal enteritis can result in prolonged moderate pain and requires constant or frequently repeated analgesic administration and gastric decompression of the foul-smelling, dark reddish-to-brownish stomach contents. However, pain often subsides and is replaced with depression after gastric decompression in horses with anterior enteritis, whereas horses with strangulating lesions often remain in pain. The presence of fever or decreased total WBC count (with neutropenia) may be an indication of

VetBooks.ir

impending or ongoing enteritis, in which case surgery may not be indicated.

Surgery is indicated in the following situations:

a. Pain is severe and intractable or nonresponsive/poorly responsive to analgesics.
b. Pulse is weak and rate is over 70 beats/min, and oleander or other cardiotoxicity and acute enterocolitis are ruled out.
c. Perfusion is poor, as evidenced by cold extremities, off-color mucous membranes, and poor capillary refill, and enterocolitis or toxicities are ruled out.
d. No gut sounds are auscultated (a lack of fecal production).
e. Bowel is markedly distended on rectal palpation or abdominal ultrasound.
f. Large volumes of yellowish alkaline gastric reflux are present.
g. Abdominocentesis indicates damaged bowel (blood tinged, increased protein, increased WBCs). When proximal enteritis remains a possibility, surgery should be avoided unless it is indicated to decompress bowel.

Surgery may be contraindicated in the following situations:

a. Fever
b. Neutropenia or marked neutrophilia
c. Severe icterus or marked enzyme abnormalities indicating primary liver disease
d. Foul-smelling, brownish-red gastric reflux characteristic of proximal enteritis (duodenitis/jejunitis), especially when removal of reflux results in discontinuation of signs of pain
e. Evidence of an extraintestinal cause not amenable to surgical correction (such as severe pyelonephritis) or hyperammonemia
f. Colitis, enterocolitis, or diarrhea
g. Abnormal behavior or neurologic signs (look for neurologic diseases and recent fluphenazine administration, and check blood ammonia concentrations)

Diagnosis and Management of Colic in Ruminants

1. Take history. Colic in neonates is most often associated with increased abomasal or intestinal gas and is discussed in Chapter 20. Perforating ulcers are not uncommon as a cause of colic in calves 1 to 6 months of age. It should be determined whether the onset of colic was acute or whether the colic is chronically recurrent. Few diseases cause recurrent colic in ruminants. Urolithiasis is the most common cause of colic in male or neutered male goats and sheep and occurs under varied dietary and environmental conditions. Urolithiasis in cattle occurs most frequently in bulls or steers eating high-grain diets, but silicate stones can occur in very young animals and animals on pasture diet.
2. Perform a physical examination. Take vital signs; with torsion or severe peritonitis, shock signs such as rapid heart rate (>90 beats/min), cold extremities, and weakness may be seen. Tympany can be detected by simultaneous auscultation and percussion. Such causes of colic as cecal dilation, bloat, free gas in the peritoneal cavity, and severe abomasal dilation can be diagnosed in this way (see Figs. 1.3 to 1.5). Rectal examination detects such abnormalities as gas in the cecum, uterine abnormalities, urinary tract disease, and intussusception. Observe animal urinating to rule out obstructive urolithiasis. Ultrasound examination of the abdomen is also useful (see Abdominal Ultrasonography, Chapter 32).
3. Examine feces. Observe grossly; intussusception usually has scant dark red (almost black) feces. Black tarry feces may also be seen with bleeding abomasal ulcer of some duration. Scant feces are seen with cecal dilation or displacement.
4. Check preputial hairs and urethral process for sediment and stones. Grit on the preputial hairs is often associated with urolithiasis. Observe animal urinating and check urine for abnormalities. Rule out pyelonephritis. Radiology and ultrasound can be useful in sheep and goats when urolithiasis is a consideration. Ultrasound can detect a distended bladder, and stones may sometimes be detected. Radiology (lateral view) may detect a stone in the urethra or stones in the bladder. A contrast urethrogram may also be diagnostic.
5. Perform paracentesis to look for peritonitis caused by perforated abomasal ulcer, serosal devitalization, intussusception, or ruptured bladder. Interpret as earlier for horses, except that normal peritoneal fluid protein concentration can go as high as 5 g/dL in ruminants.
6. Other laboratory aids such as CBC and clinical chemistries are seldom diagnostic in ruminant colic. If grossly abnormal, they may be grounds for formulating a poor prognosis. Intussusception may be associated with neutrophilia (as well as dark feces and colic) in cases where peritonitis is occurring.
7. Symptomatic treatment of colic includes analgesics and, if heart rate is over 90 beats/min, intravenous fluid therapy with a sodium-containing fluid. Take a blood sample for electrolytes and acid-base status before initiating fluid therapy.
8. Surgical exploration is indicated if colic is persistent, abdominal distention occurs, the heart rate is over 100 beats/min, feces are scant (especially those that are dark red and indicative of intussusception), there are pings indicating abomasal or cecal displacement or torsion, or the peritoneal fluid indicates bowel devitalization (blood-tinged fluid with elevated protein and WBCs). If surgical exploration is indicated, an important consideration is whether the animal will remain standing under local anesthesia during surgery. It is often best to perform abdominal surgery on animals with colic in left lateral or dorsal recumbency, aided by sedation and restraint, to avoid sudden collapse when painful surgical manipulations are performed. If the left lateral position is selected, use padding to raise the hip and shoulder so that the abdominal viscera can sit in a depression.

Melena

Bradford P. Smith

Melena (dark, tarry feces) is caused by blood in the lumen of the stomach or proximal intestinal tract, resulting in black (digested) blood appearing in the feces (Boxes 7.9 and 7.10). Usually blood is a result of a bleeding ulcer in the stomach or abomasum but may also result from ingestion, oral or pharyngeal bleeding, or coughing up blood that is then swallowed. In ruminants the presence of dark red feces from an intussusception is the main differential to be considered. Blood must stay in the intestinal tract for hours before the hemoglobin is altered and turns black. Small amounts of hemoglobin can be detected by using one of the tests for occult blood. In general, fairly large volumes of blood (1 to 2 L) are required to produce a positive fecal occult blood test in the horse (Carlson G, personal communication, 1990). A 24- to 48-hour time period is necessary for orally administered blood to reach the rectum in the horse. In ruminants, smaller volumes of blood are necessary to produce a positive fecal occult test, and a faster transit time is expected (Carlson G, personal communication, 1990).

In approaching a diagnosis, rule out pulmonary, oral, or pharyngeal bleeding. Bleeding of gastrointestinal origin can be determined to be caused by mucosal disease or full-thickness bowel disease (such as an intussusception or neoplasia) by examining peritoneal fluid for abnormalities. Abnormalities in peritoneal fluid are usually present in the case of serosal

VetBooks.ir

BOX 7.9

Causes of Melena in Horses

Common Causes

Gastric or duodenal ulcer
Gastric squamous cell carcinoma
Coughing up and swallowing blood

Less Common Causes

Phenylbutazone toxicity (nonsteroidal antiinflammatory drugs [NSAIDs])
Purpura hemorrhagica
Gastroenteritis with bleeding
Warfarin toxicity or other coagulation disorder
Colonic hematomas
Disseminated intravascular coagulation with mucosal hemorrhage
Anterior or proximal enteritis (duodenitis or proximal jejunitis)
Arsenic toxicity
Hepatic failure with hemolysis
NSAID toxicity

Uncommon Causes

Lupus erythematosus
Factor VIII deficiency, hemophilia A
Histoplasmosis
Hemangiosarcoma
Snake bite

BOX 7.10

Causes of Melena in Ruminants

Common Causes

Abomasal ulcer
Intussusception

Less Common Causes

Lung abscess with ruptured blood vessel
Oak toxicity
Coccidiosis
Gastroenteritis with bleeding
Arsenic toxicity
Ingestion of blood after parturition
Intestinal parasites
Toxicity from nonsteroidal antiinflammatory drugs
Abomasal torsion or volvulus
Hemorrhagic bowel syndrome

Uncommon Causes

Duodenal ulcers
Hemophilia A, factor VIII deficiency
Bacillary hemoglobinuria
Sulfur toxicity
Warfarin poisoning or other coagulation disorder
Snake bite
Bovine viral diarrhea
Malignant catarrhal fever
Winter dysentery
Narthecium asiaticum maxim poisoning (exotic)

involvement. Bleeding abomasal ulcers are probably the leading cause of melena in ruminants. They can be silent except for the dark feces and weakness if severe anemia develops. In older horses, gastric squamous cell carcinoma is a frequent cause of gastric hemorrhage. Significant bleeding is much less common in foals and calves with gastric ulcers, and melena is rare in foals and calves with gastric ulcers.

Consideration should be given to whether or not the melena is the result of clotting abnormalities associated with such diseases as DIC or warfarin poisoning. In cattle with colic and dark red-to-black feces, intussusception should be considered likely.

When severe anemia develops, there is evidence of blood loss because the decrease in PCV and RBCs is accompanied by a decrease in plasma proteins. Nonspecific therapy for melena consists principally of blood transfusions in life-threatening cases. Sudden, massive gastric or abomasal bleeding may result in anemia and collapse before melena has appeared.

In the foal, gastric ulcers may be treated with histamine-2 (H2) blockers such as ranitidine or cimetidine, or with hydrogen pump blockers. The H2 blockers are probably less effective in ruminants. Their benefit in ruminants with abomasal ulcers is not well understood at present. Drugs such as the hydrogen pump blocker omeprazole are useful and potent gastric pH effectors. Therapy with protectants such as sucralfate (which coats the ulcer) is a viable and clinically useful therapy in the horse. In ruminants, orally administered protectants and antacids are so diluted by the time they reach the abomasum that they are probably of limited benefit.

Blood, Fibrin, and/or Mucus in Feces (Dysentery)

Bradford P. Smith

Bloody diarrhea is termed *dysentery*. The presence of fresh blood or clots in the feces is termed *hematochezia* and is the result of bleeding into the distal intestinal tract. Occasionally blood from the female reproductive tract may appear in or on the feces. Fibrin indicates severe inflammatory bowel disease. Fibrin appears as casts, chunks of yellow-gray material, or mucosa-like sheets. Mucus in feces increases with inflammatory bowel diseases such as salmonellosis. It is often seen when fecal volume is small in animals that are anorectic, in which case the feces are often coated with mucus. This mucous coating can become obvious in the horse and is not a sign of bowel disease in this case.

Frank blood in feces without diarrhea and other evidence of gastrointestinal dysfunction or systemic illness may be a result of a bleeding disorder, a traumatic foreign body, rectal examination trauma, sadistic rectal trauma, or rectal trauma in a mare from a stallion penetrating the rectum (Boxes 7.11 and 7.12). Many of the diseases listed as causes of melena may also result in gastrointestinal hemorrhage and are therefore listed in both places. If the bleeding is in the distal gastrointestinal tract, fresh blood may be seen in the feces. With diseases midway down the tract, such as intussusception, fecal material is dark red and may appear black until a sample is examined closely and spread on a white surface.

Abdominal Distention and Constipation

Bradford P. Smith

Abdominal distention may be caused by feed, fluid, gas, feces, or a neoplasm (Boxes 7.13 and 7.14). Pregnancy or extreme obesity may also result in an enlarged abdomen. The physical examination should determine which of these is the most likely cause. Often in ruminants the distention can be seen as primarily left sided, right sided, or bilateral. For example, bloat in ruminants results in a characteristic high left-sided gas distention. It may be primary or associated with vagal indigestion, tetanus, or hypocalcemia. With vagal indigestion the rumen

Causes of Blood, Fibrin, or Mucus in Feces of Ruminants

Common Causes

Foreign body
Intussusception
Coccidiosis
Salmonellosis

Less Common Causes

Rectal tear or trauma
Rectal examination trauma
Volvulus, root of mesentery
Malignant catarrhal fever
Enterotoxemia
Bovine viral diarrhea
Arsenic toxicity
Abomasal torsion
Warfarin poisoning or other coagulation disorder
Castor bean *(Ricinus)* poisoning
Tung tree *(Aleurites)* poisoning
Solanum (nightshade, potato) poisoning
Sesbania (rattlebox) poisoning
Bracken fern

becomes enlarged and fluid filled, often giving a pear shape to the abdomen as it is viewed from the rear, or a pear shape on the right and an apple shape on the left ("papple" shape) if some degree of bloat is also present. Hypocalcemia and hypokalemia contribute to ileus and may result in constipation and abdominal enlargement. In sheep, abomasal impaction and enlargement associated with abomasal emptying defects can result in an enlarged abdomen with decreased food intake. When a mass (most commonly an abscess, a tumor, or fat necrosis [cattle only]) obstructs fecal passage, abdominal enlargement can become severe. With obstructive disease, some degree of colic is almost always present. A ruptured bladder results in a large fluid-filled abdomen, but constipation is not an obvious sign.

BOX 7.13

Causes of Abdominal Distention and Constipation in Horses

Common Causes

Ileus impaction
Intestinal foreign body such as enterolith (see Colic)
Peritonitis
Intestinal obstruction, impaction, or gas (see Colic)
Necrotizing enterocolitis (foals)
Torsion or volvulus of gut (see Colic)
Sudden decrease in exercise

Less Common Causes

Pregnancy
Pelvic mass (abscess, tumor)
Cecal tympany (see Colic)
Hernia, obstructive (see Colic)
Intussusception (see Colic)

Uncommon Causes

Anticholinergics
Opiates
Intrinsic colonic nerve dysfunction
Anorectal pain
Perineal hernia
Hypokalemia
Tetanus
Hypocalcemic tetany
Intramural hematomas on gut
Propylene glycol toxicity
Grass sickness (exotic)

The most common causes of decreased fecal output in ruminants and horses are decreased feed intake and dehydration. In such cases the animal will appear gaunt or have a relatively empty abdomen or rumen. Horse feces in cases of prolonged transit are often covered with a layer of tenacious, thick, yellow mucus. When a functional obstruction (ileus, vagal indigestion) or physical obstruction (impaction, foreign body, displaced intestine, fat necrosis) occurs as a cause of constipation, the abdomen is more likely to appear normally full or to become distended. Rectal examination is of great help in determining whether a mass or an obstruction exists because loops of distended small bowel can sometimes be palpated in the latter case.

Radiographs and ultrasound may be valuable to help determine the cause of abdominal distention in foals, calves, and small ruminants. Increased gastrointestinal gas may result in abdominal distention. Abomasal bloat and necrotizing enterocolitis in young animals may best be confirmed with lateral abdominal radiographs.

Dehydration may also result in dry feces but not in abdominal enlargement. When constipation is present and feces are drier than normal, rehydration and correction of hypocalcemia, hypokalemia, and any existing acid-base abnormalities are important parts of correction of the constipation. Other nonspecific therapies for functional constipation include laxatives, cathartics, and cholinergic drugs. When treating constipation, which is usually a secondary problem, it is important to simultaneously attempt to diagnose the primary disease.

In ruminants, when abdominal distention involves the rumen or is caused by pregnancy or obesity, colic is absent. When abdominal distention is the result of obstruction from the pylorus distal, colic is usually present. Abdominal distention and constipation are frequently accompanied by colic in the horse, regardless of anatomic site involved (review the approach to colic).

Regurgitation and Vomiting

Bradford P. Smith

Regurgitation is the reflux of esophageal, gastric, or rumen contents into the mouth or nose. This may be caused by malfunction of the esophagus or, in ruminants, as part of the normal physiology for rechewing ingested plant fiber (Boxes 7.15 and 7.16). Vomiting is a coordinated, centrally (medulla) mediated event, usually preceded by nausea (inappetence), increased salivation, or retching. In vomiting the abdominal musculature contracts, the diaphragm is pushed caudally and the cardia relaxes. The medullary vomiting center can be stimulated by visceral afferent stimuli or through the chemoreceptor trigger zone. Most toxins and drugs that cause vomiting act by directly affecting the chemoreceptor trigger zone. Other than with toxins, most cases of feed returning to the mouth in large animals are examples of regurgitation rather than true vomiting. Vomiting is unusual in both ruminants and horses.

Although regurgitation is a normal phenomenon in ruminants, it is unusual to find excessive regurgitation as a sign of disease. Physical blockage of ruminoreticular outflow by a foreign body, warts, actinobacillosis, granulomas, or diaphragmatic hernia can cause rumen distention and excessive regurgitation after eating. An esophageal foreign body can cause irritation and result in regurgitation. Animals with facial paralysis may drool feed and saliva on the affected side; this should be differentiated from animals with excessive or abnormal regurgitation. Vomiting or forced regurgitation in ruminants is rare and is seen principally with the toxins listed.

Horses have such a marked tone at the cardiac sphincter that vomiting occurs only when extreme intragastric pressures develop, usually in small intestinal obstructive diseases or proximal enteritis. Vomiting in the horse thus often occurs with gastric rupture or terminally with shock. Stomach contents are usually pH 5 or below. Because it is a terminal event, vomiting in the horse is often grounds for rendering a poor prognosis. Abdominocentesis should be performed on a horse after vomiting to rule out gastric rupture. To avoid this sequence of events, decompression using a nasogastric tube should be performed in any horse with evidence of gastric distention (see approach to colic). Regurgitation and vomiting in horses

BOX 7.17

Useful Techniques in Diagnosing Cause of Regurgitation

- Passing of stomach tube
- Endoscopy of pharynx, guttural pouches, esophagus, and stomach
- Ultrasound examination of the cervical esophagus may be helpful
- Radiographs; plain films of pharynx, guttural pouches, esophagus, and stomach
- Radiographs, barium swallows, checking gastric emptying time in horse

most commonly occur from the nose rather than into the mouth because of the anatomy of the soft palate. With choke (esophageal obstruction), esophageal regurgitation from the nares consists of mixed feed and saliva.

In foals a few weeks to several months of age, milk returning from the nares is often associated with gastric ulceration, along with signs of colic, lying in dorsal recumbency, hypersalivation, and champing movements of the mouth. In advanced cases with duodenal ulcers, pyloric outflow can be obstructed by scarring, resulting in more pronounced signs. Foals 1 to 6 months of age are most susceptible to gastric ulceration.

Occasionally, neonatal foals without cleft palate have some mild degree of dysphagia with milk regurgitation from the nose for the first 24 to 48 hours of life, which spontaneously corrects. The cause of this is unknown, but it would appear to be a failure of normal swallowing events to be sufficiently strong or coordinated in the newborn. The major ruleout in these cases is cleft palate.

Approach to Diagnosis of Regurgitation and Vomiting

Evaluation of regurgitation or vomiting should include a history to determine possible exposure to toxins or poison plants, which is most likely when multiple animals are affected. Age of the animal limits some considerations; young animals are more prone to meningitis and central nervous system (CNS) trauma, and congenital problems such as esophageal diverticula and persistent right aortic arch are found only in neonates and may not manifest as choke or regurgitation until solid food intake is increased.

The physical examination can determine whether the problem is vomiting or regurgitation. In ruminants, regurgitation often occurs as a result of distention and overfilling of the rumen, resulting in an obviously distended abdomen. Painful pharyngeal lesions can also cause pharyngeal paresis, which results in gagging and regurgitating. In horses the most common causes of feed coming from the nares are spontaneous choke and pharyngeal paresis associated with guttural pouch lesions (see the dysphagia section later).

Physical examination should also include passing a stomach tube to determine whether any impediment to passage of ingesta is present (Box 7.17). Endoscopy is useful to visualize esophageal defects. Many endoscopes currently in use are not long enough to reach the stomach of the adult horse. Endoscopy of the rumen is rarely diagnostic because it is almost impossible to empty it adequately to allow for visualization of a lesion. Ultrasound of the cervical esophagus may also be useful.

In horses and small ruminants, radiography, particularly barium contrast studies, can be useful in detecting esophageal abnormalities. In foals, prolonged gastric emptying time may be diagnosed from contrast studies. Normal emptying and movement of contrast media into the small bowel occur in less than 2 hours; contrast media reach the large bowel by 3

hours. Radiography may also be useful in detecting diaphragmatic hernia.

The most significant complications of regurgitation and vomiting include aspiration pneumonia, dehydration, and electrolyte imbalances. The marked hypochloremic alkalosis common to most monogastrics is rare in horses and occurs in ruminants mainly with internal vomiting (one type of vagal indigestion) associated with reflux of abomasal contents back into the rumen.

Vomiting, like diarrhea, is often an attempt by the body to rid itself of a noxious or toxic substance. Antiemetics are therefore rarely indicated in vomiting of central origin and rarely effective in regurgitation in large animals.

Dysphagia (Including Feed From Nares and Excessive Salivation)

Bradford P. Smith

Dysphagia is used here to refer to abnormalities of prehension, mastication, or swallowing. It is associated with diseases of the mouth, lips, teeth, pharynx, esophagus, mandible, or masseter muscles or, in the case of neurologic problems, with central or peripheral lesions resulting in malfunction in these areas. Diseases resulting in erosions, ulcers, swellings, crusts, or growths in or on the lips, mouth, or pharynx are discussed under a separate heading. Painful causes of dysphagia such as dental problems require differentiation from oral lesions such as ulcers.

The causes of dysphagia can be divided into three clinical categories: 1) pain induced, 2) neurologic, and 3) obstructive (Boxes 7.18 and 7.19). A fourth category is mechanical interference with prehension and swallowing, but this usually manifests in a manner resembling the manifestation of painful lesions. Particularly in horses, worn, missing, capped, abscessed, overgrown, or broken teeth often result in mechanical interference with chewing, resulting in half-chewed feed being dropped from the mouth (quidding). Observation of the animal as it attempts to eat and a good physical examination including oral inspection and passage of a stomach tube to rule out choke are essential in determining the cause of dysphagia. Use of a fiberoptic endoscope to visualize the pharynx, guttural pouches, and esophagus may be helpful. Plain film radiographs and barium swallows may also be indicated to see functional abnormalities in the guttural pouches, pharynx, and esophagus during swallowing and to rule out fractures of the hyoid or mandible. Ultrasound should also be employed.

Pain is probably the most frequent cause of dysphagia in ruminants and horses. Oral lesions, oral foreign bodies, and poor teeth result in decreased feed intake, in increased salivation, and often in dropping feed from the mouth while attempting to chew. Dental problems are relatively common in sheep and goats. In cattle, pharyngeal injuries from balling guns and paste wormers can result in severe pharyngeal cellulitis, which is manifested by an extended head, ptyalism, foul breath, and a painful, externally palpable pharyngeal swelling. Mandibular fractures must be ruled out by careful examination because even nondisplaced unilateral mandibular fractures can result in weak jaw tone, reluctance to eat, and drooling.

When dysphagia is associated with loss of large amounts of saliva, metabolic acid-base and electrolyte disorders may develop. Cattle and sheep have saliva high in sodium (136 to 201 mEq/L) and bicarbonate (108 mEq/L), with potassium and chloride values in the 14 to 15 mEq/L range.[36,37] As a result, losses of large amounts of saliva can result in hypovolemia and severe metabolic acidosis. In contrast, horses have relatively high levels of salivary chloride (48 to 82 mEq/L) with relatively low salivary bicarbonate (44 to 52 mEq/L). Equine salivary potassium is 14 to 18 mEq/L, and sodium is 54 to 90 mEq/L.[38,39] As a result, horses with esophageal fistulas that have lost saliva have a transient metabolic alkalosis.[38]

In the horse a common cause of acute dysphagia is choke (esophageal obstruction), followed in frequency by pharyngeal

BOX 7.18

Causes of Dysphagia in Horses

Pain

Tooth root abscess or periodontal disease
Worn, missing, capped, overgrown, or broken teeth
Foreign body in mouth, pharynx, nose
Oral vesicles, erosions, ulcers, or growths
Pharyngeal abscess, cellulitis, trauma, fistula, or neoplasia
Esophageal choke, trauma
Strangles
Rupture of rectus capitus ventralis muscle
Snake bite
Oral, mandibular, or maxillary fracture, neoplasia, or granulomas
White muscle disease
Epiglottiditis, epiglottic cysts
Trauma or excessive traction to tongue
Hyoid bone injury
Nasal mass (granuloma)
Neurogenic dysphagia

Obstruction

Pharyngeal abscess, cellulitis, trauma, fistula, or neoplasia
Esophageal choke, trauma, megaesophagus
Strangles
Rostral displacement of palatopharyngeal arch
Damaged or abnormal esophagus
Cleft palate
Dorsal displacement of soft palate
Epiglottiditis, epiglottic cysts
Nasal mass (granuloma)
Lymphosarcoma
Purpura hemorrhagica

Neurologic, Neuromuscular

Yellow star thistle (nigropallidal encephalomalacia)
Guttural pouch mycosis, infection, or tympany
Megaesophagus
Botulism
Lead toxicity
Rabies
Snake bite
Tetanus
Tick paralysis
Encephalitis, meningitis
Encephalopathy, hepatic

BOX 7.20

Conditions Accompanied by Oral Vesicles, Erosions, Ulcers, or Growths in Horses

Common Causes

Vesicular stomatitis
Phenylbutazone toxicity
Yellow bristle grass (*Setaria lutescens* or *Setaria glauca*) ulcers
Other plant awn stomatitis
Oral foreign body

Less Common Causes

Irritant or caustic chemical stomatitis
Periodontal gingivitis
Blister beetle (cantharidin) toxicity
Uremia
Drug eruption
Oral neoplasia

paresis (neurologic) resulting from lesions in the guttural pouch that affect the pharyngeal nerves. Feed coming from the nose is the most obvious sign of both conditions. In choked horses, as a result of the length and position of the soft palate, feed comes mainly from the nares rather than coming back into the mouth. Choke and other obstructive diseases can be easily identified by using a nasogastric tube, whereas pharyngeal paresis may be associated with a number of neurologic or neuromuscular conditions, such as botulism or guttural pouch mycosis, which require careful differentiation. The most frequent serious problem associated with choke or pharyngeal paresis is inhalation (aspiration, foreign body) pneumonia. Mineral oil or other material that is particularly damaging if it gains entry into the lung should never be used in choke for this reason. In any animal with dysphagia, care must be taken to prevent aspiration pneumonia and to evaluate the thorax periodically.

Animals with facial paralysis often drool from the affected side and may pack feed into the cheek on the affected side. Listeriosis in ruminants is frequently associated with facial paralysis. In horses facial paralysis is usually caused by halter trauma or a blow to the head.

Oral Vesicles, Erosions, Ulcers, or Growths

Bradford P. Smith

Oral lesions are found with many conditions (Boxes 7.20 and 7.21). In general, they result in some degree of dysphagia or reluctance to eat because of pain. The lesions include vesicles, erosions, ulcers, crusts, or growths in or on the lips, tongue, gums, palate, or pharynx. Oral lesions are often associated with champing and increased amounts of saliva being observed on the lips or running from the mouth. When the volume of saliva is increased, the condition is called *ptyalism* and the animal may be observed swallowing repeatedly. Pseudoptyalism refers to a normal volume of saliva that, because it is not swallowed, is visible to the observer and may be confused with dysphagia (see previous section).

The approach to determining the cause of oral lesions is based on first determining whether the cause is likely to be an infectious disease (Table 7.1). Essentially all these infectious diseases are associated with a fever, although it is short lived and moderate in the case of bovine papular stomatitis (BPS) and actinobacillosis. Papular stomatitis rarely causes illness and is usually an incidental finding in calves with a different clinical problem, although BPS can cause severe lesions and illness. Most of the infectious diseases are associated with additional lesions or symptoms. They can be conveniently grouped into those causing diarrhea and those not usually associated with diarrhea. Of those not associated with diarrhea in North America, BPS, actinobacillosis, and vesicular stomatitis

TABLE 7.1

Infectious Diseases Associated With Oral Lesions in Cattle, Sheep, Goats, and Horses

Disease	Natural Species	Oral Lesions	Other Lesions
Vesicular stomatitis (VS)	Cattle Horse Sheep (rare)	Vesicles for short time, then large ulcers; tongue usually severely involved	Teats and feet may be involved
Bluetongue	Sheep Goat (rare) Cattle (rare)	Large oral ulcers; dental pad and tongue most affected; generalized vasculitis	Coronitis, muscle degeneration, lameness, pulmonary edema, edema of face and ears
Contagious ecthyma (CE; Orf)*	Sheep Goat	Proliferative scabby lesion on lips to fleshy growth on gums	Occasionally on teats of nursing dams
Bovine papular stomatitis*	Cattle	Round, dark red, raised papules on muzzle and on hard palate	Occasionally in esophagus
Foot-and-mouth (exotic)	Cattle Sheep Goat	Vesicles for short time, then large ulcers	Teats and coronary bands often involved
Bovine viral diarrhea/ mucosal disease (BVD/MD)	Cattle	Ulcers in mouth, particularly on hard palate; erosive stomatitis	May have skin lesions; a few have corneal edema or enlarged lymph nodes; pneumonia and lesions in esophagus and gastrointestinal tract common; severe diarrhea
Malignant catarrhal fever (MCF)	Cattle (Bison)	Erosive stomatitis with ulcers; generalized vasculitis	Purulent nasal discharge, corneal edema, enlarged lymph nodes, ± cracking skin, ± central nervous system signs; severe diarrhea; high fever
Rinderpest (exotic)†	Cattle	Erosive stomatitis	Blepharospasm, severe intestinal involvement, and diarrhea
Peste des petits ruminants (PPR)	Sheep Goat	Erosive stomatitis	Severe diarrhea, purulent ocular and nasal discharge
Alimentary form of infectious bovine rhinotracheitis (IBR) in calves	Cattle	Gray pinpoint pustules on soft palate and occasionally in nares; minimal oral lesions	Rhinotracheitis, conjunctivitis, pneumonia

*Infectious to humans.

†Rinderpest was eradicated worldwide in 2011.

VetBooks.ir

(VS) are most common in cattle; VS in horses; bluetongue in sheep; and contagious ecthyma (CE) in sheep and goats. CE can be readily differentiated from bluetongue because it involves primarily lips and gums and is proliferative, whereas bluetongue involves the tongue and dental pad most severely, is erosive, and is associated with other signs of generalized vasculitis. Laboratory diagnosis in acute cases of VS is done by working with state and federal veterinarians. Because VS is highly contagious and similar in clinical appearance to foot-and-mouth disease, quarantine and proper diagnosis are essential. CE can be diagnosed serologically, by fluorescent antibody on the impression smear or biopsy of a lesion, and by isolation. Bluetongue is diagnosed by ELISA, serology (AGID), PCR, and virus isolation. Asymptomatic seroconversion to bluetongue is common where *Culicoides* vectors are active. Congenital defects can result from bluetongue infection of the fetus in sheep, goats, and cattle.

The two most common North American infectious diseases associated with oral lesions and diarrhea in cattle are bovine viral diarrhea/mucosal disease (BVD/MD) and malignant catarrhal fever (MCF). MCF can usually be differentiated because it most commonly occurs sporadically in single animals and has signs of generalized vasculitis such as bilateral corneal opacity, mucopurulent nasal discharge, enlarged lymph nodes, and high fever. Dysentery is common in MCF, and some animals exhibit CNS signs or have thickened and cracking skin. See Chapter 32 for more on diagnosis of MCF. Laboratory diagnosis in acute cases of BVD (see the Bovine Viral Diarrhea section in Chapter 32) involves fluorescent antibody testing of slides made from ear notch biopsies, lesion swabs, buffy coat, or tissue. Virus isolation from swabs, serum, or blood or a rise in serum titer from acute to convalescent samples is also diagnostic. Asymptomatic seroconversion is also common, and infection of the fetus may result in congenital anomalies including cerebellar hypoplasia in cattle.

In animals without fever and other signs of systemic involvement, irritants and caustic chemicals should be considered as possible causes of oral lesions. Horses and young calves are susceptible to severe ulceration when consuming hay contaminated with yellow bristle grass, which is armed with barbed bristles.[40] Horses sometimes develop gingivitis or oral ulcers associated with dry plant awns called foxtails, which become embedded into the gums around teeth. Foals and ponies are most susceptible to phenylbutazone toxicity, which can produce oral ulceration. In cattle the surfaces of masses produced by actinobacillosis and actinomycosis sometimes ulcerate. Many cattle without significant disease have one or more small ulcers of traumatic origin from plant awns on the hard palate and in the cleft (sulcus lingualis) where the base and shaft of the tongue meet.

Dental Abnormalities

Chronic fluorosis is a cause of a variety of dental abnormalities in young animals with developing teeth (Boxes 7.22 and 7.23). Although cattle are most frequently involved, all large animals are susceptible. The teeth may appear mottled, striated, chalky, or hypoplastic or may have defective calcification. In severe cases teeth may be yellow, brown, or black and have multiple caries. Animals of any age may also develop bone lesions associated with chronic fluorosis.

Porphyria is a rare congenital condition of cattle transmitted by a simple autosomal-recessive gene. The teeth often appear pink because of the presence of porphyrins and fluoresce pink, purple, or red when exposed to ultraviolet light. Affected calves often develop photosensitization and anemia. This condition must be differentiated from superficial staining caused by ingestion of black walnut hulls or other compounds with staining properties. Cattle fed sweet potato cannery waste develop dental erosions and tooth discoloration.

Excessive or uneven wear or loss of teeth is often seen in horses and ruminants as they age. Tooth wear, particularly of incisors, is more rapid in animals on sandy range. Periodontal disease can cause premature loss of teeth (broken mouth) and tends to be most common in sheep in some geographic areas; the cause of this is unknown.[41]

The most common dental disease in horses has been described as periodontal disease.[42] In horses fractured teeth or teeth with a small tract into the root through an open infundibulum often result in tooth root abscesses. This dental decay is a result of hypoplasia of the cementum of the enamel lakes and occurs most frequently in the second and third lower cheek teeth and third and fourth upper cheek teeth.[43] These can cause sinusitis and foul-smelling unilateral nasal discharge if upper cheek teeth are involved or draining tracts to the exterior skin surface if lower cheek teeth are involved.

Most of the other causes of dental abnormalities listed here are bone abnormalities that cause secondary loss of teeth. See dental sections of Chapter 32 for more details.

Icterus (Jaundice)

Icterus and *jaundice* are synonymous terms referring to the expression of a yellow coloration in the sclera and mucous membranes resulting from increased amounts of bilirubin in tissues and increased serum bilirubin levels (Boxes 7.24 and

7.25). Bilirubin especially stains elastic tissues and is thus most visible in the sclera and vulva. Icterus usually indicates decreased excretion of bilirubin with liver or biliary tract diseases or increased production of bilirubin with hemolytic anemia.

The accumulation of conjugated bilirubin results in more pronounced jaundice than does a similar amount of unconjugated bilirubin, with the result that the most pronounced jaundice is usually seen with hepatic or biliary obstructive disease. Laboratory examination of serum for relative amounts of unconjugated (indirect reacting) and conjugated (direct reacting) bilirubin is essential in determining the cause of the icterus. Generally, mainly unconjugated bilirubin levels are elevated with hemolytic anemia. Anorectic horses may have a plasma unconjugated bilirubin of 5 or 6 mg/dL without any evidence of hemolytic anemia or liver disease. Anorectic ruminants also experience a

VetBooks.ir

rise in plasma unconjugated bilirubin, often to a level between 0.5 and 2 mg/dL.

In determining the cause of icterus, laboratory tests including PCV, RBC count, and the liver enzymes SDH and GGT should be determined. In horses, alkaline phosphatase (AP) may also be useful, although it is not liver specific.

When active hepatocellular damage is occurring, SDH, which is liver specific, and aspartate aminotransferase (AST [SGOT]), which is not liver specific, are found in serum in elevated levels. GGT and AP are more indicative of biliary tract disease or proliferation and tend to rise more slowly but also remain elevated for a longer period than SDH, which has a short half-life. Elevated levels of GGT or AP are often associated with chronic liver disease, cholangitis, cholelithiasis, or liver flukes. It is possible to have liver disease without icterus. Production and elimination of bilirubin are often equal in chronic liver disease, but acute liver disease or liver failure is usually associated with icterus. Although liver function tests such as BSP half-time can be run to determine the extent of liver damage, in most cases a liver biopsy must be taken for histopathologic examination to make a specific etiologic diagnosis of the cause of liver disease.

Liver abscesses rarely result in icterus because they rarely damage a sufficient percentage of liver to impair bilirubin clearance. They do cause multifocal hepatic damage and therefore are often associated with increased levels of SDH and AST when in the acute stages of formation.

Hemolytic anemia is characterized by destruction of RBCs either intravascularly or in the reticuloendothelial organs. This increased destruction results in production of bilirubin more rapidly than it can be removed by the liver, resulting in icterus. The specific cause of hemolytic anemia may sometimes be evident, as when autoagglutination is seen (autoimmune hemolytic anemia). *Anaplasma* bodies are visible in stained RBCs of cattle, or *Anaplasma phagocytophilum* (formerly *Ehrlichia equi*) blue cytoplasmic inclusion bodies are seen in stained neutrophils from horses.

In mature sheep, the most common cause of severe icterus is copper toxicity. In lambs, yellow lamb disease caused by *C. perfringens*, type A is a leading cause.

Localization and Differentiation of Neurologic Diseases

DAVID C. VAN METRE and ROBERT J. MACKAY, *Consulting Editors*

MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Abnormal mentation, 131
Behavior, abnormal, 131
Lethargy, stupor, coma, dementia, 131
Seizures and collapse, 131
Blindness, 131-135
Ocular abnormalities, 131-134
Circling, 134
Head tilt, 134
Nystagmus, 134
Incoordination, 134-135
Hypermetria, hypometria, dysmetria, 134-135
Intention tremor, 134-135
Cranial nerve abnormalities, 135-138
Strabismus, ocular paresis/paralysis, 135
Pupil size and light responses, abnormal, 135
Facial hypalgesia or analgesia, 135-136
Deviated or dropped jaw, 135-136
Facial paresis or paralysis, 136
Head tilt, 136
Nystagmus, 136
Deafness, 136
Dysphagia, 136
Dysphonia, 136
Stridor, 136
Paresis (quadraparesis, hemiparesis, paraparesis), 136-138
Cervical spinal cord abnormalities, 138
Muscle atrophy, reduced muscle tone, flaccid paresis, 139
Focal analgesia, 139
Urinary incontinence and urine retention, 139

Terminology and Description of Clinical Signs of Neurologic Disease

(See Table 8.1)

Telencephalon (cerebrum, basal ganglia) and diencephalon (thalamus)
- Changes in behavior
- Changes in the level of consciousness
  - Dullness, obtundation
  - Stupor
  - Coma
  - Excitement, mania
  - Seizures (convulsions)
  - Narcolepsy
- Vision disturbance
  - Blindness in both visual fields (amaurosis)
  - Blindness in the contralateral visual field (hemianopsia)
  - Menace reflex deficit
  - Change in pupil size: small to pinpoint pupils
- Circling (toward the side of the lesion)
- Head turn (toward the side of the lesion)
- Gait usually normal
- Abnormal postural reactions (contralateral)
  - Decreased or absent conscious proprioception
  - Noticeable ataxia, paresis (weakness), and paralysis are uncommon
- Abnormal spinal reflexes
  - Normal to increased (hyperreflexic) myotatic reflexes
  - Altered muscle tone
  - Normal to increased muscle tone (spasticity)
- Urinary incontinence (upper motor neuron)
- Tremors

Mesencephalon (midbrain)
- Changes in the level of consciousness
  - Dullness (depression)
  - Stupor
  - Coma
  - Narcolepsy
- Abnormal posture
  - Opisthotonos
  - Decerebrate posture
- Abnormal visual or ocular function
  - Blindness in both visual fields (amaurosis)
  - Blindness in the contralateral visual field (hemianopsia)
  - Change in pupil size
  - Small pupils in early, mild lesions
  - Dilated, nonresponsive pupils in severe lesions
  - Menace reflex deficit (ipsilateral)
  - Anisocoria (asymmetric lesions)
- Circling (toward the side of the lesion—ipsiversive)
- Head turn (toward the side of the lesion—ipsiversive)
- Abnormalities of gait (usually contralateral to lesion)
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis

VetBooks.ir

TABLE 8.1

Localization of Central Nervous System Lesions According to Major Signs Encountered

Sign or Problem Encountered	Lesion Location
Changes in Gait and Locomotion	
Ataxia	Spinocerebellar tracts, spinal cord, and brainstem; vestibular system; cerebellum
Conscious proprioceptive deficit	Fasciculus gracilis and fasciculus cuneatus and connections, spinal cord, brainstem, forebrain
Knuckling	Usually LMN, ventral horn gray matter, spinal cord; occasionally UMN, spinal cord, brainstem
Abduction or adduction	Spinocerebellar tracts, spinal cord, brainstem, cerebellum
Abnormal postural placement	Spinocerebellar tracts, spinal cord, and brainstem; gracilis and fasciculus cuneatus and connections, spinal cord and brain
Hypermetria	Cerebellum, cerebellar peduncles, spinocerebellar tracts
Circling, or falling to one side	Forebrain, vestibular nuclei and connections, cerebellum
Paraplegia	UMN, T2 to S2, or LMN, L3 to S2
Hemiplegia	Ipsilateral brainstem or spinal cord, cranial to T3
Changes in Sensorium and Behavior	
Coma or semicoma	ARAS; diffuse forebrain
Obtundation	ARAS; forebrain
Seizures	Forebrain
Head pressing, compulsive walking	Forebrain
Aggression or rage	Forebrain
Inappropriate sexuality	Forebrain
Hyperphagia or hypophagia	Hypothalamus
Diabetes insipidus	Hypothalamus
Headshaking	Unknown, probably peripheral trigeminal neuralgia
Changes in Head Posture	
Stiff neck	Meninges, cervical spine
Head tilt	Vestibular nuclei and connections (medulla oblongata, cerebellum)
Head tremor	Cerebellum, basal ganglia
Opisthotonos	Cerebellum (rostral vermis), rostral brainstem, cerebrum, cranial nerve VIII
Cranial Nerve Dysfunction	
Blindness	Cerebral cortex, internal capsule, optic tracts, optic chiasm, optic nerve, eye
Anisocoria	Cervical spinal cord (tectotegmentospinal tract), cranial thoracic nerve roots, vagosympathetic trunk, midbrain (oculomotor nerve nucleus), cranial cervical ganglion, ciliary ganglion, oculomotor nerve, optic nerve
Mydriasis	Oculomotor nerve, midbrain, optic nerve, eye
Miosis	Vagosympathetic trunk, ciliary ganglia, tectum, brainstem, cervical spinal cord
Ptosis	Facial nerve, vagosympathetic trunk, cranial cervical ganglion, midbrain, oculomotor nerve, cervical spinal cord (tectotegmentospinal tract)
Strabismus	
Ventrolateral	Cerebellum, vestibular nucleus, oculomotor nerve
Dorsomedial	Trochlear nerve
Medial	Abducent nerve
Nystagmus	
Horizontal	Nerve VIII (peripheral)
Vertical or rotatory	Vestibular nuclei, peripheral vestibular receptor, cerebellum, vestibulocochlear nerve
Jaw drop	Trigeminal motor nucleus (pons), trigeminal nerve
Flaccid tongue	Hypoglossal nucleus (medulla oblongata), hypoglossal nerve, lingual muscle
Facial paralysis	Facial nucleus (medulla oblongata), facial nerve, facial muscles
Facial analgesia	Trigeminal nerve (sensory component), pons, forebrain
Dry eye	Cranial nerve VII before exiting petrous temporal bone
Changes in Reflexes	
Patellar	L3-L6 spinal cord, femoral nerve, quadriceps femoris muscle
Flexors (thoracic limbs)	C5-T2 spinal cord segments, radial, ulnar, musculocutaneous and median nerves, and innervated muscles
Flexors (pelvic limbs)	L6-S2 spinal cord segments (pelvic limbs); sciatic, peroneal, and tibial nerves; flexor muscles of the limbs
Triceps	C6-T1 spinal cord segments, radial nerve, triceps muscle
Cutaneous trunci	C8-T1 spinal cord segments, lateral thoracic nerve, white matter of thoracic spinal cord
Anal	S1-S5 sacral spinal cord segments, pudendal nerve
Cervicofacial	Dorsal columns of cervical spinal cord segments; facial nucleus (medulla oblongata), nerve, facial nucleus, muscles of ear; connections between cervical plexus and facial nerve
Dysuria (dribbling urine)	Spinal cord, S1-S5, sacral nerves, bladder wall

ARAS, Ascending reticular activating system; *LMN*, lower motor neuron; *UMN*, upper motor neuron.

VetBooks.ir

- Abnormal spinal reflexes
  - Normal to increased (hyperreflexic) myotatic reflexes
- Altered muscle tone
  - Spasticity
- Urinary incontinence (upper motor neuron)

Metencephalon (pons, cerebellum)
- Abnormal posture
  - Head tilt
  - Decerebellate posture
- Circling (usually away from side of lesion—paradoxical signs)
- Head turn (usually away from side of lesion—paradoxical signs)
- Nystagmus (variable—may be constant, positional, direction changing, or disconjugate and may occur in any direction)
- Abnormalities of gait
  - Ataxia
  - Dysmetria—typically, hypermetria
- Abnormal spinal reflexes (occasional)
  - Normal to increased myotatic reflexes (hyperreflexia)
- Altered muscle tone
  - Normal to increased muscle tone on the opposite side of the body (contralateral spasticity)
  - Normal to decreased muscle tone on the same side of the body (ipsilateral hypotonus)
  - Urinary incontinence (upper motor neuron) (rare)

Medulla oblongata
- Changes in the level of consciousness
  - Dullness, obtundation
- Abnormal posture
  - Head tilt (toward side of lesion—ipsiversive)
  - Circling (toward side of lesion—ipsiversive)
  - Head turn occasionally (toward side of lesion)
- Strabismus—variable
- Nystagmus—spontaneous, abnormal (variable—may be constant, positional, direction changing, or disconjugate and may occur in any direction)
- Dysphagia
- Facial analgesia
- Facial paresis or paralysis
- Menace reflex deficit
- Jaw weakness
- Roaring, snoring, dysphonia
- Tongue weakness, deviation, or paralysis
- Abnormalities of gait—ipsilateral
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis
- Abnormal spinal reflexes
  - Normal to increased (hyperreflexic) myotatic reflexes
- Altered muscle tone
  - Normal to increased muscle tone
- Urinary incontinence (upper motor neuron)

Spinal cord C1-C5
- Abnormalities of gait in thoracic and pelvic limbs—ipsilateral
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis
- Abnormal spinal reflexes—ipsilateral
  - Hyperreflexia in both thoracic and pelvic limbs
  - Decreased to absent caudal cervical and auricular reflexes
  - Decreased to absent slap test (horses)
- Altered muscle tone
  - Normal to increased muscle tone
- Urinary incontinence (upper motor neuron)

Spinal cord C6-T2
- Abnormalities of gait in thoracic and pelvic limbs—ipsilateral
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis
- Abnormal spinal reflexes—ipsilateral
  - Hyporeflexia in thoracic limbs
  - Hyperreflexia in pelvic limbs
  - Decreased to absent caudal cervical and auricular reflexes
  - Decreased to absent slap test (thoracolaryngeal reflex, horses)
  - Absent panniculus reflex
- Horner's syndrome (ipsilateral)
- Altered muscle tone
  - Decreased muscle tone in thoracic limbs
  - Normal to increased muscle tone in pelvic limbs
- Urinary incontinence (upper motor neuron)

Spinal cord T3-L2
- Abnormalities of gait in pelvic limbs only—ipsilateral
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis
- Abnormal spinal reflexes—ipsilateral
  - Hyperreflexia in pelvic limbs only
  - Decreased panniculus reflex caudal to lesion
- Altered muscle tone—ipsilateral
  - Normal to increased muscle tone in pelvic limbs
- Urinary incontinence (upper motor neuron)

Spinal cord L3-S3
- Abnormalities of gait in pelvic limbs only—ipsilateral
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis
- Abnormal spinal reflexes—ipsilateral
- Hyporeflexia in pelvic limbs only
- Altered muscle tone
  - Decreased muscle tone in pelvic limbs
  - Flaccidity of the tail
- Urinary incontinence (lower motor neuron)
- Fecal incontinence (lower motor neuron)

Peripheral nerve and muscle
- Abnormalities of gait
  - Paresis to paralysis
  - Decreased or absent conscious proprioception
  - Ataxia
  - Paresis (weakness)
  - Paralysis
- Abnormal spinal reflexes—ipsilateral
  - Hyporeflexia
- Altered muscle tone
  - Decreased muscle tone
  - Muscle atrophy
  - Flaccidity of the tail
- Urinary incontinence (lower motor neuron)
- Fecal incontinence (lower motor neuron)

The clinical signs of neurologic disease depend on the location of the disease process within the nervous system (Table 8.1). Widely varying disease entities may produce similar or identical clinical signs. Seizures, for example, may be the result of metabolic, toxic, traumatic, neoplastic, or other causes. Definitive diagnosis of neurologic disease, therefore, cannot be made based on clinical signs alone. Localization of lesions within the nervous system by meticulous physical and neurologic examination is the first and key step in developing a differential diagnosis list and a rational diagnostic and therapeutic plan.

Diagnosis of Neurologic Diseases

Signalment

The species, breed, age, and pedigree of an animal are important considerations in the differential diagnosis of neurologic disease.

VetBooks.ir

TABLE 8.2

Dietary Deficiencies Associated With Neurologic Disorders of Livestock

Dietary Deficiency	Disease Produced	Neurologic Sign
Copper	Demyelination, pathologic vertebral fractures	Ataxia, recumbency
Vitamin E	Demyelination	Ataxia, recumbency
Vitamin A	Encephalopathy	Convulsions, blindness
Magnesium	Grass tetany, transport tetany, milk tremors	Convulsions, tremors, ataxia
Potassium	Weakness	Postpartum recumbency
Calcium or phosphorus	Milk fever, pathologic vertebral fractures, tetany	Weakness, ataxia, recumbency, tetany
Vitamin E or selenium	Nutritional myodegeneration	Weakness, ataxia, recumbency, sudden death

Many diseases are species specific, particularly in the case of infectious and genetic diseases. Some diseases are not only species specific but also have higher incidence in certain breeds and ages of that species.[1-13]

Some diseases are found in the neonate at birth. A large number of congenital disorders of the central nervous system (CNS) can affect domestic livestock. These diseases have a variable clinical course, depending on the nature of the disorder. Congenital disorders of myelin metabolism worsen with age, whereas other developmental conditions may remain stable throughout the animal's life.[14-19] Examples of these disorders that have genetic tests available are listed in Chapter 52.

History

Many disorders of the CNS produce characteristic patterns of onset and progression. Some CNS diseases occur acutely, developing the full range of clinical signs within hours. If the disease is not fatal, the signs either stabilize by 24 hours and remain constant thereafter or improve. Diseases that may display this clinical course include traumatic injuries and some types of toxic, infectious, and metabolic diseases. Diseases with degenerative, neoplastic, and certain viral causes may develop more slowly, requiring days to weeks for development of characteristic clinical signs.[2,20,21]

Diet

The diet of patients with neurologic disease should be evaluated[20-25] (Table 8.2). Equine motor neuron disease is seen mainly in horses that are housed without access to pasture and whose diet is deficient in vitamin E.[26] Copper deficiency occurs in ruminants pastured in areas with shale or volcanic soils, which are either deficient in copper or contain high concentrations of molybdenum and sulfur; demyelination of the spinal cord in newborn small ruminants may result, as can vertebral fractures in calves. Overfeeding of protein and energy, as well as imbalance of certain trace minerals, has been linked to cervical vertebral stenotic myelopathy in horses (wobbler).[27,28]

Environment

Examination of the patient's environment may provide valuable information about the cause of CNS disease. Outbreaks of botulism and listeriosis have been associated with ingestion of rotting vegetation around haystacks, silos, and feed bunks.[29,30] Plant poisonings are common in livestock, and identification of neurotoxic plants is important whenever multiple animals are affected simultaneously[30-32] (Table 8.3). Nonplant neurotoxicants of livestock include lead, ethylene glycol, organic mercurials, chlorinated hydrocarbons, organophosphates, salt, sulfur, petroleum distillates, and many others. Dose of the neurotoxicant may be important, with different clinical signs appearing depending on the level of exposure. For example, ingestion of high concentrations of organophosphates or carbamates produces marked ataxia, coma, muscle tremors, salivation, and miotic pupils. When low doses of organophosphates are ingested chronically, however, the result is an axonopathy of spinal cord and medullary neurons, resulting in pelvic limb paresis and ataxia, which may progress to tetraparesis and recumbency.[33] Therapeutic and dietary interventions also may result in toxicoses when improperly administered. Overdosing of cattle with propylene glycol produces profound ataxia, depression, and coma.[34] Ingestion of urea or ammoniated feedstuff produces hyperesthesia, excitability, coma, and convulsions. High concentrations of salt in drinking water or, more commonly, lack of fresh water or interruption of the water supply followed by unlimited access to water can result in laminar necrosis of the cerebral cortex or eosinophilic meningitis.[33] The clinical signs are those of forebrain dysfunction, including blindness, dullness, seizures, coma, and death.[35-37] Geographic area also may be important in the differential diagnosis of neurologic disease. Certain infectious diseases may be more common in particular areas of the country or even regions within a single state where the conditions for disease vectors are optimal.[38] The travel history of the animal must be considered, as well as the animal's location at the time clinical signs appeared. Travel also may result in increased contact with other animals and greater risk of exposure to infectious diseases. Intermingling of horses from different premises is a potential risk for equine herpesvirus myeloencephalopathy (EHM).[39]

Vaccination and Disease History

When a neurologic problem is evaluated, the vaccination history and previous herd or individual disease problems should be noted. Some vaccines are highly protective, such as those for rabies and tetanus. Neurologic disease may be a secondary complication of disease in another organ system. Foals and calves with severe diarrhea, for example, may convulse secondary to hypokalemia, hypernatremia, hyponatremia, or hypoglycemia. Preexisting diseases in the population should be determined. For example, outbreaks of EHM are sometimes preceded by respiratory disease or abortions in herdmates.[39] Historical evidence of limited colostral intake may be important in the diagnosis of bacterial meningitis of neonates. Bloody diarrhea often precedes the onset of nervous coccidiosis of calves.[40]

Gestational Stage

Hypomagnesemia, eclampsia (hypocalcemia), hypokalemia, hypophosphatemia, and nervous ketosis are common causes of recumbency, convulsions, and tremors in adult livestock. These diseases usually occur between the beginning of the last trimester and the first 2 months after parturition.

Nervous System Examination

General Comments

A thorough physical examination should always precede or be performed concurrently with the neurologic examination. In some instances disease of organ systems other than the nervous system may take precedence for diagnosis and treatment. Such may be the case with animals that are in shock or suffering from other life-threatening cardiovascular or respiratory disturbances.

The neurologic examination should be carried out in a systematic fashion. The exact order of the examination is not

VetBooks.ir

TABLE 8.3

Selected Poisonous Plants Producing Neurologic Signs (Also See Chapter 54)

Plant Poisoning	Clinical Signs
Blue green algae (*Aphanizomenon*, *Anabaena flos-aquae*)	Sudden death, tremors, salivation, miosis, bradycardia
Bracken fern (*Pteridium aquilinum*)	Ataxia, weight loss, strip sweating (horses only)
Buckeye (*Aesculus* species)	Incoordination, twitching, sluggishness
Catsear (*Hypochaeris radicata*)	Hyperflexion of the hock during movement (stringhalt)
Cheesewood (*Malva*)	Tremors, worsened by forced exercise, hyperflexion of the hock during movement (stringhalt)
Creeping indigo (*Indigofera spicata*) and Birdsville indigo (*Indigofera linnaei*)	Ataxia, obtundation, blepharospasm, corneal edema, lingual ulcers, seizures
Dandelion (*Taraxacum officinale*)	Hyperflexion of the hock during movement (stringhalt)
Death camus (*Zigadenus* species)	Trembling, uncontrolled running, recumbency, opisthotonos, convulsions, vomiting, salivation
Dutchman's breeches (*Dicentra*)	Trembling, uncontrolled running, recumbency, opisthotonos
Fiddleneck (*Amsinckia intermedia*)	Ataxia, obtundation, somnolence, excitability, head pressing (hepatic encephalopathy)
Horse tail (*Equisetum arvense*)	Ataxia, weight loss, strip sweating (horses only)
Laburnum (*Laburnum anagyroides*)	Excitement, incoordination, convulsions, death
Larkspur (*Delphinium*)	Ataxia, collapse, recumbency, inability to lift head, tremors of face, flank, and hip; vomiting
Locoweed (*Astragalus* species)	Ataxia, weight loss, recumbency, hyperesthesia
Lupine (*Lupinus*)	Tremors, hyperexcitability, depression
Milkweed (*Asclepias* species)	Tremors, salivation, ataxia
Monkshood (*Aconitum*)	Restlessness, salivation, paresthesia, irregular heartbeat, recumbency, coma
Nightshades (*Atropa* species, *Solanum* species)	Tremors, ataxia, recumbency, convulsions
Poison hemlock (*Conium maculatum*)	Tremors, vomiting, ataxia, sudden death, abortions, pupillary dilation, bradycardia, coma
Rape (*Brassica napus*)	Blindness, ataxia, aggressiveness
Rattlebox (*Crotalaria spectabilis*)	Ataxia, obtundation, somnolence, excitability, head pressing (hepatic encephalopathy)
Rayless goldenrod (*Haplopappus heterophyllus*)	Lassitude, obtundation, arched back, stiff-legged gait, tremors, weakness, collapse
Russian knapweed (*Rhaponticum repens*, *Acroptilon repens*)	Facial rigidity and dystonia, lack of prehension, ataxia, depression (horses only)
Tansy ragwort (*Senecio jacobaea*) and common groundsel (*Senecio vulgaris*)	Ataxia, obtundation, somnolence, excitability, head pressing (hepatic encephalopathy)
Tobacco (*Nicotiana* species)	Tremors, salivation, ataxia, convulsions, birth defects
Water hemlock (*Cicuta maculata*)	Tremors, vomiting, ataxia, sudden death, convulsions, odontoprisis, pupillary dilation, abortions, bloat
White snakeroot (*Eupatorium rugosum*)	Tremors, salivation, convulsions
Yellow star thistle (*Centaurea solstitialis*)	Facial rigidity and dystonia, lack of prehension, ataxia, depression (horses only)

important in itself, but procedures that may cause discomfort or pain, such as palpation of the spine, should be left until last. A common system used by many neurologists is to start at the head and progress to the tail.[41] Some clinicians prefer to examine the animal standing in the stall initially and then observe the gait. Because large animals are less amenable to handling than the typical cat or dog, another system for the neurologic examination is to begin with procedures that require minimal handling of the animal, such as observation of mental status, posture, and gait, and proceed to those that require greater manipulation.

Neurologic examination alone rarely leads to definitive diagnosis but rather helps to answer the questions "Does the animal have neurologic disease?" and "What is the location of the neurologic lesion?" Once these questions are answered, a list of differential diagnoses can be made in light of other information such as the signalment of the animal and the history of the current problem. The diagnostic plan is based on the location of the lesion and the most likely differential diagnoses.

Mentation and Behavior

Initial examination should be done from a distance. The examiner observes the animal's mental state and whether its responses to its surroundings are appropriate. This is done ideally in the animal's usual environment, where it would be expected to be calmest. When this is not possible, the influence of factors such as the stress and excitement of previous travel and the animal's natural fear of unfamiliar surroundings, sounds, and smells must be taken into account. The animal's usual handler may help to discern subtle changes in an individual animal's behavior. All livestock should recognize and fear strangers and should show awareness of the examiner's position. Normal animals change the posture of the head, ears, and eyes as the examiner moves. Depending on previous conditioning, normal behavior may include cautionary moves, avoidance, belligerence, or affection. Animals with decreased mental alertness (obtunded, dull, depressed) have reduced responses to examination, lassitude, lack of recognition, unwillingness to rise or lift the head from the ground, lack of appetite, drooped ears, stupor, or coma (Fig. 8.1). Systemic illnesses also may cause dull mentation; thorough physical examination and appropriate diagnostic tests facilitate detection of these diseases.

Changes in behavior are consequences of diseases affecting the forebrain: the cerebrum or the relay areas of the diencephalon. Abnormal behavior caused by forebrain dysfunction can be termed *dementia*. Some common examples of dementia

VetBooks.ir

FIG. 8.1 Dull mentation in a horse with cerebral toxicosis caused by sage toxicity (*Salvia* species).

include head pressing, compulsive walking (often around the inside of an enclosure), frequent yawning, loss or absence of innate behaviors such as udder seeking by neonates and mutual affinity of dams and offspring, and loss of learned behaviors such as the ability to be led by a lead rope and halter. Hyperexcitability, rage, mania, exaggerated fear, or frantic motor activities are suggestive of a lesion of the limbic system of the forebrain, an assembly of interconnected neurons in the brain that is involved in emotional responses and patterns of behavior. Animals so affected may strike or kick at inappropriate times, demolish their stalls, bellow, show belligerence, or, if recumbent, struggle violently.

Maintenance of mental alertness is the role of the ascending reticular activating system (ARAS) of the brainstem, which repetitively signals the forebrain to maintain consciousness. The ARAS is important in maintaining the animal's level of consciousness and arousal. The relationship between the cerebral cortex and the ARAS is sometimes described as follows: The cerebral cortex determines the *content* (external display) of consciousness, and the ARAS determines the *level* of consciousness. Diseases affecting the ARAS tend to produce profound depression of consciousness. The forebrain is the "seat of consciousness": Conscious perception of both external stimuli (e.g., vision, hearing, touch) and internal stimuli (e.g., abdominal pain) depends on its integrity. In general, level of consciousness is *not* substantially altered by forebrain diseases unless the injury is diffuse and severe.

A seizure (convulsion, ictus) is a manifestation of forebrain dysfunction characterized by involuntary somatic and autonomic motor activities and/or loss of consciousness. Seizures may be generalized or focal (partial). Generalized seizures are characterized by recumbency, loss of consciousness, flailing or galloping motions of the limbs, elimination of feces and urine, and nystagmus. Localized involuntary movements with or without obvious alterations of consciousness characterize focal seizures. Alternatively, focal seizures may result in episodes of abnormal or bizarre behavior or momentary lapses of consciousness without collapse or significant motor activity. A third form of seizure is focal with secondary generalization. The onset of the seizure is focal within the forebrain, but seizure activity subsequently spreads throughout the brain, resulting in a generalized seizure. Animals with this form of seizure activity exhibit initial focal signs such as head turning, bellowing, and focal tremors followed by loss of consciousness and generalized seizure signs. Rarely, seizures in large animals may be preceded by an aura, a period in which the animal exhibits anxiety or restless behavior shortly before the onset of the seizure itself. A postictal phase, a period subsequent to the seizure during which the animal is obtunded or, occasionally, restless and anxious, is common after seizures in most animals. The postictal phase usually lasts a few minutes to hours but may last as long as several days. The postictal phase may be the only stage of the seizure observed by the animal's handler. Thus seizures should be considered as a possible cause in any animal with a history of episodes of abnormal behavior. The typical history is that the animal is found in a dull or excited state, without the handler observing the onset of this change of behavior. Additional signs of postictal forebrain dysfunction may include blindness, absent menace responses, and insensitivity to cutaneous noxious stimulation. Additional supporting evidence includes physical injuries such as scrapes and cuts that may have been incurred during the seizure.

Abnormalities of forebrain dysfunction are the ultimate cause of seizure activity. During a seizure, neurons in the cerebral cortex exhibit spontaneous electrical activity, beginning either focally or simultaneously throughout the cortex, resulting in the clinical manifestations of focal or generalized seizures. Causes of seizures are legion, including alterations in the neuronal environment resulting from metabolic disturbances or toxicities and the effects of structural brain diseases such as congenital or developmental disorders, traumatic injuries, neoplasia, and inflammatory conditions. Diagnosis of seizures and other states of altered mentation must include a thorough physical examination and screening for metabolic diseases such as electrolyte imbalances and hepatic or renal failure.

Abnormalities in the neurologic examination found between seizures (interictal period) support a diagnosis of primary brain disease and are an indication for diagnostic procedures such as cerebrospinal fluid (CSF) tap. Some toxins cause additional systemic signs such as neuromuscular involvement (tremors, weakness) or parenchymal organ failure (icterus, uremia). Such signs, combined with clinical history and inspection of the environment, will help to direct specific tests for toxins.

Narcolepsy is a condition reported in cattle and horses wherein the normal mechanisms of sleep are disturbed.[42-45] Although sudden onset of sleep is one manifestation of narcolepsy, the acute onset of cataplexy—complete paralysis of striated muscles—is usually a more prominent clinical feature. Animals may be observed to collapse to the ground suddenly or to buckle at the knees. Cardiac and respiratory muscles are not affected. Narcoleptic attacks may be difficult to distinguish from seizures but are not accompanied by the involuntary motor activity that characterizes most generalized seizures. In some cases, traumatic injuries to the head, face, and limbs can result.

Gait

Gait should be evaluated by moving the animal in a straight line, moving it in a tight circle, backing up, and moving it over obstacles such as a curb. Having the patient walk up and down a slope with varying steepness and with the head elevated may reveal subtler abnormalities. The examination may need to be modified depending on the species of the patient, amenability to handling, and consideration of safety concerns.

Quadrupeds begin walking by protracting the pelvic limb, followed by the thoracic limb of the same side, then the opposite pelvic limb, and finally the opposite thoracic limb. Gait on a level surface requires integrity of the musculature, motor and sensory components of the peripheral nerves, local spinal reflexes, ascending and descending pathways in the spinal cord,

and centers within the brainstem. Dysfunction of ascending pathways (spinocerebellar tracts) results in mild to severe proprioceptive disturbances when standing or walking, which are exacerbated by turning the animal in a circle or stepping it on and off a curb. Animals with cerebral disease are usually able to perform simple motor activities such as walking along a straight path without obvious deficits but may exhibit decreased proprioception when they are required to perform complex motor activities such as walking on slopes or negotiating obstacles such as curbs or ground poles.

Subtle gait deficits may be elicited by walking and then trotting the patient or by walking or trotting the patient briskly and then stopping suddenly. While a helper is walking the animal in a straight line on a level surface, the examiner should take hold of the tail on the same side and pull the animal firmly to one side during the stance phase of the stride. The normal animal will move toward the pull but should not stumble or fall. If the tension on the tail is maintained, strength can be assessed. Animals with lesions anywhere within the ascending or descending pathways controlling gait may be weak and/or show decreased proprioception in the form of stumbling, tripping, or crossing the limbs. The same test can be performed in the patient at rest. Resistance to lateral pressure at rest is provided by the antigravity myotatic reflex. Because this reflex uses peripheral nerves and spinal cord segments of the lumbosacral intumescence, inability to resist the tail-pull test at rest is suggestive of lower motor neuron (spinal cord gray matter, nerve roots, or peripheral nerves) of the L3 to S2 spinal cord segments on the side being tested. Circling the patient in a wide circle and then a tight circle also may elicit deficits, such as knuckling, stumbling, interference between feet, pivoting on one foot, or wide movements in the outside limb (circumduction), that are not observed when the animal is walked in a straight line. Assessment of gait is facilitated when animals are halterbroken and can be led. This is not the case in many ruminants, so the clinician must rely more on observing the animal in its usual environment or in a confined area such as a pen. A handler may drive animals that are not halterbroken, but this should be done with due consideration of animal and handler safety.

A grading system for gait deficits has been described elsewhere,[46] as follows:

Grade 0: Normal gait
Grade 1: Very subtle deficits, observed only by an experienced clinician
Grade 2: Deficits apparent to an inexperienced clinician
Grade 3: Deficits apparent to laypersons
Grade 4: Severe deficits, including stumbling, knuckling at the fetlock, falling
Grade 5: Recumbency and inability to rise

Proprioception is the sense of body position in space. Proprioceptive information is collected by receptors in the skin, joints, muscles, and vestibular system. General proprioceptive pathways run mainly in the lateral (spinocerebellar) and dorsal (conscious perception) funiculi of the spinal cord, relaying information to centers in the brainstem, cerebellum, and cerebral cortex. The vestibular system and pathways in the spinal cord to the vestibular centers in the medulla oblongata and cerebellum also help to control proprioception. Abnormalities of proprioception include stumbling, adduction or abduction of the limbs, circumduction, and interference between limbs (Fig. 8.2). Animals with proprioceptive deficits often slap down the feet hard, rather like the gait of a person walking down stairs in the dark, unsure of where the next step is. Walking the animal off a curb or step or down a slope exaggerates this appearance. When spun in a tight circle, normal animals lift the inside forefoot as the weight shifts. The outside rear leg is put down within a line demarcated by the lateral margin of the trunk. When spun in a tight circle, patients with abnormal

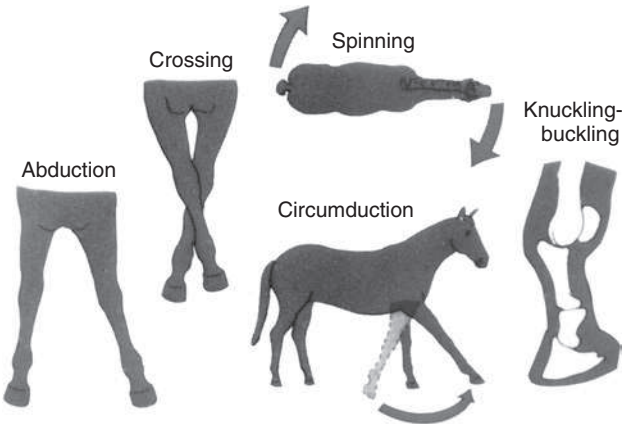

FIG. 8.2 Examples of conscious proprioceptive deficits in a horse. The signs of proprioceptive deficits in ruminants are similar.

proprioception may pivot on the inner hindfoot rather than lifting it and replacing it into a normal position. The outside foot may circumduct widely, knuckle, or buckle, and the inside foot may step on the outside foot. Animals with abnormal proprioception worsen when they are required to climb hills or lift the foot over a curb or are walked with the head elevated. The gait of noncompliant cattle may be assessed by observation of maneuvers through corrals, alleys, or a squeeze chute.

Having the animal walk backward also tests proprioception. The normal subject should be able to do so in a smooth, coordinated fashion, with conjugate movement of diagonally opposite limbs. Animals with lesions of upper motor neurons in the descending motor pathways may exhibit abnormalities such as foot dragging and weakness, sometimes to the point of "dog-sitting"; others may be reluctant to move straight backward and will try avoidance maneuvers such as circling to one side or the other to avoid it. Such tactics should raise the index of suspicion of a neurologic deficit. Care should be taken when backing an animal with severe neurologic deficits because some animals could fall backward during the procedure. Animals that are uncooperative or that have been little handled may exhibit a reluctance to walk backward that is not caused by neurologic disease. Observing the patient's general level of cooperation and having a behavioral history will help the examiner determine whether the problem is caused by neurologic disease or the animal's lack of compliance.

Cerebellar disease causes errors in the rate, range, and force of voluntary movements; there is generalized ataxia with a rolling, drunken gait. Protraction of the limbs is delayed and limb movements are exaggerated, characterized either by excessive flexion during protraction, a condition known as *hypermetria*, or by *hypometria*, characterized by reduced joint flexion. There are often coarse bobbing movements of the head when the patient is walking; an intention tremor (most notable in the head) occurs when the animal initiates purposeful movements, such as reaching out to take food. Intention tremors may disappear when the animal is relaxed or recumbent. Cerebellar diseases may also result in opisthotonos or seizure-like fits.

Spontaneous circling is seen in diseases of the vestibular system and forebrain. Circling varies from a mild tendency to move in one direction to spinning and staggering in tight circles. Circling most often occurs *toward* the side of the lesion, except in paradoxical vestibular disease (caused by lesions in the vestibular components of the cerebellum) and with some asymmetric forebrain lesions, in which the animal circles *away* from the side of the lesion. Localization of the neurologic lesion in animals that circle is made based on other neurologic abnormalities such as dementia, seizures, central blindness (forebrain disease) or proprioceptive deficits, head

VetBooks.ir

tilt, spontaneous nystagmus, obtundation, and other cranial nerve deficits (vestibular disease).

Conscious Proprioception and Postural Reactions

The integrity of conscious proprioceptive pathways may be tested by means of the postural reactions. Normal animals stand at rest with the limbs in line with the abaxial boundaries of the trunk. Normal alert animals do not permit the limbs to be placed outside of the body axis or across the midline. After the examiner places the limbs in an abnormal position, the neurologically intact animal returns to a normal stance within a few seconds. Animals with conscious proprioceptive deficits allow the limb to remain in the abnormal position for longer than the usual period. This can vary from animals in which replacement of the limb into a normal position is slightly slowed to animals that do not try to replace the limb at all. The examiner should cross one of the animal's limbs over the opposite limb or abduct one limb; the normal response is for the limb to be placed back into the resting position. Normal animals often strongly resist attempts to place the limbs in abnormal positions. It should be noted that normal animals are extremely variable in their responses to this maneuver, so undue reliance should not be placed on its results, particularly if there are no other signs of ataxia. Animals with proprioceptive deficits may spontaneously place the limbs in abnormal positions: excessively adducted, abducted, or even crossed. Abnormalities of proprioception alone are poorly localizing signs, although a couple of generalities may be stated. Unilateral lesions rostral to the medulla oblongata produce mild to moderate proprioceptive and postural deficits in the *contralateral* limbs. Unilateral lesions in the medulla oblongata or spinal cord produce more severe proprioceptive and postural deficits in the *ipsilateral* limbs. Lesions of the cerebellum rarely result in postural deficits.

Additional postural reactions such as hopping, hemiwalking, and wheelbarrowing can be tested in small ruminants, calves, and some foals. Hopping is tested in the thoracic limbs by lifting the pelvic limbs a few inches off the ground by means of a hand and arm placed around the abdomen, flexing one thoracic limb slightly, and moving the animal away from the side of the flexed thoracic limb so that it must hop laterally on the thoracic limb still in contact with the ground. It is easiest if the examiner stands in one place and turns clockwise when testing the animal's right thoracic limb and counterclockwise when testing the left thoracic limb. Hopping in the pelvic limbs can be tested similarly, supporting both thoracic limbs off the ground with an arm around the chest. Hemiwalking is done by supporting both limbs on one side of the body in a slightly flexed position and pushing the animal toward the opposite side so that it must walk laterally on the two limbs still in contact with the ground. Both hopping and hemiwalking should be done with care not to push the patient over. Adult horses can be made to hop on one thoracic limb by picking up the opposite limb and firmly pushing the head and shoulders laterally. Hopping and hemiwalking involve the same ascending and descending motor tracts involved in gait on a level surface but also require input from the forebrain. These maneuvers are abnormal on the ipsilateral side in animals with lesions in the skeletal muscles, peripheral nerves, spinal cord, and medulla oblongata and on the contralateral side in animals with lesions in the midbrain or forebrain. Animals with forebrain lesions have normal gait on a level surface but subtle deficits in hemiwalking and hopping.

Abnormalities of Posture and the Righting Response

Posture refers to the position of the body and head in space, in relationship to gravity and to each other. Animals adopt slightly different postures when on a sloped or uneven surface compared with posture on a level surface. However, sustained asymmetric postures such as head tilt (Fig. 8.3), in which one ear is closer to the ground than the other, and head turn (Fig. 8.4), in which the nose is turned back toward the trunk, are abnormal. Circling often accompanies head tilt and head turn

FIG. 8.3 Head tilt caused by vestibular dysfunction in a horse that sustained head trauma.

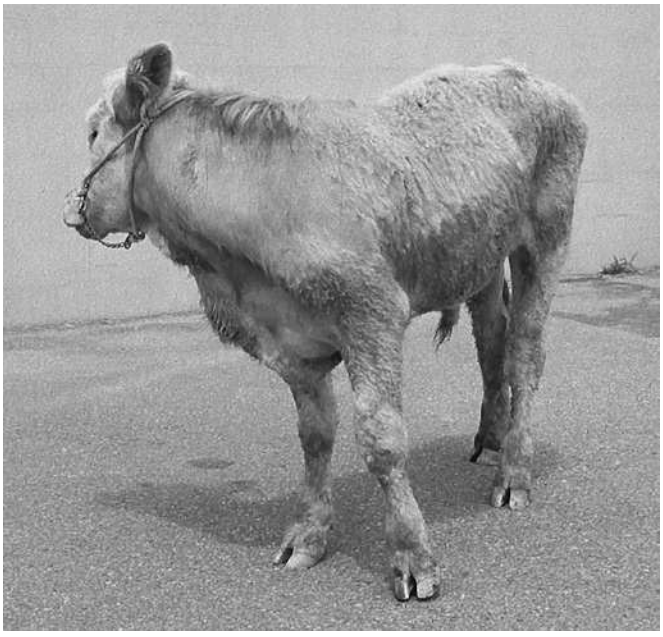

FIG. 8.4 Head turn in a steer with polioencephalomalacia.

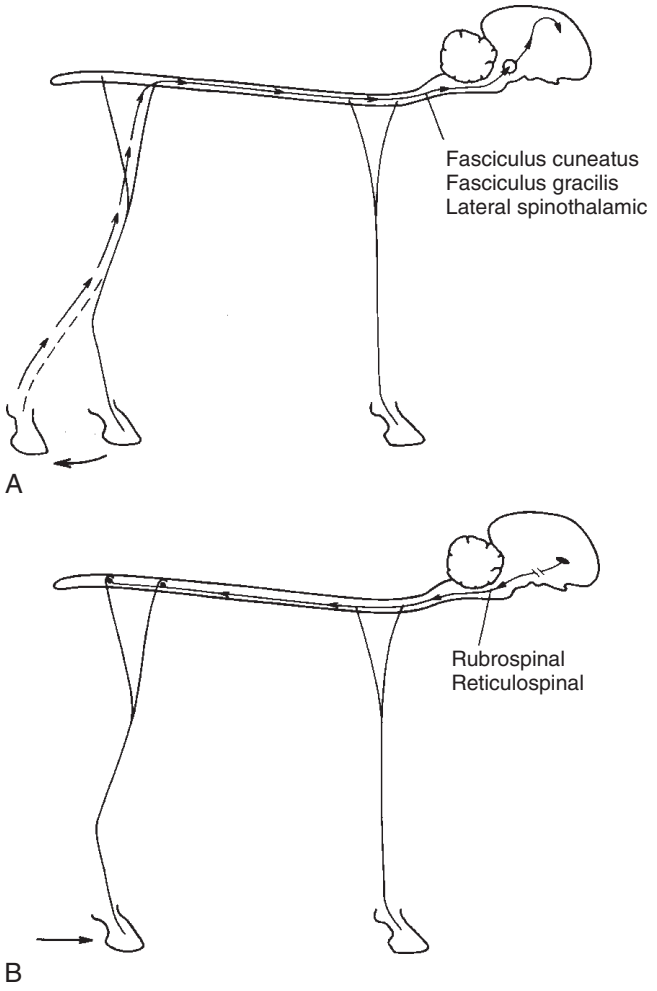

FIG. 8.5 **A,** Afferent pathways responsible for providing proprioceptive information to the brainstem and higher centers. **B,** Efferent pathways responsible for providing motor activities to the motor neurons.

in asymmetric vestibular disease, and all tend to be toward the direction of the lesion. The exception to this rule occurs in paradoxical vestibular syndrome, in which head tilt and circling occur in a direction away from the side of the lesion.

The righting response is most easily tested in small ruminants and in recumbent large animals (Fig. 8.5). The response is initiated by receptors in the eyes and vestibular labyrinths and by proprioceptive receptors in the joints, tendons, and muscles. Information regarding limb position and balance is relayed ultimately to the cerebral cortex. Descending impulses are initiated in the motor cortex and relayed via the brainstem, cerebellum, and spinal cord to the appendicular musculature. The normal response to stimulation is to lift the head, assume sternal recumbency, and rise. The normal horse rises on the thoracic limbs first, whereas the normal ruminant rises on the pelvic limbs first. Animals that are in lateral recumbency and unable to lift the head from the ground may have lesions in the peripheral or brainstem vestibular centers or in the cervical spinal cord cranial to the C4 spinal cord segment. Unilateral lesions in this area result in an inability to lift the head from the ground when the lesion side is up. When the lesion side is down, the animal can raise the head slightly. Animals with incomplete lesions of the C7 to T2 spinal cord segments can lift the head and neck but cannot rotate the thorax into a prone position, and they may remain recumbent. Animals with lesions of the thoracolumbar and lumbosacral spinal cord (T3 to S3 spinal cord segments) can usually lift the head and neck, arise on the thoracic limbs, and assume a dog-sitting position.

Spinal Reflexes

The spinal reflexes are stereotyped responses to specific stimuli. They include the myotatic or tendon reflexes, the cutaneous trunci reflex (incorrectly called the "panniculus reflex"), the perineal reflex, and several others. As their names imply, spinal reflexes depend on the integrity of local spinal cord segments; dorsal and ventral nerve roots; and peripheral nerves, neuromuscular junctions, and muscles. Lesions of descending pathways in the spinal cord that are located cranial to the spinal components of the peripheral nerves to the limbs being tested result in *normal to increased* spinal reflexes and are commonly referred to as *upper motor neuron lesions.* Lesions in the gray matter of the spinal cord segments at the level of the reflex arc, the ventral roots, or peripheral motor nerves cause *diminished* spinal reflexes and are commonly referred to as *lower motor neuron lesions.*

It is appropriate at this point to define the terms *upper motor neuron* and *lower motor neuron.* Upper motor neurons are nerve cells contained completely within the CNS, with cell bodies in the brain and axons that terminate at synapses within the brain or spinal cord. Diseases affecting upper motor neurons result in normal to increased spinal reflexes, variable severity of weakness, and variably increased muscle tone (spasticity). The nerve cell bodies of somatic lower motor neurons lie in the nuclei of cranial nerves in the brainstem or in the ventral horn gray matter of the spinal cord. The axons exit the CNS, course within the peripheral or cranial nerves, and terminate at neuromuscular junctions. Diseases affecting lower motor neurons result in decreased spinal reflexes, ataxia, moderate to severe weakness, decreased muscle tone (flaccidity), and rapid, pronounced atrophy of the denervated muscles.

Myotatic Reflexes

Myotatic or tendon reflexes are tested by sharply striking the tendon of a specific muscle (or sometimes the muscle itself) and evaluating the strength of the reflex contraction. The afferent component of the reflex arc involves the muscle spindles, which are stretch detectors; sensory fibers in the peripheral nerve; the dorsal nerve root and its ganglion; and the connection from the sensory nerve fiber to the lower motor neuron in the ventral horn of the same spinal cord segment (Fig. 8.6). The efferent component of the reflex arc involves the lower motor neuron, ventral nerve root, motor fibers in the peripheral nerve, the neuromuscular junction, and the muscle being tested. Lesions in the spinal cord cranial to the level of the reflex arc and lesions of the brain result in *normal to increased* myotatic reflexes after a period of several days. Lesions in either the afferent or the efferent components of the reflex arc result in *decreased to absent* myotatic reflexes.

In adult horses and many adult cattle, myotatic reflexes can be tested only in recumbent animals. Some cattle can be cast with ropes for this purpose, and young animals and small ruminants can be placed in lateral recumbency for testing. These reflexes should be tested only in the limbs that are uppermost when the animal is lying on one side. The animal must be turned over to test the limbs on the opposite side; however, reflexes are often diminished in limbs that have been laid upon for prolonged periods of time (hours). In adult horses and cattle, only patellar reflexes can be reliably tested. The reflex responses are assigned a qualitative clinical score as follows:

0—No reflex activity
1—Hypoactive
2—Normal
3—Hyperactive
4—Hyperactive and clonic

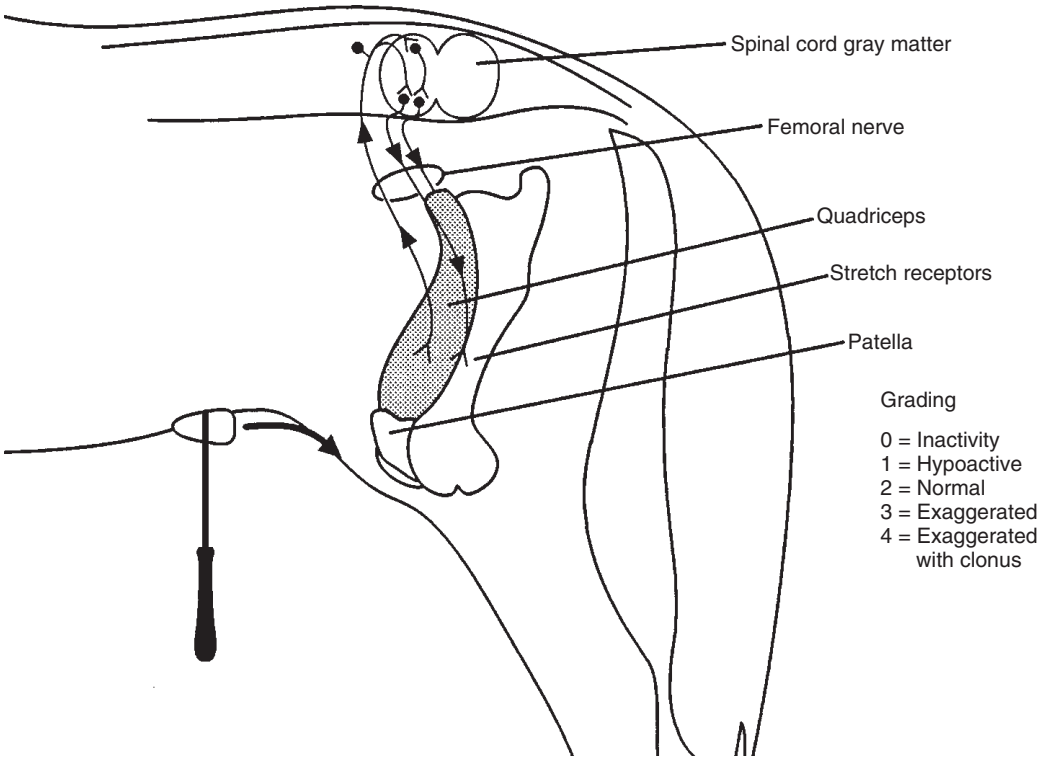

FIG. 8.6 Pathways governing patellar tendon reflex.

TABLE 8.4

Innervation of the Thoracic Limbs of Large Animals

Spinal Cord Segment	Peripheral Nerve	Muscle(s)
C7	Suprascapular	Supraspinatus, infraspinatus
C6, C7	Subscapular	Subscapularis
C7, C8, T1	Pectoral	Subscapularis, pectoral muscles
C6[a], C7, C8	Musculocutaneous	Biceps brachii, coracobrachialis, brachialis
C8, T1, T2	Median	Flexor carpi radialis, deep digital flexor, superficial digital flexor
C8[a], T1, T2	Ulnar	Flexor carpi ulnaris, deep digital flexor, superficial digital flexor
C7, C8, T1	Radial	Triceps, extensor carpi radialis, ulnaris lateralis, lateral and common digital extensors
C6[b], C7, C8	Axillary	Deltoideus, teres minor, subscapularis, cleidobrachialis
C7, C8	Long thoracic	Serratus ventralis
C8, T1, T2[b]	Thoracodorsal	Latissimus dorsi
C8, T1	Lateral thoracic	Cutaneous trunci

[a]Contributes innervation in the ruminant only.
[b]Contributes innervation in the horse only.

Clonus is a phenomenon observed with severe upper motor neuron lesions: the response of the muscle being tested is a series of rapid, repeated contractions rather than a single contraction. The innervation of the limbs is listed in Tables 8.4 and 8.5.

THORACIC LIMB MYOTATIC REFLEXES

Triceps Reflex. Hold the limb moderately flexed at the elbow, and percuss the triceps tendon just above the olecranon using a heavy instrument. The normal response is a contraction of the triceps muscle, leading to retraction of the upper limb and extension of the elbow. The triceps reflex measures the integrity of the radial nerve and the C7 to T1 spinal segments.

Biceps Reflex. Hold the limb moderately extended at the elbow and place the supporting hand over the attachment of the biceps muscle on the dorsomedial aspect of the limb at the level of the elbow joint. Percuss the biceps tendon or the taut biceps muscle with a heavy instrument. Contraction of the muscle may be perceived visually or by palpation. A slight flexion of the elbow and extension of the carpus is normal. The test measures the function of the musculocutaneous nerve and spinal cord segments C6 to C8 in ruminants and C7 and C8 in horses.

Lesions cranial to C6 result, within several days from the time of injury, in general hyperreflexia of both thoracic limbs and pelvic limbs. Lesions located in spinal segments C5 to T2 result in immediate hyporeflexia to areflexia of the thoracic limbs and, within several days, hyperreflexia of the pelvic limbs.

PELVIC LIMB MYOTATIC REFLEXES

Patellar Reflex. Flex the stifle moderately, and sharply percuss the middle patellar ligament with a heavy instrument. The normal reflex is a sharp contraction of the quadriceps

VetBooks.ir

TABLE 8.5

Innervation of the Pelvic Limbs of Large Animals

Spinal Cord Segment	Peripheral Nerve	Muscle(s)
L3[a], L4, L5, L6[b]	Femoral	Quadriceps
L5[a], L6, S1	Cranial gluteal	Gluteals, tensor fascia lata
S1-S5	Caudal gluteal, pudendal	Biceps femoris, middle and superficial gluteals
L5[a], L6, S1, S2	Sciatic, peroneal	Lateral digital extensor, long digital extensor, short digital extensor, cranial tibial
L5[a], L6, S1, S2	Tibial	Gastrocnemius, popliteus, superficial and deep digital flexor, interosseus
L5[a], L6, S1, S2	Pudendal	Retractor penis
S3-Cd5	Caudal rectal	Rectum, anal sphincter, bladder

[a]Contributes innervation in the horse only.

[b]Contributes innervation in the ruminant only.

femoris muscle resulting in extension of the stifle and a forward jerk of the lower part of the limb. The patellar reflex measures the function of the femoral nerve, the quadriceps femoris muscle, and L3 to L5 and L4 to L6 spinal cord segments in horses and cattle, respectively.

Cranial Tibial Reflex. The cranial tibial reflex is elicited by flexing the hock and sharply striking the belly of the cranial tibial muscle. The reflex consists of a slight extension of the digit. The cranial tibial reflex is mediated through the peroneal and sciatic nerves and spinal cord segments L5 to S2 and L6 to S2 in the horse and the ruminant, respectively. Lesions of the spinal cord anterior to L3 segments result in hyperreflexia, whereas lesions of L3 to L6 spinal segments result in hyporeflexia or areflexia.

FLEXOR (WITHDRAWAL) REFLEXES. The flexor reflexes are elicited on the upside front and hind limb in the recumbent large animal. For safety, the examiner should be positioned on the dorsal side of the animal or well cranial to the limb being tested. A painful stimulus is applied to the uppermost foot or distal limb. The normal response consists of two phases: (1) rapid reflex limb flexion, and (2) slower conscious perception of and response to the stimulus, characterized by attempts to assume sternal recumbency, vocalization, ear and eye movements, and/or kicking. The thoracic limb flexor reflex tests the integrity of the axillary, median, and musculocutaneous nerves and spinal cord segments C5 through T2, as well as the flexor muscles of the limb. The pelvic limb flexor reflex is mediated by the sciatic, peroneal, and tibial nerves; the pelvic limb flexor muscles; and spinal cord segments L6 to S2.

Spinal cord and peripheral nerve lesions may be localized further by testing the integrity of the sensory innervation of the skin of the limbs. Areas of decreased or absent cutaneous sensation reflect lesions of the peripheral nerves innervating the regions of the skin or of the spinal cord segments in which those sensory nerves terminate. The skin over the trunk and much of the limbs is innervated by more than one peripheral nerve. Some areas of the limbs derive sensory innervation from a single peripheral nerve. These areas are termed the *autonomous zones* for those peripheral nerves. Damage to a peripheral nerve innervating the skin of a limb therefore will result in decreased to absent cutaneous sensation in the autonomous zone for that nerve. This information can be used to localize lesions. Decrease in or loss of sensation to an entire limb or to limbs on both sides of the body suggests a lesion affecting several local spinal cord segments or a transverse spinal cord lesion rostral to the affected limbs.

Other Spinal Reflexes

PERINEAL REFLEX. The perineal reflex is elicited by pinching the mucocutaneous junction of the anus. The normal reflex includes tightening of the sphincter muscle and contraction of the ventral tail muscles. Conscious perception of the stimulus produces avoidance or protective responses that may range from a slight movement of the pelvic limbs and pelvis to a violent kick. The reflex is mediated by the pudendal nerve and spinal cord segments S1 to S5. Lesions in the nerve or in the sacral spinal cord result in a dilated, atonic rectal sphincter that fails to respond to noxious stimuli. Additional signs of sacral spinal cord injury may include fecal impaction in the rectum and a dilated urinary bladder. The bladder is full of urine and dribbles whenever digital pressure is applied through the rectum or vagina. The perineum remains wet and may become irritated from constant contact with urine.

CUTANEOUS TRUNCI REFLEX. The cutaneous trunci reflex (also known incorrectly as the "panniculus reflex") is a shrugging or flinching of the skin over the thorax when it is stimulated by light touch or by pinching. Tap the skin with an extended thumb (in adult horses) or with a hemostat. The normal reflex response is a skin twitch often followed by a conscious avoidance maneuver such as moving away from the stimulus. The afferent part of the cutaneous trunci reflex is mediated by the segmental spinal nerves and dorsal nerve roots in the territory of the reflex. The tracts ascend in the dorsal funiculi of the spinal cord and synapse on efferent neurons in spinal segments C8 to T1 in ruminants and C8 to T2 in horses. The efferent axons exit in the ventral roots and form the lateral thoracic nerve, which innervates the cutaneous trunci muscle. The degree of reflex responsiveness varies among the large animal species. Sheep, goats, and many cattle possess a poor cutaneous trunci reflex. Horses and Zebu cattle have a well-developed reflex.

CERVICAL REFLEXES. Two reflexes have been described in the cervical area of the horse.[47] The cervical reflex is tested by tapping or pinching the skin of the cervical region over the brachiocephalicus muscle and behind the second cervical vertebra. The expected response is contraction of the brachiocephalicus muscle and twitching of the skin. The pathway is believed to involve the cervical segmental spinal nerves and the local spinal cord segments. The cervicofacial reflex is elicited in horses by tapping the skin as described for the cervical reflex. As the skin is stimulated in normal horses, the ear reflexively twitches rostrally and ventrally, and the commissure of the lip retracts. This test measures the integrity of the dorsal funiculi of cervical spinal cord segments and the facial nerve in the medulla oblongata. The diagnostic usefulness of this test in ruminants is unknown.

Both reflexes may be abnormal in animals with lesions affecting the cervical spinal cord, such as cervical vertebral stenotic myelopathy in horses. The cervicofacial reflex also may be diminished or absent in animals with caudal brainstem lesions involving the facial nerve or with peripheral facial nerve lesions.

VetBooks.ir

"SLAP" TEST (LARYNGEAL ADDUCTOR REFLEX). A sharp slap applied in the saddle region on one side of a horse's thorax results in adduction of the vocal folds of the larynx on the opposite side.[48] Standing on one side of the animal, the examiner curls his or her fingers around the dorsolateral aspect of the larynx on the opposite side. A slap is applied to the saddle region on the side on which the examiner is standing. The response is palpated as a small movement of the arytenoid cartilage felt under the fingertips on the opposite side of the larynx. The laryngeal adduction elicited in this test can also be observed endoscopically. The pathway for the reflex is only partially understood. Sensory information from the skin and/or pleural stretch receptors is relayed to the spinal cord in the segmental spinal nerves. The ascending pathways cross the spinal cord and run cranially in the spinal cord to the origin of the vagus nerve in the medulla oblongata. The efferent part of the reflex runs in the cervical vagosympathetic trunk and thence to the recurrent laryngeal nerve, which branches from the vagus in the cranial thorax. The recurrent laryngeal nerve courses cranially alongside the trachea to the larynx. Reduced or absent laryngeal adductor reflexes are found in animals that have lesions of the cervical spinal cord but also in those with caudal brainstem lesions, vagus nerve lesions, and lesions of the left recurrent laryngeal nerve (some of which are clinical "roarers"). The test's accuracy may be limited. In one study there was poor correlation when predicting the presence or absence of cervical spinal cord or brainstem disease.[49]

Muscle Mass and Tone

Normal mass and tone of the musculature depends on an intact nerve supply. Primary diseases of muscle and loss of use of a limb secondary to orthopedic disease are often associated with mild to moderate muscle atrophy that develops over weeks to months. Atrophy caused by denervation, however, is more severe and rapid in onset. Visible loss of mass of specific muscles or groups of muscles is most likely caused by damage to the nerve supply to those muscles, either by direct injury to peripheral nerves or by injury to the cell bodies of those nerves in the ventral horn of the gray matter of the spinal cord (Fig. 8.7). Knowledge of the central origins of the nerves to the limbs and the course of those nerves in the periphery can be used to specifically localize neurologic lesions (see Tables 8.4 and 8.5). Electromyography and nerve conduction testing can further be used to help identify muscle denervation and peripheral neuropathies (see Chapter 35).

Muscle tone can be evaluated in the recumbent animal by passively flexing the limbs. Evaluation is not accurate in the standing animal or in animals supported in slings because of resistance from taut bands of connective tissue. In normal animals repeated flexion is accompanied by an increase in the tone in the flexed limb. The limbs of animals with a lower motor neuron deficit remain flaccid.

The tone of the thoracic limbs is controlled through spinal cord segments C6 to T2 and the radial, musculocutaneous, median, ulnar, axillary, and long thoracic nerves. The motor tone of the pelvic limbs is controlled through spinal cord segments L3 to S2 and the femoral, cranial and caudal gluteal, and sciatic nerves. The lower motor neurons to the anus originate in spinal cord segments S1 to S5, via the pudendal nerve. The tail is innervated by the coccygeal segmental spinal nerves.

Examination of Cranial Nerves

Examination of the cranial nerves is most easily carried out by examining the functions of groups of nerves that innervate particular regions of the head rather than by performing the examination in a strictly numeric order. For example, examination of vision and other ocular functions such as the menace response, pupillary light reflexes, and physiologic nystagmus reveals the integrity of several cranial nerves, not only II, III, IV, and VI but also V (sensory to the cornea), VII (motor to the eyelids), and VIII (providing vestibular input to control the functions of III, IV, and VI), as well as centers within the brain.

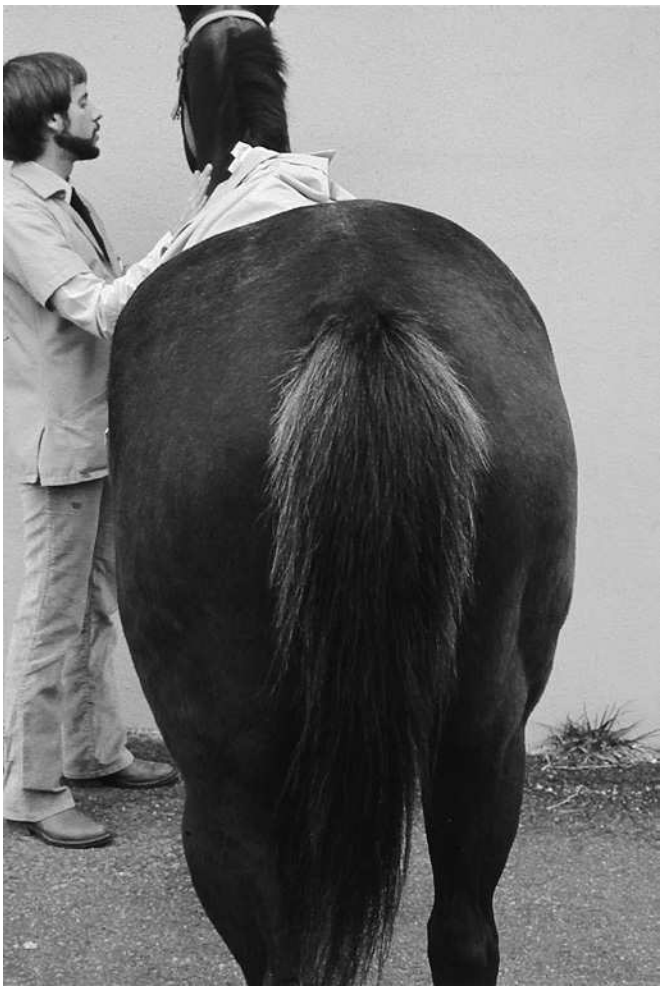

FIG. 8.7 Muscle atrophy in the gluteal muscles in a horse with equine protozoal myeloencephalitis.

CRANIAL NERVE I—OLFACTORY NERVE. Reliable and specific testing of the sense of smell is difficult in animals. Large animals require an intact sense of smell to eat properly, so it can be inferred that animals with good appetites possess an adequate sense of smell. Having a blindfolded animal track food moved from side to side in front of the nose may be helpful. Irritating substances such as ammonia should not be used for evaluation of olfactory nerve function; such compounds stimulate nociceptors in the nasal mucosa, which are the dendrites of the maxillary nerve (cranial nerve V), rather than stimulating olfactory receptors innervated by the olfactory nerve. Loss of the sense of smell is more likely to be caused by disease within the nasal passages than by a primary neurologic disease.

CRANIAL NERVE II—OPTIC NERVE. Vision and light perception are the functions of cranial nerve II, the optic nerve. Observing the animal's response to its environment provides a good initial assessment. Does it respond to visual cues such as movement or does it walk into objects? Noise may cause the animal to turn its head toward the sound, so the observer must be careful to distinguish such responses from those made in response to visual cues. A maze can be set up using straw bales or other objects, and then the animal can be gently driven

VetBooks.ir

TABLE 8.6

Guide to Neuro-Ophthalmologic Lesion Location

Lesion Location	Menace Response		Pupillary Light Reflex		Maze Test[a]
	Ipsilateral	Contralateral	Ipsilateral	Contralateral	
Unilateral retina, optic nerve	Absent	Present	Absent (direct), slightly dilated	Normal	Abnormal
Bilateral retina, optic nerve, optic chiasm	Absent	Absent	Fixed	Fixed	Abnormal
Unilateral oculomotor nerve	Absent	Present	Dilated nonresponsive	Normal	Normal
Unilateral occipital cortex	Present	Absent	Normal[b]	Normal[b]	Abnormal
Bilateral occipital cortex	Absent	Absent	Normal[b]	Normal[b]	Abnormal
Bilateral vagosympathetic trunk	Present	Present	Miotic	Normal	Normal
Bilateral cerebellar cortex	Absent	Absent	Normal	Normal	Normal[c]

[a]In unilateral cases, assumes that contralateral eye is blindfolded.

[b]Assuming that no cortical swelling has occurred.

[c]Animals walk abnormally but recognize and generally avoid obstacles.

through the maze. Normal animals will avoid colliding with objects. Animals that are severely obtunded, however, may walk into objects even when they can see. Thorough evaluation of the complete neurologic examination is necessary to distinguish this from true blindness.

The menace response measures the integrity of the entire visual pathway. The afferent pathway runs from the retina via the optic nerves and internal capsule to the visual areas in the occipital lobe of the cerebrum. Information from the visual cortex is processed and relayed to the ipsilateral motor cortex. The efferent pathway of the menace response runs from the motor cortex via the pons to the nucleus of the facial nerve in the medulla oblongata and thence via the facial nerve to the orbicularis oculi muscle. It is not known whether this pathway passes through the cerebellum, but it is clear that the ipsilateral cerebellar cortex is required for a competent menace response. The menace test is performed by rapidly advancing the hand toward the eye and observing closure of the eyelid. In addition to closure of the eyelid, some animals display a generalized avoidance response characterized by coordinated movement of the head and neck away from the stimulus. The opposite eye may be covered to ensure that only one eye is being stimulated. Care must be taken not to touch the face or eyelashes or create air currents near the face. Separate menacing gestures must be directed from both the nasal and the temporal aspects, in order to cover the entire visual arc. The menace response measures the integrity of the retina, optic nerve, optic chiasm, optic tracts, thalamus, internal capsule, and occipital cortex. There is approximately 90% crossing over of optic nerve fibers in the optic chiasm of livestock. Unilateral lesions central to the optic chiasm—in the optic tract, internal capsule, thalamus, or occipital lobe—cause loss of vision in the opposite eye, with apparently normal vision in the ipsilateral eye. It should be noted that normal neonatal animals may not display a response to a menace gesture because this is a learned response.

Menace deficit may be the result of facial nerve paralysis. In such cases the animal does not blink but shows avoidance of the stimulus by pulling the head away. Facial nerve deficits will be apparent in these animals by their inability to close the eyelids in response to cutaneous stimulation around the lid margins (palpebral reflex) and by other signs such as drooping of the lip and ear on the same side. Animals with cerebellar disease may also display a menace deficit yet possess normal vision. Menace deficits resulting from facial nerve or cerebellar disease may be differentiated from deficits in other areas by maze testing. Animals with cerebellar or facial nerve disease retain visual acuity and maneuver through the course successfully. In addition to the optic pathways, the test measures the integrative pathways in the frontal and parietal lobes of the brain, the motor neurons, and the proprioceptive pathways (Table 8.6). Myasthenic diseases (e.g., botulism, hypocalcemia, hypomagnesemia) result in bilaterally decreased menace and palpebral responses but do not produce blindness.

The pupillary light reflex measures the integrity of the retina, optic nerves, optic chiasm, pretectal and oculomotor nuclei in the midbrain, oculomotor nerve, ciliary ganglia, and constrictor pupillae muscle. The test is performed by shining a bright light into each eye and observing constriction of the pupil in the ipsilateral eye (direct reflex) and the contralateral eye (indirect reflex). Lowering the ambient light level may facilitate this test by causing the pupils to dilate. The reflex in large animals is considerably slower than those observed in cats and dogs. A "swinging light" test has been recommended in large animals to reduce the dazzle and startle responses elicited by suddenly shining a bright light into the eyes.[46] From a position directly in front of the animal, a strong light is slowly swung from one eye to the other while bringing the light closer and closer to the head and observing the responses in each pupil. The effects on the pupillary light reflex of lesions at various levels along the visual pathway are shown in Table 8.6.

Unilateral lesions in the forebrain may result in blindness of the opposite eye. With forebrain lesions, the pupillary light reflexes are usually normal. If the forebrain disease is accompanied by increased intracranial pressure, the oculomotor nerve or nucleus may be compressed in the midbrain, resulting in ipsilateral mydriasis.

CRANIAL NERVES III, IV, AND VI—OCULOMOTOR, TROCHLEAR, AND ABDUCENT NERVES. The position of the globe in the orbit is governed by the activities of the oculomotor, trochlear, and abducent nerves. Dysfunctions of these nerves result in deviation of the globe that is constant in all head positions. Loss of oculomotor nerve function results in ventrolateral strabismus. Trochlear nerve dysfunction results in rotation of the dorsal aspect of the globe away from the midline (dorsomedial strabismus). Loss of abducent nerve function results in medial strabismus and inability to retract the globe, which is best demonstrated by closing the eyelid and then pushing on the globe through the eyelid. The normal reflex is a retraction of the globe.

Competent function of the oculomotor, trochlear, and abducent nerves is also required for the oculocephalic reflexes. When the head is turned from side to side in a horizontal plane, physiologic horizontal nystagmus is observed, with the fast phase of the nystagmus in the direction of head movement. The sensory receptors for this reflex lie within the semicircular canals of the inner ear, and they detect angular acceleration of the head. Input

VetBooks.ir

from the semicircular canals is transferred to the vestibular centers in the medulla oblongata and the cerebellum and then to the nuclei of cranial nerves III, IV, and VI. Lesions of the peripheral or central components of the vestibular system can also result in abnormal eye position (strabismus) and movement (nystagmus), described in more detail later. With peripheral or central vestibular lesions, however, eye position typically changes when the head and neck are moved, in contrast to the constant deviation of the globe seen with direct lesions to the oculomotor, trochlear, and abducent nerves.

The oculomotor nerve is motor to the levator palpebrae superioris muscle, the most important of the muscles responsible for elevation of the upper eyelid. Lesions of the nerve cause ptosis (drooping of the upper eyelid) in addition to the signs described previously. Ptosis can also be induced by lesions of the sympathetic nerve supply to the eye because of paralysis of the superior tarsal (Müller's) muscle and, in the horse only, by lesions of the facial nerve, which innervates the levator anguli oculi medialis muscle (see later).[50]

CRANIAL NERVE V—TRIGEMINAL NERVE. The trigeminal nerve is sensory to the face and motor to the muscles of mastication. The sensory functions of the trigeminal nerve are tested by lightly stimulating the forehead, upper and lower jaws, and muzzle using the tip of a closed hemostat or a finger. The normal response is one of avoidance using neck, facial, and appendicular musculature; the animal usually pulls the head away and blinks simultaneously. Some areas such as the cheeks, forehead, and chin are normally less sensitive, whereas the periorbital region, nasal planum, nasal septum, and lips are sensitive. The test evaluates the function of the sensory part of the trigeminal nerve, the trigeminal ganglion, the nucleus and spinal tract of the trigeminal nerve, the pontine sensory tract nucleus of cranial nerve V, the thalamus, and the sensorimotor cortex. After the trigeminal nerve enters the lateral aspect of the pons, axons both ascend and descend through the medulla as the spinal tract of the trigeminal nerve. Ascending information ultimately reaches the sensorimotor cortex via the thalamus, where it is consciously perceived. Descending information projects to the nucleus of the facial nerve in the medulla and also into the first cervical spinal segment. Unilateral loss of facial perception of touch most commonly results from damage to the peripheral portion of the trigeminal nerve, the trigeminal ganglion in the petrosal bone of the skull, or the contralateral forebrain (i.e., thalamus or cerebrum). Lesions affecting the spinal tract of the trigeminal nerve in the medulla and midbrain would likely be fatal because they also would affect adjacent respiratory and cardiovascular centers in the brainstem. Patients with bilateral facial hypalgesia most often have bilateral forebrain disease.

The palpebral reflex is elicited by lightly touching the periorbital area (both above and below the eye) and observing a brisk closure of the eyelid. This reflex reflects the sensory function of the trigeminal nerve and the motor function of the facial nerve and orbicularis oculi muscle. Simultaneous loss of the menace response and the palpebral reflex suggests a lesion in the facial nerve or the orbicularis oculi muscle. Loss of the palpebral reflex with normal menace responses suggests a lesion in the trigeminal nerve or ganglion. Loss of menace response with preservation of the palpebral reflex and pupillary light reflex suggests the presence of either contralateral forebrain disease or ipsilateral cerebellar cortical disease.

The jaw should be opened to assess the strength of the masticatory muscles. This measures both the sensory (proprioceptive) fibers of the trigeminal nerve and the motor component of the nerve. Bilateral lesions of the motor component of the trigeminal nerve result in a dropped jaw. Affected animals may protrude the tongue but can retract it normally when stimulated. Animals with dropped jaws may drool because they cannot hold saliva within the oral cavity. Unilateral lesions of the trigeminal nerve produce asymmetric jaw closure, with deviation of the mandible away from the affected side, and neurogenic atrophy of the visible masticatory muscles (i.e., masseter and temporalis).

CRANIAL NERVE VII—FACIAL NERVE. The motor nucleus of cranial nerve VII (the facial nerve) originates in the middle and ventral part of the medulla oblongata. The motor fibers are distributed to muscles of facial expression. Just as the motor fibers are exiting from the lateral aspect of the brainstem, they merge with axons from the parasympathetic facial nucleus. These autonomic fibers innervate the lacrimal and salivary glands and separate from the motor component of the facial nerve as it traverses the petrous temporal bone. Lesions of cranial nerve VII located between the brainstem and this separation usually result in "dry eye." More distal lesions, however, have no effect on tear production. The tone of the facial musculature is examined by palpation of the ears, lips, eyelids, and muzzle. Clinical signs of facial nerve dysfunction include drooped ear and lips, drooling saliva, and retention of food in the cheek pouch on the denervated side (Fig. 8.8). Closure of the eyelids is weak in partial facial nerve lesions and absent in severe lesions. Despite this, there is slight drooping of the upper eyelid (ptosis) because of paralysis of the levator

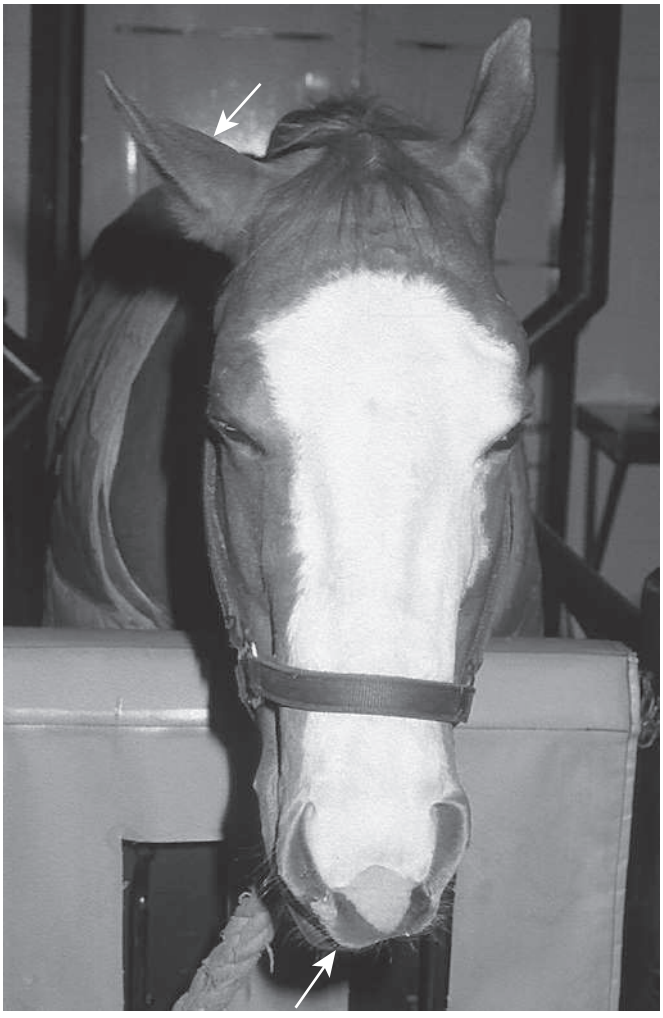

FIG. 8.8 Acute right facial paralysis in a horse with guttural pouch mycosis. Note the drooped right ear and deviation of the muzzle toward the left side *(arrows)*.

VetBooks.ir

anguli oculi medialis muscle, which contributes to eyelid retraction. In species with a soft muzzle (e.g., horses, sheep, goats), there is a marked deviation of the nasal filtrum *away* from the side with the lesion after unilateral loss of facial nerve function. The filtrum of affected cattle is not deviated because of the large amount of fibrous tissue in the planum nasale. In *chronic* facial paralysis the face may be deviated *toward* the affected side because of atrophy and contracture of the denervated musculature of the face. In horses neurogenic atrophy of the parotidoauricularis muscle is evident as a groove behind the vertical ramus of the mandible.

CRANIAL NERVE VIII—VESTIBULOCOCHLEAR NERVE

Vestibular System. The function of the vestibular system—which is composed of the sensory structures in the inner ear (semicircular canals, utriculus, saccule), the vestibular portion of cranial nerve VIII, and the central components of the vestibular system in the medulla oblongata and cerebellum—is tested by assessment of gait, extensor tone, head posture, and eye movements. Signs of vestibular dysfunction include a staggering gait, circling, falling, rolling, head tilt, and spontaneous nystagmus. Lesions can be classified as peripheral or central. Diseases affecting the inner ear or cranial nerve VIII result in signs of peripheral vestibular disease. Lesions affecting vestibular structures in the medulla oblongata result in central vestibular signs, and lesions affecting vestibular structures in the cerebellum result in paradoxical vestibular signs. Blindfolding affected patients results in a worsening of clinical signs because of elimination of visual compensatory mechanisms. Recumbent animals with vestibular lesions tend to lie with the side of the vestibular lesion downward. When turned, these animals spontaneously rotate back to the lesion-down position and may strongly resist attempts to turn them over. Animals with unilateral vestibular disorders typically have ventral strabismus in the ipsilateral eye and dorsal strabismus in the contralateral eye. Bilateral, symmetric lesions of the vestibular system are rare. Bilateral vestibular dysfunction does not cause head tilt, nystagmus, or strabismus. Affected animals are reluctant to move. They stand with a basewide posture, with the head held low, and fall easily when forced to move.

CRANIAL NERVES IX, X, AND XI—GLOSSOPHARYNGEAL, VAGUS, AND SPINAL ACCESSORY NERVES.

Cranial nerves IX, X, and XI originate in the nucleus ambiguus, a column of motor neurons in the medulla oblongata. They provide motor control to the muscles of the neck, pharynx, and palate. The vagus nerve contains efferent fibers that stimulate the secretions of glands of the visceral and respiratory mucosa and control forestomach motility in ruminants. The glossopharyngeal and accessory nerves carry afferent fibers from the mucosa of the tongue, larynx, and pharynx.

The signs of glossopharyngeal and vagus nerve dysfunction include dysphonia (roaring, snoring), dysphagia, and regurgitation. Animals with pharyngeal paralysis regurgitate food and saliva from the nose. Roaring is a characteristic stridor emanating from the larynx. The abnormal sound may be heard only during exercise. Functional examination of these nerves should include auscultation of the larynx for stridor, observation of the animal as it swallows, passage of a nasogastric tube to evaluate deglutition, endoscopic examination to evaluate pharyngeal and laryngeal movements, and palpation of the larynx for muscle atrophy. The slap test, described earlier, is a test for function of the vagal innervation of the larynx via the recurrent laryngeal nerve. Specific descriptions of the endoscopic appearance of pharyngeal paralysis and roaring are presented elsewhere (see Chapter 31).

Signs of spinal accessory nerve dysfunction are extremely rare and include atrophy of the trapezius, sternocephalicus, and brachiocephalicus muscles.

SYMPATHETIC INNERVATION OF THE HEAD—HORNER'S SYNDROME.

Preganglionic sympathetic motor fibers that innervate structures of the head originate from the first three thoracic spinal cord segments. These fibers ascend the neck in the vagosympathetic trunk to the cranial cervical ganglion under the tympanic bulla, where they synapse with postganglionic sympathetic fibers. The postganglionic fibers are distributed to the smooth muscles of the head via the ciliary nerves, passing through the petrous temporal bone area. Lesions anywhere along the course of the preganglionic or postganglionic sympathetic nerves, in spinal cord segments T1 to T3, or, rarely, in the upper motor neuron component of the sympathetic pathway in the cervical spinal cord or brainstem (tectotegmentospinal tract) cause a characteristic constellation of clinical signs known as *Horner's syndrome*. Signs include miosis, ptosis, and increased warmth on the ipsilateral side of the face. In cattle there is a loss of sweating on the ipsilateral half of the planum nasale, whereas in horses there is excessive sweating on the affected side of the head and upper neck. Miosis is produced by lack of sympathetic tone to the affected pupil. Diseases that could produce Horner's syndrome in large animals include lesions of the T1 to T3 spinal cord segments, mediastinal or thoracic abscesses or neoplasia, trauma or infection involving the cervical sympathetic trunk, esophageal perforations, guttural pouch mycosis in horses, otitis media and interna, and retrobulbar abscesses. Lesions of the midbrain may produce miotic pupils without other signs of Horner's syndrome.

CRANIAL NERVE XII—HYPOGLOSSAL NERVE.

The hypoglossal nerve supplies motor innervation to the muscles of the tongue and the geniohyoideus muscle. The nucleus is located in the caudal medulla oblongata. Hypoglossal nerve function is tested by pulling the tongue out of the mouth. Normal animals should have forceful resistance to passive manipulation of the tongue. Lesions of the hypoglossal nerve result in flaccidity and atrophy of the tongue. Acute lesions result in deviation of the tongue away from the side of the lesion; with time the tongue may deviate toward the affected side because of muscle atrophy and contracture.

Other Aspects of Physical Examination of the Patient With Neurologic Disease

Diagnosis of a neurologic disease can often be facilitated by the observation of physical abnormalities in other systems. When one examines animals with limb ataxia or tetraparesis, the head, neck, and back should be gently manipulated while the spine is palpated for pain, crepitation, or swelling. These findings could indicate the presence of a fracture, malformation, or luxation of one or more cervical vertebrae, vertebral osteomyelitis, diskospondylitis, or osteoarthritis of intervertebral joints. Do not manipulate the neck when there is evidence of acute cervical vertebral trauma. Swelling, bruising, or hair loss on the skin around the head or bleeding from the ears or nose could signify cranial trauma. Hair loss and dermatitis around the perineum and medial thigh may indicate urinary incontinence. In neonates a hairless patch over the dorsum of the spine or skull could indicate a meningomyelocele or meningoencephalocele. Crepitation over coxofemoral or stifle joints of recumbent cattle could indicate a luxation or fracture. The pelvic limb and pelvis should be examined in all recumbent large animals to detect displacement of the hip joint into the obturator foramen or fractures through the shaft of the ilium. All joints should be passively manipulated to detect dislocations or fractures. The heart should be auscultated for murmurs that could suggest left-sided endocarditis because such lesions can shower bacteria into the meninges. Odors on the breath such as ammonia, ketones, or petroleum distillates could provide clues about possible toxic causes. The ocular fundus should be examined ophthalmoscopically to detect retinal hemorrhages (trauma), papilledema (increased intracranial pressure), or vasculitis.

VetBooks.ir

Examination of the Neonate

Most of the physical diagnostic techniques described in the preceding paragraphs for the adult may be applied to examination of the neonate. Most spinal reflexes of livestock are well developed after birth. In the normal foal younger than 3 weeks of age, the limbs are hypertonic and hyperreflexic, with occasional myoclonus occurring after percussion of the patellar or triceps tendons. This hyperreflexia is most pronounced in the pelvic limbs. A lack of menace response for up to 2 weeks after delivery is expected because the menace response must be learned. When restrained, the newborn foal relaxes into a trancelike state, periodically awakening and struggling violently before becoming passive again.

Bottle-reared calves aggressively attempt to suck while being examined, including vigorously head-butting the handler. Beef calves attempt to escape restraint and do not attempt to suck. See Chapter 17 for more on foals and Chapter 20 for more on neonatal ruminants.

Localization of Central Nervous System Lesions

Localization of a CNS lesion based on clinical signs is vital because many specific diseases are restricted to particular regions of the CNS. Lesions can be localized to one of seven regions of the CNS: forebrain, midbrain, cerebellum, medulla oblongata, spinal cord, peripheral nerve (either cranial nerves or spinal nerves), and muscle. Once the clinician has located the anatomic site of a neurologic lesion, a list of rule-out diagnoses may be formulated. Additional tests, including CSF analysis, radiography, magnetic resonance imaging (MRI), computed tomography (CT), serology, electroencephalography, brainstem auditory evoked response (BAER), and myelography, can be performed to further characterize the disease.

Localization of Neurologic Diseases by Major Clinical Signs

Abnormal Mentation and Behavior and Seizures

Decreased mental alertness (dullness, obtundation, stupor, coma) is the most common change of mental status in animals with neurologic disease, although increased responsiveness to external stimuli (anxiety, mania, aggression) sometimes occurs. Altered mentation results from lesions in the ARAS or after diffuse severe forebrain disease. Diseases affecting the ARAS tend to produce severe changes in mentation (stupor, coma), whereas those affecting the forebrain tend to produce mild obtundation with concurrent behavioral abnormalities (i.e., dementia). In order of worsening severity, decreased mental status in animals can be categorized as follows.

LETHARGY. Animals respond to normal stimuli but are duller than normal.

STUPOR. Animals appear to be asleep and will respond only to vigorous and painful stimuli. Responses are blunted even to these stimuli. Semicoma is a severe form of stupor wherein patients are too obtunded to remain standing.

COMA. Animals are unconscious and will not respond even to the most painful stimuli. Animals in coma are recumbent.

DEMENTIA. Animals with dementia exhibit abnormal reactions and responses to their environments, including to inanimate objects, humans, and other animals within those environments. Signs are extremely variable, from head pressing and yawning to compulsive walking, bellowing, rearing, self-mutilation, and aggression.

SEIZURES, COLLAPSE. Episodic abnormalities of behavior or consciousness are usually the result of seizure activity, narcolepsy or cataplexy, or syncopal attacks caused by cardiovascular or respiratory dysfunction. Intermittent toxicities or fluctuating metabolic abnormalities such as occasionally occur with hepatic encephalopathy may also cause episodic changes in mentation and behavior. Animals with a history of episodic collapse should undergo a thorough physical examination to determine whether disease of the cardiovascular system (e.g., cardiac arrhythmias, intermittent hemorrhage) or respiratory system (e.g., laryngeal paralysis) is present. Animals that have seizures usually have a period of abnormal behavior after the seizure (postictal phase of the seizure), whereas those with narcolepsy, cataplexy, or nonneurologic causes of collapse usually do not.

Diffuse forebrain disease often results from metabolic, toxic, or infectious diseases. Increased intracranial pressure, the consequence of early acquired hydrocephalus, mass lesions within the cranial vault, inflammatory diseases, or cerebral edema, tends to produce signs of diffuse forebrain dysfunction, which can range from mild to severe. Mild to moderate forebrain dysfunction usually results in an animal with decreased mental awareness or, more rarely, excitement and overreaction. Diffuse disease does not result in circling, and gait on a level surface may appear normal, or almost so. Gait may be abnormal, however, when the animal is challenged to ascend or descend slopes, step over objects on the ground, step onto and off curbs, circle, or back up. Postural and proprioceptive reflexes and reactions similarly may be abnormal. When an animal is walking at normal speed on a level surface, local reflexes in the spinal cord and regulatory information from the red and reticular nuclei in the brainstem control simple gait patterns. Movements that require visual input or complex limb and body integration of movements are initiated in motor centers of the cerebral cortex and regulated by the cerebellum. The combination of normal gait on a level surface with obvious proprioceptive and postural deficits should immediately alert the examiner to the likelihood of forebrain disease.

Vision and the menace response may be defective (see Blindness and Ocular Abnormalities, later). Pupillary light reflexes and oculocephalic reflexes are usually normal in animals with forebrain disease. Responses to noxious tactile stimuli, especially around the head, are reduced.

The hypothalamus regulates primitive functions such as eating, drinking, cardiovascular function, and sexual behavior. Lesions of the hypothalamus may cause behavioral changes ranging from profound depression, rage, and inappropriate sexual activities to unusual affection, as well as polydipsia, polyuria, bradycardia, and abnormal appetite (pica).

Seizures are the physical manifestations of spontaneous paroxysmal electrical activity arising in the forebrain. When seizure activity is limited to a small area of the cerebral cortex, the seizure is focal, resulting in localized abnormal motor activity such as muscular twitching in the face or in one limb or episodes of lateralizing abnormal behavior. More commonly the seizure is generalized or starts focally and becomes generalized to the entire cerebral cortex. Generalized seizures cause loss of consciousness, collapse, and generalized tonic-clonic motor activity. The presence of seizures indicates forebrain dysfunction, but the initiating cause may lie elsewhere in the brain; the origin may even be extracranial. *Epilepsy* is a term that means repeated seizures of any cause, although it is often used to indicate seizures of unknown cause. The nature of the seizure, whether focal or generalized, is not a reliable indicator of the underlying cause. Congenital, familial, or idiopathic epilepsy syndromes such as benign epilepsy of Arabian foals are usually characterized by generalized seizures. Partial or focal seizures more commonly indicate an acquired cause. Animals with seizures should undergo a complete physical examination, together with diagnostic testing for suspected toxins and underlying metabolic diseases, as well as a thorough

VetBooks.ir

neurologic examination to localize any interictal neurologic signs. Further diagnostics such as CSF analysis and MRI are performed as indicated after this initial work-up.

When forebrain disease is unilateral or asymmetric, asymmetry of clinical signs becomes apparent. Circling often occurs, ranging from a tendency to drift toward one side to obvious and compulsive circling around the inside of an enclosure. It is usually possible to stop the circling, although the animal may be reluctant to turn in the opposite direction. Proprioceptive and postural reaction deficits may be present in the limbs on the side of the body opposite to the lesion (contralateral) and vary in severity with the severity of the underlying neurologic disease. The head and neck may be turned to one side (usually toward the side of the lesion), but the head tilt characteristic of vestibular disease is not seen. The absence of signs such as head tilt, nystagmus, and strabismus, together with the presence of contralateral proprioceptive and postural reaction deficits, distinguishes forebrain lesions from those affecting the vestibular system.

Specific diseases associated with the forebrain of ruminants and horses are given in Tables 8.7 and 8.8, respectively.

Blindness and Ocular Abnormalities

Blindness may be the result of lesions in the eye, optic nerve, optic chiasm, optic tracts, or central projections of the visual pathways. Ophthalmic examination, including fundic examination, should be part of the routine physical examination. Animals

TABLE 8.7

Diseases of Ruminants That May Produce Forebrain Signs

Disease	Predominant Clinical Signs	Species Affected
Ammoniated feed toxicosis	Trembling, fear, uncontrolled running, crashing through objects, coma, convulsion	Cattle
Babesiosis (exotic)	Odontoprisis, ataxia, conscious proprioceptive deficits, coma, convulsions	Cattle
Border disease	Ataxia, tremors, bunny-hopping	Sheep, goat
Borna disease (exotic)	Head tremors, hyperesthesia, ataxia, anorexia, compulsive walking, coma, convulsions	Cattle, sheep, goat
Bovine spongiform encephalopathy	Aggression, weight loss, milk production, ataxia, recumbency, coma	Cattle
Brain abscess, meningitis	Recumbency, opisthotonos, blindness, hyperesthesia, stiff neck, proprioceptive deficit, ataxia, head pressing, depression, coma	Cattle, sheep, goat
Brain tumor	Obtundation, facial paresis or paralysis, facial analgesia, head tilt, strabismus, nystagmus, loss of menace, hypermetria, ataxia	Cattle
Caprine arthritis-encephalitis	Obtundation, ataxia, head pressing, convulsions, coma	Goat
Ceroid lipofuscinosis	Blindness, ataxia, weight loss, coma, convulsions	Cattle
Citrullinemia	Recumbency, coma, convulsions, death by 4 days of age	Cattle
Coenurus cerebralis	Blindness, circling, ataxia, conscious proprioceptive deficit, head tilt, recumbency, coma, convulsions	Sheep
Ethylene glycol poisoning	Obtundation, somnolence, blindness, ataxia, facial analgesia, weak tongue, head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cattle, sheep, goat
Globoid cell leukodystrophy	Ataxia, proprioceptive deficits, hyperreflexia, depression, coma	Sheep
Grass staggers	Tremor, ataxia that worsens with excitement or exercise	Cattle, sheep, goat
Heartwater (exotic)	Hyperesthesia, behavioral changes, muscular fasciculations, hypermetria, ataxia, head pressing	Cattle, sheep, goat
Hepatic encephalopathy	Hyperexcitability, aggression, rage, odontoprisis, ataxia, head pressing, coma, convulsions, semicoma, blindness, tenesmus, rectal prolapse	Cattle, sheep, goat
Hydrocephalus, hydranencephaly, microcephaly, anencephaly	Blindness, ataxia, proprioceptive deficit, ventrolateral strabismus, failure to suckle, dysphonia	Cattle, sheep, goat
Hypocalcemia	Cattle, doe: weakness, ataxia, inappetence, bloat, proprioceptive deficit, cool extremities, weak pulse, bizarre head posture, dysuria	Cattle, goat
Hypoglycemia	Coma, semicoma, convulsions, blindness, hyperesthesia, cold extremities	Cattle, sheep, goat
Hypomagnesemia	Stiffness, hyperexcitability, recumbency, ataxia, muscle tremors	Cattle
Idiopathic epilepsy	Intermittent psychomotor seizures	Cattle, goat
Infectious bovine rhinotracheitis	Fever, bellowing, coma, convulsions, somnolence, hyperexcitability, hyperesthesia, proprioceptive deficit, recumbency	Cattle
Insecticide poisoning (organophosphate carbamate)	Salivation, vaginal discharge, diarrhea, tremors, coma, convulsions, ataxia, recumbency	Cattle, sheep, goat
Lead poisoning	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, facial analgesia, weak tongue, anisocoria (late), head pressing, opisthotonos, odontoprisis, convulsions, decerebrate rigidity	Cattle, sheep, goat
Louping ill (exotic)	Fever, anorexia, obtundation, constipation, muscular tremors, head tremors, hypermetria, ataxia, proprioceptive deficits, hyperexcitability, incoordination, rabbit-hopping gait, recumbency, convulsions, coma	Sheep, cattle
Maedi-visna	Obtundation, ataxia, head pressing, convulsions, coma	Sheep
Malignant catarrhal fever	Aggression, rage, ataxia, depression, head pressing, blindness, nystagmus, bellowing, mucosal and skin erosions, lymphadenopathy, diarrhea	Cattle
Narcolepsy	Sleep state, recumbency, loss of consciousness, loss of motor activity, rapid eye movement	Cattle

TABLE 8.7

Diseases of Ruminants That May Produce Forebrain Signs—cont'd

Disease	Predominant Clinical Signs	Species Affected
Nervous coccidiosis	Diarrhea, recumbency, obtundation, somnolence, blindness, ataxia, compulsive walking, head pressing	Cattle
Nervous ketosis	Aggressiveness, tremors, ataxia, paresthesia, recumbency, hyperesthesia, bellowing	Cattle
Nitrofurazone poisoning	Obtundation, proprioceptive deficit, recumbency, convulsions, coma	Cattle, sheep, goat
Nitrofurazone toxicosis	Hyperirritability, compulsive running, muscular tremors, blindness, convulsions	Cattle
Organochlorine poisoning	Tremors, hyperesthesia, recumbency, coma, convulsions	Cattle, sheep, goat
Plant poisonings	Convulsions, blindness, ataxia, compulsive walking, head pressing, odontoprisis, hyperexcitability, salivation, proprioceptive deficit, sudden death, vomiting, fetal malformations	Cattle, sheep, goat
Polioencephalomalacia	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, facial analgesia, weak tongue, anisocoria (late), dorsomedial strabismus, head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cattle, sheep, goat
Propylene glycol poisoning	Depression, bloat, ataxia, recumbency	Cattle, sheep, goat
Propylene glycol toxicosis	Ataxia, obtundation, bloat, characteristic garlic-like odor	Cattle, sheep, goat
Pseudorabies	Obtundation, ataxia, hyperesthesia, paresthesia, self-mutilation, aggressiveness, fear, head pressing, compulsive walking, hypersexuality, salivation, coma, convulsions, recumbency, conscious proprioceptive deficit	Cattle, sheep, goat
Rabies	Obtundation, excitement, aggressiveness, hyperesthesia, analgesia, anesthesia, proprioceptive deficits, recumbency, compulsive walking, head pressing, tenesmus, hypersexuality, salivation	Cattle, sheep, goat
Salt poisoning	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, opisthotonos, facial analgesia, weak tongue, convulsions, anisocoria (late), head tilt, head pressing, decerebrate rigidity	Cattle, sheep, goat
Sarcocystis	Fever, weight loss, tremors, weakness, diarrhea, loss of hair on the tail switch, abortions	Cattle
Sarcocystis species infection	Seizures, blindness, opisthotonos, nystagmus, ataxia, muscular weakness, tremors, hyperexcitability, hypersalivation, recumbency	Cattle
Scrapie	Chewing, licking, wool break, depression, weight loss, ataxia, reduced menace, hypertonicity, hyperreflexia, proprioceptive deficit, recumbency, coma	Sheep, goat
Sporadic bovine encephalomyelitis	Blindness, circling, ataxia, proprioceptive deficits, pleural friction rubs, pericardial friction rubs, abdominal tenderness	Cattle
Theileriosis (central nervous system form, exotic)	Depression, hypersensitivity, ataxia, circling, paralysis, convulsions	Cattle
Trauma, hematoma, brain edema	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, opisthotonos, facial analgesia, weak tongue, convulsions, anisocoria (late), head tilt, head pressing, blood from ears or nose, decerebrate rigidity	Cattle, sheep, goat
Trypanosomiasis (exotic)	Ataxia, somnolence, circling, head pressing	Cattle
Urea poisoning	Muscle tremor, bloat, salivation, incoordination, struggling, ataxia, proprioceptive deficit, recumbency, bellowing, coma, convulsion	Cattle
Vitamin A deficiency	Obtundation, somnolence, blindness with fixed pupils, ataxia, facial analgesia, weak tongue, head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cattle, sheep, goat

presented with the complaint of blindness should receive a more detailed ophthalmic examination to determine whether primary ocular disease is the cause of the problem (see Chapter 39). Sophisticated diagnostics such as electroretinography (ERG) may be indicated in some animals. When no ocular disease can be found to account for blindness, a lesion in the nervous system is likely to be responsible. Observing the animal's ability to negotiate its environment, particularly in unfamiliar surroundings, and testing the menace responses are the primary methods of determining visual function. Further testing can be performed by setting up a maze of objects for the animal to negotiate, by using different light levels and assessing vision in bright versus dim light, and by blindfolding each eye in turn when unilateral deficits are suspected. About 90% of optic nerve fibers (i.e., axons of retinal ganglion cells) cross to the opposite side of the brain in the optic chiasm of ungulates; thus central representation of vision in these species is predominantly *contralateral*. Fibers that remain uncrossed originate from the temporal extreme of the retina. Lesions in the visual apparatus distal to the optic chiasm (i.e., lesions of the globe, the retina, or the optic nerve) produce ipsilateral visual deficits. Lesions proximal or central to the optic chiasm produce lesions in the opposite visual field.

The following discussion refers to severe or complete lesions because these are most easily understood and described. Partial lesions will produce similar but milder signs (e.g., reduced visual acuity rather than complete blindness). Absent or reduced menace response can be caused by lesions of the facial nerve (cranial nerve VII), the cerebellum, or the forebrain. Animals with facial nerve lesions can see, but palpebral reflexes cannot be elicited. Animals with cerebellar disease can see and have normal palpebral reflexes. Forebrain disease causes defective menace responses with intact pupillary light and palpebral reflexes. Localization of lesions causing blindness is summarized in Table 8.6.

VetBooks.ir

TABLE 8.8

Diseases of the Horse That Produce Forebrain Disease

Disease	Predominant Clinical Signs
Brain abscess, meningitis	Head pressing, blindness, conscious proprioceptive deficit, ataxia, circling, depression, convulsions, hyperexcitability, stiff neck, rigid legs, fever, compulsive walking
Brain tumor	Depression, facial paresis or paralysis, facial analgesia, head tilt, strabismus, nystagmus, loss of menace, hypermetria, ataxia
Hepatoencephalopathy, gastrointestinal hyperammonemia	Aggression, rage, hyperexcitability, odontoprisis, ataxia, head pressing, convulsions, obtundation, coma, semicoma, blindness, fear, red urine (hemolysis), icterus
Hydrocephalus	Coma, semicoma, blindness, somnolence, head pressing, dysphonia, ataxia, weak tongue
Idiopathic epilepsy	Intermittent psychomotor seizures, normal interictal periods
Leukoencephalomalacia	Recumbency, ataxia, aggression, obtundation, coma, semicoma, head pressing, circling, compulsive walking, mydriasis, tenesmus, fear, continual chewing
Rabies	Recumbency, ataxia, aggression, depression, coma, semicoma, head pressing, circling, compulsive walking, mydriasis, tenesmus, fear, continual chewing
Trauma, hematoma	Head pressing, blindness, ataxia, circling, depression, convulsions, hyperexcitability, stiff neck, rigid legs, fever, compulsive walking, blood from ear or nose
Verminous encephalitis	Head tilt, hyperexcitability, odontoprisis, ataxia, head pressing, circling, coma, semicoma, blindness, anisocoria, convulsion, tongue dystonia
Viral encephalomyelitis (nonrabies) Eastern equine encephalomyelitis Western equine encephalomyelitis Venezuelan equine encephalomyelitis Borna disease	Head pressing, blindness, ataxia, circling, depression, coma, convulsions, recumbency, hyperexcitability, stiff neck, rigid legs, fever, compulsive walking

Pupillary size and movement of the globes are affected by cranial nerves II, III, IV, and VI and the sympathetic innervation of the eye. Clinical signs of diseases affecting these nerves are described earlier.

Circling

Circling is a sign of lateralized disease in the forebrain or vestibular system. Circling associated with forebrain disease is usually toward the side of the lesion. Animals that circle secondary to cerebral disease often also keep the head and neck turned toward the side of the lesion. Whereas gait may appear normal on a level surface, there are proprioceptive and postural reaction deficits on the side of the body contralateral to the lesion. Head tilt and spontaneous nystagmus are not observed. Physiologic nystagmus is normal. The severity of circling seen with lateralized cerebral disease is variable, from a subtle tendency to marked compulsive circling.

Head Tilt and Nystagmus

The presence of a head tilt, wherein the head is rotated so that one ear is held closer to the ground than the other, indicates dysfunction of the vestibular system. Head tilt is usually accompanied by spontaneous or positional (abnormal) nystagmus and a variety of other clinical signs. Vestibular disease can be classified as peripheral or central. Peripheral vestibular disease occurs with lesions of the vestibular apparatus of the inner ear (utricle, saccule, semicircular canals) or vestibulocochlear nerve (cranial nerve VIII) or, theoretically, when there is involvement of vestibular afferents from the proximal part of the neck. Animals with peripheral vestibular lesions have normal mentation but may be extremely disoriented, making assessment of mentation difficult. The head tilt (i.e., the lower ear) in animals with peripheral vestibular disease is toward the side of the lesion. Unilateral peripheral vestibular dysfunction causes decreased extensor tone in the limbs ipsilateral to the lesion and increased extensor tone in the contralateral limbs, resulting in the clinical signs of leaning, falling, curling, and rolling toward the affected side. Asymmetric peripheral vestibular lesions produce horizontal or rotatory conjugate nystagmus, with the fast phase directed *away* from the side of the lesion. The direction of the nystagmus in relation to the head is unchanged no matter what the position of the head. Physiologic nystagmus may be absent or decreased, particularly when the head is moved in a horizontal plane toward the side of the lesion. The facial nerve is closely associated with the vestibulocochlear nerve within the skull, and there may be facial paralysis along with peripheral vestibular disease when the facial nerve is also damaged by the underlying cause such as may occur in skull trauma, temporohyoid osteoarthropathy of horses, or severe otitis media or interna. Rarely, involvement of the postganglionic sympathetic nerve to the eye as it courses through the petrous temporal bone results in ipsilateral Horner's syndrome (ptosis, miosis, facial sweating in horses, reduced sweating on the nasal planum in cattle).

Lesions within the vestibular centers in the medulla oblongata and cerebellum also cause signs of vestibular dysfunction. Head tilt in central vestibular disease is usually toward the side of the lesion but may be in the opposite direction when the underlying disease involves the cerebellum (i.e., paradoxical vestibular syndrome). Similarly, nystagmus may be horizontal or rotatory as in peripheral vestibular disease but also may be vertical, diagonal, or different in each eye (disconjugate nystagmus); may change in direction when the position of the head is changed (positional nystagmus); or may be horizontal or rotatory with the fast phase toward the side of the lesion (paradoxical vestibular syndrome). Signs of involvement of the motor and sensory tracts to and from the limbs as they course through the medulla usually accompany central vestibular disease. Proprioceptive and postural reaction deficits are present in the ipsilateral limbs, together with mild hyperreflexia. Obtundation and signs of other cranial nerve dysfunctions may accompany central vestibular disease and can be used diagnostically to distinguish central from peripheral lesions.

Animals with either peripheral or central vestibular lesions tend to lean against walls and may fall when forced to perform a complex motor maneuver. They may adopt recumbency with the lesion side directed down and have poor righting responses, particularly from lesion-side-down recumbency. When positioned so that the lesion side is directed up, they often will roll to a lesion-down position. Blindfolding the patient eliminates visual compensatory mechanisms and therefore increases the severity of the clinical signs (Romberg's test). Blindfolding

VetBooks.ir

may help reveal subtle dysfunction but should be done with caution. Animals with vestibular disease occasionally may have slight ventral strabismus in the ipsilateral eye and slight dorsal strabismus in the contralateral eye. These deviations are exaggerated when the head is held in the median plane and the chin is lifted. This *vestibular* strabismus can be differentiated from the ventrolateral *true* strabismus seen with lesions of the oculomotor nerve because the former changes when the head is rotated, whereas the latter does not.

Animals with bilateral vestibular lesions do not have strabismus, head tilt, or nystagmus. The animal stands with the legs basewide and may fall to either side when head position is rapidly altered. Affected animals may show a coarse side-to-side head tremor. Bilateral vestibular lesions are usually peripheral and are rarely encountered in clinical practice. Central lesions extensive enough to cause bilateral vestibular disease are likely to be fatal.

Incoordination, Hypermetria, Hypometria, Dysmetria, and Intention Tremor

Clinical signs that occur in animals with cerebellar disorders include hypermetria, hypometria, intention tremor, and truncal ataxia (excessive body sway during movement along a straight path). Conscious proprioceptive fibers do not pass through the cerebellum. Consequently, postural placement of the limbs is normal. Animals with cerebellar disease move the limbs with imprecise and variable rate, range, and force. There is a slight delay in lifting the limb from the ground. At the peak of protraction the limbs are lifted too high and too far anteriorly. The legs then hit the ground with excessive force. During the exaggerated protraction, thoracic limbs may flex excessively, termed *hypermetria*, or may appear stiff because of reduced flexion, termed *hypometria* or *spasticity*. The animal may violently thrust the outside pelvic limb backward and laterally when turned. The thoracic limbs and the pelvic limbs occasionally collide during the turn (interference). At rest the animal stands with the legs abducted, in a basewide stance. This is not a conscious proprioceptive deficit, however, because the animal consciously returns the limbs to the basewide posture if the leg position is manually corrected. There is intention tremor, most marked in the head. When the animal attempts to reposition the head, it overshoots the intended position, corrects, and then overshoots again. The sequence of overcompensation and overcorrection results in a coarse oscillation or bobbing of the head. The head tremor is most conspicuous when the animal is alert, especially when eating. Intention tremor disappears when the animal is recumbent and the musculature is relaxed. In animals with cerebellar disorders, the extensor muscles of the limbs may be hypertonic, and spinal reflexes occasionally are exaggerated. Lesions of the rostral cerebellum can result in opisthotonos. Animals with cerebellar cortical disease may lack a menace response but retain their vision and can negotiate around obstacles. Animals with pure cerebellar dysfunction remain bright, alert, and responsive to external stimuli. Animals with severe lesions of the cerebellum may be recumbent and unable to rise and show opisthotonos. Cerebellar disease is often bilaterally symmetric, but lateralized lesions cause signs on the ipsilateral side of the body. Diseases that cause spasticity or tremors in livestock are listed in Table 8.9.

Involvement of the vestibular components of the cerebellum (caudal cerebellar peduncle, flocculonodular lobe, and fastigial nucleus) results in signs of paradoxical vestibular syndrome, described earlier.

Abnormalities of Cranial Nerve Function

The normal functions of the cranial nerves were described earlier, in the discussion of the neurologic examination. Cranial nerve dysfunction may be central or peripheral in type, depending on whether the neurologic lesion lies within the central components of the cranial nerves within the brain or in the peripheral portions of the nerves. Clinical signs of cranial nerve dysfunction are ipsilateral to the lesions that cause them.

BLINDNESS, STRABISMUS, OCULAR PARESIS OR PARALYSIS, ABNORMALITIES OF PUPIL SIZE OR PUPILLARY LIGHT REFLEXES. Lesions involving cranial nerves II, III, IV, and VI were described earlier, in the discussion of blindness and other visual dysfunctions.

FACIAL HYPALGESIA OR ANALGESIA, DEVIATED OR DROPPED JAW. Loss of or reduced sensory perception on the face, including the inside of the mouth, the nasal planum, the nasal septum, the cornea, and the lower jaw area, occurs with lesions of the trigeminal nerve. It is important to distinguish this from the signs of contralateral forebrain disease. Unilateral loss of facial sensation may result from damage to the peripheral portion of the trigeminal nerve or the trigeminal ganglion in the petrosal bone of the skull, or its connections in the pons, or from contralateral forebrain disease. Bilateral facial hypalgesia is most likely caused by diffuse forebrain dysfunction rather than trigeminal nerve disease. The mandibular branch of the trigeminal nerve also carries motor innervation to the muscles of mastication from the pontine motor nucleus of the trigeminal nerve. Bilateral involvement of the motor component of the nerve results in a dropped jaw and inability to prehend and chew food, together with drooling saliva. The muscles of mastication atrophy rapidly over a few weeks, most obviously in the masseter and temporalis muscles. Unilateral disease causes atrophy of the denervated muscles, and mild jaw weakness may be appreciated, but the animal can still eat and close the jaw. Usually the mandible is deviated away from the side of the trigeminal nerve lesion. Central lesions in the trigeminal nerve may also involve adjacent structures in the brainstem, such as the facial nerve, the vestibular system, and the long motor and sensory tracts to and from the limbs.

FACIAL PARESIS OR PARALYSIS. Lesions of the facial nerve result in ipsilateral atonia or hypotonia of the facial muscles. The clinical signs of facial nerve paralysis in all large animals include ptosis, dropped ear, and absence of the menace response and palpebral reflex. There is accumulation of food in the cheek pouch and commissure of the lips on the ipsilateral side. Affected animals frequently drool saliva from the lip commissure on the affected side. The animal is unable to open the nostril on the affected side during inspiration. The muzzle of the horse, goat, and sheep deviates away from the direction of the neurologic lesion. Deviation of the muzzle is not seen in cattle because of the normal rigidity of the planum nasale. If the neurologic lesion is located between the medulla oblongata and the stylomastoid foramen, the ipsilateral eye may be dry because of loss of innervation from the parasympathetic nucleus of cranial nerve VII. Lesions of the central components of the facial nerve in the medulla oblongata also destroy upper motor neurons, proprioceptive tracts, and reticular activating system (RAS) neurons, resulting in limb weakness, ataxia, and sometimes obtundation. Lesions of the peripheral component of cranial nerve VII cause facial atonia or hypotonia but do not produce obtundation or ataxia.

HEAD TILT, SPONTANEOUS NYSTAGMUS, DEAFNESS. Lesions involving cranial nerve VIII, the vestibulocochlear nerve, produce signs of vestibular dysfunction, as described previously. Deafness may also be a consequence of vestibulocochlear nerve disease. Bilateral deafness has been reported in Paint horses,[51] where it may be a heritable defect associated with the gene for white coat color, similar to the situation that exists in a number of breeds of dogs with white or merle coat color. Deafness can also result from severe aural disease. Although bilateral deafness

TABLE 8.9

Diseases of Spasticity or Tremors in Horses and Ruminants

Disease	Clinical Manifestations	Affected Species
Cerebellar hypoplasia Bovine viral diarrhea Bluetongue Akabane Border disease Wesselsbron disease Hereditary	Intentional head tremor, basewide stance, hypermetria, hypertonia, hyperreflexia, truncal ataxia, menace deficit, opisthotonos	Cattle, sheep, goats
Cerebellar abiotrophy	Intentional head tremor, basewide stance, hypermetria, hypertonia, hyperreflexia, truncal ataxia, menace deficit, opisthotonos	Cattle, horses, goats
Grass staggers	Hypermetria, hyperreflexia, truncal ataxia, head tremors, basewide stance, recumbency, ptyalism, hyperexcitability, hyperesthesia	
Bermuda staggers		Cattle, horses
Paspalum staggers		Horses
Perennial ryegrass staggers		All species
Other fungal tremorgens		All species
Annual ryegrass toxicity		All species
Kikuyu grass		Cattle, sheep
Phalaris (canarygrass)		Sheep
Hypomagnesemia	Hypermetria, hyperreflexia, truncal ataxia, recumbency, hyperesthesia, menace deficit, opisthotonos, aggressiveness, hypertonia	Cattle, horses
Lysosomal storage disease	Intentional head tremor, basewide stance, hypermetria, hypertonia, hyperreflexia, truncal ataxia, menace deficit, opisthotonos, blindness, aggressiveness	Cattle, goats
Locoism and *Swainsona* poisoning	Ataxia, obtundation, intentional head tremor, loss of herd instinct, maniacal behavior, flaccidity of the nose and lips, basewide stance	All species
Aspergillus clavatus toxicosis	Ataxia, weakness, muscle tremors, hypersalivation, altered behavior, recumbency, opisthotonos, death	Cattle, sheep
Hereditary neuraxial edema	Recumbency, head tremor, good appetite, hyperesthesia, nystagmus, strabismus, muscular fasciculations	Cattle
Bovine familial convulsions and ataxia	Tetaniform seizures, ataxia, hypermetria, hyperreflexia, head tremors, truncal ataxia	Cattle
Maple syrup urine disease	Obtundation, recumbency, opisthotonos, stimulus-induced tetanic spasms, convulsions, generalized decrease of spinal reflexes	Cattle
Solanum spp. storage disease	Head tremors, hypermetria, hypertonia, hyperesthesia, weight loss, opisthotonos, recumbency, and convulsions	Cattle, goats

is fairly easy to recognize clinically, unilateral deafness may be less obvious. Inability to localize sound occurs when animals have unilateral deafness and may be suspected when animals alert to sound but do not turn toward the sound. Auditory evoked potentials can be used to determine the integrity of the auditory pathway in the inner ear and medulla oblongata.[51,52]

DYSPHAGIA, DYSPHONIA, STRIDOR. Lesions in the nuclei of cranial nerves IX, X, and XI in the medulla oblongata produce dysphonia, inspiratory dyspnea, dysphagia, and neurogenic atrophy of the trapezius, sternocephalicus, and brachiocephalicus muscles. The inspiratory dyspnea is characterized by roaring and stridor. Roaring is a stridor that is made during peak inspiratory flow in horses with idiopathic left recurrent laryngeal neuropathy. It is caused by paralysis of the left cricoarytenoideus dorsalis muscle, resulting in failure to abduct the arytenoid cartilages during inspiration. Additional evidence of paralysis of cranial nerves IX and X may be obtained by endoscopic examination of the pharynx. Other signs of paralysis of cranial nerves IX and X include failure to abduct the vocal folds, collapse of the pharynx, dorsal displacement of the soft palate, and inability to swallow a nasogastric tube. Animals with peripheral nerve deficits remain alert and appetent and do not show conscious proprioceptive deficits, whereas animals with centrally located lesions may be depressed and inappetent and may have ataxia and limb weakness. Animals with bilateral lesions in the peripheral nerves are unable to open the glottis during inspiration and display extreme respiratory distress. Peripheral lesions of the accessory nerve that have been present for longer than 1 month may produce neurogenic atrophy of the trapezius, brachiocephalicus, and sternocephalicus muscles. This is frequently accompanied by aspiration pneumonia. Lesions of the visceral efferent component of cranial nerve X in ruminants produce vagal indigestion, which is characterized by ruminal distention with fluid, ruminal tympany, abomasal stasis, and sometimes a hypochloremic, hypokalemic metabolic alkalosis.

Hypoglossal nerve lesions produce a weak or flaccid tongue. In animals with unilateral lesions, the tongue deviates away from the side with the lesion and is flaccid when it is manually extended from the mouth. After prolonged denervation (2 weeks or more) the ipsilateral side of the tongue atrophies and the tongue deviates toward the affected side. Horses with lesions in the forebrain may also fail to retract the tongue normally; however, the lingual musculature is normal, the tone is variable, and the animal can retract the tongue if it receives sufficient stimulation. In comparison, the tongue tone is consistently weak in cases of hypoglossal paralysis.

Signs of cranial nerve dysfunction, together with the central origins or projections of the nerves, are summarized in Table 8.10. Diseases that involve the brainstem and cranial nerves are summarized in Table 8.11.

Lesions of the medulla oblongata can produce severe obtundation, somnolence, or coma as a result of ARAS dysfunction in

VetBooks.ir

TABLE 8.10

Clinical Signs of Cranial Nerve Dysfunction

Cranial Nerve	Central Origin or Projection	Clinical Signs of Dysfunction	Comments
I—Olfactory	Olfactory bulb, limbic system (behavior and emotion centers), cerebral cortex	Loss of sense of smell (anosmia)	Olfactory nerve lesions are rare and difficult to detect clinically.
II—Optic	Optic chiasm, optic tract, lateral geniculate nucleus, optic radiation, occipital cortex	Blindness	See text for additional comments (blindness).
III—Oculomotor	Midbrain somatic and parasympathetic nuclei	Ventrolateral strabismus, ptosis (somatic component); dilated, nonresponsive pupil (parasympathetic component)	
IV—Trochlear	Midbrain	Dorsomedial strabismus	Trochlear nerve lesions are rare and usually accompanied by other signs of midbrain dysfunction.
V—Trigeminal	Pons (motor nucleus), medulla, and rostral cervical spinal cord (sensory tract)	Dropped jaw in bilateral motor paralysis; deviated jaw in unilateral paralysis; decrease or loss of sensation to most of the structures of the head and face in sensory nerve disease	Rabies is an important differential diagnosis in animals with a dropped jaw.
VI—Abducent	Rostral medulla oblongata	Medial strabismus (paralysis of the lateral rectus muscle)	
VII—Facial	Medulla oblongata (rostral to middle); motor, sensory, and parasympathetic components	Facial paralysis (motor component); loss of sense of taste to rostral two thirds of the tongue; decreased tear production (dry eye) and decreased salivation (parasympathetic components)	The facial nerve is particularly susceptible to damage in its peripheral course because of its proximity to the middle ear and to the guttural pouch in horses and its superficial location on the face.
VIII—Vestibulocochlear	Medulla oblongata (middle)	Decreased hearing or deafness; vestibular signs (head tilt, nystagmus, falling, rolling)	See description of vestibular disease in text.
IX, X, XI—Glossopharyngeal, vagus, accessory	Medulla oblongata (nucleus ambiguus in middle to caudal medulla and rostral cervical spinal cord)	Dysphagia (IX and X), laryngeal paresis to paralysis (X), atrophy of sternocephalicus, brachiocephalicus, and trapezius muscles (XI)	Rabies is an important differential diagnosis in animals with dysphagia or choke.
XII—Hypoglossal	Medulla oblongata (caudal)	Paralysis of the tongue	Acute unilateral lesions result in the tongue being deviated away from the side of the lesion. In chronic disease, atrophy and contracture of the affected side of the tongue result in deviation toward the affected side.

addition to signs of vestibular dysfunction and functional deficits in cranial nerves V to XII. Other clinical signs of medullary lesions include ipsilateral paresis and proprioceptive deficits. The spinal reflexes of the ipsilateral limbs are exaggerated, and the extensor muscle tone is increased. Further details are given later in the discussion of quadriparesis and hemiparesis.

Measurement of Brainstem Function Using Auditory Evoked Potentials

The integrity of the vestibulocochlear apparatus can be examined using brainstem auditory evoked potentials.[51-54] This method examines the averaged brain waveform that is generated after an auditory click in the ear. Ablation of the entire cochlear apparatus and vestibular nerve, as might occur with otitis interna, results in a loss or attenuation of waveform activity after the click stimulus. Injury to the brainstem vestibular nuclei or pons results in specific losses of certain waveforms.

Paresis and Ataxia in Two or Four Limbs

Quadriparesis and hemiparesis are seen with lesions affecting the mid to caudal brainstem (midbrain, pons, medulla oblongata) or the cervical spinal cord (C1 to T2 spinal cord segments). Quadriparesis can also be seen in generalized peripheral nerve or muscle disease, discussed later. Paraparesis results from disease lesions of the spinal cord affecting segments T3 to S2 or the peripheral nerves to the pelvic limbs. Disease of the forebrain does not produce appreciable paresis and ataxia when the animal is walking in a straight line on a level surface, but these signs may become apparent in the limbs contralateral to the lesion when the animal is asked to circle, back, step over obstacles, or walk on a slope. Localization of the lesion when signs of paresis and ataxia are present depends on the assessment of muscle mass and tone, spinal reflexes, and evaluation of brainstem function; the last is determined by the presence or absence of signs such as altered mentation and cranial nerve deficits.

VetBooks.ir

TABLE 8.11

Diseases of the Brainstem and Cranial Nerves

Disease	Location	Clinical Signs and Laboratory Findings
Nonrabies viral encephalomyelitis, rabies, malignant catarrhal fever (cattle only)	Multifocal brainstem, particularly medulla oblongata	Head tilt, nystagmus, circling, ataxia, tongue paralysis, anisocoria, dilated nonresponsive pupils, strabismus, lingual paralysis, dysphonia, dysphagia; CSF may show pleocytosis (mainly mononuclear cells) and high protein concentration
Listeriosis (ruminants, horses [rare])	Multifocal brainstem, particularly basal ganglia, metencephalon, and medulla oblongata	Circling, head tilt, facial paralysis, stridor, stertor, dysphagia, obtundation, coma, convulsions, ataxia; CSF shows pleocytosis (mainly mononuclear) and a high protein concentration
Thromboembolic meningoencephalomyelitis (cattle)	Multifocal brainstem	Circling, nystagmus, head tilt, strabismus, tongue paralysis, dysphagia, facial paralysis, coma, convulsions, obtundation; xanthochromic CSF with increased neutrophils and protein concentration
Peripheral vestibular disease	Petrous temporal bone, membranous labyrinths, vestibulocochlear nerve, often accompanied by facial nerve paralysis	Head tilt, circling, or leaning toward lesion side; ventrolateral strabismus on ipsilateral side; dorsomedial strabismus on contralateral side; nystagmus (usually horizontal and constant)
Verminous encephalitis	Multifocal brainstem, most commonly thalamus	Circling, nystagmus, head tilt, strabismus, tongue paralysis, facial paralysis, obtundation, coma, convulsions, depression, proprioceptive deficit, bradycardia, salivation, head pressing, blindness; high protein concentration and increased nucleated cell count in CSF
West Nile virus	Multifocal brainstem	Fasciculations of neck and facial muscles in addition to the other signs
Equine protozoal myeloencephalitis	Multifocal brainstem and cerebrum	Seizures, head tilt, facial paralysis, circling, nystagmus, dysphagia, facial paralysis, blindness, ataxia, paresis, hyporeflexia, hyperreflexia
Space-occupying mass Tumor, abscess	Cerebellopontine angle; cranial nerves V, VII, and VIII	Head tilt, strabismus, proprioceptive deficit, facial analgesia, jaw drop, obtundation, coma, strabismus, nystagmus, hyperreflexia, hypertonia, falling or circling toward affected side, blindness on contralateral side, tongue paralysis, hemianopsia, bradycardia, coma, convulsion
Horner's syndrome	T1 to T3 motor neurons (gray matter), spinal roots, vagosympathetic trunk, sympathetic UMN of spinal cord (tectotegmentospinal), periorbita	Miosis, lack of nasal sweat (cattle only), ipsilateral facial swelling (horses only)
Guttural pouch mycosis (horses)	Guttural pouch	Dysphagia, head shyness, headshaking, roaring, dysphonia, protrusion of the tongue from the mouth, epistaxis, head tilt, nystagmus, facial sweating, shivering, Horner's syndrome, colic, facial paralysis

CSF, Cerebrospinal fluid; *UMN*, upper motor neuron.

Quadriparesis and ataxia with normal muscle mass and tone and normal to increased spinal reflexes can be explained by a lesion of the descending and ascending tracts in the brainstem or spinal cord segments C1 to C5. Note that such a finding does not exclude multifocal lesions within the same areas of the CNS. Presence of clinical signs of brain disease indicates that the lesion (if singular) is in the brainstem, as described earlier. Lesions in the midbrain cause contralateral postural and proprioceptive deficits, whereas those in the medulla oblongata cause ipsilateral signs. Cerebellar disease causes head, neck, truncal, and limb ataxia, without limb weakness. Lesions of the forebrain (thalamus and cerebrum) cause minimal to no paresis or ataxia when the animal moves on a level surface, but contralateral subtle proprioceptive and postural reaction deficits are present. Altered mentation and other signs of forebrain disease such as compulsive circling or central blindness are expected. Animals with spinal cord disease have normal mentation. The clinical signs shown by such patients depend on the location of the lesion and the relative amount of damage to gray (cell bodies) and white (myelinated spinal cord tracts) matter. Loss of white matter affects upper motor neurons and proprioceptive and other sensory pathways, whereas gray matter damage produces lower motor neuron deficits. The sensory losses manifest as either proprioceptive deficits or loss of cutaneous sensation. Spinal cord diseases may be localized to one of the following five regions: high cervical (C1 to C5), cervicothoracic (C6 to T2), thoracolumbar (T3 to L2), lumbosacral (L3 to S2), and sacrococcygeal (S3 to Cd5) regions. Tables 8.4 and 8.5 list the peripheral nerves and the spinal segments that innervate them.

Cervical Spinal Cord

Animals with incomplete section of the cervical region of the spinal cord display hemiparesis or tetraparesis. The clinical signs include knuckling, stumbling, failure to lift the inside feet when turned in a tight circle, circumduction of the outside pelvic limb during circling, interference, hypometria or hypermetria, abnormal postural placement responses, crossing over midline

VetBooks.ir

when turned, and excessive truncal sway. Animals with more severe lesions of the cervical spinal cord become recumbent and are unable to lift the head from the ground. There is an asymmetric righting response in animals with unilateral lesions. They can raise the head and neck to a variable distance only when lying with the lesion side facing down. Within several days of the time of spinal cord injury, muscle tone and spinal reflexes in the limbs of recumbent animals are exaggerated. The urinary bladder is distended. Affected animals have difficulty posturing and urinating, and afterward the bladder contains a large amount of residual urine and sediment. Animals with complete spinal cord transection anterior to C5 die suddenly from respiratory failure because of paralysis of the intercostal muscles and diaphragm.

Lesions from C6 to T2 spinal segments (i.e., brachial intumescence) result in proprioceptive deficits in all four limbs and tetraparesis or tetraplegia (recumbency). There is flaccidity and hyporeflexia of the thoracic limbs and hypertonia and hyperreflexia of the pelvic limbs. Unilateral lesions result in ipsilateral signs. Lesions of C6 to T2 segments involving white but not gray matter do not produce thoracic limb hypotonia. Perception of painful stimuli over all four limbs may be reduced. Flexor reflexes in the thoracic limbs may be depressed but are normal in the pelvic limbs. The righting responses of the head and neck are normal, but the animal may have difficulty rolling onto its sternum from a laterally recumbent position. Voluntary control of urination is poor or absent, posturing for urination is difficult, and the urinary bladder is distended and has a large residual volume. After 2 weeks or more, lesions of the gray matter of the spinal cord or the peripheral nerves may result in neurogenic atrophy of one or more muscle groups of the thoracic limbs. Gray matter lesions of T1 to T3 spinal segments may cause Horner's syndrome, which is characterized by miosis and ptosis in all species. Unilateral facial sweating occurs in horses; lack of sweating on the planum nasale occurs in cattle. Differentiation of high (C1 to C5) and low (C6 to T2) cervical spinal cord lesions may be difficult in horses, especially when signs are fairly mild.

Lesions of the thoracolumbar region (T3 to L3 inclusive) cause paraparesis and ataxia in the pelvic limbs but usually do not affect the thoracic limbs. There may be knuckling, stumbling, abduction, adduction, interference, excessive truncal sway, circumduction of the outside limb, and failure to lift the inside foot when pivoted in a tight turn. With complete lesions, the animal becomes recumbent but intermittently assumes a dog-sitting position, with the thoracic limbs extended and weight bearing and the pelvic limbs flexed. Muscle tone and spinal reflexes are exaggerated in the pelvic limbs. The urinary bladder is distended and, because of poor coordination of bladder filling with detrusor and sphincter tone (dyssynergia), residual volume is large. The tone of the urethral sphincter is normal. Rarely, animals with severe spinal cord lesions between T2 and L2 display transient hypertonia of the thoracic limbs (Schiff-Sherrington syndrome).[55] This condition is caused by interference with inhibitory fibers ascending from the lumbar segments in the dorsal funiculi to the lower motor neurons of the thoracic limbs.[55] These fibers synapse on the lower motor neurons of the brachial intumescence. Hypertonia from this deficit may be differentiated from cervical cord lesions by the lack of conscious proprioceptive deficits in the thoracic limbs of animals with thoracolumbar lesions.

The lumbosacral region (L3 to S2) of the spinal cord contains lower motor neuron efferents to and general proprioceptive afferents from the pelvic limbs. Lesions in this area result in paraparesis or paraplegia. Affected animals are ataxic and have conscious proprioceptive deficits of the pelvic limbs. Patients with complete spinal cord lesions of L3 to S2 exhibit flaccid paraplegia, which is accompanied by hyporeflexia or areflexia of the pelvic limbs. With prolonged denervation, there is neurogenic atrophy of the pelvic limb musculature.

Lesions located between L3 and L6 spinal cord segments result in urinary bladder distention and maintenance of a large residual volume. The sphincter tone is intact, but urine is not voided unless the intravesicular pressure exceeds that of the sphincter. These animals usually have contact dermatitis of the perineum and preputial area because of urine scalding. Lesions located around the S1 and S2 segments result in bladder distention and flaccidity. Urine may drip continuously from the urethral orifice, and perineal or preputial scalding can be present. The rate of flow may be increased by manually pressing on the bladder during a rectal examination.

Lesions of the sacrococcygeal (S3 to Cd5) spinal cord segments or cauda equina produce flaccidity and muscular atrophy of the tail and anus and, in males, penile paralysis (paraphimosis). Lesions in this area also result in desensitization of the tail, penis, vulva, rectum, anus, and perineum. The urethral sphincter is dilated, and urine constantly drips from the urethral orifice. The animal does not evacuate the bladder and is unable to defecate, resulting in a large dilated urinary bladder and distention of the rectum with feces (obstipation).

If the entire neurologic lesion is located caudal to S2, ataxia or limb weakness is not seen. The combination of flaccidity of the tail and anus and the constant urine leakage produces contact dermatitis of the perineum and pelvic limbs. Perineal scalding is characteristic of lesions of the cauda equina. Specific diseases of the spinal cord, peripheral nerves, and motor end plate are listed in Table 8.12.

Muscle Atrophy, Reduced Muscle Tone, Flaccid Paresis, Focal Analgesia

Reduced muscle tone, muscle atrophy, and flaccid paresis are characteristic of peripheral nerve, muscle, or neuromuscular diseases. Signs may be localized to a single limb, as in the case of traumatic peripheral nerve injury; generalized, as in botulism and many myopathies; or multifocal, as in equine protozoal myeloencephalitis and other diseases that attack multiple areas of the CNS. Details of neuromuscular diseases and the use of ancillary diagnostic testing to localize peripheral nerve, muscle, and neuromuscular disease are described in Chapter 35. Muscle disorders are discussed in Chapter 42.

Peripheral nerve lesions, whether of the central components of the nerves in the spinal cord and brainstem or along their peripheral course in the limbs and head, can also result in focal hypalgesia or analgesia. Knowledge of the autonomous zones for the peripheral nerves innervating the limbs can be used to localize such peripheral nerve lesions.[56]

Urinary Incontinence and Urine Retention

The clinical signs of urinary bladder denervation are variable and depend on the lesion location. Lesions of the sacral segments of the spinal cord produce a flaccid bladder, which distends with a large residual volume. Spontaneous urine leakage occurs continuously through the paralyzed atonic urethral sphincter. Additional urine flow occurs when the abdominal pressure is increased. Lesions of the brainstem or spinal cord anterior to S1 produce reflex dyssynergia, a disturbance in coordination of micturition, wherein the facilitatory influence of the bladder stretch receptor (afferents) maintains tonic activity on the efferents of the urethral sphincter. The lack of inhibition of these reflexes from the upper motor neuron pathways produces hypertonicity of the urethral sphincters and results in an impediment to urine flow. There is a high intravesicular pressure and a large postvoiding urine volume. The urine escapes paroxysmally only when the intravesicular pressure exceeds the sphincter pressure. After approximately 1 month of denervation, local spinal reflexes between the sacral afferent and efferent neurons develop in the S1 to S5 segments, and incomplete voiding occurs. In these cases the residual volume remains large, and the normal urination posture is not attained.

TABLE 8.12

Diseases of the Spinal Cord, Peripheral Nerve, and Motor End Plate of Large Animals

Disease	Signs	Species Affected
Occipitoatlantoaxial malformation	Ataxia, spasticity, hyperreflexia, crepitation or pain with neck flexion, head tilt, torticollis, ataxia, visible swelling or asymmetry	All species
Fractures and dislocations	Tetraparesis, tetraplegia, paraparesis, paraplegia, hyperreflexia, stiff neck, recumbency, ataxia, acute death, crepitation, pain, swelling	All species
Cervical spinal abscesses	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, ataxia, sudden death, crepitation, pain, swelling	All species
Cervical vertebral stenotic myelopathy	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, ataxia, strip sweating	Horse
Spinal tumor (lymphosarcoma, neurofibroma)	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, ataxia	All species
Equine herpesvirus myeloencephalopathy	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, ataxia, flaccid anus, flaccid tail, dysuria, distended bladder, impacted rectum, urine scalding	Horse
Copper deficiency	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, ataxia	Sheep, goat
Cauda equina neuritis	Pruritus in perineum, hair loss in perineum, analgesia in perineum, flaccid tail, flaccid anus, paraphimosis, dysuria, facial palsy, head tilt, leaning, nystagmus	Horse
Ischemic myelopathy (fibrocartilaginous embolism)	Paraplegia, tetraplegia, flaccid tail, flaccid anus, areflexia at site of lesion, hyperreflexia distal to site of lesion, ataxia	Horse, sheep
Postanesthetic myelopathy	Paraparesis to paraplegia, ataxia, hypalgesia, scoliosis	Horse, cattle
Caprine arthritis-encephalitis virus	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, ataxia	Goat
Segmental myelitis	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, ataxia, strip sweating, hyporeflexia, areflexia, lower motor neuron deficit, facial nerve paralysis, jaw drop	Horse
Developmental defects (spina bifida, Arnold-Chiari syndrome, syringomyelia, hemivertebrae, spinal cysts)	Paraplegia, paraparesis, tetraplegia, tetraparesis, hypotonia, atonia, neurogenic atrophy, torticollis, scoliosis, kyphoscoliosis, misshapen tail, absence of skin over dorsal midline	All species
Verminous encephalitis	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, ataxia, head tilt, hyporeflexia, areflexia, hyperreflexia, hypertonia, hypotonia	All species
Tetanus	Stiffness, normal reflexes, flashing third eyelid, trismus, bloat, convulsions, coma, raised tailhead	All species
Botulism	Flaccidity, ataxia, dysphagia, hyporeflexia, pupillary dilation, facial hypotonia, flaccid tail, flaccid anus	All species
Progressive ataxia	Ataxia, recumbency	Charolais cattle
Locoism	Ataxia, recumbency, bizarre behavior	All species
Dying back axonopathies	Hypermetria, hyperreflexia, ataxia, flaccid tail, flaccid anus, fecal and urine retention, urine scalding, recumbency	All species
Elso heel (spastic paresis)	Affected pelvic limb is hyperextended and swings in pendulum fashion; tailhead is elevated	Cattle
Bovine spastic syndrome	Episodic hyperextension of the pelvic limb, extension of the limb behind the cattle, head and neck extension	Cattle
Peripheral nerve injuries	Areflexia, hypotonia, hyporeflexia, atonia, anesthesia, analgesia of a specific area of limbs or trunk, inability to support weight, normal function of limbs distal to denervated site	All species
Ionophore toxicosis (salinomycin, lasalocid, monensin)	Tetraparesis, tetraplegia, ataxia, colic, cardiac dysrhythmia, sudden death	All species
Periodic hyperkalemia (HYPP)	Episodic tremors, weakness, spasticity during episodes, recumbency	Horse
Myotonia congenital	Episodic weakness, spasticity during episodes	All species
Bromide intoxication	Weakness, ataxia, stumbling, closed eyelids, drooped head and neck, paraphimosis	Horse
Coyotillo poisoning	Progressive weakness, hypermetria, areflexia	Goat
Neosporosis	Recumbency, ataxia, neurogenic atrophy	Calf
Cycad palm poisoning	Posterior paresis, elevated tailhead, paraparesis, paraplegia	Cattle
Acquired torticollis	Abnormally positioned head and neck	All species
Sorghum toxicosis	Ataxia, paraparesis, paraplegia, rabbit-hopping gait, ataxia, recumbency, weight loss	Horse, cattle
Stringhalt	Normal at rest, involuntary hyperflexion of the hock and stifle	Horse
Tick paralysis	Progressive generalized paresis, ataxia, recumbency, flaccid tail, flaccid anus, weak facial muscles	All species

Alterations in Body Weight or Size

ALEXANDRA HUND, *Consulting Editor*
SHANNON E. PRATT-PHILIPS

■ MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Mechanisms of decreased growth and decreased weight gain, 141
Weight loss, 152
Obesity, 164
Pica, 165

Slowed growth and below-normal weight gain usually happen at the same time, although occasionally they develop separately. By definition a decrease in growth and weight gain is limited to the growing animal. Similar pathogenic mechanisms cause weight loss or an emaciated condition in an adult patient. This arbitrary age division allows the clinician to consider possible causes that are more or less common for a given age group.

Potential growth and weight gain are genetically and partially environmentally determined.[1] They differ according to species, breed, and sex, and marked differences in potential growth exist within a breed. In ruminants the size is greater in the offspring of multiparous females than in those from primiparous females at birth, but the potential for growth may not differ overall.[2-5] The normal or minimum growth and weight gain rates for common breeds of the various large animal species are outlined in the section on assessment of growth and weight gains.

Mechanisms of Decreased Growth and Decreased Weight Gain

Major pathogenic mechanisms that result in decreased growth and decreased weight gain include the following:

- Inadequate dietary intake of essential nutrients
- Infections or inflammation
- Parasitism
- Genetic errors in metabolism or physiologic function
- Concurrent toxicosis
- Environmental causes
- Multiple causes

Inadequate intake of one or more essential nutrients is an important cause of decreased growth. In many cases growing animals are not provided with a sufficient volume of feed to meet their nutrient requirements. Young animals rely on a highly digestible diet that provides energy and essential nutrients for growth. Even animals fed an appropriate volume of a poor-quality milk replacer could suffer from poor growth. Milk replacers formulated with sources of protein, fat, vitamins, and minerals that have limited nutrient digestibility may induce a state of energy, protein, vitamin, or mineral malnutrition. The process of weaning may pose substantial challenges for the growing animal, especially in dairy calves when performed abruptly, and may lead to a depression in growth.[6] Weaned foals and ruminants rely on forages and cereal grains to provide essential nutrients.

Hay that has been harvested at a late stage of growth usually has a lower nutrient digestibility compared with young forages. Diets low in digestible energy or protein or both reduce total daily intake in ruminants because of the decreased turnover time ($T_{1/2}$) in the gastrointestinal tract and subsequent decreased throughput. This compounds the problems caused by an inadequate intake of digestible nutrients. The digestibility of forages is even lower for horses than for ruminants.

Protein-calorie malnutrition (PCM) is the most common clinical cause of decreased growth and decreased weight gain in young animals. It is characterized by smaller size and lower weight than the normal minimums for age, breed, and sex. Inadequate intake of digestible energy and protein (or essential fatty acids in the neonate primarily adapted to a milk diet) results in inadequate levels of amino acids, fats, and carbohydrates for normal metabolism and growth. Diets that lack any of the other essential nutrients (essential fatty acids, vitamins, macrominerals, or trace minerals) can also decrease growth. Deficiencies of calcium, phosphorus, and magnesium result in improper skeletal formation. Deficiencies in other macrominerals (e.g., sodium, chloride, potassium), trace minerals (e.g., copper, zinc, manganese, cobalt, iron), and vitamins (e.g., A, D, E, thiamin) cause biochemical dysfunctions that lead to inefficient metabolism and growth. Large animal patients that grow slowly as a result of inadequate diets often have normal or increased appetites until they are terminally ill. Physical findings and clinical chemistry profiles from animals with PCM are often within the normal range until the disease process is well advanced.

Infections or inflammatory processes are important causes of decreased growth and decreased weight gain in young horses and ruminants. The decrease in growth can be of short duration

followed by recovery and compensatory gain (cryptosporidiosis) or can persist (chronic bronchopneumonia). Infections or inflammatory processes can also result in nutrient malabsorption (chronic salmonellosis, acute rotavirus diarrhea, equine proliferative enteropathy), anorexia (pharyngeal abscesses, systemic disease), increased nitrogen turnover, and direct protein losses (gastrointestinal disease). Both energy and protein requirements may be increased as a result of infection and inflammation.

Parasitism often affects young horses and ruminants and results in decreased growth and decreased weight gain by increasing nutrient requirements, increasing nutrient losses, and/or decreasing nutrient absorption. The animal's metabolic rate and nutrient requirements may also increase as a result of inflammatory and immune reactions that arise secondary to parasitism.

Genetic diseases (α-mannosidosis, dwarfism) result in decreased growth through generalized errors in the genetic code or interference with strategic reactions in one or more metabolic pathways. Congenital cardiac malformations (tetralogy of Fallot, ventricular septal defect) create physiologic inefficiencies that require energy beyond the body's ability to supply it. Congenital renal disease (agenesis, dysplasia, hypoplasia, polycystic kidney disease) affects homeostatic mechanisms that regulate electrolyte and acid-base balance, results in the production of uremic toxins, and often results in partial anorexia and PCM. Digestive tract malformations, especially oral and dental defects such as cleft palate, parrot and monkey mouth, megaesophagus, and brachygnathism, can reduce nutrient ingestion and impair growth.

Toxicities, although rare in growing animals, result in decreased weight gain by interfering with metabolic pathways (e.g., ammonia toxicity, zinc-induced copper deficiency with abnormal skeletal development in foals) by causing loss of body reserves (e.g., thiamin deficiency in horses, bone marrow hypoplasia and associated bleeding diatheses in ruminants associated with bracken fern toxicity), inducing anorexia, or a combination of mechanisms. The pathogenic mechanisms of many toxins are not yet known.

Tall fescue *(Festuca arundinacea)* is a popular pasture grass (marketed as "Kentucky 31") for both cattle and horses. Tall fescue is typically infected with an endophyte *(Neotyphodium coenophialum)* that causes ergot alkaloid toxicity problems in animals. In cattle, tall fescue consumption can decrease feed intake and weight gain. In both cattle and horses, the toxins produced by the endophyte decrease serum dopamine and prolactin, which affects reproduction in these animals. Consumption of endophyte-infected fescue in the last trimester results in late-term abortion, prolonged gestation periods, thickened and/or retained placentas, and agalactia, a decreased ability to produce milk. While foals of mares fed fescue tend to be larger in size at birth (due to a longer gestation), decreased milk production and thus consumption by the foals can greatly affect growth rate and potential. It is recommended that pregnant animals be removed from endophyte-infected pastures for their third trimester. Alternatives are other pasture grasses, or the endophyte-free fescue varietals. In horses, domperidone paste (a dopamine antagonist) may be administered to mitigate the effects of endophyte-infected pasture on mares.

Environmental factors including extreme heat or cold or high humidity result in decreased growth and decreased weight gain. Extremely cold conditions increase an animal's daily energy requirements. During extremely hot weather feed intake often decreases, which may contribute to decreased growth. Often, environmental conditions influence the development of disease, resulting in a subsequent increase in nutrient requirements in a growing animal (e.g., calves with PCM housed in poorly ventilated or overly humid conditions become much more susceptible to infectious pneumonia).

In many cases a combination of these diverse factors may influence the growth and weight gain of young animals. A period of increased growth rate and weight gain, called *compensatory gain*, often occurs after a period of restricted growth once adequate dietary energy and protein are available. In growing foals, compensatory gain should be closely monitored to prevent rapid growth and abnormal skeletal development, which could lead to developmental orthopedic disease.

Boxes 9.1 and 9.2 list many of the possible causes of decreased growth and decreased weight gain in horses and ruminants, respectively.

BOX 9.1

Causes of Decreased Growth and Decreased Weight Gain in Horses

Common Causes

Protein-calorie malnutrition (PCM), inadequate nutrient intake
Extreme environmental factors (cold, heat)
Diarrhea (*Clostridia* species, *Salmonella* species, rotavirus, sand enteropathy, other causes)
Parasitism (*Parascaris equorum,* small strongyles, large strongyles, tapeworms, threadworms, bots)
Gastric ulcers
Bacterial pneumonia (*Rhodococcus equi, Streptococcus zooepidemicus,* other)
Viral pneumonia (equine herpesvirus, equine influenza)
Lameness (e.g., physitis, osteochondritis dissecans, contracted tendons, osteomyelitis)
Prematurity, dysmaturity

Less Common Causes

Jaw pain (fracture, dental abnormality)
Esophageal stricture, megaesophagus (idiopathic, acquired)
Campylobacter jejuni
Cryptosporidium parvum
Equine proliferative enteropathy
Fungal pneumonia
Congenital cardiac and great vessel anomalies
Endocarditis
Ventricular septal defect
Abdominal abscess
Peritonitis
Osteodystrophy
Goiter
Calcium deficiency
Copper deficiency
Phosphorus deficiency
Selenium deficiency
Zinc deficiency
Vitamin A deficiency

Uncommon Causes

Hydrocephalus
Biliary atresia
Hepatic portosystemic shunt
Congenital renal abnormalities (hypoplasia, dysplasia, agenesis, polycystic kidney disease)
Wound myiasis
Agammaglobulinemia
Fell Pony syndrome
Selective IgM deficiency
Severe combined immunodeficiency
Transient hypogammaglobulinemia
Congenital hypothyroidism
Gonadal dysgenesis, intersex (XO, XXY)
Thiamine deficiency
Vitamin D deficiency

Toxins

Ammonia toxicity
Fluorosis
Phenylbutazone, flunixin meglumine, and other nonsteroidal antiinflammatory drugs
Lead toxicity
Zinc toxicity

VetBooks.ir

VetBooks.ir

BOX 9.2

Causes of Decreased Growth and Decreased Weight Gain in Ruminants

Common Causes

Protein-calorie malnutrition (PCM)
Extreme environmental factors (cold, heat)
Diarrhea (Enterotoxigenic *Escherichia coli,* attaching and effacing *E. coli, Shiga* toxin-producing *E. coli, Salmonella,* bovine virus diarrhea, coronavirus, rotavirus infection, *Cryptosporidium parvum,* coccidiosis, other causes)
Ostertagiasis I and II
Parasitism (flukes, gastrointestinal worms, lungworms)
Bacterial bronchopneumonia
Viral bronchopneumonia
Umbilical infections (omphaloarteritis, omphalourachitis, omphalophlebitis, hepatic abscessation)
Hepatic abscessation
Sarcoptic mange
Lameness (infectious and claw horn lesions, bovine digital dermatitis, sole ulcers, white line disease, etc.), osteomyelitis, septic arthritis)
Agammaglobulinemia (failure of passive transfer) in neonates
Copper deficiency (molybdenosis)
Selenium deficiency

Less Common Causes

Pharyngeal abscess, injury
Severe bovine papular stomatitis
Abomasal ulcers
Peritonitis
Urachal or bladder abscess
Osteodystrophy, rickets
Immune-mediated anemia
Neonatal isoerythrolysis
Sarcocystosis
Myiasis
Tick infestation
Goiter
Cobalt deficiency
Vitamin A deficiency
Zinc deficiency

Uncommon Causes

Brisket disease
Calf lymphosarcoma
Mucormycosis
Zygomycosis
α-Mannosidosis[31]
Hypersensitivity to soy protein
Phosphorus deficiency

Congenital Abnormalities

Hydrocephalus
Cardiac or great vessel anomalies
Arthrogryposis
Osteogenesis imperfecta in Friesians
Congenital porphyria
Granulocytopathy[32]
Epidermolysis bullosa
Generalized glycogenosis (GM1 gangliosidosis, type II glycogenosis)[33]
Gonadal dysgenesis, intersex
Familial acantholysis[34]
Bovine leukocyte adhesion deficiency (BLAD)[32]
α-Mannosidosis (B)[31]
Bovine hereditary zinc deficiency (lethal trait A-46)[35]

Toxins

Aflatoxicosis
Ammonia (urea) toxicity
Fluorosis
Herbicide toxicity
Iodine toxicity
Selenium toxicity
Zinc toxicity

Plant Toxins

Bracken fern *(Pteridium aquilinum)*
Cassia spp.
Fescue toxicity
Oxalate toxicity
Pyrrolizidine alkaloid toxicosis (*Senecio* spp., *Amsinckia* spp., *Crotolaria* spp., and others)
White leadtree *(Leucaena leucocephala)*

Exotic Diseases

Babesiosis *(Babesia bigemina, Babesia bovis)*
Schistosomiasis
Trypanosomiasis (*Trypanosoma* spp.)

Approach to Diagnosis and Management of Decreased Growth and Decreased Weight Gain in Horses

1. Take a general history and a diet history.
   a. General history
      i. Foal factors: What is the patient's age? Was the foal born prematurely? Were any congenital defects identified during the initial examination of the foal after birth? Did the foal have any complications from sepsis? What is the vaccination history of the mare and the foal? Has the foal shown any evidence of systemic illness (diarrhea, nasal discharge, cough, pyrexia)?
      ii. Environmental factors: How is the foal housed? What type of protection is provided from adverse weather conditions? Has the foal experienced any extreme weather conditions (cold, heat, humidity)? Does the foal have access to a pasture or dry lot? Are there any toxins in the foal's environment? What is the stocking density of the herd? Is the foal exposed to a high parasite load in the environment? What is the foal's deworming history? Have there been previous problems with gastrointestinal parasitism on the farm? Does the farm have a history of infectious disease agents (*Rhodococcusequi*, *Streptococcus equi* subsp. *equi*, *Clostridium difficile*)? Are there any sick horses on the same farm? If so, what age cohort is sick?
   b. Diet history
      i. Foal: If the foal is nursing, is the mare at an ideal body weight? Is the mare producing a sufficient amount of milk for the foal? Has the mare had access to endophyte-infected tall fescue? If the foal is an orphan, what type of milk replacer is the owner using? What is the daily energy and protein intake of the foal? Is the owner mixing the milk replacer properly? Does the foal have access to a creep feed? What is the owner using as a creep feed? How much of the creep feed does the foal consume daily?
      ii. Weaning: When was the foal weaned? Does the foal compete with other foals for feed? Has the owner changed the foal's diet recently? If yes, what changes were made? Does the foal have a good appetite? Has the foal's appetite changed recently?
         (1) Forage: What type of forage is fed to the foal? Does the foal have access to pasture? How long is the foal turned out in the pasture? What is the nutritional quality of the hay or pasture? Is there gross evidence of dirt, mold, or weed contamination in the hay? Has a hay analysis been performed?

VetBooks.ir

TABLE 9.1

Body Condition Scoring System for Horses

Score	Description
1	Poor. Animal is extremely emaciated. Spinous processes, ribs, tailhead, tuber coxae, and tuber ischii project prominently. Bone structure of the withers, shoulders, and neck is noticeable. No fatty tissue can be felt.
2	Very thin. Animal is emaciated. There is a slight fat covering over the base of the spinous processes; the transverse processes of the lumbar vertebrae feel rounded. Spinous processes, ribs, tailhead, tuber coxae, and tuber ischii are prominent. Bone structure of the withers, shoulders, and neck is faintly discernible.
3	Thin. Fat buildup is present about halfway on the spinous processes; the transverse processes cannot be felt. There is a slight fat cover over the ribs. Spinous processes and ribs are easily discernible. Tailhead is prominent, but individual vertebrae cannot be visually identified. Tuber coxae appear rounded but are easily discernible; tuber ischii are not distinguishable. Bone structure of the withers, shoulders, and neck is accentuated.
4	Moderately thin. Negative crease can be seen along the back. Faint outline of ribs is discernible. Tailhead prominence depends on conformation; fat can be felt around tailhead. Tuber coxae are not discernible. Withers, shoulders, and neck are not obviously thin.
5	Moderate. Back is level. Ribs cannot be visually distinguished but can be felt easily. Fat around tailhead is somewhat spongy. Withers appear rounded over spinous processes, and shoulders and neck blend smoothly into the body.
6	Moderately fleshy. Slight crease may be seen down the back. Fat over ribs is spongy, and fat around tailhead is soft. Fat is beginning to be deposited along withers, behind shoulders, and along neck.
7	Fleshy. Crease may be seen down the back. Individual ribs can be felt, but there is noticeable filling of fat between ribs. Fat around tailhead is soft. Fat is deposited along withers, behind shoulders, and along neck.
8	Fat. Crease is seen down the back. Ribs are difficult to feel. Fat around tailhead is very soft. Areas along withers and behind shoulders are filled with fat, and neck is noticeably thickened. Fat is deposited along inner thighs.
9	Extremely fat. Obvious crease is seen down the back. Patchy fat appears over ribs. Bulging fat is seen around tailhead along withers, behind shoulders, and along neck. Fat along inner thighs may cause thighs to rub together. Flank is filled with fat.

From Henneke GD, Potter GD, Kreider JL, et al. Relationship between condition score, physical measurements and body fat percentage in mares. *Equine Vet J* 15:371, 1983.

Is the nutrient density of the hay/pasture appropriate for a growing horse? How much hay is offered to the foal (in weight) daily? How much forage (in weight) does the foal eat each day?

(2) Supplemental feeds and grain: What type of supplemental feed or grain is fed to the foal? Is the feed of high quality and indicated for a growing foal? What is the nutrient composition of the supplemental feed? Does it contain appropriate protein quality, vitamins, and minerals? How much of the supplemental feed or grain (in weight) does the foal eat each day?

(3) Vitamins and minerals: If the foal is consuming commercial feed designed for a growing foal, it should not need supplemental vitamins or minerals. However, if the foal is being fed whole grains and hay/pasture, vitamin/mineral supplementation is warranted. Is the foal offered a vitamin and mineral supplement? Is the vitamin and mineral supplement appropriate for a growing foal? Is the vitamin and mineral supplement offered free choice? How much of the supplement (in weight) does the foal eat each day? Could any nutrients be consumed in a toxic amount? Has the owner provided any supplemental parenteral vitamins or minerals to the foal?

2. Perform a physical examination.
   a. What is the body weight of the foal (measured by using either a scale or weight tape if the foal is 3 months of age or older)? What is the body condition score (BCS) of the foal (see Table 9.1)? Is the foal small, thin, or underweight according to growth charts (Tables 9.2 and 9.3; Fig. 9.1)?
   b. Does the foal have evidence of a congenital abnormality (cardiac, renal, gastrointestinal, oral)?
   c. Does the foal show any signs of infectious disease (current or resolved)?
   d. Does the foal have any musculoskeletal abnormalities?

TABLE 9.2

Weight as Percentage of Mature Body Weight in Horses

Age (Months)	Ponies[4] (%)	Light Horses[1-3,5] (%)	Draft Horses (%)
6	55	46	40
12	75	67	57
18	84	80	75

3. Examine the feces. What is the consistency of the feces? Refer to Chapter 17 for the diagnosis and management of neonatal diarrhea; refer to Chapter 7 if the foal is older and has evidence of diarrhea. Is there evidence of sand in the manure? If yes, the foal should be treated with psyllium. Perform a fecal egg count. If the foal has a positive fecal egg count, follow the parasite control program recommendations in Chapter 49. If a negative fecal egg count is reported but parasitic infestation is still suspected, repeat the test in 2 to 3 weeks or follow the deworming protocols in Chapter 49. Evaluate the feces for occult blood. If the foal has a positive fecal occult blood test, review the medical management for melena in Chapter 7.
4. Perform blood analyses.
   a. Perform a complete blood count (CBC) and include a plasma protein and fibrinogen concentration. If the foal is anemic, determine the cause of the anemia following the guidelines in Chapter 24. If the foal's CBC indicates inflammation, review Chapters 25 and Chapter 26 and select appropriate ancillary diagnostic tests to identify the source of the infection or inflammation.
   b. Perform a serum biochemical analysis. Evaluate the results for evidence of systemic disease. Serum albumin is usually within normal limits with PCM until the condition is

	6	335	388.6
	12	500	578.2
	18	665	697.5
	24	760 (84.4%)	773 (85.9%)
	36	No value	850

Values in parentheses represent % of mature body weight. Equation (1) $Y = 9.7 + (100 - 9.7) \times (1 - (e(-0.0772 \times X))$ ($R2 = 0.99$); Y = percent mature body weight; X = months of age.

From National Research Council [NRC]. 2007. Nutrient requirements of horses. National Academies Press, Washington DC.

terminal. Serum glucose is usually normal, but it may be decreased in neonatal foals with sepsis. Serum glucose may be elevated in stressed animals. Serum urea nitrogen and creatinine concentrations are elevated in foals with renal disease. Serum urea nitrogen decreases in cases of chronic protein malnutrition.

c. If the foal has evidence of systemic disease, perform ancillary diagnostic tests to identify the source of the illness and then manage the case with appropriate medical or surgical intervention.

5. Analyze the diet and improve the feeding program.
   a. Determine whether the energy, protein, mineral, and vitamin content of the diet meets the requirements of the growing foal (Table 9.4). Use the Nutrient Requirements of Horses free companion computer program as a reference for all essential nutrients (www.nap.edu/catalog/11653/nutrient-requirements-of-horses-sixth-revised-edition).
      i. Dietary protein and essential amino acids are especially important in young growing horses. Lysine is the first, and threonine is the second limiting amino acid in the equine. Growing foals should consume 4.3% of their crude protein requirement as lysine (multiply the crude protein requirement by 4.3%).[7] Growing foals should also consume at least 0.5% threonine dry matter (DM) in their diet. Soybean meal and alfalfa hay contain approximately 3.3% and 0.9% lysine (DM), respectively. Cereal grains are poor sources of lysine. Commercial feeds typically designed for growing horses should have sufficient lysine and threonine content, either via the inclusion of soybean meal as an ingredient, and/or direct addition of lysine and threonine as ingredients.
      ii. Milk replacer: If the foal is consuming a milk replacer, review the guaranteed analysis and ingredient list of the product. Review the mixing instructions with the owner or farm manager. Develop a feeding program appropriate for the foal's age.
      iii. Forage: Determine the nutrient content of forage or pasture with an analysis. Equi-Analytical forage laboratory service (www.equi-analytical.com) can analyze for major energy, protein, and major and some minor minerals. NP Analytical Laboratories (https://www.npal.com) can analyze feeds further for amino acids and vitamins if warranted. Forage sampling instructions and forage analysis companies are listed in Boxes 9.3 and 9.4. University extension services often provide a forage analysis service. If the client does not purchase a large volume of hay, or if analysis cannot be performed, forage tables from the Nutrient Requirement Council reference books (www.nap.edu) and nutrient tables from the Equi-Analytical Laboratories forage laboratory database can be referenced to estimate the concentration of different nutrients in common forages and supplemental feeds; however, if nutrient deficiency/toxicity are suspected, forage analysis should be conducted. Use the daily nutrient requirements (see Table 9.4) to recommend the type and amount of forage the foal should consume on the basis of the nutrient content of the forage.

Modified from National Research Council. *Nutrient requirements of horses.* Washington, D.C., 2007, National Academies Press.

BOX 9.3

Forage and Large Animal Feed Sampling Instructions

Sampling Pasture

1. Collect pasture samples from a 1-foot-square area. Sample only the same type of forage that the horses are grazing. Sample 10 to 20 sites.
2. Using scissors, cut the pasture to within 1 inch of the ground. Do not collect soil-contaminated pasture. Cut all samples to a length of 1 inch, and place all samples into a clean bucket.
3. After sampling is complete, mix the samples well and place the forage into a plastic sealable bag (1-gallon Ziplock). Label the bag with the date of sampling, the collection site, and the owner's name.
4. If the sugar and starch content of the sample is of special interest, the sample should be frozen and shipped on ice to the analysis company.

Sampling Hay Using a Core Hay Sampler

1. Choose 10 to 20 bales randomly from the hay shipment. Only one type of forage should be submitted for analysis in the same container. If more than one type of hay is analyzed, each should be placed into a separate, labeled plastic bag.
2. Use the core hay sampler with a ratchet brace or drill to collect two samples from each bale. Square bales should be sampled from the long end of the bale. Round bales should be sampled along a horizontal line at the curve of the bale. Place all samples into a plastic sealable bag (1-gallon Ziplock), and label the bag with the date, type of hay, and owner's name.

Sampling Hay by Hand

1. Choose 10 to 20 bales randomly from the hay shipment. Only one type of forage should be submitted for analysis in the same container. If more than one type of hay is analyzed, each should be placed into a separate, labeled plastic bag.
2. Open the bale, and divide the bale in thirds. Collect a handful of hay from the center of the bale at each site (two samples per bale). Include everything that you have grabbed (including weeds and other plants) in the sample. Cut all samples to a length of 1 inch, and place all samples into a clean bucket. Thoroughly mix the cut hay samples, place the forage into a plastic sealable bag (1-gallon Ziplock), and label the bag with the date, type of hay, and owner's name. Ensure that all parts of the sample (leaves and stems) are included in the final sample.

Sampling Grain or Pelleted Feed

1. Analysis of two to four samples from 10 bags is recommended to obtain a representative sample of feed. Only one type of feed should be submitted for analysis in the same container. If more than one type of grain or pelleted feed is analyzed, each should be placed into a separate, labeled plastic bag.
2. Open a bag or a bin, and obtain a 2- to 4-oz sample from two to four locations in the bag or bin. A sample should be obtained from the bottom of the bin or bag to ensure that a sample of the settled feed is analyzed. When multiple bags or bins are sampled, samples from each bin or bag should be placed into a clean plastic bucket. Once all sampling has been completed, the feed sample should be mixed well, and approximately 1 lb of the feed should be placed into a plastic sealable bag (1-gallon Ziplock). Label the bag with the date, type of feed, and owner's name.

BOX 9.5

Targets for Growth in Dairy Heifers[27]

- Target weight first bred = mature shrunk body weight (SBW) × 0.55
- Target shrunk weight gain (SWG) before first pregnancy = (Target weight first bred − current SBW)/(Target age for first pregnancy − current age)
- Target first calving weight = mature SBW × 0.82
- Target second calving weight = mature SBW × 0.92
- Target third calving weight = mature SBW × 1.00
- First pregnant SWG = (Target first calving weight − Target weight first bred)/280

Modified from National Research Council. *Nutrient requirements of dairy cattle*, 7th revised ed. Washington, DC, 2001, National Academies Press.

iv. Commercial feeds and grain mixes: The guaranteed analysis on the feed tag label provides the nutrient content of certain ingredients. Contact commercial feed companies for the energy content of their product and nutrients not required for the guaranteed analysis tag. Make recommendations about the appropriate use of commercial equine feeds, grain, or grain mixes to complement the forage-based ration for growing foals on the basis of the clinical health of the foal.

v. Vitamins and minerals: Ensure that the ration meets the vitamin and mineral requirements of the foal and that proper mineral ratios are maintained in the ration. Supplement the ration if necessary.

b. If the foal or weanling has a nutrient deficiency, the problem should be corrected by a change in the ration or through appropriate parenteral supplementation.

c. If the diet history indicates that nutrients for maintenance and growth have been available and steadily consumed, the search for another cause of decreased growth and decreased weight gain should continue.

6. Perform ancillary diagnostic tests. If the cause of the decreased growth and/or poor weight gain has not been determined, additional diagnostic tests should be performed. Possible tests include, but are not limited to, ultrasound, radiographs, serum or whole blood trace mineral analysis, and carbohydrate absorption tests (oral D-glucose, D-xylose).

Approach to the Diagnosis and Management of Decreased Growth and Decreased Weight Gain in Ruminants

1. Take a general history and a diet history.
   a. General history
      i. What is the age of the animal? When was a decrease in growth observed? How many animals in the herd are affected? What are the ages of the affected animals? Has the herd had historical problems with growth of the young?
      ii. Identify the problem as acute, subacute, or chronic.
      iii. Check for signs or history of previous infectious disease in the herd.
      iv. Determine the parasite control procedures for the animal or herd.
      v. Examine the environment, including feed preparation areas and equipment, for possible toxic substances (e.g., zinc from galvanized buckets). Ensure cleanliness of bottles and equipment used with nursing animals.
   b. Diet history
      i. Obtain an accurate diet history, including diet information when milk or a milk replacer is being fed (birth to 2 or 3 months of age). Note the age and condition of the dam if patient was suckled before weaning. An accurate postweaning dietary history is essential. Suckled animals are developed ruminants at weaning, but hand-reared animals (dairy calves, bummer lambs, and dairy kids) are usually not fully developed ruminants at the time they are weaned from milk.
      ii. Inspect all forages and concentrates for quality, signs of spoilage, or abnormal color or odor. Has an analysis been performed on the forage or feed? Is the feed formulated appropriately for a young growing animal? Is the feed stored appropriately?
      iii. Because ruminants are often fed in groups, note whether all animals have adequate space to eat simultaneously.
2. Perform a physical examination.
   a. Determine the patient's age, weight, and body condition score. Is the patient growing appropriately? The growth curve depends on multiple factors including genetic and environmental factors and can be predicted using a number of different equations, each being adequate for different species or breeds.[8-10] One example is the Brody growth curve[11]
      (1) $Wt = A(1 - B\ e^{-kt})$
      (Wt: body weight at age t; A: mature weight; B: initial weight; k: growth rate; t: age in days)
      Targets for growth in dairy heifers are shown in Box 9.5.
   b. Does the animal show any signs of infectious or parasitic disease?
   c. Does the animal show any signs of congenital abnormalities?
3. Examine the feces. Perform flotation, sedimentation, and Baermann's procedures to detect patent parasitic infestation. Perform a fecal occult blood test; if the result is positive or if there is evidence of diarrhea, see the section on melena or diarrhea in Chapter 7. If diarrhea is noted in neonatal calves, refer to Chapter 20 for diagnostic and therapeutic management.
4. Perform blood analysis.
   a. Perform a CBC, including plasma protein and fibrinogen. Use the erythrocytic indices to document and characterize the anemia if present. If a herd problem exists in a selenium-deficient region, measure the whole blood selenium concentration or glutathione peroxidase activity.
   b. Perform a serum biochemical analysis. Serum albumin is decreased late in PCM. Albumin is normally lower in neonates (≈1 g/dL less) than in adults. The blood urea nitrogen (BUN) level is often low in ruminants as a result of urea recycling through saliva. Total serum calcium may be decreased with hypoalbuminemia (ionized serum calcium remains normal), anorexia, or hypocalcemic syndromes (milk fever). Serum phosphorus may be increased during severe starvation or decreased with anorexia. Hypophosphatemia may be the result of dietary deficiency or *Brassica* feeding, or it may be associated with copper deficiency. Measure serum (plasma) copper if a herd problem exists in a copper-deficient

region (or a region with excess molybdenum or sulfate or both). Copper (serum or plasma) concentrations below 0.5 µg/mL (ppm) indicate deficiency. The concentration of copper in the liver is even more indicative of status. Serum glucose may be increased with stress or decreased or normal near death.

5. Analyze the diet and improve the feeding program. Compare nutrient intake with the requirements for maintenance and growth of the various ruminant species (Tables 9.5 to 9.11). If the neonate is being fed a milk diet, evaluate the quality of the product and ensure that the animal's intake meets the dietary requirements (see Tables 9.5 and 9.6). Requirements for other breeds and life stages can be found in the nutrient requirement textbooks for dairy cattle, beef cattle, and small ruminants. Ensure that the milk replacer is mixed properly. If the ruminant is consuming a grain mix or forage, ensure that the quantity and quality of the feed are adequate to allow sufficient intake in developed ruminants. Equations to predict dry matter intake are available; some examples are listed in Table 9.12. Forage sampling instructions are listed in Box 9.3. If anorexia is present, look for more specific signs of a primary disease process. If the diet supplies adequate nutrients for maintenance and growth, consider decreased growth and decreased weight gain to be caused by a primary disease condition.

Weight Loss

The clinical problem of weight loss suggests that an individual large animal patient or a herd has lost weight over a known period of time. It may also suggest that the patient has reached a subnormal adult weight and size (see section on decreased growth and decreased weight gain, earlier). Late pregnancy, early lactation, and intense exercise are normal physiologic conditions commonly accompanied by mild to moderate weight loss. Late pregnancy can be associated with decreased body condition (Fig. 9.2) without actual weight loss because weight is gained with the conceptus. During pregnancy and lactation the loss of body condition may be mild, resulting in a low normal BCS, or the loss may be severe and can threaten the health of both the dam and neonate.

Weight loss in adult animals is most commonly associated with one or more of the following circumstances (other causes are listed in Boxes 9.6 and 9.7):

- Anorexia
- Increased nutrient demands
- PCM
- Micronutrient deficiencies
- Parasitism

Anorexia usually occurs secondary to a primary disease. A decrease in DMI occurs in dairy cows when temperature and humidity (Temperature Humidity Index, THI) exceed the coping mechanisms of the animals.[12] Increased nutrient requirements are associated with normal physiologic conditions (e.g., pregnancy, lactation, exercise, cold weather) and pathologic processes (e.g., sepsis, trauma, parasitism, burns). Mild to severe PCM is often associated with inadequate feed quality or quantity but can also be caused by increased energy requirements resulting from adverse environmental conditions. Weight loss can also occur with a deficiency of essential micronutrients such as copper, cobalt (vitamin B_{12}), or vitamin A. Parasitism should always be on the differential list in an animal that has lost weight.

Mechanisms of Weight Loss

Anorexia is the loss of appetite or lack of desire for food; it may be complete or partial. It is a primary mechanism for weight loss of short or intermediate duration. Weight loss results from decreased nutrient intake. When partial anorexia occurs over a long period, the weight loss may be subtle and go unrecognized. Acute, complete anorexia results in more dramatic rapid weight loss.

In domestic species, anorexia is usually associated with a primary disease condition and is regulated by cytokines including interleukin (IL-1) and tumor necrosis factor alpha (TNF-α), released during an inflammatory response.[13] Resolution of the primary disease process usually results in a return to voluntary food consumption. Anorexia must be differentiated from dysphagia by observation. The distinction between the conditions that cause anorexia and those that control hunger and satiety is not clear; however, many diseases that cause anorexia also result in dehydration, electrolyte imbalances, and/or acid-base disorders.

In addition to causing anorexia, many disease processes cause an increase in the nutrient requirements for basal metabolism. Nutrient requirements for maintenance, growth, pregnancy, lactation, and exercise have been well defined for many large animal species. Nutrient requirements in disease have not been adequately evaluated in large animals, and most information is currently extrapolated from humans, laboratory animals, and small animal species. In human patients, published estimates indicate that requirements for energy and protein increase approximately 10% after elective surgery, 20% with fractures, 30% to 60% with severe infection or sepsis, 40% with peritonitis, and 50% to 110% with major burns.[14,15] In humans, the resting energy expenditure is estimated to increase by 14% for each degree Celsius increase in body temperature.[16] Extrapolation of these data directly to equine and ruminant patients is probably not possible; however, the figures do indicate the degree of change in nutrient requirements as a result of disease. The stress of many disease processes results in an increase in serum cortisol and glucagon. The decreased insulin/glucagon ratio alters the production of glucose and results in hyperglycemia because of enhanced hepatic gluconeogenesis. An increase in sympathetic activity appears to regulate fat oxidation, the increased release of fatty acids from cellular lipid stores, and the development of hypertriglyceridemia in many patients with sepsis. Protein degradation and a negative nitrogen balance are also hallmarks of the acute response to infection. Weight loss resulting from protein and lipid catabolism is often observed in large animal patients with sepsis, owing to altered metabolic activity and nutrient requirements. In horses, particularly obese ponies or donkeys or pregnant mares, who may be stressed, the increased cortisol coupled with innate insulin resistance may predispose these animals to the development of hyperlipemia and/or hyperlipidemia.

In conditions such as burns, peritonitis, pleuritis, colitis, and granulomatous bowel disease, nutrients (particularly proteins) are lost. In many disease conditions, concurrent anorexia and increased nutrient requirements greatly increase the risk of PCM and weight loss. Certain conditions such as Johne's disease in ruminants and granulomatous enteritis in horses are also associated with a malabsorption or malassimilation syndrome. In these types of diseases, nutrients are not efficiently digested and absorbed; anorexia may be absent, and dietary intake may appear normal, but weight loss still occurs.

PCM continues to be a persistent problem in domestic animals. Inadequate ingestion of energy and protein obviously

BOX 9.6

Causes of Weight Loss in Horses

Common Causes

Protein-calorie malnutrition (PCM)
Dental disease
Jaw abnormalities
Gastric ulcers
Right dorsal colitis
Parasitism (small strongyles, large strongyles, tapeworms, bots)
Sand enteropathy
Pneumonia (bacterial, viral)
Pleuritis, pleuropneumonia, pulmonary abscessation
Recurrent airway obstruction
Internal abdominal abscess
Peritonitis
Streptococcus equi (lymph node abscessation, pulmonary or mesenteric abscessation)
Acute renal failure
Chronic renal failure
Pituitary pars intermedia dysfunction
Neoplasia (alimentary tract)

Less Common Causes

Equine herpes myeloencephalopathy
Equine motor neuron disease
Oral foreign body
Guttural pouch infection
Otitis media, interna
Paranasal sinus infection
Esophageal abnormalities (esophagitis, diverticula)
Vesicular stomatitis
Gastric impaction
Gastric squamous cell carcinoma
Duodenal ulcers
Inflammatory bowel disease (basophilic enterocolitis, eosinophilic enterocolitis, granulomatous enteritis, lymphocytic-plasmacytic enteritis, multisystemic eosinophilic epitheliotropic enterocolitis)
Chronic colonic impaction
Idiopathic diarrhea
Giardiasis
Fungal pneumonia
Pneumoconiosis (silicosis)
Tuberculosis
Cholelithiasis
Chronic hepatitis
Toxic hepatopathy
Atrial fibrillation
Cardiac or great vessel anomalies
Congestive heart failure
Endocarditis, pericarditis
Splenic rupture, abscess
Amyloidosis
Glomerulonephritis
Pyelonephritis
Renal neoplasia
Renal tubular acidosis
Urinary bladder neoplasia
Urolithiasis
Infectious arthritis
Osteomyelitis
Granulosa cell tumor
Lymphoma, lymphosarcoma
Malignant melanoma
Autoimmune anemia or thrombocytopenia
Purpura hemorrhagica
Coccidioidomycosis
Cryptococcosis
Nocardiosis
Agammaglobulinemia
Equine adenovirus
Equine infectious anemia
Equine viral arteritis
Anhidrosis

Uncommon Causes

Botulism
Micronema deletrix, infection of the central nervous system
Nigropallidal encephalomalacia
Nutritional rhabdomyolysis
Rabies
Rectus capitus ventralis muscle rupture
Spinal abscessation
Prognathia, brachygnathia
Pyloric stenosis
Basophilic enterocolitis
Colonic fistula
Ileal hypertrophy
Strongylus vulgaris, thromboembolism
Micropolyspora faeni, hypersensitivity pneumonitis
Pleural mesothelioma
Rhodococcus equi, infection
Tuberculosis
Mammary carcinoma
Malignant mesothelioma
Ovarian adenoma
Pancreatic neoplasia
Pulmonary neoplasia
Skeletal or vertebral neoplasia
Testicular neoplasia
Portal vein shunt
Liver fluke
Theiler's disease-associated virus (TDAV)
Enzootic cystitis
Polycystic disease
Diabetes mellitus
Hyperparathyroidism
Pheochromocytoma
Steatitis
Brucellosis
Multiple cartilaginous exostoses
Bullous pemphigoid
Eosinophilic dermatitis
Fungal granuloma
Horsefly-deerfly infestation
Lupus erythematosus
Panniculitis
Pemphigus foliaceous
Seborrhea
Wound myiasis
Babesiosis
Erythrocytosis
Histoplasmosis
Myeloproliferative disease
Phycomycosis
Tularemia
Goiter
Phosphorus deficiency
Thiamine deficiency
Vitamin A deficiency

Toxins

4-Aminopyridine
Aflatoxicosis
Arsenic toxicity
Dioxin
Fluorosis
Mercury toxicity

BOX 9.6

Causes of Weight Loss in Horses—cont'd

Pentachlorophenol
Phenylbutazone, flunixin meglumine, and other nonsteroidal antiinflammatory drugs
Selenium toxicity
Vitamin D calcinosis
Vitamin K_3 toxicity
Zinc toxicity

Plant Toxins

Crofton weed *(Ageratina adenophora)*
Plant calcinosis (*Cestrum diurnum, Trisetum flavescens,* others)
Pyrrolizidine alkaloid toxicosis (*Senecio* spp., *Amsinckia* spp., *Crotolaria* spp., others)
Red maple leaf *(Acer rubrum)*
Jimsonweed (*Datura* spp.)
White snakeroot *(Eupatorium rugosum)*
Yellow star thistle *(Centaurea solstitialis),* Russian knapweed *(Centaurea repens)*

Exotic Diseases

Besnoitiosis *(Besnoitia bennetti)*
Burkholderia pseudomallei
Dourine *(Trypanosoma equiperdum)*
Equine dysautonomia (grass sickness)
Glanders *(Burkholderia mallei)*
Mal de caderas *(Trypanosoma equinum)*
Nagana (*Trypanosoma* spp.)
Stachybotryotoxicosis
Surra *(Trypanosoma evansi)*
Trombiculiasis
Trypanosoma hippicum

BOX 9.7

Causes of Weight Loss in Ruminants

Common Causes

Protein-calorie malnutrition (PCM)
Dental abnormalities
Pharyngeal, retropharyngeal abscess
Actinobacillosis
Actinomycosis
Diarrhea (Enterotoxigenic *Escherichia coli, Salmonella,* bovine virus diarrhea, coronavirus, rotavirus infection, *Cryptosporidium parvum,* coccidiosis, winter dysentery [B], other causes)
Johne's disease (paratuberculosis)
Parasitism (lungworms, gastrointestinal parasites)
Abomasal ulcer
Displaced abomasum
Subacute ruminal acidosis
Vagal indigestion
Bacterial pneumonia, pulmonary abscessation
Infectious bovine rhinotracheitis
Traumatic reticuloperitonitis, pericarditis
Hepatic abscess
Liver fluke infestation
Ketosis
Fat necrosis (B)
Leptospirosis
Pyelonephritis, cystitis
Urolithiasis
Mammary abscess
Mastitis
Anaplasmosis (B)
Bovine leukosis
Septic arthritis
Lameness (infectious and claw horn lesions [bovine digital dermatitis, sole ulcers, white line disease, etc.], pedal osteomyelitis)
Lice or ked infestation
Sarcoptic mange
Wound myiasis
Copper deficiency
Selenium deficiency
Bluetongue (O)

Less Common Causes

Coenurosis (gid)
Sarcocystis
Mandible, maxilla fracture
Loss of teeth, periodontal disease
Lingual injury, abscess
Otitis media, externa
Sinusitis
Esophageal malfunctions
Omasal impaction
Abomasal impaction
Colonic obstruction
Aspiration pneumonia
Micropolyspora faeni hypersensitivity pneumonitis
Pleuritis
Tuberculosis
Brisket disease
Endocarditis
Vena caval thrombosis
Thymic lymphosarcoma (B)
Stomatitis (ulcerative, vesicular, papular [B])
Glomerulonephritis
Urachal abscess, bladder abscess
Postparturient hemoglobinuria
Renal amyloidosis
Eperythrozoonosis
Sarcocystosis (B)
Dermatophilosis
Psoroptic mange

Trypanosomiasis (*Trypanosoma* spp.)

B, Bovine; *O*, ovine.

results in weight loss, but PCM and associated weight loss can occur through several other mechanisms. The most direct cause is that the animals receive an inadequate volume of feed to meet their dietary requirements. This can occur as frank underfeeding of all animals or as a consequence of inadequate feeding facilities that create competition among animals for available feed. The latter circumstance occurs most dramatically when animals of varying ages are mixed; the younger animals with the highest requirements are often pushed away by older, dominant individuals.

The quality of the diet, particularly dietary forages such as hay and pasture, is an important factor in the development of PCM and total nutrient intake. Table 9.1 lists guidelines for estimating the maximum daily intake by cattle. It is evident that as forage quality (digestibility) decreases, maximum daily intake decreases because poor-quality feed must remain in the rumen for an increased period of time before it is sufficiently digested to allow passage through the reticuloomasal orifice. Maximum dry matter intake (DMI) as a percentage of body weight is somewhat higher in small ruminants than in cattle. However, the energy requirement per kilogram of body weight is higher in small ruminants than in cattle. Similar estimates for maximum DMI in horses related to forage quality are not available, yet horses will consume on average 2% of their body weight as DMI, with some studies reporting intakes as high as 4% of body weight. Horses do not have a pregastric fermentation organ (rumen) and can ingest slightly more of the same quality forage than cattle. Low-quality forages are often the cause of PCM, even when an unlimited quantity is available. The best way to determine the nutrient content of forage, grain, and pelleted feeds is to have the feed analyzed by a forage laboratory. Feed analysis instructions are provided in Box 9.3. Feed tag labels or forage databases can be referenced if an analysis is not performed.

Environmental factors can have a major influence on nutrient requirements and can increase the subsequent risk for PCM and weight loss. The most important environmental factor is the ambient temperature. Nutrient requirements for maintenance change with a decreasing ambient temperature as follows:

- *Adult horses:* Estimated increase in digestible energy (DE) requirements by 2.5% for every degree Celsius below the lower critical temperature (LCT). The LCT for adult horses ranges from 5° C to −15° C, depending on the horse's adaptation to the environment. In cold temperatures, when the hair coat is wet, the maintenance DE requirement may be increased by as much as 50%.[7]
- *Beef cattle:* 1% increase in maintenance energy requirements (total digestible nutrients [TDN], net energy of maintenance [NE_m], digestible energy [DE], and metabolizable energy [ME]) for each 1° C drop below 20° C (68° F).
- *Dairy cattle (lactating):* 25% increase in energy requirements (TDN, net energy of lactation [NE_L]) as ambient temperature drops from 20° C (68° F) to −10° C (14° F).
- *Sheep with 10-cm wool:* 1% increase in energy requirements (TDN, ME, DE) for each 1° C drop below lower critical temperature (approximately −10° C).

VetBooks.ir

There are also additive effects of wind and rain that increase energy requirements in large animal species. As nutrient requirements increase, the dietary intake must also increase to prevent weight loss associated with PCM. Horses in inclement weather may not be able to consume enough forage to meet their increased energy requirements, and for these animals, dietary fat and limited grain supplementation may be required.

Deficiencies of micronutrients (trace minerals, B vitamins) often result in inefficiencies in basic biochemical pathways. These inefficiencies, if marked, can be associated with weight loss. Genetic errors in metabolism can cause similar disturbances, but these usually manifest as decreased growth and even death in young animals.

Parasitism is a common cause of weight loss in adult domestic animals. The mechanisms by which parasite infestation can result in weight loss include a loss of body fluid and tissues resulting in increased nutrient requirements, competition for nutrients in the gastrointestinal tract, malassimilation and malabsorption, inflammation resulting in increased nutrient requirements, micronutrient deficiencies, and organ or vascular damage from migrating parasite larvae. Anorexia may also develop in the advanced stages of severe parasitism.

Approach to the Diagnosis and Management of Weight Loss in Adult Horses

Use the flow sheet in Fig. 9.3 to aid in decision making.

1. Take a general history and a diet history.
   a. General history
      i. Is the weight loss affecting one animal or many animals? If many horses are affected, what is the age range of the affected animals? How long has the caretaker noticed the weight loss? Has the diet been changed to manage the weight loss? What is the change in BCS of the horse(s)? How much weight has been lost? Is this an estimate of weight loss, or has the horse(s) been monitored on a scale or with a weight tape? Weight loss is often suspected but not documented in the initial complaint or history. Acute weight loss of 5% to 10% is significant. If a weight tape will not fit around the girth of the horse or if the horse has a BCS of 1 to 3, a rough estimate of body weight can be made using measurements of the length and girth of the horse.[17,18] Length is measured from the tuber ischium to the point of the shoulder, and girth is measured at the withers, behind the elbows, at the end of expiration.

$$\text{Body weight (kg)} = \frac{\text{Chest girth (cm)}^2 \times \text{Length (cm)}}{11{,}877}$$

The weight of miniature horses should be obtained using a small animal clinic scale. If a scale is not available to weigh a miniature horse, then the following equation can be used to estimate the weight of the miniature horse.[19]

$$\text{Body weight (kg)} = \frac{(3.7 \times \text{Chest girth in cm}) + (2 \times \text{Length in cm}) - 348.5}{2.2}$$

      ii. Is there any past or current clinical disease in the horse or herd? If so, when was the disease first diagnosed? How many animals were affected? What type of treatment was administered? Was the diet changed during this period of time? Question the caretaker closely about any clinical signs of diarrhea, coughing, dysphagia, or polyuria. What is the deworming history of the horse and herd? Has the deworming protocol been changed lately?
   b. Diet history
      i. Type of feed. Obtain an *accurate* dietary history including the type and amount of feed offered (in pounds, ounces) and the amount of feed refused by the horse(s). It is essential that feeds are weighed accurately. What type and volume of forage is available? Inspect the pasture and all feeds for gross quality, evidence of

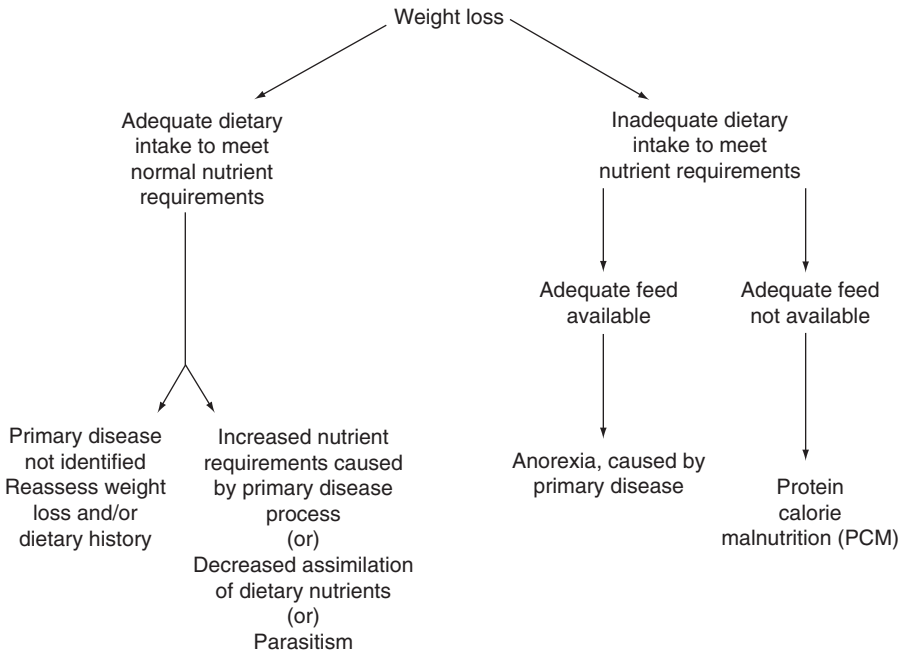

FIG. 9.3 Flow sheet for classifying conditions associated with weight loss.

TABLE 9.13

Daily Nutrient Requirements of Ponies and Horses of Mature Body Weight

Category	Digestible Energy (Mcal)	Crude Protein (g)	Calcium (g)	Phosphorus (g)
Mature Ponies, 200 kg (440 lb) of Mature Body Weight				
Maintenance, average activity	6.7	252	8	5.6
Mares, last 90 days of gestation	7.7-8.6	319-357	14.4	10.5
Lactation, first 3 mo	12.7-12.2	614-587	23.6-22.4	15.3-14.4
Mature Horses, 400 kg (880 lb) of Mature Body Weight				
Maintenance, average activity	13.3	504	16	11.2
Mares, last 90 days of gestation	15.4-17.1	637-714	28.8	21
Lactation, first 3 mo	25.4-24.5	1228-1174	47.3-44.7	30.6-28.8
Mature Horses, 500 kg (1100 lb) of Mature Body Weight				
Maintenance, average activity	16.7	630	20	14
Mares, last 90 days of gestation	19.2-21.4	797-893	36	26.3
Lactation, first 3 mo	31.7-30.6	1535-1468	59.1-55.9	38.3-36
Mature Horses, 600 kg (1320 lb) of Mature Body Weight				
Maintenance, average activity	20	756	24	16.8
Mares, last 90 days of gestation	23.1-25.7	956-1072	43.2	31.5
Lactation, first 3 m	38.1-36.7	1842-1761	70.9-67.1	45.9-43.2
Mature Horses, 900 kg (1980 lb) of Mature Body Weight				
Maintenance, average activity	30	1134	36	25.2
Mares, last 90 days of gestation	34.6-38.5	1434-1607	64.8	47.3
Lactation, first 3 mo	54.4-52.4	2763-2642	106.4-100.6	68.9-64.9

Modified from National Research Council. *Nutrient requirements of horses.* Washington, D.C., 2007, National Academies Press.

spoilage, abnormal color or odor, presence of weeds and mold, and quantity of feed the owner has at the facility. Has an analysis been performed on the forage (pasture grass and/or hay)? If yes, obtain a copy of the analysis for the patient record. How much time does the horse have to graze in a pasture? What type of grass is available in the pasture? Is the pasture overgrazed? Are there any plant toxins in the pasture or environment? Have there been any changes in the type of forage offered to the horse(s)? Hay quality is often not consistent between shipments. If grain or other supplemental feeds are used, what volume is fed and consumed by the horse(s)? Are any diet supplements fed to the horse? If so, what amount is fed? Does the horse have access to a salt or trace mineral block? How long has this diet been fed? Nutrient requirements of adult ponies and horses are listed in Table 9.13 and can also be calculated using the Nutrient Requirements of Horses free companion computer program (www.nap.edu/catalog/11653/nutrient-requirements-of-horses-sixth-revised-edition).

ii. Feeding management. How often are the horses fed? What type of feeder is used? Are mats placed under the feeders to reduce sand and dirt ingestion? Is there competition among the horses for food? Are there any toxic substances in the horse's environment? What is the water source for the horses? How many water sources are available? Is the water clean?

2. Perform a physical examination.
   a. Observe the horse while it is eating. Can the horse prehend, masticate, and swallow food normally? Is the horse dysphagic? Does the horse have a good appetite? Is the horse hungry? Are there any signs of neurologic disease?
   b. Examine the patient closely to identify signs of concurrent disease (e.g., pyrexia, diarrhea, melena, dysphagia, abnormal dentition, icterus, nasal discharge, cough, dyspnea, tachycardia, cardiac murmur, dysuria).
   c. What is the horse's body weight (scale or weight tape) and BCS (see Table 9.1)?
3. Examine the feces. What is the consistency of the feces? If the horse has evidence of diarrhea, review the section on diarrhea in Chapter 7. How long are the fibers in the feces? Perform a glove test. Is there evidence of sand in the feces? Horses can have a significant volume of sand in the large intestine while having negative fecal sand test results. Perform a fecal egg count. An enzyme-linked immunosorbent assay (ELISA) may be useful in diagnosing a tapeworm infection. Follow the parasite control program in Chapter 49 if the horse has evidence of fecal parasites or if a parasite infection is suspected despite a negative fecal egg count. Perform a fecal occult blood test; if the result is positive, see the section on melena in Chapter 7.
4. Perform blood analyses.
   a. Perform a CBC including plasma protein and fibrinogen. Examine the results closely for indication of an inflammatory process (e.g., leukocytosis, neutrophilia, leukopenia, neutropenia, hyperfibrinogenemia, decreased plasma protein/fibrinogen ratio [below 10]). Calculate the erythrocytic indices, and characterize anemia, if present.
   b. Perform a serum biochemical analysis. The serum albumin half-life is approximately 19 days in horses. Hypoalbuminemia may be associated with colitis, internal abscessation, PCM, liver disease, renal disease, and granulomatous bowel disease, among other conditions. Albumin is often within normal limits in PCM until the patient is near death. Globulin (particularly γ-globulins) may be increased with inflammation, and the albumin/globulin ratio may be decreased. The glucose concentration is usually normal or elevated as a result of stress and may also be elevated in horses with pituitary pars intermedia

dysfunction (PPID) and equine metabolic syndrome. Hyperlipidemia (serum triglyceride between 100 and 500 mg/dL) is commonly associated with early anorexia and can be present in horses with PPID. Hyperlipemia (serum triglyceride above 500 mg/dL) is a serious condition associated with prolonged anorexia and hepatic lipidosis and is often found in miniature horses, ponies, and donkeys under severe physiologic stress (PCM and lactation). Unconjugated bilirubin levels can rise to 6 or 7 mg/dL with anorexia or decreased food intake. An elevated γ-glutamyltransferase (GGT) (above 25 IU/L) may indicate hepatic disease. Horses with PCM may have a low serum urea nitrogen if the protein malnutrition is prolonged and severe.

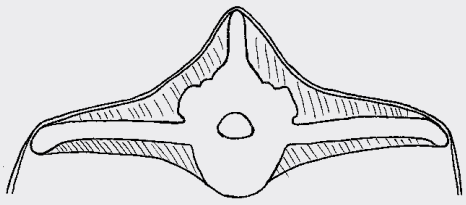
5. Analyze the diet and improve the feeding program.
   a. Determine if the energy, protein, mineral, and vitamin content of the diet meets the nutrient requirements of the horse at its current metabolic state and activity level (see Table 9.13). Include pertinent environmental and management factors in the nutrient requirement calculations. The quality of the feeds should be assessed.
      i. Forage. Determine the nutrient content of forage or pasture with an analysis (see Boxes 9.3 and 9.4). A university extension service often can assist with a forage analysis. If the client does not purchase a large volume of hay, or if analysis cannot be performed, forage tables from the Nutrient Requirement Council reference books (www.nap.edu) or nutrient tables from the Equi-Analytical Laboratories forage laboratory database (www.equi-analytical.com) can be used to estimate the concentration of different nutrients in common forages and supplemental feeds.
      ii. Grain, commercial feeds, and other supplemental feeds. Review the feed tag label to determine the nutrient concentration of protein and other essential nutrients. Contact commercial feed companies for the energy content of their products. Use nutrient databases to estimate the nutrient content of other feeds.
      iii. Vitamins, minerals, and other dietary supplements. Review all products used on the horse(s). Ensure adequacy of all essential nutrients. Are there any nutrient toxicities? Are all products necessary? If botanical ingredients are fed, are there any nutrient-drug interactions or contraindications in feeding the botanicals?
   b. If the horse has a dietary deficiency, the problem should be corrected by a change in the diet or through appropriate supplementation. Contact an equine clinical nutritionist for guidance on ration formulation.
   c. If the dietary history indicates that adequate nutrients for maintenance, or the appropriate life stage, or performance have been steadily consumed, continue to search for another cause of the weight loss.
6. Perform ancillary diagnostic tests. If the weight loss is not caused by inadequate or poor-quality feed, additional diagnostic tests should be performed. Possible tests include but are not limited to ultrasound, gastric endoscopy, radiographs, serum or whole blood trace mineral analysis, serum insulin concentration, carbohydrate absorption tests (oral D-glucose, D-xylose [see Chapter 32]), and appropriate organ biopsy.

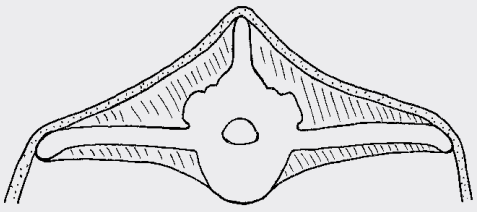
Approach to the Diagnosis and Management of Weight Loss in Adult Ruminants

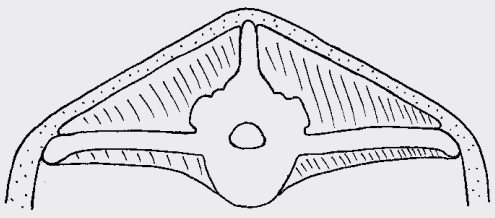
1. Take a general history and a diet history.
   a. General history: Question the caretaker closely about any clinical signs that might indicate a primary disease (e.g., diarrhea, coughing, dysphagia, polyuria, depression, agalactia). Note if body condition is less than desired. Quantitate the weight loss or BCS if possible. Acute weight loss of 5% to 10% is quite significant. Carefully note the production level of the animal or herd (e.g., pregnancy [single, twins, triplets], lactation [level of milk production]). Evaluate the parasite control program. Does the herd have a history of chronic or recurrent disease (Johne's disease, bovine virus diarrhea, subacute ruminal acidosis, mastitis, pneumonia)?
   b. Diet history: Obtain an *accurate* dietary history, particularly when signs of a primary disease are absent. Inspect all forages, concentrates, and feed additives for quality, signs of spoilage, abnormal color or odor, and quantity on hand. Be sure the feeding system allows for adequate consumption by all animals and that competition for feedstuffs does not occur, for example, due to a lack of bunk space in freestall barns. Check to see if the feeding program was changed before the onset of observed weight loss or loss of body condition. The history should include the *weight* of each feedstuff and supplement fed and consumed per day. The maximum DMI can be predicted for different types of cattle using the equations given in Table 9.1.
   c. Determine or estimate the nutrient analysis of the feedstuffs being fed. Examine the environment for possible toxic plants or substances.
2. Perform a physical examination. Examine patients carefully for signs of concurrent disease (e.g., diarrhea, decreased ruminal motility, pyrexia, dysphagia, abnormal dentition, melena, icterus, mastitis, metritis, dyspnea, tachycardia). Is the patient hungry? Weigh the patient (or use a heart-girth measurement) and note the BCS (see Tables 9.14 and 9.15 and Fig. 9.2). Observe the patient for signs of muscle wasting and the presence or absence of subcutaneous fat. Test the milk with nitroprusside powder (a positive reaction indicates an acetoacetate concentrate above 5 mg/dL and is diagnostic of ketonlactia and ketonemia), or measure the ketone concentration in the urine. In order to detect subclinical ketosis with higher accuracy, it is beneficial to use hand-held devices that measure β-hydroxybutyrate (BHB) in whole blood.[20] The level of nonesterified fatty acids is a good indicator for excessive body fat mobilization, especially in close-up cows. Measure the ruminal pH (pH above 7 is indicative of anorexia). Examine the skin for evidence of lice or keds.
3. Examine the feces. Perform flotation, sedimentation, and Baermann's procedures to detect patent parasitic infestations. If the feces test positive for occult blood or are dark, see the section on melena in Chapter 7. If there is evidence of or apparent diarrhea, see the section on diarrhea in Chapter 7.
4. Perform blood analysis.
   a. Perform a CBC including plasma protein and fibrinogen. Interpret for evidence of inflammation, and characterize the anemia if present. Analyze for blood selenium concentration or glutathione peroxidase activity if a herd problem of weight loss exists in a selenium-deficient region.
   b. Perform a serum chemistry analysis. The serum albumin half-life is approximately 16.5 days in cattle and 14 days in sheep and goats. Hypoalbuminemia is associated with internal abscessation, PCM, liver disease, renal disease, and Johne's disease, among other conditions. In the first two of these conditions, albumin is often normal until the patient is near death, whereas with protein-losing renal or gastrointestinal disease or with failure to make albumin in severe hepatic disease, hypoalbuminemia is often seen by the time noticeable weight loss occurs. Globulins, particularly γ-globulins, may be increased with inflammation, and the albumin/globulin ratio may

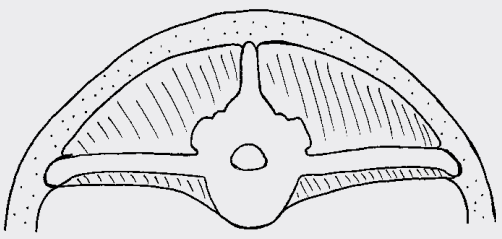
VetBooks.ir

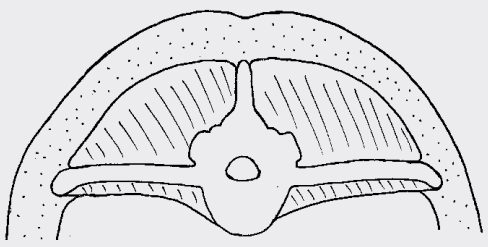
TABLE 9.14











Body Conditioning Scoring System for Beef Cows

Group	Score	Definition
Thin condition	1	Emaciated (body fat = 3.8%) The cow is severely emaciated and physically weak. Bone structure of shoulder, ribs, spinous processes, transverse processes, hooks, and pins are sharp to the touch and easily visible. No evidence of fat deposits or normal muscling. Cattle in this score are extremely rare and are usually inflicted with a disease and/or parasitism.
	2	Very thin (body fat = 7.5%) The cow appears emaciated, similar to 1, above, but not weak. Muscle atrophy is significant in the shoulder, over the loin and rump, and through the hindquarters. The spinous and transverse processes, hooks, and pins feel sharp to the touch and are easily seen. Ribs can be easily identified.
	3	Thin (body fat = 11.3%) The cow appears thin with no fat in the brisket. There is evidence of muscle atrophy over the shoulder, lion, and rump and through the hindquarter, but there is the beginning of some fat deposition over the shoulder, loin, and rump. The foreribs have slight evidence of fat deposition, but the last 3 or more ribs (11th, 12th, and 13th) are visible. Vertebrae of the spine are easily visible and can be identified individually by touch. Spaces between the processes have some evidence of some fat infiltration. Bone structure of the hooks and pins are evident under the hide.
Borderline condition	4	Borderline (body fat = 15.1%) The cow appears thin, with the last 2 ribs (12th and 13th) easily visible, especially in mature cows with a big spring of rib and broad, flat ribs. Muscle atrophy over the shoulders and loin and through the hindquarters is evident but approaching normal. Movement of the muscles in the shoulder is prominent just under the hide as the animal moves. Individual spinous processes along the topline, and transverse processes along the edge of the loin between the hooks and last rib, are not visible, but can be easily palpated with minimal pressure and feel rounded rather than sharp. The hooks and pins are covered in minimal fat and easily identified.
Optimum moderate condition	5	Moderate (body fat = 18.8%) There is a slight evidence of fat deposition in the brisket. Muscle expression in the shoulder, loin, rump, and hindquarters are normal. A thin layer of fat covers the muscles in the shoulder, and when the animal is in motion; the muscle and scapula movement under the hide are not prominent. The last 2 ribs can only be seen if the cow has less than normal gut fill. Individual spinous processes along the topline and transverse processes along the loin edge between the hooks and last rib appear smooth and are not visible, but they can be palpated with firm pressure. The hooks and pins are covered with a layer of fat, but still distinguishable. Areas on each side of the tail head are fairly smooth, but not mounded.
	6	Good (body fat = 22.6%) Some fat deposition in the brisket is evident. The cow exhibits a smooth appearance throughout without any evidence of muscle atrophy. A layer of fat covers the muscles in the shoulder, and shoulder movement visually takes on a fluid motion. There is noticeable sponginess over the foreribs just behind the shoulder. The ribs on young cows are fully covered by fat and cannot be detected visually. Flat, wide ribs on older cows may be seen. The spinous processes along the topline and transverse processes between the hooks and last rib are embedded in muscle and fat and can only be felt with firm pressure. The hooks are embedded in fat and appear round and smooth. The pins are embedded in fat, and there is noticeable sponginess on each side of the tail head.
	7	Fleshy (body fat = 26.4%) The brisket is full but not distended. A layer of fat covers the muscles in the shoulder, and the movement appears fluid. The ribs appear smooth, and there is a uniform layer of fat from the forerib to the last rib. The spinous processes along the topline and transverse processes between the hooks and last rib are embedded in fat, and the topline is beginning to take on a square appearance. The pins are embedded in a layer of spongy fat, and there are pones of fat forming on either side of the tail head.
Fat condition	8	Obese (body fat = 30.2%) The neck appears short and thick and the brisket is distended with fat. There is no evidence of bone structure in the shoulder, along the topline, hooks, or pins. A thick layer of fat covers the shoulder, and shoulder muscle movement under the hide is not evident. The animal appears very square and blocky over the topline and smooth along the sides. Fat cover over the shoulder, topline, and ribs appear spongy both visually and by touch. The pins are embedded in pones of fat on both sides of the tail head. There is evidence of fat deposition in the udder. Animal movement may be somewhat impaired due to excess fat.
	9	Very obese (body fat = 33.9%) These cows are very obese and are rarely seen. The animal appears very square and blocky over the topline, smooth along the sides, and spongy throughout. Bone structures are difficult to identify, and the animal appears short necked with a full, distended brisket. The pins are embedded in patchy pone fat on both sides and over the top of the tailhead. There is evidence of significant fat deposition in the udder. Animal mobility may be seriously impaired due to excess fat.

TABLE 9.15

Body Condition Scoring System for Sheep

Score	Description	Illustration
1	The spinous processes are prominent and sharp. The transverse processes are also sharp, with fingers passing easily under the end of this process. The eye muscle areas are shallow with little to no fat cover.	
2	The spinous processes are smooth but still prominent. The individual processes can still be felt but only as fine corrugations. The transverse processes are smooth and rounded. However, it is still possible to pass the fingers under the ends of the processes with some pressure. The eye muscle areas are of moderate depth, but have sparse fat cover.	
3	The spinous processes are smooth and rounded, and individual bones can only be felt with some pressure applied. The transverse processes are also smooth and well covered. Firm pressure is required to feel over the ends. Eye muscle area is full and covered by a moderate degree of fat.	
4	With pressure applied, the spinous processes can just be detected, although the ends of the transverse processes cannot. Eye muscle areas are full with a thick covering of fat.	
5	Even with firm pressure applied, the spinous processes cannot be detected. Due to a high level of fat adjacent to the spinous process, a depression directly above where the spinous processes would normally be felt may be present. It is not possible to detect the transverse processes. The eye muscle areas are very full with very thick fat cover. It is possible to have significant deposits of fat cover over the rump and tail.

VetBooks.ir

be decreased. The serum glucose concentration is usually not helpful in determining the cause or causes of weight loss. An elevated serum GGT (>25 IU/L) may indicate hepatic disease or, in rare cases, pancreatic disease. Serum BUN is often low with PCM in ruminants because of salivary urea recycling. Serum (total) calcium may be decreased with hypoalbuminemia, anorexia, or periparturient hypocalcemia. Serum phosphorus may be increased during severe starvation or Johne's disease or decreased with anorexia. The serum (plasma) copper concentration may be decreased if a herd problem of copper deficiency exists. Weight loss is particularly associated with copper deficiency when diarrhea is present in a region known to be copper deficient or in a region with excess dietary molybdenum or sulfates or both. A low serum copper concentration (below 0.5 µg/mL or ppm) indicates deficiency. Ketonemia may be associated with anorexia. Hand-held meters measuring BHB concentrations have been reported to be a useful tool in diagnosing pregnancy toxemia in pregnant sheep.[21] BHB concentrations ≥1.0 mmol/L indicate that the animals are at greater risk to develop severe hyperketonemia.[22]

5. Analyze the diet and improve the feeding program. Is the feed quantity and quality adequate to allow sufficient intake of nutrients? Compare the nutrient intake from the diet with the requirements for the appropriate species (Tables 9.16 to 9.20). Consider any important environmental and management factors in the daily nutrient requirements. Review nutrient analysis profiles on the feeds and total mixed ration (TMR) ingredients. Is the TMR mixed properly? Are grain rations mixed properly? Is too much grain being fed to the animal or herd? Analyze the pasture,

forage, or concentrate rations (see Box 9.3). Make appropriate recommendations to optimize the ration. Determine if the patient or patients have a normal appetite. Is anorexia present? If the dietary history and analysis indicate that adequate nutrients have been steadily consumed, the search for a primary cause for the weight loss should be resumed.

6. Perform ancillary diagnostic tests.
   a. If the weight loss is not related to the diet, additional diagnostic tests should be performed on the animal or on a number of animals in the herd. Possible tests include but are not limited to trace mineral analyses, ultrasound, and appropriate organ biopsy.
   b. Pathologic findings of affected ruminants often provide evidence of the effects of a systemic disease or of chronic malnutrition. Ruminants with PCM exhibit serous atrophy of fat in the coronary grooves of the heart and bone marrow at necropsy. Subcutaneous, abdominal, and perirenal fat are not present.

Obesity

Mechanisms of Obesity

Obesity is a common problem in domestic large animal species, especially in horses, and in ruminants raised as companion animals. In ruminants, obesity increases the risk of metabolic disease, reproductive failure, and health complications during late pregnancy and lactation. The risk of obstructive urolithiasis increases in overweight bucks and rams, especially wethers. In horses, obesity is related to a variety of diseases including insulin resistance, equine metabolic syndrome, laminitis, and colic associated with strangulating lipomas. Obese horses and ponies that have increased metabolic energy demands (late pregnancy, lactation) that are rapidly losing weight or that are anorexic are particularly susceptible to hyperlipidemia and hyperlipemia.

Obesity results from the consumption of more calories than are required by an animal based on its stage of life and level

VetBooks.ir

of activity. Individual animals and certain breeds appear to be predisposed to obesity even if they are fed to meet their maintenance energy requirements. Obesity frequently occurs in horses fed high-energy feeds including grain and energy-dense commercial feeds and in horses grazing highly digestible pasture. Even horses that are only fed hay may gain weight if they consume an excess amount of energy. Purebred or pet sheep and goats (particularly wethers) tend to be overfed. In dairy cattle, obesity occurs when cattle are fed well above requirements for maintenance and milk production. Poor reproductive performance is often associated with the initiation of obesity in ruminants and is also a common sequela to obesity. Feeding for high milk production for lengthy periods in production groups predisposes infertile cows to become fat cows. Dairy cows dried off with a body condition above target are also predisposed to hepatic lipidosis, increasing the risk for periparturient diseases. The systemic complications associated with hepatic lipidosis, as well as its diagnosis and treatment, are described in Chapter 33.

Diagnosis of Obesity in Horses and Ruminants

Obesity is diagnosed by measuring the animal's body weight and assigning a subjective BCS number on the basis of muscle mass and external fat deposits. The clinical description of obesity provided by the BCS system is straightforward (see Figs. 9.2 and 9.3, Tables 9.1, 9.14, and 9.15). Overweight and obese animals have an elevated BCS (7 to 9/9 for horses; 8 to 9/9 for beef cattle; 4 to 5/5 for dairy cattle, sheep, and goats). Palpation of the back, gluteal area, and ribs should be included in the physical examination of sheep and camelids with long wool or fiber and of horses with a long winter hair coat so that a BCS can be determined. In some animals, external signs of fat deposition may be subtle. In horses, a BCS greater than 5 to 6/9 does not accurately predict the total body fat mass of the animal in a linear fashion as may be expected using the linear BCS system.[23] Instead, body fat shows an exponential increase in horses with moderate to obese BCS.[23] Other measurements of body fat deposition including abdominal girth and fat depth (subcutaneous and retroperitoneal) measured by ultrasound may provide a better assessment of obesity in horses when the BCS is greater than 5.[23,24] Assessment of back fat thickness in dairy and beef cattle can also be evaluated with an ultrasound examination and has been shown to correspond well with total body fat.[25]

In some animals, obesity can be mistaken for the normal physiologic condition of pregnancy. In other cases, obesity could be mistaken for a distended abdomen from acute pathologic disease conditions including uroabdomen and peritonitis. A CBC and serum biochemical analysis can identify many subclinical diseases in an obese animal. A full physical examination should always be performed on a large animal patient before a weight loss ration is fed.

Treatment of Obesity

Overweight and obese horses and ruminants should lose weight to improve their health, extend life span, and improve production efficiency. In many cases a reduction in energy intake can be achieved by simply eliminating excess calories in the ration. Animals that fail to lose weight after 1 to 2 months after removing high-calorie feeds often require a more aggressive weight loss program with a therapeutic ration and a gradual implementation of an exercise program. Voluntary activity in animals that are turned out in pasture is rarely high enough to promote weight loss. Obese laminitic horses present a difficult challenge because exercise may not be practical, and weight loss must rely solely on dietary energy restriction.

Horses and companion ruminants that require a managed weight loss program should have the energy content of their diet evaluated by the veterinarian or nutritionist. The actual energy intake should be compared against the energy requirement for the animal's current life stage (see Tables 9.10, 9.11, 9.13, 9.16 to 9.20). The animal's current calorie intake should be reduced by 10% to 20% at the start of the weight loss program. This can typically be achieved in horses by decreasing forage intake to 1.5% of body weight and removing supplemental concentrates. Decreasing forage to 1% of body weight may be required under veterinarian care for some horses resistant to weight loss. Dietary protein should not be restricted, and adequate protein intake can be met by ensuring the forage available has appropriate protein content, or through the addition of soybean meal. Supplemental feeds and treats should be reduced or eliminated from the diet; however, a vitamin and mineral supplement should be fed with a weight loss ration to ensure all nutrient requirements other than energy are met. For horses, a concentrated vitamin-mineral supplement (typically offered in amounts <100 g, or about 4 oz) is often sufficient. A forage analysis can be used to select feeds that are low in nonstructural carbohydrates, as these may exacerbate any conditions associated with glucose metabolism.

Feeding straw to horses increases the risk of impaction colic and other gastrointestinal complications and should be avoided. To prevent boredom and improve the regulation of glucose, small amounts of forage should be fed in multiple small meals throughout the day. Horses can be fed hay in a hay bag, in doubled hay nets, in a NibbleNet, or with a mechanical feeder (Stable Grazer, The Grazer Hay Feeding Machine) as long as the horse can safely tolerate this equipment in its stall. The target weight loss goal is between 0.5% and 1% body weight each week. A weight tape should be used to assess the horse's weight if a scale is not available. Abdominal girth measurements, ultrasonographic evaluation of subcutaneous fat at the 12th intercostal space, and BCS measurements can be made to monitor weight loss every month.[23,24]

Owner compliance is essential during a weight loss program for horses and companion large animals. Owners should be encouraged to keep a journal of their animal's ration, body weight, and BCS. Horse owners can also monitor the horse's abdominal circumference, measured around the widest part of the abdomen.[24] Digital photos can help document physical changes over time. Excessive, rapid weight loss should be avoided. Weight loss programs should be approached with caution in animals that are either pregnant or lactating. Once the animal has achieved the ideal body weight and BCS, it should be placed on a maintenance ration and exercise program that will ensure the ideal weight is maintained.

In a production management setting the ration should be evaluated and revised to reduce calories while maintaining sufficient energy intake to maximize reproduction or milk production. Care should be taken to ensure the animals consume an adequate concentration of vitamins and minerals to meet their requirements when they are fed an energy-restricted ration.

Pica

Pica (geophagia) is defined as a depraved or abnormal appetite. It is usually associated with animals that chew or eat wood (fences, trees, buildings); dirt; bones; or other inanimate objects not usually considered feedstuffs. The mechanism or mechanisms of pica are not yet understood. Pica has been associated with PCM, parasitism, obesity, and deficiencies of phosphorus, salt, protein (kwashiorkor), and micronutrients. Diagnosis is by observation or history or both. The main emphasis must be placed on identification and resolution of the primary problem. Pica must be differentiated from abnormal behavior associated with central nervous system diseases, bovine ketosis, and equine behavioral abnormalities associated with boredom.

Alterations in Urinary Function

EMILY A. BARRELL and ALEXANDRA J. BURTON, *Consulting Editors*

■ MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Dysuria, stranguria, and incontinence, 166
Hematuria and pigmenturia, 169
Pyuria, 170
Crystalluria, 171
Polyuria, 172
Anuria and oliguria, 173
Uremia, 173

Dysuria, Stranguria, and Incontinence

Dysuria is defined as difficult or painful urination. *Stranguria* is defined as straining to urinate, with the normal rate of voiding and urine egress being decreased and the effort required to void increased. Because these signs are often difficult to distinguish from each other and often present concurrently, they are considered together in this section. The most common causes of dysuria and stranguria are urethral obstruction, inflammation of the urethra and/or bladder, and neurologic conditions that prevent normal emptying of the bladder. Adhesions between the bladder and other structures in the abdominal or pelvic cavities can create mechanical interference with bladder emptying, resulting in dysuria and stranguria.

The horse voids urine actively and forcefully. Both male and female adult horses may briefly groan and strain slightly during normal urination. This should not be misinterpreted as dysuria or stranguria. In ruminants, urination is more passive, and straining or groaning is not normally observed, although vocalization during urination may signal dysuria. Conditions in which the horse may spuriously appear to have dysuria include lower urinary tract (LUT) disease, abdominal pain, peritonitis, pleuritis, severe musculoskeletal disease, or neurologic disease. With any of these conditions, the horse may attempt to posture and urinate but may not be able to sufficiently increase intraabdominal pressure to allow complete voiding. Owners of horses frequently misinterpret abdominal pain (colic) as "straining to urinate."

Signs of dysuria and stranguria include treading, repetitive switching or flagging of the tail, pollakiuria (frequent voiding of small amounts of urine), flatulence during voiding, and retention of the urination posture after voiding has ceased. Urine scalding of the perineal region or rear legs may be noted in large animals with dysuria or stranguria. While straining to void, forceful contractions of the abdominal musculature may be seen. Male horses and ruminants experiencing dysuria or stranguria typically stand with the back slightly extended (mild lordosis), with the front legs held farther ahead of the body and the hind feet positioned farther behind the body than normal (Fig. 10.1).

Dysuria or stranguria may be confused with rectal tenesmus (straining to defecate). This is most frequently a dilemma in neonatal foals when trying to distinguish a ruptured bladder from meconium impaction. However, with tenesmus the rear feet of the foal tend to be positioned slightly more anteriorly than with stranguria or dysuria. Stranguria may be severe enough in some cases to induce secondary rectal prolapse; therefore when examining an animal with rectal prolapse, the clinician must establish whether the underlying cause might be urinary tract disease. Conversely, animals with tenesmus may strain to defecate with sufficient force to void small amounts of urine, and the problem may be mistakenly attributed to primary urinary tract disease.

Urinary *incontinence* is the involuntary voiding of urine. It is most frequently indicative of impaired neuromuscular control of urination. Concurrent fecal incontinence is commonly found if disease or trauma to the sacral segments of the spinal cord is present. Urinary incontinence may also occur with severe cases of LUT trauma and inflammation. In young animals, congenital abnormalities such as ectopic ureter must be considered in the differential diagnosis for urinary incontinence. Causes of dysuria, stranguria, and urinary incontinence are shown in Box 10.1.

Approach to Diagnosis of Dysuria, Stranguria, and Incontinence

Initially, the signalment, dietary and environmental history, onset of signs, duration, progression, and response to treatment should be established. Urethral calculi should be considered a top differential in castrated ruminants on high-grain diets. A history of one or more horses showing clinical signs of spinal cord disease, respiratory disease, fever, stranguria, or urinary incontinence should immediately lead the practitioner to consider equine herpesvirus myeloencephalopathy. A history of dysuria or stranguria that develops after parturition usually indicates an injury to the LUT; such injuries can increase the female's risk of subsequent urinary tract infection (UTI). For safety's sake, the clinician should consider the potential for rabies as a primary cause before initiating the examination. A

VetBooks.ir

FIG. 10.1 Lordosis and stranguria in a steer with urethral obstruction.

full physical examination should be performed because abnormal urination may be a sign of disease in other body systems, such as those characterized by diffuse muscular weakness.

When possible, the animal should be observed urinating, and a sample of urine should be collected for dipstick urinalysis, measurement of specific gravity, and sediment examination; urine can be collected in a separate, sterile container for culture, if indicated. Urination can be induced in cows by gently rubbing the perineum immediately ventral to the vulva. In male cattle, the examiner may induce urination by placing a finger into the preputial cavity and gently rubbing the preputial mucosa. In ewes, urination can be induced by holding off the nose until the ewe struggles; urination typically occurs at this point. This procedure should not be performed on weak ewes or those in shock or with poor cardiac or respiratory function. In horses, goats, and male sheep, the examiner simply must wait until the animal is ready to void, although urination may be encouraged by placing the animal in a freshly bedded stall. Recumbent animals will often void soon after standing. Horses will often cease urinating midstream if approached quickly; thus, a urine collection cup taped to a long stick or straightened wire coat hanger affords the clinician a better chance of catching urine quickly and safely. In some species, urinary catheterization is possible and sometimes required to obtain a sample. The vulva or penis should be cleaned with dilute chlorhexidine solution, and aseptic technique should be maintained. In female horses and ruminants the urethral opening is located under the suburethral diverticulum, a mucosal flap on the floor of the vagina. A lightly lubricated stiff urinary catheter can be passed blindly into the urethra by sliding it gently along the ventral floor of the vagina, taking care to stay exactly on the midline. Alternately it can be located by placing a hand in the vagina. In male horses sedation is required to relax and exteriorize the penis, which then should be grasped firmly and extended; then a lubricated flexible catheter can be passed. Acepromazine sedation should be avoided in stallions due to the risk of paraphimosis. Normal equine urine is variably turbid owing to the presence of mucus and calcium-based crystals (Fig. 10.2).

The male's preputial hairs and the female's perineal region should be closely inspected for the presence of blood, exudate, or crystalline debris (Fig. 10.3). Sedation and/or epidural anesthesia may be necessary to induce sufficient relaxation of the retractor penis muscles to enable examination of the penis. In prepubescent ruminants the frenulum often prevents complete exteriorization of the penis for examination of the urethral orifice; general anesthesia may be necessary to induce sufficient relaxation. In bulls and steers transrectal massage of the pelvic segment of the urethra may stimulate penile relaxation and visualization. The

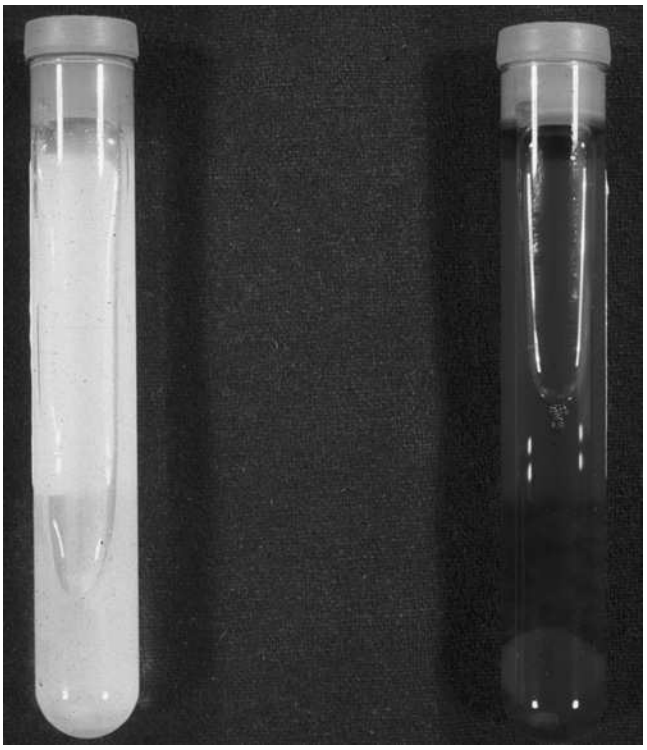

FIG. 10.2 Normal equine urine *(left)* and urine with severe myoglobinuria *(right)*. Urine containing myoglobin is not always so markedly discolored. *(Photo courtesy Paul S. Morley.)*

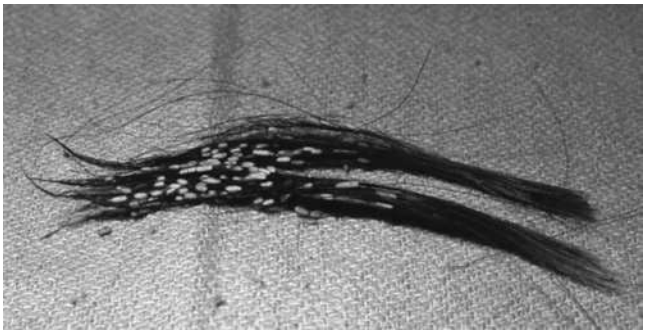

FIG. 10.3 Crystals adherent to the preputial hairs of a steer with urolithiasis. The crystals were analyzed and found to be composed of struvite (magnesium ammonium phosphate).

glans penis and urethral orifice should be carefully examined for masses such as papillomas, evidence of trauma, encircling hair rings, and embedded foreign bodies (e.g., grass awns). Penile examination is particularly important in the dysuric or stranguric small ruminant because urinary calculi frequently become lodged in the urethral process (see the Urolithiasis in the Ruminant Renal System section in Chapter 34).

An accumulation of smegma, composed of mucus and cellular debris, may cause preputial swelling and dysuria in adult male horses. Smegma can usually be found as a hard, waxy mass in the urethral diverticulum. Preputial swelling without urinary dysfunction may be seen with equine metabolic syndrome, and in equine pituitary pars intermedia dysfunction.[1,2]

In the male the penis and the urethra should be palpated percutaneously from the perineum distally to the sheath. Swelling, pain, abnormal urethral pulsations, and calculi lodged in the urethra may be detected. Urethral calculi are most commonly lodged just below the anus in male horses, and these can occasionally be palpated on the midline of the perineum.

BOX 10.1

Causes of Dysuria, Stranguria, and Urinary Incontinence in Horses and Ruminants

Adhesions of the bladder
Balanitis, posthitis, vulvitis, vaginitis
Bracken fern intoxication (R)
Botulism
Cobalt toxicosis (E)
Cantharidin (blister beetle) toxicosis (E)
Ectopic ureter
Equine dysautonomia (grass sickness) (E)
Equine herpesvirus myeloencephalopathy (E)
Equine protozoal myeloencephalitis (E)
Equine neonatal maladjustment (E)
Estrogen-responsive dysuria (E)
Everted bladder
Habronemiasis (E)
Hemorrhage into the urinary tract
Hendra virus (E, Australia and Southeast Asia)
Laminitis
Lumbosacral spinal cord trauma, inflammation, or neoplasia
Lumpy skin disease virus (R, Africa)
Myopathy
Neoplasia of the urinary tract or accessory sex glands
Painful conditions of the abdominal organs or abdominal wall
Painful conditions of the thoracic organs or thoracic wall
Parturition
Penile, vaginal, urethral, or preputial trauma
Penile masses or encircling hair rings
Pelvic entrapment of the bladder
Pelvic, sacral, or vertebral fracture
Polyneuritis equi (Cauda equina neuritis)
Prolapsed bladder
Prolonged recumbency
Rabies
Rectovaginal fistula
Ruptured urethra, bladder, or ureter
Seminal vesiculitis
Smegma accumulation (E)
Sorghum intoxication
Squamous cell carcinoma (penis, prepuce, or vulva)
Tetanus
Ulcerative posthitis and vulvovaginitis (pizzle rot) (R)
Urachal infection or abscesses
Urinary calculi (urolithiasis)
Urinary tract infection
Vaginal prolapse
Vertebral or spinal malformation

E, Found only in horses; *R*, found only in ruminants.

Marked swelling along the prepuce and ventral body wall in a bull or steer with active or recent dysuria or stranguria can indicate urethral rupture.

The vulva, caudal vagina, and urethral orifice should be visualized and palpated in females. Sacrocaudal epidural anesthesia may facilitate examination if painful lesions are present. In females of breeding age the cervix should be visualized or palpated and the uterus evaluated by palpation or ultrasonography because the pollakiuria and apparent dysuria that may occur at the onset of parturition may be the primary complaint of a novice observer. Previous dystocia can result in sufficient soft tissue trauma, laceration, swelling, and pelvic neuropraxia to induce dysuria or stranguria. The ventrum of the tail, perineum, udder, and hindlimbs should be examined for adherent blood or exudate originating from the female's reproductive or urinary tract.

In adult horses and cattle rectal palpation should be performed when dysuria and stranguria are present. Before examination the clinician should take careful note of the tail and anal tone of the animal; reduction of either or both may indicate underlying neurologic or muscular disease. Introduction of the examiner's hand and wrist into the rectum is usually sufficient for palpation of the pelvic segment of the urethra and bladder trigone. The caudal extent of the pelvic cavity should be carefully palpated for masses that might mechanically interfere with voiding. The bladder is typically located on the midline at the level of the pubic brim. Its presence in the caudal pelvic cavity, particularly in the standing animal, may suggest pelvic entrapment of the bladder.

Bladder distention is commonly found in persistently recumbent horses and cattle, and on rectal examination the bladder is often positioned farther caudally than in standing animals. In the horse bladder distention may also be found with abdominal or thoracic pain. Apparently the abdominal pressure necessary to empty the bladder incites sufficient pain of diseased structures to cause reluctance to void. Musculoskeletal and neurologic disease may also result in bladder distention. These other possibilities should be carefully investigated when bladder distention is detected yet no primary disease is found in the urinary tract.

A careful rectal examination of the bladder and the proximal urethra of the horse might allow identification of urethral or cystic calculi. Most cystic calculi in the horse are singular, located in the trigone of the bladder, and are palpable with the examiner's arm inserted to the level of the wrist. If there is a large amount of urine in the bladder, the stone may not be palpable; in such cases, transrectal ultrasound examination may enable visualization of the stone. Detection of calculi in the bladder or urethra should prompt consideration of concurrent nephrolithiasis.

If bladder dysfunction is not caused by structural abnormalities, trauma, or infectious disease, a thorough neurologic examination should be conducted. If neurologic dysfunction is suspected, an attempt should be made to determine whether the primary lesion is affecting the detrusor muscle (lower motor neuron [LMN]) or the urethral sphincter muscles (upper motor neuron [UMN]) of the bladder. This determination is often helpful in localizing the lesion and is important when selecting treatment.

When bladder paralysis is caused by UMN dysfunction, signs of UMN dysfunction may be evident in the rear limbs. The animal frequently postures and strains to urinate but voids only a small amount of urine because the striated urethral muscles are disinhibited from higher centers and their resultant increased tone impedes urine outflow from the bladder. Frequent, small-volume urine egress from the distended bladder occurs when the animal responds to the urge to void or when the bladder undergoes reflex contraction.

With severe disease of the sacral spinal cord or sacral nerve plexus, LMN input to the detrusor muscle is impaired or absent. Urinary incontinence is often the predominant clinical sign (e.g., cauda equina neuritis in horses, spinal cord lymphoma in cattle). The bladder is usually moderately to severely distended, and urine can be expressed easily if pressure is applied to the bladder during rectal examination. With LMN dysfunction, urine may also be voided as the animal walks. Voluntary or involuntary voiding is often incomplete, leading to retention of urine in the bladder. This, in turn, increases the patient's risk of UTI. In horses with bladder paralysis, sabulous accumulations may form a doughy sludge in the ventral bladder, and on rectal examination the clinician may interpret the palpation findings as a bladder tumor.[3] Other neurologic signs involving the sacral and coccygeal nerves may be apparent, such as decreased tail and anal tone and atrophy of the gluteal or tailhead musculature. Ataxia or weakness of the rear limbs may or may not be present with bladder paralysis due to LMN dysfunction. Urethral and bladder pressure profiles can be determined to better assess the location of the lesion.[4-6]

VetBooks.ir

In small ruminants and neonates, transabdominal palpation is useful for evaluation of the urinary tract. In these animals a distended bladder can usually be palpated by simultaneously placing one hand on each side of the caudal ventral abdomen at the level of the pelvic brim and pressing the fingers of each hand toward the abdominal midline. If the bladder has been ruptured, it will be difficult to identify by palpation, but ascites due to uroperitoneum can be detected. Digital rectal palpation of the pelvic segment of the urethra can be performed in neonatal cattle and horses and in small ruminants. The umbilicus should be carefully palpated in neonates with dysuria or stranguria because urachal abscesses and adhesions to the bladder may impair voiding. An infected urachus will occasionally communicate with the bladder lumen, creating concurrent septic cystitis.

Ectopic ureter(s) should be considered in young animals with persistent urinary incontinence; stranguria and dysuria are less common primary complaints. In affected females vaginal urine pooling is often present. Vaginoscopic or cystoscopic examination can be performed, but the opening of the ectopic ureter can be difficult to locate during routine examination. Location of the ectopic ureter(s) often requires intravenous contrast urography or intravenous administration of a dye that is excreted in the urine, such as fluorescein. As for all congenital defects, a careful assessment for defects in other organs should be performed in confirmed cases.

If physical examination and urinalysis do not reveal the source of dysuria, stranguria, or incontinence, transabdominal and/or transrectal ultrasonographic evaluation of the urogenital tract should be performed. Transrectal ultrasound can be performed in geldings to evaluate the accessory sex glands, caudal ureters, and pelvic urethra.[7] An endoscope can be used to visualize the vaginal vault or preputial cavity and penis; air insufflation can be used to expand the walls and achieve a clear view of these structures. When advanced retrograde into the urethra, the urethral wall, bladder, and ureteral openings can be visualized. In neonates and small ruminants, plain abdominal radiographs, positive contrast urethrocystography, and intravenous contrast urography are additional options.[8]

Hematuria and Pigmenturia

Hematuria is defined as blood in the urine. It may appear as occult blood detected during urinalysis, as uniformly red-colored urine throughout urination, or as blood clots passed at any phase of urination. If large clots are present, obstruction of the urinary tract may occur, resulting in concurrent stranguria and dysuria. *Pigmenturia* is defined as the presence of abnormal pigment in the urine; in large animals such pigments are usually limited to hemoglobin or myoglobin. Hemoglobin, myoglobin, and blood all cause a positive reaction for blood and protein on an ortho-toluidine–based urine dipstick test. Certain oxidizing disinfectants can also trigger a positive reaction for blood on these strips. In addition, contamination of the urine with blood from the reproductive organs can result in hematuria, as can admixture of fecal blood with voided urine in females. Blood from penile or preputial injuries can contaminate the urine of males.

When clots of blood are visible in the urine, the presence of hematuria is confirmed. Also, when scattered spots of color change are evident on the blood reagent pad of the urine dipstick, the reaction pattern reflects the presence of small aggregates of red cells deposited on the pad. Otherwise, differentiation of hematuria from hemoglobinuria and myoglobinuria requires that the discolored urine be centrifuged and the sediment examined. Hematuria is characterized by red-, pink-, or brown-colored urine that clears partially or entirely after centrifugation, resulting in a pigmented sediment pellet. With hematuria, red cells or red cell "ghosts" (red cells devoid of pigment) are visible on microscopic examination of urine sediment.

Urine containing hemoglobin is clear to dark red in color, depending on the concentration of hemoglobin in the sample. If visibly discolored, the urine sample with hemoglobinuria does not clear when centrifuged. Animals with hemoglobinuria may be experiencing intravascular hemolysis, which leads to passage of hemoglobin from the plasma into the tubular fluid of the nephrons. The serum or plasma of these animals may be pink in color. Mucous membrane pallor or icterus may be evident, and tachycardia and tachypnea are present when red cell destruction is rapid and extensive. The packed cell volume (PCV) may be decreased at the time of initial examination, or it may decrease progressively during subsequent measurement. Intravascular hemolysis may result in elevation of the plasma and serum total protein concentration. The clinician should note that hemoglobin is potentially nephrotoxic; renal function and hydration should be monitored. Sediment findings vary according to the underlying disease, and hyaline or cellular casts may be seen if pigment nephropathy is present.

Urine containing myoglobin may be of normal color; if present in high concentrations in a sample, it imparts a dark red to brown color to the urine (see Fig. 10.2). If visibly discolored, urine containing myoglobin does not clear when centrifuged. Sediment findings are variable but can include hyaline or cellular casts if pigment nephropathy is present. Myoglobin can be differentiated from hemoglobin in urine through ammonium sulfate precipitation, electrophoresis, or spectroscopy. Animals with myoglobinuria have muscle necrosis or injury, which leads to release of myoglobin from damaged muscle cells into the plasma and renal tubular fluid. Extensive muscle trauma (e.g., dog attacks, trailer accidents) or primary myopathies can induce myoglobinuria. Affected animals may show abnormal stance, gait, or other evidence of muscle swelling, pain, or weakness. The serum activity of the enzymes creatine phosphokinase (CPK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) is variably increased, depending on the duration and severity of muscle injury. As for hemoglobin, the persistence of myoglobin in the tubular fluid of the nephrons is nephrotoxic and can induce renal tubular necrosis. Causes of hematuria and pigmenturia are listed in Box 10.2.

Approach to Diagnosis of Hematuria and Pigmenturia

The history should include data on recent infectious diseases, exercise, diet, and treatment, and a full physical examination should be conducted. Hematuria after exercise may indicate the presence of erosions in the urinary tract mucosa, anomalous vascular structures, or mucosal trauma from uroliths. Ingestion of certain toxins (e.g., cantharidin, bracken fern) can create hematuria. Geldings and stallions may develop spontaneous hematuria associated with a vascular fistula or cavernosal rupture in the most proximal urethra.[9-11] Hemoglobinuria can result from exposure to hemolytic toxins such as red maple leaves, copper, onions, and certain bacterial hemolysins. Intravenous infusion of markedly hypotonic (e.g., water) or hypertonic (e.g., undiluted dimethyl sulfoxide [DMSO]) fluids can also result in intravascular hemolysis and hemoglobinuria. In dehydrated animals, ingestion of large volumes of water (water intoxication) can reduce intravascular osmolality to the point of causing hemolysis, with resultant hemoglobinuria.

Hemolysis should be investigated through examination of the serum or plasma, serum total protein measurement, and/or a complete blood count (CBC). A urine sample should be obtained for full urinalysis, centrifugation, and sediment examination. The patient with potential hematuria should be carefully examined for clinical signs suggestive of impaired coagulation. Severe vulvitis often develops in females with diarrhea because of prolonged contact of the vulvar mucosa with fecal contents, and a trace reaction for blood is often evident in the urine. However, the possibility of hemorrhage

VetBooks.ir

BOX 10.2

Causes of Hematuria and Pigmenturia in Horses and Ruminants

Hematuria

Aberrant parasite migration within the urinary tract
Admixture of fecal blood with urine
Admixture of blood from the reproductive organs with urine (e.g., metritis, orchitis, seminal vesiculitis)
Arsenic toxicosis
Bleeding diatheses (e.g., warfarin, disseminated intravascular coagulation [DIC])
Cantharidin (blister beetle) poisoning (E)
Cobalt toxicosis (E)
Contamination of urine with oxidant disinfectants
Enzootic hematuria (R)
Exercise-induced hematuria (E)
Habronemiasis (E)
Leptospirosis
Neoplasia of the urogenital tract
Penile, vaginal, preputial, or urethral trauma
Penile masses or encircling hair rings
Renal papillary necrosis (e.g., related to nonsteroidal antiinflammatory drugs [NSAIDs])
Ulcerative cystitis
Urinary calculi (urolithiasis)
Urinary tract infection
Vascular anomaly, corpus cavernosum rupture (proximal dorsal urethral hemorrhage in males) (E)

Hemoglobinuria

Burns (severe)
Clostridium haemolyticum infection (redwater) (R)
Copper intoxication
Ethylene glycol toxicosis (severe)
Excess water intake, water intoxication
Hepatic failure
Intravenous (IV) hypotonic fluid administration (e.g., 0.45% saline or water)
IV hypertonic fluid administration (e.g., dimethyl sulfoxide [DMSO])
Leptospirosis
Onion and *Brassica* species (rapeseed, kale, mustard, etc.) intoxication
Neonatal isoerythrolysis
Postparturient hemoglobinuria (combined phosphorus/selenium and/or copper deficiency) (R)
Red maple intoxication (E)

Myoglobinuria

Clostridial myonecrosis
Compartment syndrome, down cow syndrome
Exertional or capture rhabdomyolysis
Hereditary or congenital myopathies
Infarctive purpura hemorrhagica (E)
Muscle trauma
Myopathy associated with streptococcal infections (E)
Nutritional myodegeneration
Postanesthetic myoneuropathy
Toxic myopathies (e.g., *Acer* species, *Cassia* species, ionophores, gossypol)
Viral myopathies (influenza, equine herpesvirus [EHV], bluetongue)

E, Found only in horses; *R*, found only in ruminants.

from tubular injury caused by hypovolemia should also be considered.

Lesions of the urethra most often produce hematuria at the beginning of urination. Hematuria that originates from the bladder is most likely to be seen or appear more pronounced at the end of urination. Hemorrhage originating from the upper urinary tract is likely to be more pronounced at the end of urination. It should be noted, however, that it is not always possible to accurately localize the source of urinary tract hemorrhage by the timing of the appearance of blood in the voided sample. If the urine discoloration appears uniform throughout urination and no clots are obvious, it must be determined that the discoloration is hematuria and not hemoglobinuria, bilirubinuria, or myoglobinuria. This can be accomplished by routine dipstick urinalysis; urine sediment examination; assessment of the patient's PCV, plasma protein concentration, and serum muscle enzyme activities; and visualization of the color of the plasma and mucous membranes.

Hematuria often accompanies pyuria and bacteriuria UTI. If hematuria is confirmed and UTI or genital or perineal trauma is *not* the cause, rectal examination may reveal calculi or tumors in the proximal urethra or bladder. Endoscopic examination of the urethra and bladder is necessary if the lesion cannot be detected during rectal or physical examination. During endoscopic examination of the urethra and bladder, if the source of hemorrhage is not apparent, the openings of the ureters and the color of the urine coming from both of them should be visualized. This is best performed after suctioning urine from the bladder and then distending the bladder with air, taking care that bubbling of the urine does not occur. The two openings can be visualized simultaneously by passing the scope farther into the bladder and retroflexing the scope caudally until the entire trigone area is visualized. If hemorrhage is seen to originate from one or both ureteral openings, ultrasound examination of the kidneys and ureters should be performed, as the hemorrhage has now been localized to the upper urinary tract (UUT).

When myoglobinuria is present, the potential for exposure to gossypol and ionophores should be investigated. Certain viral and bacterial infections, such as streptococcal infections in horses, can induce myopathy and myoglobinuria. A recent history of heavy exertion or very high ambient temperature (heatstroke) may exist in cases of myopathy with myoglobinuria. The potential for nutritional myodegeneration from vitamin E and/or selenium deficiency should be considered in light of the animal's diet and the regional soil selenium content. A previous history of recurrent exercise intolerance or muscle dysfunction may be evident in certain inherited, idiopathic, or diet-associated cases of rhabdomyolysis. Prolonged recumbency (e.g., general anesthesia, downer animals) can induce sufficient pressure myopathy to cause myoglobinuria. Rarely, idiosyncratic responses to medications can induce hemolysis or muscle injury, resulting in hemoglobinuria and myoglobinuria, respectively.

Pyuria

Pyuria is defined as gross or microscopic evidence of inflammatory cells in the urine. Dysuria, stranguria, pollakiuria, crystalluria, urine scalding, and hematuria can accompany it. Pyuria may result from systemic septic inflammatory disease, localized microbial UTI, or nonseptic inflammation (sterile pyuria; see Fig. 10.2). In horses, the normal variable turbidity of equine urine should be considered when assessing gross pyuria. Causes of pyuria are listed in Box 10.3.

Approach to Diagnosis of Pyuria

A complete examination of the urinary tract should be performed, including rectal palpation or transabdominal palpation of the bladder. Cystitis may be characterized by a thickened bladder wall, but this is often difficult to detect during rectal palpation and ultrasonographic examination may be necessary. Predisposing factors for UTI such as urinary calculi, dystocia, abnormal urethral or genital structure, and neurologic diseases should always be considered.

VetBooks.ir

BOX 10.3

Causes of Pyuria in Horses and Ruminants

Admixture of inflammatory exudate from the reproductive tract (spurious pyuria)
Calculi (uroliths, nephroliths)
Ectopic ureter
Encircling hair rings of the penis
Infection of the urinary tract (urethritis, cystitis, ureteritis, and/or pyelonephritis), including Leptospirosis
Neoplasia
Nephritis (sterile)
Penile, preputial, or urethral trauma
Rectovaginal fistula
Ulcerative posthitis (small ruminants) and vulvovaginitis
Viral infections of the genitalia
Vulvar, vaginal, or urethral trauma or neoplasia

Pyuria is confirmed by obtaining a midstream (free catch) or catheterized urine sample and by quantitating the number of white blood cells (WBCs) and bacteria in the urine sediment. Evaluation of urine sediment within 30 to 60 minutes of collection enables preservation of the greatest cytologic detail. In human medicine, pyuria is defined as the presence of more than 10 WBCs per mm^3 urine, 3 or more WBCs per microscopic high-power field (HPF) or positive Gram staining on unspun urine, or leukocyte esterase positive on a urinary dipstick.[12] In horses, to the authors' knowledge, no peer-reviewed study has specifically assessed the cellular content of urine in healthy horses. Pyuria is generally considered to be the presence of more than 10 WBCs per HPF of a midstream-voided or catheterized sample, and the urine of normal horses and cattle generally is said to have fewer than 5 WBCs per HPF.[13,14] However, a study assessing quantitative cultures in free catch urine from healthy horses found that no horse had a WBC count of more than 1 per HPF.[15] This suggests that the generally accepted number of more than 10 WBCs per HPF to diagnose pyuria may be too high for horses and that pyuria should be suspected if more than 5 WBCs per HPF are seen, providing collection is aseptic and there is clinical suspicion. When bacterial infection is the cause of pyuria, there are typically more than 20 organisms visible per HPF. The cytologic features of urine sediment and quantitative culture are influenced by the method of collection, rigor of aseptic technique, and degree of contamination of the prepuce, vulva, and urethral orifice. Catheterization can be used to obtain urine from the bladder of most male and female horses and female ruminants. If adequate quantity is obtained, the first 20 mL collected should be discarded and analysis done on the subsequent 20 mL.[15] In male ruminants, the urethral recess (diverticulum) prevents retrograde catheterization of the bladder, and collection of a midstream sample is usually the sole option. Cystocentesis of a large animal with a UTI carries the risk of induction of septic peritonitis.

Urine samples should be refrigerated and quantitative culture performed as soon after collection as possible to avoid false increases in the colony count that can occur from bacterial proliferation in the sample during storage. The results of quantitative culture are greatly influenced by the method of collection and the degree of contamination of the prepuce and vulva. In specimens collected by midstream free catch, bacterial counts greater than 1×10^4 bacteria/mL of urine are indicative of UTI if compatible dipstick and sediment examination findings are present. Normal equine urine has fewer than 20,000 colony-forming units (CFUs)/mL in a free catch sample and fewer than 500 CFUs/mL in a catheterized sample.[15] In free catch urine samples from horses, mean CFU/mL bacterial counts are significantly higher in females (6054 CFU/mL) than in males (490 CFU/mL).[15] A culture that yields a large number of a variety of bacterial species may reflect heavy contamination of the vulva or penis, fecal admixture, a UTI involving multiple bacterial species (rare), or delay before culture was initiated, especially if the urine sample was not kept refrigerated.

Once pyuria is confirmed, its location or origin, inciting cause(s), and any predisposing conditions should be determined. In males, the accessory sex glands should be carefully examined because inflammatory exudate from these structures may be admixed with urine, resulting in a spurious diagnosis of pyuria. In females, mixing of urine and inflammatory exudate in the urethra and vestibule may also result in spurious pyuria. Trauma or inflammation of the glans penis or prepuce can also result in admixture of exudate with urine, as often occurs in ulcerative posthitis in rams and bucks. Endoscopic examination of the vaginal vault or preputial cavity may be helpful, using air insufflation to aid in visualization of the mucosa. Inflammatory diseases of the LUT usually produce obvious clinical signs of dysuria but minimal to no signs of systemic disease. Low-grade fever is occasionally present in cases of localized cystitis, although affected animals are often not apparently systemically ill.

If the pyuria originates from the UUT, the animal is usually persistently or intermittently febrile and shows systemic signs of disease, and changes suggestive of inflammation are often present on a CBC. Inflammation of the ureter(s) and kidney(s) may result in colic. Rectal examination may reveal enlargement of one or both ureters, pain on palpation, and possibly enlargement and/or abnormal shape of the left kidney. If grossly enlarged, the right kidney can occasionally be palpated per rectum in horses or cattle. In cows and heifers, thickening and pain of one or both ureters is often more readily identified during vaginal palpation than rectal palpation. Casts of blood, protein, or cellular debris may be seen in the urine sediment in cases of pyelonephritis. An ultrasonographic examination of both kidneys and ureters should be performed in all animals with evidence of upper UTI. The technique for ultrasound examination of the urinary tract is described in Equine Abdominal Ultrasonography and Ruminant Abdominal Ultrasonography in Chapter 32.

If *Leptospira interrogans* serotype Pomona is suspected as a cause of pyuria (cattle), urine sediment should be placed on a microscope slide, air-dried, and examined by fluorescent antibody for *Leptospira* antigen.[16] Polymerase chain reaction testing for *Leptospira* species can be performed on urine sediment in cattle, goats, and horses; in cattle, greater sensitivity may be achieved by obtaining a urine sample after administration of furosemide.[17-19]

Crystalluria

Crystalluria is defined as the presence of crystals in the urine. Calcium carbonate and calcium phosphate crystals are abundant in normal equine urine. These, along with mucus, impart a turbid, slightly opaque quality to normal equine urine (see Fig. 10.2). Herbivore urine is normally alkaline, which reduces the solubility of certain calcium- and phosphate-based compounds in urine, inducing crystal development. Therefore calcium phosphate, calcium carbonate, or calcium oxalate crystals may be present as an incidental finding in highly concentrated ruminant urine if the animal is healthy and free from signs of urinary tract disease. However, in male ruminants, heavy or persistent crystalluria may be a risk factor for urolithiasis because the combination of highly concentrated urine and urinary mineral precipitation is considered instrumental in calculogenesis. A precautionary review of diet, salt intake, and water management may be indicated in such cases.

Crystalluria presents a medical problem when crystals enlarge through precipitation, causing microscopic or gross traumatic injury to the urinary epithelium and urinary tract obstruction. When crystals coalesce and enlarge to form calculi (uroliths), the calculi may remain occult or cause disease through trauma

BOX 10.4

Causes of Crystalluria in Horses and Ruminants

Alkaline urine
Calcium-based crystalluria of horses (normal)
Concentrated urine
Ethylene glycol intoxication
Oxalate intoxication
Urinary tract infection
Urolithiasis
Vitamin C intoxication

to and obstruction of the urinary tract.[20-22] As a result, the clinician usually detects crystalluria in these animals during the diagnostic work-up for hematuria, dysuria, stranguria, pyuria, or signs of urinary tract obstruction. It is critical to note that the *absence* of crystalluria does not indicate that the urinary tract is free of calculi or renal mineralization, just as the presence of crystalluria does not necessarily indicate disease.[23,24] Causes of crystalluria are listed in Box 10.4.

Approach to Diagnosis of Crystalluria

Toxins such as oxalic acid and ethylene glycol can induce calcium oxalate crystalluria, so access to oxalate-containing plants and storage areas or garages should be investigated.[23,25] High doses of parenteral vitamin C can induce calcium oxalate deposition in the urinary tract, and there is also a suggestion that primary hyperoxaluria may be related to inherited metabolic defects.[25,26] Previous urinary tract surgery, dystocia, or genital trauma may indirectly contribute to crystalluria, as abnormal structure of the urinary tract, suture material inadvertently placed in the tract, or loss of uroepithelial integrity can promote crystal precipitation into calculi.

The hairs surrounding the preputial orifice or vulva should be carefully examined for visible crystals that cling to the hair, indicating heavy crystalluria (see Fig. 10.3). In males, given that urolithiasis is an important diagnosis to investigate, urinary tract patency should be determined.

Crystalluria and calculus formation can be caused by UTI because urease-producing bacteria may increase the pH of urine to the point of inducing precipitation of certain minerals suspended in the urine into calculi.[27] In addition, inflammatory exudation into the urinary tract provides nidi for deposition of urinary minerals.[27]

Polyuria

Polyuria can be defined as the passage of abnormally large amounts of urine. This may be a normal response when excessive fluid, electrolytes, or both are presented to the tubules of a healthy kidney. It may also occur with renal failure when tubular function is impaired or when sufficient nephron loss overwhelms the remaining nephrons with excess fluid and/or solute. Polyuria is also present in central or neurogenic diabetes insipidus (DI) (caused by insufficient secretion of antidiuretic hormone [ADH]), nephrogenic DI (caused by diminished effect of ADH on receptors in the kidney), renal medullary washout (caused by an insufficient interstitial concentration gradient), excessive drinking (polydipsia), liver failure, and certain electrolyte abnormalities. A phenomenon termed *postobstructive diuresis* results in polyuria after relief of urinary tract obstruction. Common causes of polyuria are listed in Box 10.5.

Approach to Diagnosis of Polyuria

Evaluation should begin with careful inquiry about any history of recent disease, drug administration (e.g., diuretics, corticosteroids, xylazine), fluid therapy, change in diet, change in water quality or availability (e.g., drought, frozen water), or known laboratory evidence of renal disease. The next step is to collect a urine sample to measure the osmolality or specific gravity (UspG). If the osmolality is close to the isosthenuric range (UspG of 1.008 to 1.014) in the face of dehydration, primary renal disease should be considered. This is typically confirmed by measuring the serum creatinine and blood urea nitrogen (BUN) concentrations, although radionuclide clearance studies and/or 12- or 24-hour urinary creatinine clearance can also be performed. If evidence of renal failure is not present on these tests (see Polyuria and Polydipsia in the Equine Renal System section, Chapter 34), a water deprivation test may be necessary to determine the tubules' ability to concentrate urine. This should be performed in a normovolemic patient with careful monitoring of patient status because the mild dehydration induced during this test may exacerbate preexisting, occult renal disease.

BOX 10.5

Causes of Anuria, Oliguria, and Polyuria in Horses and Ruminants

Anuria and Oliguria

Acute or chronic renal failure (multiple causes)
Blood loss
Cardiac failure
Dehydration
Rupture of the urethra, bladder, or ureter(s)
Septic or toxic shock
Urinary tract obstruction (e.g., urinary calculi)

Apparent Anuria or Oliguria

Bladder paralysis or atony
Botulism
Dysautonomia (grass sickness) (E)
Ectopic ureter(s)
Encephalopathies
Equine herpesvirus myeloencephalopathy (E)
Neonatal maladjustment syndrome
Painful diseases of the abdomen or abdominal wall
Painful diseases of the thorax or thoracic wall
Patent urachus
Prolonged recumbency
Ruminal acidosis/grain overload
Severe spinal cord disease

Polyuria

Acute or chronic renal failure (multiple causes)
Cantharidin intoxication
Diabetes insipidus (central or nephrogenic)
Diabetes mellitus
Drugs: diuretics, xylazine, corticosteroids
Encephalopathies
Excessive intravenous fluid therapy
Excessive water or salt ingestion
Hepatic failure
Hypercalcemia (including iatrogenic)
Hyperglycemia (including iatrogenic)
Medullary washout
Organophosphate intoxication
Pituitary pars intermedia dysfunction (PPID) (E)
Postobstructive diuresis
Psychogenic polydipsia
Renal amyloidosis
Salt deficiency
Vitamin D intoxication

E, Equine.

VetBooks.ir

As an alternative to the water deprivation test used to identify tubular disease and dysfunction as the cause of polyuria, the fractional clearance (fractional excretion) of sodium in the urine can be measured. This test is performed by collecting urine and plasma samples at exactly the same time, then measuring the creatinine and sodium in both samples. The fractional clearance of sodium (Fc_{Na} [%]) is then determined using the following formula:

$$Fc_{Na}(\%) = \frac{[Na_u]}{[Na_p]} \times \frac{[Cr_p]}{[Cr_u]} \times 100$$

where Na_u is the urine sodium concentration, Na_p is the plasma sodium concentration, Cr_u is the urine creatinine concentration, and Cr_p is the plasma creatinine concentration. A fractional sodium clearance value above 1% in adult horses is suggestive of primary tubular disease, particularly if the animal's diet and physiologic state are such that avid sodium conservation is expected.[28] Fractional clearance of sodium values of up to 4% have been measured in healthy, lactating dairy cattle.[29] For this test to be valid, salt intake must be normal and the animal must not be given diuretics, parenteral fluids, or fluids administered orally other than what is drunk voluntarily.

If the UspG or osmolality is less than that of the plasma (1.007), DI, psychogenic polydipsia, and renal medullary washout should be considered. Although rare, DI has been reported in the horse and may be the result of inadequate secretion of vasopressin (neurogenic DI) or inadequate response to vasopressin in the kidney (nephrogenic DI).[30,31] However, the patient may simply be ingesting large amounts of water in response to exercise or a high ambient temperature, so interpretation of low UspG requires due consideration of the animal's physiologic state.

Anuria and Oliguria

Anuria is defined as the absence of urine production, and *oliguria* is defined as scant or subnormal urine production. These two disease conditions are often difficult to distinguish at the onset of evaluation. Furthermore, the difficulties associated with maintaining urine collection devices in large animals make an accurate measurement of urine production difficult. Causes of anuria and oliguria are listed in Box 10.5.

Volume of urine produced by healthy animals varies tremendously according to breed, age, physiologic status, exercise, diet, and environmental factors. In 1961 Altman determined normal urine output for the large animal species to be as follows: horses, 3 to 18 mL/kg/day; cattle, 17 to 45 mL/kg/day; and sheep and goats, 10 to 40 mL/kg/day.[32] Neonates urinate more frequently than adults and often directly after nursing. Anuria and oliguria frequently become apparent to the clinician when an azotemic animal is diagnosed with a primary disease in which renal function is commonly threatened (e.g., severe diarrhea, congestive heart failure) and urine output after initiation of fluid therapy is subnormal or absent.

If urine collection and measurement cannot be performed, the adult animal with potential anuria or oliguria can be closely watched or placed in a stall with no or minimal bedding or fine, fresh bedding (e.g., sawdust) to facilitate detection of urine on the floor. When indicated, fluid therapy should be initiated and expectations for urine output predicted based on the rate and route of fluid administration. Animals with painful thoracic or abdominal disease may refrain from urination, and the clinician must remember to evaluate *bladder filling* by transrectal or transabdominal ultrasonography, and not just the volume of urine voided. Recumbent, obtunded foals, particularly males, may not reliably void urine; monitoring bladder fill by ultrasound or directly monitoring urine output by placement of an indwelling urinary catheter is recommended to avoid bladder rupture. The same applies for some recumbent neurologic horses and cattle. Urachal leakage of urine must be considered in neonates with suspected anuria or oliguria because they may void less frequently than normal. Animals with encephalopathies (again, rabies warrants mention) or severe spinal cord disease may not be capable of voluntary voiding.

When evidence for anuria mounts, the clinician must determine whether the urinary tract is patent and rule out the presence of rupture of the bladder, urethra, or ureters. Repeat physical examination and ultrasonography of the upper and lower urinary tract and abdominal cavity is warranted in such instances. Obstructive diseases of the LUT are typically accompanied by signs of colic and stranguria. However, these signs will not be present if the patient has a preexisting rent in the urinary tract or if the animal is severely obtunded from uremia.

Oliguria is a physiologic adaptation to dehydration and can be expected in animals with prerenal azotemia. Assessment of UspG is critical in determining the presence of renal failure in such cases. If urine cannot be collected from the dehydrated animal, fluid therapy should be initiated and the azotemia monitored. Oliguria is a relatively common feature of acute renal failure, particularly if the disease process involves obstruction of the nephron lumen with crystals, cellular debris, or proteinaceous casts. However, volume of urine produced by a patient in renal failure can vary greatly according to hydration status, diet, and the inciting cause. Urine production can be normal, increased, or decreased in renal failure. Renal failure is covered in detail in Chapter 34.

Uremia

Uremia is defined as the constellation of clinical signs, impaired metabolic processes, and alteration of organ function that occurs as a result of failure to excrete waste products from the body via the kidneys and urine. Uremia may be the result of either acute or chronic renal failure, retention of urine in the body because of urinary tract leakage (e.g., bladder rupture), or both. In humans more than 100 retained toxins, including urea, guanidine, phenolic compounds, and phosphorus, are associated with the uremic process, and it can be assumed that similar magnitudes of toxins are present in uremic large animals.[33] The predominant clinical signs of uremia seen in large animals are depression and anorexia, along with progressive weight loss, polyuria, polydipsia, melena, and diarrhea. Oral erosions or ulcers, gingivitis, diffuse stomatitis, dental tartar, and halitosis may be evident on examination of the oral cavity. Gastroscopy may reveal gastric ulceration. Coagulopathy and platelet dysfunction make uremic patients prone to gastrointestinal hemorrhage and impaired clotting. Pulmonary edema and uremic encephalopathy may develop in severe cases. Uremia and renal failure are discussed in further detail in Chapter 34.

Nodules, tumors, and swellings, 181
Ulcerations and erosions, 182
Papules, pustules, and vesicles, 182
Scaling and crusting, 183
Abnormal coat length and density, 184
Abnormal pigmentation, 187

General Approach to Diseases That Alter the Skin

It is important to remember that the skin has a limited repertoire with regard to its presentation; many diseases with various causes may manifest with similar lesions. However, certain patterns of response to disease are also recognized. In order to manage skin problems successfully, the veterinarian must use a systematic approach by obtaining a complete history, performing a thorough physical examination, and, when appropriate, using one or more simple diagnostic techniques.[1] The following sections discuss the materials and methods necessary to perform techniques commonly used to diagnose large animal skin disease.

History

To obtain a differential diagnosis list, the questions listed on the sample history form (Fig. 11.1) should be answered. Often it is helpful to repeat the questions to the owners at a later time or to give them a history form to complete at their leisure, which allows them greater opportunity to remember details relevant to the skin disease. The goals should be to determine the initial features of the skin disease, how the problem has progressed, and what factors have influenced its progression to the present state.

Physical Examination

The diagrams and terms listed on the sample form (Fig. 11.2) may serve as a useful guide for recording the physical findings. The animal's overall condition should be assessed, and a general physical examination should be performed to determine if the disease is limited to the skin or if systemic signs of disease are also present. The distribution, morphology (e.g., papules, nodules, wheals, patches of alopecia), and size of skin lesions should be noted. Mucous membranes should also be examined, and the skin surface should be palpated to determine features not readily noted visually (e.g., crusts beneath the hair, dryness, ability to epilate hairs, presence of peripheral lymphadenopathy).

The practitioner's goal should be to describe accurately the animal's clinical appearance in a written record for future reference.

Diagnostic Techniques

For most of the techniques that follow, a good-quality microscope equipped with ×4, ×10, ×40, and ×100 (oil immersion) objectives is recommended.

SKIN SCRAPINGS. Skin scrapings are used primarily to demonstrate microscopic ectoparasites, specifically mites. Scraping is a quick, simple, inexpensive diagnostic technique that is more useful in ruminants than in horses because equine mite infestations are relatively uncommon. The materials needed to perform a skin scraping are a sterile container, mineral oil, a medical-grade spatula (Fisherbrand Microspatula with Flat-Ended Blade, catalogue no. 21-401-20, Fisher Scientific, Pittsburgh, Pa.; www.fisherscientific.com), glass slides, and cover slips. Although a No. 10 scalpel blade may be used, a medical-grade spatula will not cut the skin in cases of sudden movement of the animal yet is just fine enough to be able to scrape deep enough to find *Demodex* species mites, if indicated. If the hair coat is thick, a small area should be clipped before scraping. Multiple superficial scrapings that cover large surface areas should be performed, as well as several scrapings covering a small area that are deep enough to create capillary oozing. The collected material should be placed in a container until it can be examined microscopically. Some of the sample can then be placed on a glass slide and finely dispersed in enough mineral oil to provide a confluent layer without air bubbles beneath a cover slip. The slide should be scanned systematically with the ×10 objective. If something of importance is noted, the ×40 objective can be used to examine the specimen in more detail.

DERMATOPHYTE CULTURE. The materials necessary to perform a dermatophyte culture include dermatophyte test

medium, mosquito forceps, a medical-grade spatula, and sterile empty containers such as evacuated blood collection tubes. The forceps should be sterile, and each lesion to be sampled should be wiped gently with either water or isopropyl alcohol (there is some controversy as to which is better; the author uses water out of concern that the alcohol may inhibit fungal growth on the culture medium) to remove as many bacterial and fungal contaminants as possible and allow them to dry. Multiple small, scaling, and slightly crusted lesions should be sampled; the samples should be stored in individual containers. Broken hairs, scales, and crusts from the periphery of the lesions are collected (because dermatophytes cause peripherally expanding lesions). A spatula may be useful for scraping scales and debris from the skin surface. The forceps are used to pluck broken hairs.

If the clinician's practice performs its own fungal cultures, the samples should be removed from the containers with a sterile forceps in a clean working area and gently pressed onto, but not buried beneath, the culture medium. The top of the culture dish or vial should be loosely replaced to allow sufficient

ventilation for the culture to grow. Most dermatophytes grow at room temperature, except for some strains of *Trichophyton verrucosum* that require incubation at 37° C (98.6° F). The colony usually first appears in 5 to 7 days, although all cultures should be allowed to incubate for 3 weeks before a negative result is declared.

Dermatophyte test medium is an amber-colored Sabouraud's dextrose agar containing phenol red, a pH indicator, and several antibacterial and antifungal agents to inhibit growth of contaminant organisms. Dermatophytes preferentially use the protein in the medium as they begin to grow, producing alkaline metabolites that cause the medium to turn red. The dermatophyte colony is typically a white to beige, powdery to fluffy growth; the colonies are never dark colored. Most saprophytic (contaminant) fungi metabolize the carbohydrates first, producing acidic metabolites that do not change the color of the medium. It should be stressed that after the carbohydrate source has been depleted, saprophytes use the proteins and produce a red color change.

Positive identification of a dermatophyte is made in most instances if a white to beige, powdery to fluffy colony begins to appear on the medium at the same time or within 24 hours of the appearance of a red color change in the medium (Fig. 11.3, shown as the darker area in the figure). An infrequently encountered exception to this rule is growth of the saprophyte *Scopulariopsis brevicaulis*, a tan to light brown, smooth or mealy colony that produces a concurrent red color change in the medium. It is essential to check the cultures daily to determine if the red color change and colony growth occur nearly simultaneously. If any doubt exists about the type of colony growth, the sample should be submitted to a diagnostic laboratory for specific identification.

POTASSIUM HYDROXIDE PREPARATION. A potassium hydroxide (KOH) preparation may permit immediate diagnosis of dermatophytosis. However, examination of KOH preparations requires considerable experience because fungal elements may be easily overlooked (false-negative result) and numerous artifacts such as fibers, cholesterol crystals, or oil droplets may be mistaken for fungal elements (false-positive result). It is always advisable to perform a dermatophyte culture in conjunction with a KOH preparation.

The materials necessary to perform a KOH preparation include mosquito forceps, a medical-grade spatula, a sterile empty container, glass microscope slides, cover slips, a Bunsen burner, and clearing solution. As with a dermatophyte culture, it is important to sample several lesions to increase the chances of obtaining a diagnostic sample. Hairs and scales are collected from the periphery of the lesions with the mosquito forceps and the spatula. The samples are stored in the sterile container until a microscopic examination can be performed. A drop of the KOH clearing solution is placed on a glass slide, hairs and scales are added to the solution, and a cover slip is placed over the material. The slide should be scanned systematically with the ×10 objective for abnormal-appearing hairs with a fuzzy internal structure. If these features are noted, a higher-powered objective should be used for more detailed examination. A positive result with a KOH preparation demonstrates hyphae, which are usually uniform in width and septate. Beadlike chains of arthroconidia may be seen as well (Fig. 11.4).

The purpose of the clearing solution is to dissolve the hard keratin and bleach the melanin of the hair shaft so that the fungal hyphae and arthroconidia can be identified more readily. Care should be taken not to spill any clearing solution on the microscope because it can damage the lenses. Several types of clearing solutions are available. If 15% KOH is used, the slide should be heated for 15 to 20 seconds to facilitate clearing before examination. As an alternative, the preparation can be allowed to stand at room temperature for 30 minutes before viewing.

ACETATE TAPE PREPARATION. Acetate tape preparations for parasites are used primarily to diagnose infection with *Oxyuris equi*, although they may also be used to diagnose *Chorioptes* species. The materials required to perform an acetate tape preparation include acetate (nonfrosted) tape, mineral oil, and glass microscope slides. A piece of the tape is pressed over several areas in the anal and perianal region when looking for *O. equi* or over an affected region that has been lightly clipped when looking for *Chorioptes* species. The tape is then placed with the adhesive side down on a line of mineral oil that was placed lengthwise on a glass microscope slide. The purpose of the oil is to help clear the debris and facilitate examination of the preparation for parasites. The preparation is scanned with the ×10 objective for organisms.

DERMATOPHILUS PREPARATION. This test is used as an aid in identification of *Dermatophilus congolensis.* Crusts should be removed from the patient, and the excess hair should be carefully trimmed from the crusts with a small pair of scissors. The crusts are minced with the scissors and mixed with several drops of saline on a glass slide. After the crusts have softened in the saline for several minutes, they should be crushed with the tip of an applicator stick. The excess debris is removed, and the slide is allowed to air dry. The slide should then be

VetBooks.ir

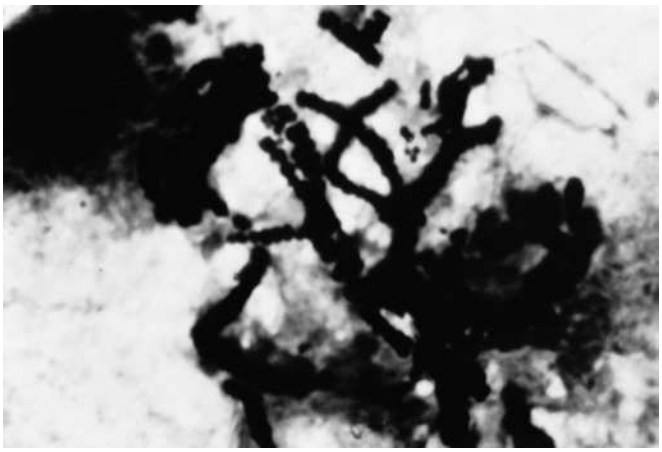

FIG. 11.5 Positive result on *Dermatophilus* preparation. *D. congolensis* is a large, gram-positive, filamentous bacterium that divides horizontally and longitudinally, forming parallel rows of cocci (zoospores) that are commonly described as "railroad tracks."

heat fixed; stained with Gram, Giemsa, or Wright stain; and examined for the characteristic bacteria. *D. congolensis* organisms are gram-positive, branching, filamentous bacteria that divide horizontally and longitudinally, forming parallel rows of cocci (zoospores) that are commonly described as resembling "railroad tracks" (Fig. 11.5).

CYTOLOGIC STUDIES. Cytologic studies are of value when dealing with crusts, scales, pustules, vesicles, nodules, or tumors. They can quickly indicate the presence of infectious organisms and provide a rough assessment of the spectrum of cell types present in a lesion (e.g., neoplastic, acantholytic, or inflammatory). The surface of the lesion should be gently shaved (if necessary); particular care must be taken not to rupture fragile pustules and vesicles or remove crusts. Crusts and scales may be evaluated by performing a superficial scrape with a spatula, placing the material on a dry (i.e., no mineral oil) microscope slide, heat fixing, and then staining with Gram, Giemsa, or Wright stain. Alternatively, acetate tape may be used to collect the material, and instead of placing the tape on a slide that has mineral oil (as is done when looking for parasites), the tape is placed on a slide on which several drops of the "blue" solution from the Wright stain have been placed. With either of these methods, the slide is scanned for areas of sufficient stain with the ×4 objective and then examined using the ×100 objective with immersion oil.

Cytologic evaluation of intact pustules and vesicles is best accomplished by gently opening an intact lesion with the tip of a sterile No. 15 scalpel blade or 25-gauge needle and smearing the contents on the surface of a glass slide. The slide should be air dried, heat fixed, stained with one of the previously mentioned stains, and examined. Nodules, tumors, and swellings are best evaluated by fine-needle aspiration. A 25- or 22-gauge needle on a 12-mL syringe is introduced into the mass, and negative pressure is applied. Several passes through the mass at different angles should be performed. After negative pressure has been released, the needle is removed from the mass. The needle is then removed from the syringe, the syringe is filled with air, and the needle is reattached. Alternatively, just the needle is introduced into the mass in several places and then attached to a syringe filled with air. The contents of the needle are pushed out onto glass slides, which are subsequently dried, fixed, and stained as described previously.

BIOPSY FOR ROUTINE HISTOPATHOLOGIC EXAMINATION. The following materials are necessary to perform a skin biopsy:

- 6-mm and 4-mm biopsy punches
- No. 15 scalpel blade
- Sharp scissors
- Curved mosquito forceps
- Needle holders
- No. 2-0 or 3-0 nonabsorbable suture
- 2% lidocaine
- 3-mL syringe with a 22- to 25-gauge needle
- Tongue depressor or cardboard
- Gauze
- 10% buffered formalin

It is important *not* to surgically prepare a lesion that is going to be biopsied for histopathologic examination. Shaving and scrubbing remove crusts and epithelial tissue that may be important in reaching a diagnosis. Cutaneous infections caused by biopsies taken in this manner are extremely uncommon. If the clinician is concerned about infections, surgically prepare the site *after* the biopsy has been taken, before suturing.

Local anesthesia is sufficient for obtaining most skin biopsies. A 22- to 25-gauge needle is inserted at the margin of the lesion until the bevel is buried in the subcutaneous tissue beneath the lesion. The 2% lidocaine (0.5 to 1 mL) is injected, allowing 1 to 2 minutes for the anesthetic to take effect. Infiltration of the dermal or epidermal tissue with lidocaine should be avoided because this causes artifactual changes in the specimen.

Four techniques can be used to biopsy skin: the excisional, wedge, punch, and elliptic techniques. When the lesion to be sampled is a single nodule, the ideal biopsy technique is excisional because the lesion can be eliminated at the same time the histologic diagnosis is made. If the lesion is a tumor and too large to be excised, a generous wedge biopsy should be performed, which ideally extends from the margin to the center and includes the full depth of the lesion.

Most lesions can be sampled with a 6-mm biopsy punch. A disposable biopsy punch (Baker's Biopsy Punch, Chester A. Baker Laboratories, Miami, Fla.) can usually be used to obtain two or three biopsies before its edge is dulled and it must be discarded. The punch is placed directly over the lesion and rotated in a continuous circular motion while pressure is applied until the blade of the punch is in the subcutaneous tissue. If the punch has cut to a sufficient depth, when it is removed the tissue sample is free of the adjacent dermis and remains only loosely attached to the underlying subcutaneous tissue by a thread of connective tissue. A small pair of curved mosquito forceps is used to gently grasp the subcutaneous part of the biopsy and elevate it from the surrounding tissue. The specimen is then cut free with a pair of sharp scissors. It is important to avoid handling the epidermal and dermal parts of the sample during this procedure to minimize artifactual changes in the tissue sample. The sample is *gently* blotted to remove any surface hemorrhage and immediately placed in 10% buffered formalin for fixation. The site from which the sample was taken may then be cleaned with an antiseptic solution and closed with either two simple interrupted sutures or a cruciate stitch using No. 2-0 or 3-0 nonabsorbable sutures.

Although punch biopsies are convenient and easy to use, they are not appropriate for vesicular, bullous, and ulcerative lesions (unless the first two are small enough to be completely enclosed within the biopsy punch). For these lesions the method of choice is a surgical elliptical biopsy. The biopsy of vesicular and bullous lesions should encompass the entire lesion. Biopsy of samples of ulcerations should include abnormal tissue, the leading edge of the lesion, and normal tissue. Because an ulcer lacks epithelial tissue, the leading edge where epithelium remains may be the most rewarding in providing a histologic diagnosis. Thus the skin is biopsied so that the long axis of the ellipse crosses perpendicular to the leading edge of the ulcer (Fig. 11.6). It is important to mount surgical elliptical biopsies before placing them in formalin or they will curl during fixation, resulting in distortion of the histologic features during sectioning.

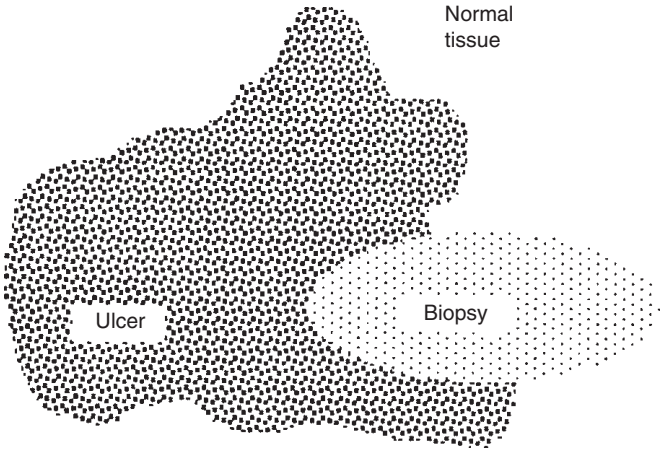

FIG. 11.6 An ulcerative lesion should be biopsied in an elliptical fashion, using a No. 15 scalpel blade, so that the long axis of the ellipse crosses perpendicular to the leading edge of the lesion.

To mount the specimen, the subcutaneous surface is placed on a small piece of a wooden tongue depressor or cardboard while gentle pressure is applied to the tissue so that it adheres to the surface. Then the specimen is placed in the formalin.

Ideally biopsy specimens should be submitted to a veterinary histopathologist with special interest and training in dermatopathology. Submission of adequately biopsied specimens of properly chosen lesions is the clinician's responsibility. To further increase the chances of securing clinically valuable information from the biopsy samples, the clinician must also provide the pathologist with a concise history of the skin problem, physical findings, a description of the morphology and location of the lesions (and, if possible, images of the lesions), and a list of differential diagnoses. When the suspected clinical diagnoses are provided, the pathologist's efforts can be directed specifically toward confirming or ruling out those diagnoses.

BIOPSY FOR IMMUNOPATHOLOGY. Immunopathology may be used as an adjunct to conventional histologic testing when the clinician suspects that the patient has an immune-mediated skin disease. The two methods used are direct immunofluorescence, which requires a special medium for fixation (Michel's fixative), and immunoperoxidase techniques, which may be performed on the paraffin block prepared for the histopathologic study (i.e., the formalinized tissue section). The materials and the technique for biopsy for immunopathology are essentially identical to those for a routine histologic examination. Administration of corticosteroid medications within 3 weeks of testing may be associated with false-negative test results. It is advisable to bisect biopsy samples along their long axis, submitting half for direct immunopathology and half for histopathologic examination. It should be borne in mind that histopathology of the lesions, rather than immunopathology, is often the more accurate of the two methods in the diagnosis of autoimmune diseases; thus if faced with the choice (because of financial reasons or paucity of lesions), the clinician should always choose the former.

MICROFILARIAL PREPARATION. The microfilarial preparation technique is applicable to the diagnosis of cutaneous onchocerciasis in horses, stephanofilariasis in cattle, and elaeophorosis and parelaphostrongylosis of sheep and goats. After selecting the lesion to be sampled, a 6-mm punch biopsy is used to obtain the tissue sample in the same manner as for the histopathologic biopsy. The tissue should be split and half preserved in 10% buffered formalin for routine histologic studies. The other half is placed on a dampened gauze sponge in a tightly closed container until the preparation can be performed. A small piece of the tissue that includes the dermis is placed on a glass slide and minced with a razor blade; a few drops of nonbacteriostatic saline are added. Bacteriostatic saline should not be used because it kills the microfilaria and thus makes their identification more difficult. The specimen is incubated at room temperature for 15 minutes. The slide is then scanned with the ×4 objective along the margins of the tissue debris while the clinician searches for indication of motion in the saline. If the characteristic whiplash movement of the parasite is noted, a higher-powered objective should be used. If the preparation result is negative, a small amount of water is added to a Petri dish, the glass slide is rested on two wooden sticks above the water, and the cover is replaced on the dish. The preparation should be incubated for several hours or overnight and reexamined. The Petri dish helps prevent the sample from drying out.

BACTERIAL CULTURE. The method of bacterial culture depends on the type of lesion. All haired lesions should be gently shaved. Nodules and tumors should be cultured by aseptically excising the lesion or by obtaining a generous wedge of the tissue. To prevent culture contamination by surface bacteria, the nodules should be gently shaved, washed with an antiseptic soap, and dried with a sterile gauze pad. A perilesional injection of 2% lidocaine is used to anesthetize the tissue. The sample is placed in a transport medium and sent to a microbiology laboratory for culture. A papular eruption (rash) is best cultured by obtaining a sterile 6-mm punch biopsy of skin. Crusts may be lifted up, and the underside should be cultured via a sterile culturette. Ulcerative lesions should not be cultured because any bacteria isolated are more likely to be opportunistic rather than primary pathogens. If the lesions are fluctuant (vesicles, pustules), the overlying skin can be opened gently with a No. 15 blade and some of the contents of the lesion transferred with the blade to the tip of a sterile culture swab. Although some older literature recommends not using sterile culturettes directly on the skin surface, due to concerns that nonpathogenic bacteria from the skin surface may be cultured,[1] the author has used this method of culturing papular eruptions or scale when a biopsy is not feasible.

SUBCUTANEOUS AND DEEP FUNGAL CULTURE. Subcutaneous and deep fungal cultures should be performed on nodules, tumors, and swellings. The technique is identical to that described for bacterial culture of these lesions.

POLYMERASE CHAIN REACTION. This molecular test has been shown to be helpful in diagnosing bacterial, mycobacterial, fungal, and viral infections, as well as determining the precise causative organism.[2-5] Further details on this method are found in Chapter 29.

Pruritus

Definition

Pruritus is an unpleasant sensation that provokes the desire to scratch. It is designated a primary cutaneous sensation, along with heat, cold, pain, and touch. There are two broad categories of pruritus. Physiologic or spontaneous itch is a sharp, well-defined, pruritic sensation that is sufficiently intense to prompt scratching but does not result in significant irritation of the skin; this is a frequent daily occurrence in normal individuals. Pathologic itch is the less well-defined pruritus that occurs in a variety of primary and secondary skin disorders and in systemic diseases. It is an intense cutaneous discomfort that provokes vigorous scratching.[6]

Mechanisms of Pruritus

The investigation of the mechanism of pruritus has been primarily in laboratory animals and humans. It is presumed that much of this knowledge is applicable to other animal species. Pruritus

is a distinct sensory quality transmitted from an arborizing network of nerve endings situated at or near the dermoepidermal junction. The sensation is carried to the spinal cord through small, unmyelinated C fibers. The fibers enter the dorsal root of the spinal cord and ascend in the ventrolateral spinothalamic tract through the posterior ventral nucleus of the thalamus to the sensory cortex. The pruritic sensation may be modified in the sensory cortex by behavioral factors or competing stimuli.[7,8]

Many physical and chemical stimuli can evoke pruritus, and many substances have been implicated as mediating pruritus in humans. Examples of these mediators, which are assumed to have importance in domestic animals as well, include the following[8]:

- *Histamine.* Histamine has been regarded as the classic mediator of pruritus. Histamine is present in mast cells in the dermis and in blood basophils. An intradermal injection of histamine produces pruritus within 20 to 50 seconds. Because many pruritic disorders respond poorly to antihistamines given either therapeutically or prophylactically, histamine is not believed to be the sole mediator of pruritus.
- *Endopeptidases.* Examples include trypsin, papain, and kallikrein.
- *Prostaglandins (E series* and *endoperoxidases).* Prostaglandins induce pruritus by potentiating the release of proteases from keratinocytes and leukocytes and by lowering the threshold and increasing the duration of histamine-induced pruritus.
- *Endogenous opioid peptides.* Opiates may potentiate preexisting pruritus. The opiate antagonist naloxone hydrochloride has an attenuating effect on the histamine-induced component of pruritus.
- *Substance P.* Substance P is a neurotransmitter found in the central and peripheral nervous systems. When introduced intradermally, it elicits a pruritic response.

Many factors can potentiate existing pruritus. Neurologic factors such as boredom and fatigue can potentiate a pathologic itch and possibly transform a physiologic itch into a pathologic itch. Local axonal reflexes can potentiate pruritus; that is, if a second stimulus is applied to an area close to one that is pruritic, the second stimulus, irrespective of its type, is perceived as an itch. In addition, skin with chronic dermatitis has limited perception of stimuli, and any stimulus applied to the affected region may be perceived as either a burning sensation or an itch. This phenomenon is known as "conversion itch." Secondary bacterial infections, vasodilatation, and inflammation result in a local increase in proteases that potentiate pruritus.[7]

Pruritus can be diminished by several nonpharmacologic mechanisms, the most common being application of competing stimuli. Pruritus is a minor sensation compared with the other primary sensations of heat, cold, touch, and pain; thus local application of a competing stimulus to a pruritic area often suppresses the pruritic sensation. Scratching is an example of a competing stimulus. Scratching may relieve pruritus by disturbing the rhythm of afferent impulses traveling toward the central nervous system. An alternative theory is that scratching may cause transient damage to nerve fibers that convey the pruritic sensation. Unfortunately, the effect is short lived because the epidermal damage induced by scratching causes the release of epidermal proteases that may later increase the degree of pruritus. Centrally acting factors such as diversions or distractions can also diminish the perception of pruritus by providing competing stimuli directly to the cortex rather than locally to the skin.[7]

Approach to Diagnosis of Pruritus

Pruritus is the most common sign of cutaneous disease. Most often in large animals, it is caused by ectoparasites or a hypersensitivity reaction, or both (e.g., *Culicoides* hypersensitivity); it may also be caused by cutaneous bacterial or fungal infections (e.g., dermatophytes, *Malassezia* species) (Box 11.1). Because pruritus may be a feature of a more generalized disease process, it is important to take the patient's general health into account. Hypersensitivity reactions, which are commonly pruritic, may or may not be limited to the skin. For example, anaphylaxis is a life-threatening hypersensitivity reaction that may manifest as pruritus in its early stages. Other pruritic skin diseases include immune-mediated diseases such as atopic dermatitis or pemphigus foliaceus; direct irritation by chemicals; and photoactivated dermatoses. It is helpful to formulate a differential diagnosis by considering each of these broad categories of diseases and using historic information, other cutaneous signs, and appropriate diagnostic tests to narrow the list of differential diagnoses.

BOX 11.1

Most Common Causes of Pruritus in Horses and Ruminants

Ectoparasites

Culicoides species (horses)
Other flying insects
Lice
Psoroptes cuniculi (goats)
Psoroptes ovis (sheep)
Sarcoptes scabiei (ruminants)
Chorioptes species (horses and cattle)

Hypersensitivity (Horses)

Atopic dermatitis

Infectious

Staphylococcal pyoderma (horses)
Dermatophytes

The following steps are a guide to the diagnosis of pruritus in the horse and ruminant:

1. History and physical examination (see Fig. 11.1).
   a. Determine if the pruritus is a seasonal or year-round problem. A seasonally recurrent pruritic disease tends to suggest either seasonal exposure to a parasite (e.g., lice in the winter, flies in the summer) or a seasonal environmental allergen (e.g., pollens) as the cause. Determine the level of fly exposure for the animal that is pruritic in the warmer months.
   b. Determine if the pruritus is generalized or localized and, if localized, what areas of the body are affected. For example, photoactivated dermatoses are limited to the white-haired regions.
   c. Determine if contact animals of the same and/or different species are affected or unaffected. The presence of multiple pruritic animals is suggestive of a contagious disease (e.g., dermatophytes, ectoparasites) or a disease of common exposure *(Culicoides).* A single pruritic animal among a group of unaffected animals is more likely to be experiencing a hypersensitivity reaction (drug or environmental).
   d. Determine what topical and systemic medications were given to the animal both before and after the onset of the problem. Medications given before onset may be the cause of the pruritus, and those given after onset may interfere with the results of diagnostic tests.
   e. Determine whether all the cutaneous lesions can be attributed to self-trauma or if primary cutaneous changes are present (e.g., wheals, nodules, pigmentary changes).
   f. Determine whether, on close inspection, the coat shows evidence of small but grossly visible parasites such as lice or their eggs.
2. The most useful diagnostic tests are skin scrapings, acetate tape preparations, dermatophyte culture plus KOH preparation, *Dermatophilus* preparation, microfilarial preparation, biopsy for routine histopathologic examination, and intradermal testing (see Chapter 40).

VetBooks.ir

Nodules, Tumors, and Swellings

Definition

A *nodule* is a circumscribed, solid elevation larger than 1 cm in diameter that does not deform when palpated. Nodules extend into the deeper layers of the skin and are usually the result of cellular infiltrates in the dermis or subcutis. *Tumor* is a less precise term that usually refers to a neoplastic, nodular enlargement of the skin or subcutaneous tissue.[7] The term *tumor* is most commonly used to describe large nodular neoplasms. In addition to nodules and tumors, *swellings* include elevated lesions that pit with pressure (wheals) and fluctuant lesions (cysts and abscesses).

Mechanisms of Nodule, Tumor, and Swelling Formation

Nodular lesions can be subdivided into inflammatory and neoplastic lesions. Inflammatory nodules are composed of a massive mixed cellular infiltrate involving the dermis, the subcutis, or both. The inflammatory infiltrate may contain variable numbers of neutrophils, histiocytes, lymphocytes, plasma cells, and eosinophils. Cellular infiltration is usually stimulated by the presence of foreign material, and the nature of that material influences the composition of the inflammatory infiltrate. The foreign material may be infectious (parasite, bacteria, or fungi) or noninfectious (fibrin, crystalline material, or other inert substances). Grossly visible nodules develop as the masses of inflammatory cells accumulate in the tissues to phagocytize or "wall off" the foreign material. As the lesion enlarges, the dermis and subcutis are obliterated by the inflammatory infiltrate and the overlying epidermis may become atrophic, resulting in ulceration of the nodule's surface.

Most cutaneous and subcutaneous neoplasms form nodular lesions. Cutaneous and subcutaneous neoplasms may either arise from a cell type of the epidermis, dermis, or subcutis or less commonly metastasize from another tissue of origin. Cytologically and histologically, neoplasms are composed of a uniform population of pleomorphic cells with variable atypia. Neoplasms may stimulate a secondary inflammatory reaction.

Swellings include solid lesions such as nodules and tumors, as well as urticaria, cysts, and abscesses. Urticarial lesions (wheals, hives) are often transient, localized, inflammatory lesions caused by a vascular reaction in the dermis in which vasodilatation results in fluid transudation with or without erythema. The fluid is not compartmentalized but dispersed evenly throughout the dermal tissue. The result is an elevated lesion that, unlike a nodule, pits with pressure and often dissipates within minutes to hours as the fluid is resorbed. Typically a sparse, perivascular infiltrate that is usually lymphocytic is seen, although the infiltrate may be dense and intermingled with eosinophils. Urticaria is usually well circumscribed, although with confluence the edema may assume geometric shapes.

A cyst (Latin for *sac*) is an epithelium-lined cavity containing fluid or semisolid material.[7] A cyst usually presents as an elevated, smooth, well-circumscribed, fluctuant mass. Cutaneous cysts are usually lined by adnexal epithelium (hair follicle, sebaceous or apocrine epithelium) and are filled with cornified cellular debris and sebaceous or apocrine secretions.

An abscess is a localized, fluid-filled, fluctuant lesion; if large enough, it may be ballotted. It results from a dermal or subcutaneous accumulation of the debris of dead cells and tissue elements liquefied by the proteolytic and histolytic enzymes elaborated by polymorphonuclear cells (e.g., pus). Abscesses most commonly result from localized infection, although they occasionally result from septicemia or may be sterile.

Approach to Diagnosis of Nodules, Tumors, and Swellings

Nodules, tumors, and swellings may arise from a variety of cutaneous disorders and, in rare cases, are signs of a systemic disease. The major categories of diseases that should be considered when forming a differential diagnosis include hypersensitivity reactions, infectious diseases, sterile inflammatory diseases, and neoplasia (Box 11.2). The primary systemic diseases that should be considered are amyloidosis, lymphosarcoma, and anaphylaxis.

The following steps are a guide to the diagnosis of nodules, tumors, and swellings in horses and ruminants:

1. History (see Fig. 11.1). Pay particular attention to:
   a. Signalment. Older animals are at greater risk for cutaneous neoplasia (e.g., gray horses and melanomas). However, neoplasia is not restricted to older animals; equine sarcoids are frequently recognized in horses as young as 3 years of age.
   b. Number and progression of lesions. If one or only a few lesions are present, hypersensitivity to arthropod bites should be considered, particularly if there is rapid onset of the lesion. Rapid onset of generalized lesions such as urticaria suggests a differential diagnosis of drug, flying insect, environmental (pollen), or (rarely) food allergies.
   c. A recent history of systemic illness, which might suggest that the lesion is a bacterial abscess.
2. Physical examination (see Fig. 11.2). In particular:
   a. Determine by palpation if the cutaneous lesions are nodules or swellings.
   b. Inspect the lesion or lesions closely for evidence of cutaneous parasitism (ticks, breathing pores associated with *Hypoderma* larvae, yellow granules associated with cutaneous habronemiasis).
   c. Determine if the lesions are painful or pruritic (e.g., evidence of excoriations).
3. Perform fine-needle aspiration for cytologic studies.
4. Perform biopsy for histopathologic examination.

BOX 11.2

Most Common Causes of Nodules, Tumors, or Swellings in Horses and Ruminants

Horses

Infectious

Corynebacterium pseudotuberculosis
Habronema species
Sporotrichosis

Neoplasia

Sarcoid
Squamous cell carcinoma
Melanoma

Sterile, Nonneoplastic

Eosinophilic granuloma
Exuberant granulation tissue (proud flesh)
Urticaria (hives)

Ruminants

Infectious

C. pseudotuberculosis
Hypoderma species (warbles)
Sporotrichosis
Actinobacillosis
Actinomycosis

Neoplasia

Squamous cell carcinoma
Fibroma or fibrosarcoma
Epidermal inclusion cysts

Sterile, Nonneoplastic

Urticaria (hives)

5. Perform bacterial culture and sensitivity.
6. Perform subcutaneous and deep fungal cultures.
7. Perform dermatophyte culture and KOH preparation.

Ulcerations and Erosions

Definition

An *ulcer* is a cutaneous defect that results from a complete loss of the epidermis and usually part of the underlying dermis.[7] Ulcers often heal with scarring that is caused by destruction of dermal collagen. An *erosion* is a cutaneous defect that results from a partial loss of the epidermis that does not penetrate beneath the basal laminar zone. Because an erosion does not involve the dermis, it heals without leaving a scar. Because the epidermis is a cutaneous barrier to invading microorganisms, ulcers and erosions are often secondarily infected.

Mechanisms of Ulcer and Erosion Formation

Ulcers and erosions are secondary lesions. Primary lesions develop spontaneously and are a direct reflection of underlying disease. Secondary lesions evolve from primary lesions or are artifacts induced by excoriation or external trauma. Primary lesions that may lead to the formation of ulcers and erosions include fluid-filled lesions such as pustules and vesicles. Rupture of these fragile lesions results in epidermal destruction and erosion or ulcer formation. Swellings such as abscesses and cysts may also rupture, resulting in ulceration, but these primary lesions are more stable and often remain intact. Nodules and tumors may become secondarily eroded or ulcerated. As the nodule or tumor enlarges, the mass exerts pressure on the overlying epidermis, leading to epidermal atrophy and ultimately a break in epidermal confluence, resulting in ulceration and erosion. The most common cause of ulceration and erosion is pruritus, which induces excoriation and hence epidermal destruction. Ulcers and erosions may also result from external trauma such as epidermal destruction arising from mechanical, thermal, or chemical causes (Box 11.3).

Approach to the Diagnosis of Ulcerations and Erosions

To diagnose the cause of an ulcer or erosion, the clinician must first determine the primary lesion that resulted in ulceration and erosion. Ulcers and erosions occurring secondary to pustules and vesicles, to swellings such as abscesses and cysts, to nodules and tumors, to pruritus, and to external trauma must be differentiated. The list of differential diagnoses relevant to each of these groups of primary lesions is then considered.

BOX 11.3

Most Common Causes of Ulcerations and Erosions in Horses and Ruminants

Immune-Mediated

Adverse drug reaction
Contact irritant or hypersensitivity
Photosensitivity
Purpura hemorrhagica (horses)
Vasculitis

Infectious

Dermatophilus congolensis
Habronema species (horses)
Viral diseases (in ruminants; e.g., infectious bovine rhinotracheitis, vesicular stomatitis, bovine herpes mammillitis)

Neoplasia

Squamous cell carcinoma

The following steps are a guide to the diagnosis of ulcerations and erosions in horses and ruminants:

1. History (see Fig. 11.2)
   a. Determine if the animal is pruritic.
   b. Determine if the animal has been subjected to external trauma (mechanical, thermal, or chemical).
   c. Determine what topical and systemic medications were given to or used on the patient before the onset of the problem. Use of certain topical agents may suggest a diagnosis of contact dermatitis, whereas administration of systemic medications may suggest a drug hypersensitivity.
2. Physical examination (see Fig. 11.2)
   a. Examine the oral cavity and mucocutaneous junctions for lesions. Oral or mucocutaneous lesions (or both) in the horse might suggest accidental ingestion of a vesicant or the rare diagnosis of bullous pemphigoid or pemphigus vulgaris. In a ruminant these lesions are often seen with viral infections.
   b. Look for evidence of excoriation, suggesting that the ulcerations and erosions have occurred secondary to pruritus.
   c. Look for evidence of primary lesions such as pustules, vesicles, nodules, tumors, or swellings, which may have preceded the ulcerations and erosions.
3. Biopsy for routine histopathologic examination
4. Biopsy for direct immunofluorescence testing

Papules, Pustules, and Vesicles

Definition

A *papule* is a solid, circumscribed, elevated lesion up to 1 cm in diameter. Papules are essentially small nodules that do not extend beneath the dermis. A *pustule* is a fluctuant, circumscribed, elevated accumulation of pus (inflammatory cells and often necrotic debris) up to 1 cm in diameter (e.g., a small abscess). Pustules are frequently associated with infectious diseases, although sterile pustular diseases (such as pemphigus foliaceus) exist. A *vesicle* is a fluid-filled, acellular, circumscribed, elevated lesion up to 1 cm in diameter. A *bulla* is a vesicle that is larger than 1 cm in diameter. All these lesions can be either follicular or nonfollicular in orientation, depending on the underlying cause. Pustules and vesicles are rarely seen clinically because of their fragility and hence their susceptibility to rupture. Because papules are solid lesions, they are more stable and therefore more commonly encountered.

Mechanisms of Papule, Pustule, and Vesicle Formation

Papules usually form as a result of an infiltrate in the dermis, either cellular or noncellular. Cellular infiltrates may include inflammatory or neoplastic cells, although neoplastic papular lesions are relatively uncommon in large animals. Inflammatory infiltrates may be mixed, containing variable numbers of neutrophils, histiocytes, lymphocytes, plasma cells, and eosinophils, or one cell type may predominate. The composition of the inflammatory cells is influenced by the underlying cause of the papule, and the possible causes are extensive. Noncellular papular infiltrates include substances such as edema fluid, amyloid, and proliferative collagen, although these are relatively rare.

Pustules form as the result of an intraepidermal, subcorneal, or, less commonly, subepidermal accumulation of inflammatory cells. Infiltration of inflammatory cells, particularly polymorphonuclear leukocytes, leads to the release of proteolytic enzymes that liquefy tissue elements and result in the formation of a fluctuant lesion. Eosinophils, acantholytic cells, and infectious organisms may also be noted in a pustule, depending on the underlying cause. The stimulus leading to pustule formation is most commonly infectious, although pustules can result from noninfectious causes such as hypersensitivity reactions and autoimmune disease.

VetBooks.ir

VetBooks.ir

Vesicles form either at the dermoepidermal junction (subepidermal) or in the epidermis (intraepidermal) as a result of malformation or destruction of the basement membrane zone, or confluence of intercellular edema (spongiosis). Clinically, these types of vesicles are indistinguishable. Vesicles form as the result of certain viral diseases, during severe inflammatory reactions (allergic contact dermatitis), or with cutaneous physical damage (mechanical, chemical, or thermal). In pemphigus foliaceus or pemphigus vulgaris, autoantibodies bind to transmembrane proteins between the epidermal cells, causing disruption of epidermal intercellular attachments. The result is intraepidermal cleft formation that leads to vesiculation. In bullous pemphigoid, complement-activating antibodies bind to antigens in the basement membrane zone, causing degranulation of mast cells, chemotaxis of neutrophils and eosinophils, and release of tissue-destructive enzymes that injure the basement membrane zone. The result is loss of dermoepidermal adherence and vesicle formation.[7] Vesicles are transient, fragile lesions and therefore are rarely recognized clinically. If they are not destroyed by surface trauma, rapid infiltration by inflammatory cells often transforms a vesicle into a pustule.

Approach to Diagnosis of Papules, Pustules, and Vesicles

Although papules, pustules, and vesicles may look somewhat similar on a cursory physical examination, the clinician must differentiate among the three and determine which of the lesions are present. Examination with a hand lens may help. The differential diagnoses relevant to papules, pustules, and vesicles are not necessarily the same (Box 11.4). In all cases it is important to determine if disease is limited to the skin or if the animal's general health is compromised as well.

Papular lesions have the most extensive differential diagnoses:

- *Hypersensitivity reactions.* Parasitic hypersensitivities are the most common (e.g., *Culicoides* hypersensitivity), although drug and (rarely) food hypersensitivities should also be considered. Many hypersensitivity reactions are pruritic.
- *Parasites.* Some species simply irritate the skin with their bites (e.g., horn fly [*Haematobia irritans*]) without inducing a hypersensitivity reaction.
- *Infectious diseases (bacterial, fungal, and viral).* Typically papules caused by infections have a follicular orientation.
- *Certain neoplastic diseases (papillomas or sarcoids).*
- *Uncommon causes* including autoimmune diseases such as pemphigus foliaceus and diseases of uncertain cause such as equine sarcoidosis.

BOX 11.4

Most Common Causes of Papules, Pustules, and Vesicles in Horses and Ruminants

Horses

Hypersensitivity—Usually Papules

Culicoides species
Other flying insects

Infectious—Papules or Pustules

Staphylococcal pyoderma
Dermatophilus congolensis

Immune-Mediated

Pemphigus foliaceus—papules or pustules
Bullous pemphigoid—vesicles

Ruminants

Ectoparasites—Usually Papules

Sarcoptes scabiei
Psoroptes cuniculi (goats)
Lice

Infectious

Viral diseases (e.g., vesicular stomatitis)—vesicles
Staphylococcal pyoderma (goats)—pustules or papules

Pustules are most commonly associated with bacterial infections, although fungi and, in rare cases, parasites (*Demodex* species) can cause pustule formation. Sterile pustular diseases are less frequently seen (drug eruptions, sterile eosinophilic folliculitis of cattle)[9] but should be included in the differential diagnoses. Vesicles are rapidly infiltrated by inflammatory cells and transformed into pustules. Diseases commonly associated with vesicles include viral diseases of ruminants, autoimmune diseases, contact dermatoses, and burns.

The following steps are a guide to the diagnosis of papules, pustules, and vesicles in horses and ruminants:

1. History (see Fig. 11.1)
   a. In particular, determine whether the lesions are pruritic, painful, or asymptomatic.
   b. Determine if contact animals of the same and/or different species are affected or unaffected. If contact animals are affected, a contagious problem should be considered: fungal (dermatophytosis), bacterial (dermatophilosis), viral (contagious ecthyma), or parasitic (*Culicoides* hypersensitivity).
   c. Trace the temporal course of development. Rapid onset of lesions may suggest a hypersensitivity reaction.
   d. Check for seasonality. A seasonal problem suggests a parasitic or hypersensitivity (pollens) cause. Lice are a problem in the winter, trombiculidiasis tends to occur in the fall, and most of the flying insects are present in the spring, summer, and early fall.
   e. Determine what topical and systemic medications were given to or used on the animal before the onset of the problem. Use of certain topical agents may suggest a diagnosis of contact dermatitis, whereas administration of systemic medications may suggest drug hypersensitivity.
   f. Determine if the animal has been subjected to external trauma (thermal or chemical).
2. Physical examination (see Fig. 11.2)
   a. Gently palpate the lesions to determine if they are solid (papules) or fluctuant (pustules or vesicles).
   b. Note if the lesions have a follicular orientation, suggesting an infectious cause.
   c. Check for lesions involving the oral cavity and mucocutaneous junctions.
   d. Look for evidence of excoriation, suggesting that pruritus is a feature of the disease.
   e. Inspect the coat closely for small but grossly visible parasites such as lice or their eggs.
   f. Inspect contact animals for evidence of disease.
3. Skin scrapings of papular lesions
4. Cytologic studies
5. Dermatophyte culture and KOH preparation
6. *Dermatophilus* preparation
7. Bacterial culture and sensitivity
8. Microfilarial preparation
9. Biopsy for routine histopathologic examination
10. Biopsy for direct immunofluorescence testing

Scaling and Crusting

Definition

Scale is a visible accumulation of fragments of the horny layer of the skin (stratum corneum); it represents the final product of epidermal keratinization.[7] The process of forming the stratum corneum is termed *cornification.* Histologically, scale is recognized as hyperkeratosis and can be subdivided into parakeratosis

(cornification with nuclear retention) or orthokeratosis (cornification without nuclear retention). In some conditions parakeratosis and orthokeratosis may be present together. Grossly the scale varies in appearance. The color may be white, silver, yellow, brown, or gray. The consistency may be like that of bran flakes or powdery, coarse, greasy, or dry. Scale can be either loose or adherent to the skin or hair shafts.

Crusts are composed of variable amounts of serum; cells (leukocytes, erythrocytes, keratinocytes); fibrin; infectious agents (bacteria and fungi); debris; and/or medications. They often cover erosions or ulcerations. Heaped-up crusts are referred to as *vegetations*. On the basis of their histologic composition, crusts may be subdivided into cellular, serocellular, serous, and hemorrhagic types.

Mechanisms of Scale and Crust Formation

Scaling results from increased desquamation (exfoliation) of the stratum corneum. Exfoliation is the final stage of keratinization, the process by which the permanent population of cells of the basal layer of the epidermis divides, undergoes specific patterns of differentiation, and progresses toward the surface, where it is shed.[7,9] Excessive exfoliation and scale formation occur when the rate of keratinization is accelerated; when trauma to the surface of the epidermis (chemical, mechanical, or thermal) loosens the stratum corneum; or when the structures sustaining epidermal intercellular cohesion (such as transmembrane proteins) are destroyed, resulting in a loss of cohesion between epidermal cells.

Because crusts are composed primarily of serum and cells, their presence on the skin surface implies that vascular and epidermal permeability has increased to permit their formation. Serum and inflammatory cells are released into the tissues from the dermal vasculature and then cross the epidermis to the skin surface either through erosions or ulcerations or by permeating between the intercellular spaces. The exudate dries on the skin surface, in combination with any medication or debris that was already present on the hair or skin, to form the visible crust. Desquamating keratinocytes may be swept up in the exudate and become part of the crusts. Bacteria frequently invade crusts after they have formed and will be noted on histologic examination, even though they may not be a factor in the pathogenesis. Fungal organisms, when present, are more likely to be important to the pathogenesis of the underlying disease process.

Approach to Diagnosis of Scaling and Crusting

The most important factor in determining the underlying cause of scale or crust formation in either a horse or a ruminant is to determine if the patient is pruritic and if some or all of the lesions are induced by self-trauma. If pruritus is a feature, the approach to diagnosis of pruritus should be used because all pruritic diseases can cause scale and crust formation. If the patient is not pruritic, the most important differential diagnoses include infectious diseases (particularly dermatophilosis and dermatophytosis), nutritional disorders, toxicities, autoimmune disease (pemphigus foliaceus), cutaneous filariasis, photosensitization, irritant contact reactions or burns, and diseases of uncertain cause (e.g., in equine patients, sarcoidosis, aural plaques, and primary seborrhea) (Box 11.5).[7,10] Viral diseases are important nonpruritic causes of scaling and crusting in ruminants, although they are usually associated with ulceration and erosion with involvement of the oral cavity and mucocutaneous regions. Rarely, congenital genetic diseases such as ichthyosis may cause excessive crusts and scale, as has been reported in cattle and sheep.

The following steps are a guide to the diagnosis of scaling and crusting in horses and ruminants:

1. History (see Fig. 11.1)
   a. In particular, determine if the patient is pruritic.
   b. Determine if contact animals of the same and/or different species are affected. If they are, a contagious problem should be considered: fungal (dermatophytosis), bacterial (dermatophilosis), viral, or parasitic.
2. Physical examination (see Fig. 11.2)
   a. Look for evidence of excoriation, suggesting that pruritus is a feature.
   b. Inspect the coat closely for small but grossly visible parasites such as lice or their eggs.
   c. Inspect contact animals for evidence of disease, suggesting a contagious cause.
3. Skin scrapings
4. Acetate tape preparations
5. Dermatophyte culture and KOH preparation
6. *Dermatophilus* preparation
7. Biopsy for routine histopathologic examination (careful histologic examination of scale and crusts is essential to the search for the underlying cause of their formation)
8. Microfilarial preparation
9. Biopsy for direct immunofluorescence testing
10. Bacterial culture and sensitivity

BOX 11.5

Abnormal Coat Length and Density

Definition

Abnormalities in coat length and density can be subdivided into decreased coat length and density (alopecia, hypotrichosis) and increased coat length and density (hirsutism, hypertrichosis). *Hirsutism*, or excessive body hair, is far less common than alopecia, which is an absence of hair from areas where hair is normally present. *Alopecias* are usually classified as scarring (cicatricial) or nonscarring (noncicatricial). In cicatricial alopecias the hair follicles are destroyed, and hair loss is permanent because neogenesis of the hair follicle does not occur in an adult mammal. In nonscarring alopecias the hair follicles are retained; therefore the potential for regrowth remains. Both alopecia and hirsutism may be complete or partial, diffuse or focal, and congenital or acquired.

Mechanisms of Development of Abnormal Coat Length and Density

A basic understanding of the dynamics of hair structure and development is essential to an understanding of the mechanisms associated with pathologic changes in coat length and density.

The hair follicle and the sebaceous and apocrine glands are epidermal appendages. The hair follicle forms during fetal development as a downgrowth of epidermal cells toward a

VetBooks.ir

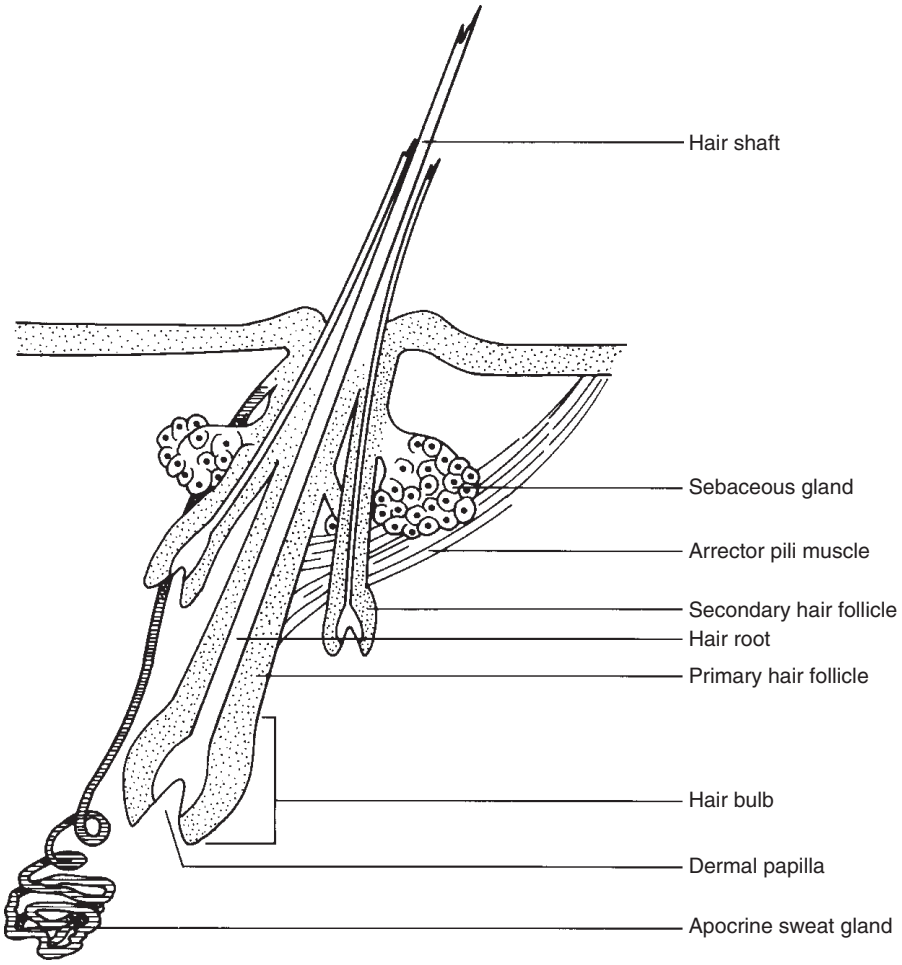

FIG. 11.7 Longitudinal section of a compound hair follicle.

group of mesenchymal cells that ultimately become the dermal papillae. The sebaceous and apocrine glands begin as buds of epithelium from the sides of the developing hair follicle.

Hair is composed of keratin and is the product of the hair follicle. The hair shaft is the part of the hair that emerges from the skin surface. The hair root is the part of the hair in the follicle. The hair bulb is a knob of epidermal cells that attaches the follicle to the dermal papilla. Both the hair follicle and the shaft have distinct layers. There are two types of hair follicles: simple and compound. A simple hair follicle produces a single hair. A compound hair follicle produces multiple hairs with bundles of hairs sharing a common skin opening and a single follicle down to the level of the sebaceous gland. Below the sebaceous gland the follicle branches so that each hair has its own hair bulb. Horses and cattle have only simple follicles. Goats and sheep have a mixture of simple and compound hair follicles (Fig. 11.7).[7,9]

The normal hair growth cycle is divided into repeating stages: anagen, catagen, telogen, and exogen, with the size and shape of the follicle changing during each stage (Fig. 11.8). The amount of time a follicle spends in each phase varies with the species, breed, individual, and body region. In addition, it is influenced by factors such as photoperiod, stress, and disease. Anagen is the active phase of hair growth. Catagen is the transition stage from the growing to the resting state. Catagen is short, and the hair quickly enters the telogen phase, in which hair growth stops. As the follicle reenters anagen, a new hair grows up beside the old and dislodges it (exogen). The signal that stimulates progression from telogen to anagen is unknown.

Coat abnormalities may result from a multitude of endogenous and exogenous factors that can modify the normal pattern of hair growth and development.

The length, density, and texture of the coat of a normal animal are determined genetically, and a variety of hereditary defects result in coat abnormalities. These defects may cause changes in hair length, density, or quality. Coat quality may be abnormal at birth or may become apparent sometime before 6 months of age. A given defect may alter the number of follicles present in the skin, or the number of follicles present may be normal but there may be genetic alterations in the way the hair is produced. Altered hair production may manifest as an increased or a decreased growth rate or as structural deformities that result in weak hair shafts that break easily.

Nutritional imbalances can affect growth and maintenance of the coat in various ways, depending on the species. Nutritional deficiencies may result in a shift of greater numbers of follicles into telogen, thus increasing shedding. Dietary carbohydrate and protein deficiencies reduce the length, diameter, and strength of hair. Supplementing the diet with carbohydrate and protein releases protein for keratin formation, provides energy to use protein, and maintains mitotic activity in the hair matrix. Fatty acid deficiencies affect lipid production in the skin, leading to a dry coat with increased fragility. A variety of vitamin and mineral deficiencies may also result in poor hair growth or quality.

Inflammatory skin diseases frequently result in hair loss. Infectious inflammatory processes such as dermatophytosis and pyoderma are usually directed specifically at the hair or hair follicle. Inflammatory processes directed elsewhere may still affect the hair follicle by sweeping it up as an "innocent bystander."

Hormonal effects on hair growth are complex. Thyroid hormones, corticosteroids, sex hormones, melanocyte-stimulating

VetBooks.ir

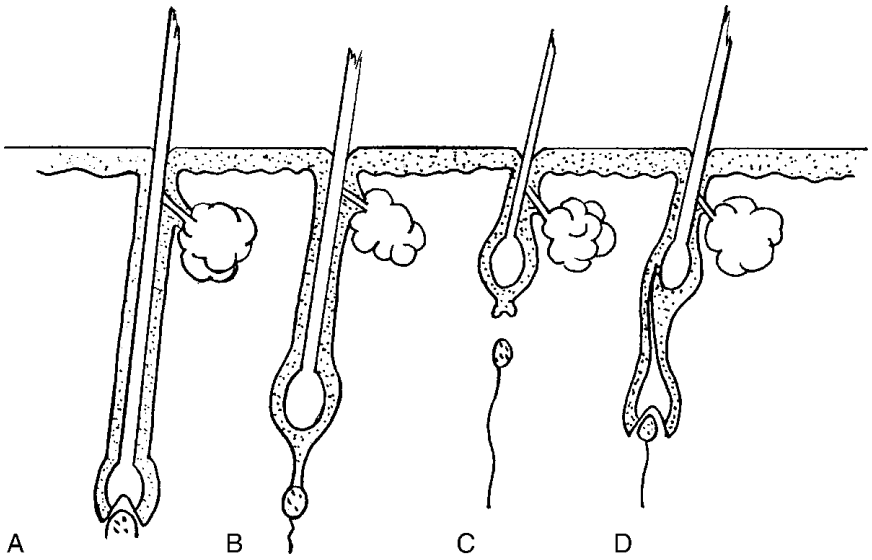

FIG. 11.8 **Stages of the hair growth cycle. A,** Anagen. **B,** Catagen. **C,** Telogen. **D,** Early anagen/exogen.

hormone (MSH), adrenocorticotropic hormone (ACTH), growth hormone, and prolactin all affect hair growth. The effect of a single hormone may be modified in the presence of other hormones, and the importance or effect of any one hormone on hair growth may differ from species to species. Hormonal variations affect the hair coat quality and length by altering the period of time that hair follicles spend in any given part of the cycle, by influencing the rate of hair growth, and by inducing follicular atrophy. External factors such as changes in the photoperiod influence hair growth by altering hormonal levels.

Trauma to the skin is a frequent secondary cause of hair loss. Self-trauma induced by pruritus is the most common cause of alopecia. Hairs may be lost either from trauma to the hair shaft, resulting in breakage, or from trauma to the dermis, resulting in destruction of the hair follicle. In the former case, the hair regrows once the source of trauma has been removed. In the latter case, hair loss is permanent.

A variety of factors can result in hair loss by causing an abrupt shift of hairs into the telogen phase. Recognized causes of telogen effluvium include stress from high fever or severe illness and parturition.

Approach to Diagnosis of Abnormal Coat Length and Density

The differential diagnosis of abnormalities resulting in *increased* coat length and density is relatively limited and does not provide much of a diagnostic dilemma for the clinician. In the horse increased coat length and density is an acquired abnormality associated with equine hyperadrenocorticism.[7] In ruminants defects are congenital and are the result of either an in utero infection (border disease) or a breed-specific hereditary defect.[9,11]

The differential diagnoses of *decreased* coat length and density are extensive. The initial step is to determine if the alopecia is congenital, implying a hereditary defect, or acquired. If the abnormality is acquired, the clinician must determine if it is a primary alopecia or secondary to another cutaneous abnormality such as pruritus or ulceration. If alopecia is the result of another primary cutaneous abnormality, the clinician should focus on the differential associated with that primary abnormality. Finally, to help provide a prognosis for hair regrowth, the clinician should biopsy to determine if the alopecia is scarring (cicatricial) or nonscarring (noncicatricial). Regardless of the underlying cause and its resolution, hair will not regrow with a cicatricial alopecia because by definition the hair follicle has been destroyed. In a noncicatricial alopecia the potential for hair regrowth remains if the underlying cause for hair loss can be identified and resolved (Box 11.6).

BOX 11.6

Most Common Causes of Abnormal Coat Length and Density in Horses and Ruminants

Alopecia[a]

Dermatophytosis
Staphylococcal pyoderma (horses)
Alopecia areata (horses, cattle)
Drug reaction
Congenital hypotrichosis (cattle)
Onchocerciasis (horses)

Increased Coat Length

Pars intermedia pituitary dysfunction (horses)
Congenital hypertrichosis

[a]Alopecia without pruritus, crusts, or other clinical signs.

The following steps are a guide to the diagnosis of decreased coat length and density in horses and ruminants:

1. History (see Fig. 11.1)
   a. Determine whether the lesions are congenital or acquired. If they are congenital, determine if any related animals are affected and if the lesions have progressed since birth.
   b. If the alopecia is acquired, determine if the animal is pruritic and if other cutaneous lesions have been observed.
   c. Determine if the animal's diet is nutritionally complete.
   d. Determine if the animal has been exposed to any toxic substances.
   e. Determine if contact animals of the same and/or different species are affected. If contact animals are affected, a contagious problem such as dermatophytosis or dermatophilosis should be considered. Because feed and environment are also shared, dietary deficiencies and toxicities should be included in the differential diagnosis.
   f. Determine what medications have been given systemically or applied topically to the patient. Use of certain topical agents, along with a history of an inflammatory stage

VetBooks.ir

preceding or coincident with the alopecia, may suggest a diagnosis of contact dermatitis. Administration of systemic medications may suggest that the cause is a drug hypersensitivity.

g. Determine if the animal has been subjected to any stresses that might provoke a telogen effluvium.

2. Physical examination (see Fig. 11.2)
   a. Check for evidence of disease in organ systems other than the skin. Does the animal appear thin and malnourished, suggesting hair loss related to a dietary deficiency? Is it febrile or suffering from a severe systemic disease, suggesting a telogen effluvium?
   b. Can the hairs be epilated readily from the coat? If not, hair loss may be caused by trauma (self-induced or external). If so, underlying nutritional, hormonal, or stress-related causes of alopecia are more likely.
   c. Look for evidence of excoriation, suggesting that self-trauma is the cause of the hair loss.
   d. Determine whether the lesions are generalized or localized, either to particular areas of the body or to certain hair colors (e.g., black hair follicle dystrophy). Note if the hair loss has a symmetric pattern.
   e. Inspect the coat closely for small but grossly visible parasites such as lice or their eggs.
   f. Inspect contact animals for evidence of disease.
3. Microscopic examination of the ends of affected hairs (squared or broken ends suggest that the hair loss is traumatically induced; tapered ends suggest an abnormality in the hair follicle, growth cycle, or an inflammatory process such as dermatophytosis)
4. Skin scrapings
5. Acetate tape preparations
6. Dermatophyte culture and KOH preparation
7. Microfilarial preparation
8. Biopsy for routine histopathologic examination (sagittal sections should be evaluated to determine the proportion of hairs in the various phases; for the presence or absence of inflammation and infectious organisms; and for evidence of scarring, which suggests a poor prognosis for hair regrowth; cross-sections of the biopsy specimen should be evaluated in noninflammatory alopecias to determine the number of hair follicles present per given area)

The following steps are a guide to the diagnosis of increased coat length and density in horses and ruminants:

1. Horses demonstrating increased coat length and density should be evaluated with appropriate laboratory tests for hyperadrenocorticism.
2. Lambs with increased coat length and density should be evaluated for evidence of border disease.
3. Cattle with increased coat length and density probably have hereditary hypertrichosis.

Abnormal Pigmentation

Definition

The following terms are used when discussing pigmentation and pigmentary abnormalities.[7]

- *Melanin* is a brown-black, light-absorbing, insoluble pigment formed in many organisms by specialized cells called *melanocytes.*
- *Hyperpigmentation* is an excessive tissue deposition of pigment, usually melanin.
- *Hypopigmentation* refers to less than normal pigmentation and can be congenital or acquired.
- *Leukoderma (hypomelanosis)* is a partial or total acquired loss of melanin pigment from the skin. The term *vitiligo* also refers to an acquired loss of melanin from the skin but is often reserved for a specific type of leukoderma found in humans.
- *Leukotrichia* is an acquired loss of pigment from the hair.
- *Albinism* is a congenital lack of pigment in all tissues.

Mechanisms of Pigmentation Abnormalities

Cutaneous pigmentation results from the interaction of melanocytes and keratinocytes. The degree of "baseline" pigmentation observed in an animal is genetically controlled. Melanocytes are of neural crest origin and migrate from this site during embryologic development. They are present in nearly all tissues but occur in the highest numbers in the epidermis, mucous membrane epithelium, dermis, hair follicles, leptomeninges, uveal tract, and retina. Epidermal melanocytes are found in the basal cell layer, and each melanocyte is presumed to supply melanin to 10 to 20 keratinocytes. Melanin is usually found in the deeper layers of the epidermis, although darkly pigmented animals may have melanin throughout the epidermal layers.

Melanocytes produce membrane-bound organelles called *melanosomes* that fuse with vesicles containing the enzyme tyrosinase. Melanin, a black-brown pigment, is produced from tyrosine in the presence of tyrosinase and copper. It is deposited on the protein matrix in the melanosomes. Once melanosomes are fully melanized, they disperse to the periphery of the dendrites of the epidermal melanocytes and the dendritic tips are phagocytized by keratinocytes. Melanin is also synthesized and transferred to cells of the hair shaft during the anagen phase.[7]

In general, mechanisms associated with pathologic pigmentary disturbances in large animals are poorly understood. Hyperpigmentation results from increased amounts of melanin in the epidermis or dermis or both. The melanin may be present in melanocytes, keratinocytes, or melanophages (dermal macrophages that have phagocytized melanin pigment). Hyperpigmentation is an uncommon problem in horses because most normally have darkly pigmented skin. Hyperpigmentation may be reversible: with removal of the pigment-promoting stimulus, it tends to decline over time to the baseline level.

MSH may stimulate hyperpigmentation. MSH acts by affecting the levels of cyclic adenosine monophosphate (cAMP), resulting in increased tyrosinase activity. MSH also causes increased dispersion of melanosomes into melanocyte dendritic processes, where they are phagocytized by keratinocytes. Increased levels of ACTH, estrogens, progesterones, and androgens may also affect pigmentation, although the importance and mode of action in large animals are not clear.

Inflammation from a variety of causes and persistent cutaneous trauma from friction induce hyperpigmentation. Stimuli that may be factors in large animals include physical cutaneous damage (trauma, friction); chemicals (primary irritants, allergic sensitizers, photosensitizers); infectious agents; and nutritional disturbances.

Hypopigmentation is the result of a decreased amount of melanin in the epidermis or dermis (or both) and may be congenital or acquired (depigmentation). Possible mechanisms include decreased melanin production (defects in melanocyte migration during embryogenesis or disorders of melanin synthesis), decreased dispersion of melanin granules (defective transfer of melanin to keratinocytes), and increased loss of melanin (accelerated desquamation of epidermal melanin, epidermal pigment loss caused by disruption of the basement membrane with resultant pigmentary incontinence, or immunologic destruction of melanin or melanocytes).

Several congenital genetic abnormalities that result in partial or total hypopigmentation have been identified in large animals. Albinism is a recessive condition in which a normal complement of melanocytes is present but a biochemical defect results in lack of ability to synthesize tyrosinase, so melanin is not produced. There is complete lack of melanin in all tissues in

VetBooks.ir

a true albino. Pseudoalbinism, in which there is ocular pigmentation, may be more common. Other genetic disorders include abnormal melanosome production and abnormalities in melanocyte development and migration from the neural crest (piebaldism).[7,9]

Acquired hypopigmentation (leukoderma) may be caused by several factors, including genetic abnormalities, trauma, inflammation, dietary imbalances, hormonal influences, and immunologic disorders. In some cases acquired hypopigmentation is idiopathic. Juvenile Arabian leukoderma appears to have a genetic basis because of the predilection for the Arabian breed and the occurrence of the disease in young animals.[10] Trauma and inflammation are the most common factors associated with depigmentation, particularly in the horse. The intensity of the inflammatory reaction may bear little relation to the degree of postinflammatory leukoderma. Dietary abnormalities, particularly molybdenum toxicity and copper deficiency, are associated with faded or washed-out coat color in food animals. Severe protein deficiency, such as occurs in kwashiorkor in humans, can lead to deficient melanin pigmentation. Melatonin is a hormone produced by the pineal gland that antagonizes MSH, thus causing decreased pigmentation, although an association with pathologic hypopigmentation in large animals has not been documented. Immunologic destruction of melanocytes has been documented in humans and is suspected of being a factor in acquired hypopigmentation in the dog but has not yet been documented in large animals. Idiopathic leukodermas are noted in all species.

Leukotrichia is the result of decreased amounts of melanin in the hair shaft. In most cases the pathogenesis is speculative, and the actual factors are unknown. Melanocytes in the hair bulbs can be affected independently of melanocytes in the epidermis, and leukotrichia without a coexistent leukoderma is common. Leukoderma, however, is usually accompanied by leukotrichia; thus when the two conditions are seen in combination, their pathogenesis is the same. Several leukotrichias that occur independently of leukoderma appear to be genetically induced because of breed predilections (e.g., reticulated leukotrichia of Quarter Horses).

Approach to Diagnosis of Pigmentation Abnormalities

The initial approach to diagnosis of pigmentary abnormalities is to determine whether the defect is congenital or acquired. Congenital pigmentary abnormalities are almost always caused by a genetic defect, whereas acquired abnormalities most commonly do not have a hereditary basis. If the abnormality is acquired, the clinician must determine if it is a primary pigmentary abnormality or if it is associated with some other pathologic change such as inflammation or trauma. If associated changes are a feature of the disease, differential diagnosis should focus on the initial pathologic changes (Box 11.7).

The following steps are a guide to the diagnosis of pigmentation abnormalities in horses and ruminants:

1. History (see Fig. 11.1)
   a. If the pigmentary change is congenital, determine if related animals are affected and if the lesions have progressed or regressed since birth. Take note of the patient's signalment and determine if that breed has been documented to have congenital pigmentary abnormalities.
   b. If the pigmentary change is acquired, determine if the animal has been subjected to cutaneous trauma that could result in posttraumatic pigmentary change. Determine if other cutaneous lesions in addition to the pigmentary changes have been observed (e.g., inflammation, ulceration).
   c. Determine if the animal's diet is nutritionally complete and balanced.
   d. Determine if the animal has been exposed to any toxic substances.
   e. Determine if contact animals of the same or different species are affected. Because feed and environment are shared, if contact animals are affected, dietary imbalances and toxicities should be included in the differential diagnosis.
   f. If the affected animal is a horse, determine what parasiticidal agents have been administered and if they are effective in the treatment or prevention of onchocerciasis.
2. Physical examination (see Fig. 11.2)
   a. Check for evidence of disease in organ systems other than the skin. Does the animal appear thin and malnourished, suggesting a pigmentary change secondary to a dietary deficiency or toxicity?
   b. If the patient's problem is hypopigmentation, examine the coat closely to determine if leukoderma, leukotrichia, or both are present.
   c. Look for evidence of other cutaneous lesions (inflammation, ulceration) that could result in postinflammatory pigmentary changes.
3. Microfilarial preparation
4. Biopsy for routine histopathologic examination (affected, unaffected, and marginally affected areas should all be biopsied and labeled appropriately for histologic comparison).

Anestrus, 194
Repeat breeder, 196
Pregnancy loss, 198
Fescue toxicosis, 200
Prolonged gestation, 204
Dystocia, 205
Retained fetal membranes, 207
Alterations in lactation, 209
Mammary gland, enlarged, 209
Udder edema, 210
Galactorrhea (inappropriate lactation), 211

Alterations in Male Sexual Function

Stallions, bulls, rams, and bucks intended to be used as breeding animals need to have 1) normal genital organs, 2) the libido necessary to tease females and gain an erection, 3) the physical ability to mount and intromit the penis into the female's vagina, and 4) an adequate number of morphologically normal, motile spermatozoa in each ejaculate to be considered as satisfactory breeders under natural service conditions. Digression from normal sexual function in males is usually recognized clinically by changes in sexual behavior, abnormalities or diseases of the genital organs, or by a decreased pregnancy rate in dams bred. Subfertile males may be responsible for significant economic loss in the livestock industry.

Mechanisms of Altered Male Sexual Function

Sexual function may be altered by any of four major mechanisms: general physical abnormalities, abnormalities of the genital organs, decreased libido, and poor semen quality (Boxes 12.1 and 12.2).

The male must be mobile enough, especially in a pasture breeding program, to locate, tease, mount, and breed estrual females successfully. Musculoskeletal abnormalities may limit reproductive ability or desire. Hindlimb conformation defects in bulls and rams, degenerative joint disease involving the hock in stallions, and foot problems in rams are examples of conditions that may cause enough discomfort to interfere with the normal breeding process or prevent normal mobility, impairing reproductive performance.[1–3]

Congenital or acquired abnormalities of the genital organs, including the penis, prepuce, scrotum, testicles, spermatic cords, or accessory sex glands, can lead to altered sexual function or infertility. Congenital abnormalities such as persistent penile frenulum and penile deviations in bulls may prevent normal intromission.[4] Acquired lesions such as a penile hematoma caused by rupture of the tunica albuginea of bulls at time of service may limit sexual function by causing paraphimosis, adhesions, or sensory nerve damage.[5]

Libido is an essential component of breeding performance but may be difficult to measure during a breeding soundness examination and cannot be evaluated if semen is collected by electroejaculation. Libido has been demonstrated to be an inherited behavioral trait in bulls.[6]

Semen volume, concentration of spermatozoa, percentage of progressive motility, and percentage of morphologically normal spermatozoa are semen parameters commonly measured during a breeding soundness examination. Fertility in stallions can be predicted with high accuracy using a combination of motility, morphology, viability, oxidation level, acrosome integrity, DNA integrity, and hypoosmotic resistance.[7,8] Abnormalities of semen quality associated with decreased fertility in bulls include spermatozoa morphology and, to a lesser degree, motility.[2,4,9]

Approach to Diagnosis of Altered Male Sexual Function

A complete breeding soundness examination and history should be obtained, including number of females bred each year, conception rates, breeding methods (natural service or artificial insemination), and results of previous breeding soundness examinations (Box 12.3). A medical or health history, including medications, vaccinations, and previous illnesses, should be obtained. The animal should be given a general physical examination. Hindlimb conformation and the presence of degenerative joint disease, laminitis, foot abscesses, abnormal foot wear, corkscrew claw defect, weak pasterns, postleggedness, sickle hock, interdigital fibromas (bulls), foot rot, ulcerative dermatitis and pizzle rot (rams), and caprine arthritis-encephalitis (CAE) (bucks) should be noted. An ophthalmologic examination should be done to ensure that the animal has adequate vision and that no significant pathologic condition is present. A special emphasis is placed on identification of squamous cell carcinoma and pinkeye *(Moraxella bovis)* and corneal lesions in bulls. Range animals showing weight loss and a decline in reproductive performance should be given an oral examination, and the parasite control program should be evaluated.

BOX 12.1

Causes of Altered Sexual Function in Stallions

Abnormalities of Penis

Balanoposthitis
Paraphimosis
Phimosis
Trauma
Hematoma, seroma
Abscess
Urolithiasis
Equine coital exanthema
Tumor (squamous cell carcinoma)
Cutaneous habronemiasis (equine summer sores)
Improper use of stallion rings

Abnormalities of the Prepuce

Trauma
Foreign body
Preputial stenosis
Balanoposthitis
Tumor (squamous cell carcinoma, sarcoid)
Hematoma
Abscess
Cutaneous habronemiasis
Varicosities of the preputial vein
Equine viral arteritis

Abnormalities of Testicles, Spermatic Cord, and Scrotum

Testicular hypoplasia, atrophy
Testicular degeneration
Segmental aplasia
Testicular, scrotal neoplasia
Thrombosis of the spermatic cord
Torsion of the spermatic cord
Orchitis, epididymitis
Sperm, parasitic granuloma
Trauma
Hematoma, hematocele
Inguinal, scrotal hernia
Androgen, anabolic steroid effects
Cryptorchidism
Pseudohermaphrodism
Actinomycosis
Chemical irritation of the scrotum
Equine viral arteritis

Lack of Libido

Malnutrition, protein-calorie starvation
Testicular neoplasia
Lameness
Trauma, foreign body of the prepuce
Overuse
Equine coital exanthema
Iodine deficiency
Penile trauma, hematoma, abscess
Neurologic dysfunction
Ocular deficiencies
Psychological impotence

Infertility

Segmental aplasia of the reproductive tract
Seminal vesiculitis
Blocked ampullae
Malnutrition, protein-calorie starvation
Testicular degeneration
Testicular hypoplasia, atrophy
Testicular neoplasia
Thrombosis of the spermatic cord
Torsion of the spermatic cord
Urolithiasis
Vitamin A deficiency
Hemospermia
Lameness
Iatrogenic causes, including artificial insemination–associated infertility
Bacterial contamination of the semen
Trauma, foreign body of the prepuce
Balanoposthitis
Paraphimosis
Orchitis, epididymitis
Sperm, parasitic granuloma
Androgen, anabolic steroid use
Testicular trauma, hematoma, hematocele
Chromosomal abnormalities
Hermaphrodism, pseudohermaphrodism
Cryptorchidism
Ejaculation failure
Frostbite
Abnormalities of spermatogenesis
Sperm storage dysfunction
Iodine deficiency
Heat stress, heat stroke
Inguinal, scrotal hernia
Psychological impotence

The external genital organs should be examined carefully. The penis of the stallion is easiest to examine after an erection is obtained by teasing to an estrual female. In ruminants manual palpation of the penis per rectum or by use of an electroejaculator is suitable in many cases. The penis should be normal in size and shape and free of lesions. In bulls, deviations or other abnormal configurations such as corkscrew penis may occur with use of an electroejaculator and therefore cannot be considered abnormal.[5] Rams and bucks should be carefully examined for abnormalities of the urethral process, including the presence of calculi.[10] The lesions most often observed on the penises of stallions are squamous cell carcinoma and cutaneous habronemiasis.[11,12]

The prepuce should also be examined for lesions. Strictures of the preputial orifice may increase the risk of phimosis or paraphimosis. Bulls of the *Bos indicus* breeds often have a pendulous prepuce that is predisposed to traumatic injury, abscessation, stricture formation, and eversion.[5,13] Ulcerative posthitis (pizzle rot) caused by *Corynebacterium renale* in rams on a high-protein diet is the most common lesion of the prepuce.[14]

The scrotum, testicles, and spermatic cords should be examined for size, consistency, symmetry, and presence of lesions. Two scrotal testicles should be present, each smooth, resilient on palpation, and freely movable. Testes volume and consequently the amount of testicular parenchyma present are highly correlated with daily sperm production in all species. Each gram of testicular tissue should produce 15 to 20 million sperm per day. In ruminants, scrotal circumference has been determined to be highly correlated with testes weight or volume. Yearling beef bulls should have a scrotal circumference of 30 cm or more, depending on the animal's age and breed.[9] In stallions, measurements of total scrotal width or, more accurately, testicular volume have been evaluated and correlated to potential daily sperm production. Mature stallions should have a scrotal

10. Serologic tests

width of at least 8 cm. Testicular volume in stallions can be determined by the following steps[15]:

1. Measure the length (L), width (W), and height (H) of each testicle.
2. Volume of each testicle can be determined using the formula:

$$\text{Testicular volume (cm}^3\text{)} = 0.5233 \times L \times W \times H$$

3. Add the volume of each testicle to obtain total testicular volume.
4. Expected daily sperm production (DSP) (in billions of sperm per day) can be calculated using the formula:

$$\text{Expected DSP} = 0.024\,(\text{Total testicular volume in cm}^3) - 1.26$$

The epididymides should be palpated for position, size, and presence of lesions. The most common palpable abnormality in rams is epididymitis caused by infection with *Brucella ovis*, *Actinobacillus seminis*, or *Histophilus ovis*.[10,14,16] A definitive diagnosis is obtained by isolation of bacterial organisms in the semen and serologic testing.

Diseases of the accessory sex glands are diagnosed most frequently in bulls and stallions. Vesicular gland adenitis in both species is clinically recognized by the presence of leukocytes in the semen and enlargement, induration, and loss of lobulation noted during palpation and ultrasonographic examination of the glands per rectum.[17,18] Culture of the ejaculate is indicated to guide antibiotic treatment. Medications in the stallion may be delivered directly into the glands via urethroscopy. In stallions, azoospermia can be caused by bilateral sperm granuloma blockage of the ampullae. Lower than normal levels of alkaline phosphatase in the clear ejaculate will indicate a lack of epididymal contribution to the ejaculate. Transrectal ultrasound evaluation of the ampullae will demonstrate dilated ampullae, filled with hypoechoic fluid or mixed echogenicity. Treatment involves a combination of gentle transrectal massage, low-dose prostaglandin or oxytocin administration, and frequent semen collections in an effort to dislodge the granuloma. When the blockage is cleared, the first ejaculate will contain a large number of dead sperm with abnormal morphology. Subsequent semen collections should show improved semen quality. Frequent continuing semen collections will likely be necessary to prevent recurrence.

Libido and the ability to mate should be assessed after the physical examination. The male should be teased to a female in estrus. Interest in and interactions with the female and ability to gain an erection, mount, intromit the penis into the vagina (or into an artificial vagina), and ejaculate are noted. Libido and mating ability cannot be evaluated when using an electroejaculator to collect semen from ruminants. Tests for "serving capacity" have been described for bulls.

The evaluation of semen quality is a major part of the breeding soundness examination. Semen from stallions is collected into an artificial vagina. Semen from ruminants may be collected into an artificial vagina or obtained by use of an electroejaculator. Semen collected by electroejaculation usually has a higher volume and a lower concentration of spermatozoa than semen collected by an artificial vagina. Semen quality in ruminants is scored primarily on the basis of motility and morphology.[9] Evaluation of semen from stallions should include determination of volume, concentration, motility, and morphology. The motility of the spermatozoa should be evaluated microscopically on raw and extended semen immediately after collection. In ruminants, bright-field microscopy at ×40 to ×125 magnification is used to detect mass motion or swirling to evaluate gross motility. Changes in sperm concentration, progressive motility, or speed of progression of spermatozoa will decrease or eliminate the swirling effect. Phase contrast microscopy at ×200 to ×500 is used to evaluate motility of individual spermatozoa. Computer-assisted semen analysis (CASA) is commonly used at larger reproduction facilities.

Concentration can be measured by use of a hemocytometer, calibrated spectrophotometer or densimeter, CASA system, or image cytometry (e.g., NucleoCounter, ChemoMetec, Allerod, Denmark). Morphology can be evaluated microscopically, using stained semen samples (e.g., eosin-nigrosin stain or a variety of bright-field stains), phase-contrast, or differential interference contrast microscopy.

Ejaculates from stallions may be collected once daily for 5 to 10 days until daily sperm output (DSO) is achieved to fully evaluate potential fertility.[19] However, this is time consuming, labor intensive, and expensive. Consequently, most stallions are evaluated by the collection of two ejaculates 1 hour apart, with the total number of progressively motile, morphologically normal spermatozoa in the second ejaculate most critically evaluated.

The age of the stallion or male ruminant being evaluated for potential fertility may influence the semen parameters, measurements of the testicular size, mating ability, and libido. Puberty is attained in the stallion at 18 months, in the bull at 9 to 12 months, and in the ram and buck at 7 to 8 months.[20] Semen parameters and testicular size continue to increase until sexual maturity is reached. The season of the year in which the fertility evaluation is done may affect semen parameters in the stallion, ram, and buck.

Microbiological samples should be routinely collected when evaluating infertility in the stallion and when evaluating high-risk populations of bulls. Smegma samples should be collected from the prepuce of bulls and cultured for *Trichomonas foetus* and *Campylobacter fetus*. Swabs from the preejaculate and postejaculate urethra, semen, fossa glandis, and prepuce of stallions should be cultured for potentially pathogenic bacterial organisms, especially *Taylorella equigenitalis* (requires specific culture techniques), *Escherichia coli*, *Streptococcus zooepidemicus equi*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*.[11] The semen of rams should be cultured for *B. ovis*, *A. seminis*, and *H. ovis*.[10,14,16] Serologic testing for exposure to equine arteritis

virus (EAV), the causative agent of equine viral arteritis (EVA), is important for breeding stallions. Determination of negative serologic status should be required before vaccination against the virus may be performed.

Other tests that are occasionally performed to evaluate male reproductive function, health, or pathology include hormone analysis, chemical evaluation of seminal plasma, transmission electron microscopy of semen, karyotype, sperm chromatin structure assay, urethral endoscopy (stallion), and testicular biopsy.

After summarizing the results of the entire breeding soundness evaluation, stallions and male ruminants may be categorized into classifications such as satisfactory, questionable, or unsatisfactory. In bulls a fourth category of "decision deferred" may be used for young prepubertal bulls or mature bulls that have recently experienced a transient disturbance in spermatogenesis.

It must be emphasized that the breeding soundness examination is a measure of potential fertility.[21] True fertility can be determined only by the results of breeding trials or by conception and live birthrates in dams bred.

Cyclic Irregularity

Claudia Klein

Cyclic irregularities become evident in the display of irregular estrous cycles (i.e., an abnormal interval from one estrus to the subsequent estrus). Irregular estrous cycles can be physiologic, such as during the transition period in seasonal breeders; can be pathologic such as a sequel to endometritis; or may be an artifact, such as failure in estrus detection (Box 12.4).

Cattle

Irregular estrous cycles in the cow may result from a number of factors (Box 12.5). Detection of heat in cattle is challenging given that the average duration of estrus is 18 hours and in many cows may be appreciably shorter. Failure to detect heat in intensively managed herds bred by artificial insemination is common and is one of the most important management factors contributing to a perceived abnormal estrus interval.[22] Missed heats should be expected if the heat intervals approximate multiples of 21 days, the normal cycle length. Errors in estrus detection are further indicated when 1) more than 10% of the interestrus intervals are 3 to 17 days or 25 to 35 days long, 2) more than 5% of the cows have two artificial inseminations within 3 days, or 3) cows are calving early or are further in gestation than predicted from the last breeding when examined for pregnancy. Seventy percent of cows should have an interestrus interval of fewer than 30 days, and 60% should be in the range of 18 to 24 days. The ratio of 18- to 24-day cycles to 38- to 46-day cycles should be 5:1.[23] Evaluation of heat detection methods is important in artificial insemination programs. Cows need to be observed at least twice daily for signs of estrous behavior. Heat detection aids such as tailhead chalking (will be rubbed off), adhesive heat pads (will change color), and pedometry (record an increase in activity) are indispensable tools for efficient estrus detection. Especially pedometry can detect estrus accurately, is least labor intensive, and through a software program generates daily lists of cattle with increased activity.[24]

Silent heat, which is the lack of cycling cows to express estrous behavior (silent ovulation), occurs most commonly in the immediate postpartum period. More than 50% of cattle display a silent heat on their first ovulation postpartum with the incidence declining thereafter.[25] This may be related to insufficient progesterone priming of the behavior center for optimum expression of estrus. Lameness or general disease impairing an animal's ability to move will mask signs of heat

BOX 12.4

Causes of Cyclic Irregularity in Mares

Common Causes

Transition season
Erroneous heat detection
Diestrus ovulation
Intrauterine therapy
Diestral endometrial biopsy
Pneumovagina
Endometritis
Pubertal cycles
Early embryonic death
Spontaneous corpus luteum prolongation
Endophyte-infested fescue
Cervical dilation

Less Common Causes

Urovagina
Rectovaginal fistula
Ovarian tumors
Pyometra
Persistent follicles
Split heats
Endotoxemia
Hemorrhagic anovulatory follicles
Old age
Use of Deslorelin implant

Uncommon Causes

Contagious equine metritis
Corpus luteum inadequacy
Anabolic steroids
Progesterone therapy
Phosphorus deficiency
Sex chromosome anomalies
Administration of oxytocin during days 7 to 14 of the estrous cycle

BOX 12.5

Causes of Cyclic Irregularity in Ruminants

Common Causes

Erroneous heat detection
Endometritis
Intrauterine therapy
Cystic ovaries
Heat stress
Leptospirosis
Infectious bovine rhinotracheitis (IBR) (B)
Bovine virus diarrhea (BVD) (B)
Campylobacteriosis
Trichomoniasis
Embryonic death after maternal recognition of pregnancy

Uncommon Causes

IBR- or BVD-infected semen
Bluetongue-infected semen
Zearalenone toxicity
Ovarian neoplasia
Corpus luteum inadequacy
Copper deficiency (O, C)
Molybdenum deficiency (O, C)
Iodine deficiency
Phytoestrogen toxicity
Segmental aplasia of the uterus

B, Bovine; *C*, caprine; *O*, ovine.

VetBooks.ir

independently from its reproductive status. Silent heat can be diagnosed only through rectal palpation of the ovaries or the use of progesterone assay in milk or plasma.

While the cow cycles normally in the face of failure in heat detection or silent heat, true, irregular cyclicity does occur. Endometritis, through the release of prostaglandin, can result in premature lysis of the corpus luteum (CL) and therefore a shortened diestrus phase.[26] Cystic ovarian follicles, either in the form of follicular or luteal cysts, interfere with regular cyclic ovarian activity. This condition is mainly observed in high-yielding dairy cows during the first months postpartum. Estrogen-producing follicular cysts may result in nymphomania, a state of persistent or frequent heats. Progesterone-producing luteal cysts result in absence of estrous behavior and prolonged interestrus interval.[27] Early embryonic death occurring after the time period of maternal recognition of pregnancy will prevent lysis of the CL, and the cow will undergo a prolonged interestrus interval due to the action of progesterone.[28] A less common cause for prolonged diestrus is segmental aplasia of the uterine tract.[29] If ovulation occurs ipsilateral to a missing uterine horn, the CL will persist due to the lack of exposure to prostaglandin.

Mares

Irregular estrous cycles in the mare are most commonly encountered during the transitional period and are considered physiologic then. Follicles will initiate growth during the transition from winter anestrus to spring reproductive activity, resulting in estrous behavior. Due to inadequate gonadotropin, support follicles may fail to ovulate and eventually regress after a varying period of time leading to irregular estrus intervals.[30] Mares that have been artificially induced to develop a follicle and ovulate during seasonal anestrus using gonadotropin-releasing hormone (GnRH) or recombinant follicle-stimulating (FSH) usually do not display regular estrous cyclicity following the artificially induced ovulation till the onset of breeding season. Likewise, mares foaling during the nonbreeding season may display foal heat, which may be followed by a variable period of anestrus. Mares older than 20 years of age may experience irregular estrous cycles independent of the time of the year, and it is not unusual for mares older than 25 years of age to stop cycling altogether. During the regular breeding season, prolonged interestrus intervals may occur in association with diestrous ovulations.[31] Follicles developing during diestrus may either regress or, less commonly, ovulate. If this ovulation occurs on or after day 10 of diestrus, the newly resulting CL will be refractory to the actions of prostaglandin released from the endometrium around day 14 of the cycle. This becomes evident in a prolonged interestrus interval. Prolonged diestrus may also be observed following early embryonic death occurring after the time of maternal recognition of pregnancy. If a pregnancy is lost following formation of endometrial cups, the mare may not display regular cyclic activity during the remainder of that breeding season. Ovulation failures such as hemorrhagic luteinized follicles or anovulatory persistent follicles interfere with regular cyclicity. Anovulatory hemorrhagic follicles that luteinize may persist for more than a month without treatment, which is reflected in a prolonged diestrus phase. Anovulatory persistent follicles may or may not interfere with cyclic activity. Some mares will develop a new dominant follicle despite the presence of this abnormal structure, whereas other mares will not show signs of heat as long as these structures are present.[32] Persistent estrous or stallion-like behavior is commonly described as a sequel to the presence of a granulosa cell tumor.[33] Following unilateral ovariectomy, mares usually return to regular cyclicity within 6 months. Endometrial irritation such as endometritis or uterine lavage can result in shortened intervals between heats due to the release of prostaglandin.[34] A less commonly encountered cause of irregular cyclicity in mares is chromosomal abnormalities such as XO genotype.[35] Iatrogenic causes of irregular cyclicity are the accidental administration of prostaglandin (shortened luteal phase) or the twice-daily administration of oxytocin during days 7 to 14 (prolonged luteal phase).[36]

Sheep and Goat

The first ovulation at the beginning of the breeding season is often not accompanied by overt signs of estrus due to the absence of progesterone priming. The corpora lutea arising from these ovulations often regress prematurely, again because of the inadequate progesterone priming. A pathologic cause of irregular or prolonged estrous cycles is the consumption of phytoestrogens from plants such as clover and alfalfa, which may lead to signs of irregular and prolonged estrous cycles.

Anestrus

Claudia Klein

Anestrus is the absence of estrous behavior and can be a physiologic state during pregnancy, lactation, or seasonal anestrus, or it may be a pathologic condition (Boxes 12.6 and 12.7). Anestrus can occur either in the face of or the absence of ovarian activity; in the case of the latter, acyclicity is present. Causes underlying anestrus can be subdivided into physiologic and pathologic. The lack of estrous behavior due to ovarian inactivity is physiologic in seasonal species and is mediated via melatonin levels, which vary with day length. The mare is a long-day breeder, whereas the ewe and doe are short-day

BOX 12.6

Causes of Anestrus in Mares

Common Causes

Season (fall, winter)
Poor heat detection
Corpus luteum persistence
Diestrus ovulation
Pregnancy
Early embryonic death after recognition of pregnancy
Fetal death after endometrial cup formation
Psychological impediments
Maternal behavior

Less Common Causes

Ovarian tumors
Pituitary tumors
Pyometra
Weight loss
Chronic disease
Lactation
Old age

Uncommon Causes

Gonadal dysgenesis
Intersex conditions
Progesterone therapy
Nonsteroidal antiinflammatory drugs (NSAIDs)
Phosphorus deficiency
Ovarian hypoplasia
Anabolic steroids
Zearalenone toxicity
Chromosomal abnormalities
Persistent endometrial cups
GnRH immunization
Deslorelin implants

breeders, although breed variations occur in small ruminants.[37] Certain breeds of sheep are less affected by the season and can have longer breeding seasons or practically cycle year-round. Some sheep and goats near the equator have cycles throughout the year presumably because of the consistency of the photoperiod. Prepubertal animals naturally do not show signs of estrus, as do some dams during lactation. The most common physiologic cause for the lack of estrous behavior is pregnancy; mares, however, are an exception because some of them may display signs of heat despite being pregnant. In intensively managed cattle herds bred by artificial insemination, failure in heat detection is a major contributor to perceived cases of anestrus.[38] A plethora of pathologic conditions can lead to anestrus, and a thorough examination of the history and evaluation of the reproductive tract is required for a definite identification of the underlying cause. Congenital conditions such as ovarian aplasia, chromosomal abnormalities, or freemartinism in cattle; intersex conditions that occur in polled goats; and gonadal dysgenesis in the mare are accompanied by the lack of estrous behavior. These animals frequently have rudimentary or hypoplastic ovaries.[39] Uterus unicornis will lead to persistence of the ipsilateral CL and subsequently interfere with regular estrous behavior.[40] Nutritional anestrus due to a negative energy balance during times of high milk production can lead to anestrus in cattle.[41] In mares, anestrus due to nutritional deficiencies is less commonly observed than in cattle. In beef cattle nursing their offspring, a delayed resumption in ovarian activity is frequently observed.[42] This is related to both the physical act of the calf nursing and olfactory and auditory cues received by the dam from the calf. Anestrus related to lactation is not observed in mares. Mares foaling during the short day–length period that have not been kept under lights for 2 months preceding parturition may show a first ovulation within the first 2 weeks postpartum (i.e., foal heat) but then revert to an anestrous state with cyclic activity not resuming until increasing day length. Persistent endometrial cups, a rare condition in mares, may also lead to the failure of presenting regular estrous activity in the period postfoaling.[43] Both conditions may easily be misinterpreted as cases of lactational anestrus. In mares, psychogenic factors have to be considered in the differential diagnosis for anestrus. A mare being overly protective of her foal or of nervous constitution may not show signs of heat. Teasing with a stallion may be necessary to elicit estrous behavior in these animals.

A variety of conditions can lead to hypothalamic or pituitary suppression, preventing the release of GnRH from the hypothalamus, in turn resulting in a lack of FSH and luteinizing hormone (LH) released by the pituitary. Consequent ovarian inactivity results in the absence of behavioral estrus. Most common underlying conditions are poor nutrition, heavy lactation, periparturient disease, weight loss, or idiopathic condition.

Any condition discussed in the Cyclic Irregularity section that results in prolonged luteal function will result in absence of overt estrous signs. Differential diagnoses further include the presence of cystic ovarian disease in cattle and anovulatory follicles in mares. Uterine abnormalities such as mucometra, hydrometra, and pyometra prevent the release of $PGF_{2\alpha}$ in ruminants.[44] Thus the CL persists and perceived anestrus results. Pyometra in the mare may result in anestrus if the endometrial damage is severe enough to prevent production of $PGF_{2\alpha}$. The presence of a mummified or macerated fetus in the ruminant uterus prevents release of $PGF_{2\alpha}$ and results in a persistent CL and perceived anestrus.[45] Ovarian atrophy leading to persistent anestrus can be seen in high-producing dairy cattle as a sequel to nutritional problems or can be occasionally encountered as an idiopathic condition in mares.[41] If no overt reason for ovarian atrophy can be identified, dysfunction at the hypothalamic-pituitary-ovarian axis has to be considered as a potential underlying cause. Iatrogenic causes of anestrus in mares, such as previous immunizations with GnRH or the application of a deslorelin implant, have to be considered, especially if the reproductive history of the mare is unknown.[46] Mares exposed to a deslorelin implant used to hasten ovulation can display pituitary downregulation induced by constant high GnRH input. Older mares undergo reproductive senescence, which is accompanied by atrophying ovaries and lack of cyclicity. Anecdotally, some mares coming off the race track show anestrous behavior and small ovaries on examination. No studies have been undertaken to determine the cause for this, but stress and possible medications during the racing career have been suspected.

Knowledge of the reproductive physiology of the species involved is essential to understanding the cause of anestrus. Determining the cause of anestrus relies on an in-depth general and reproductive history, a thorough physical examination, and evaluation of estrus detection programs involved. Pregnancy must be ruled out when dealing with any case of anestrus.

Repeat Breeder

Bruce W. Christensen

Managing repeat breeders is often frustrating and expensive. The repeat breeder is an animal that has been bred during three or more successive heat periods without being diagnosed pregnant.[47] An incidence of 10% to 15% repeat breeders is considered acceptable for dairies.[48] The incidence increases with the herd size and the level of milk production and with the use of artificial insemination.[48] This may be an even greater problem in the horse because pregnancy rates per cycle are normally between 60% and 70%, and 5% to 8% of mares lose their pregnancy in the first 4 months of gestation.[49] The use of ultrasonography and embryo collection indicates that the incidence of early embryonic death (EED) in the mare is likely even higher.[50] The syndrome of repeat breeders in mares is completely different from that in cows. In mares it is often associated with persistent endometritis. This is discussed in detail in Chapter 43.

The causes of repeat breeding are numerous and are related to male, female, and management factors (Boxes 12.8 and 12.9). The pathogenesis of repeat breeding involves either a failure of fertilization or EED.[48] Some etiologies, such as heat stress in the herd, may involve both mechanisms. Fertilization rates are normal in heat-stressed cows that are bred artificially, but heat stress increases the rate of EED. Heat stress can cause failure of fertilization by affecting spermatogenesis in males used in a natural breeding program.[51] When dealing with an individual repeat breeder, it is often wise to begin with the female. When several females are affected, the male should be eliminated as a source of the problem before proceeding. Management errors may be related to either male or female factors.

Fertilization failure is often the cause of repeat breeder syndrome. Studies have demonstrated delayed or inadequate release of LH, as well as consequent delayed ovulation, in repeat breeder cows compared with those cows showing normal fertility rates.[52] This observation has led to the investigation of GnRH (or its analogs) and prostaglandins as treatment options for repeat breeders, with some success.[53,54] In addition to LH abnormalities, repeat breeder cows showed prolonged duration of estrus, prolonged lifespan of the preovulatory follicle, and a late postovulatory rise in progesterone.[52] These changes negatively contribute to final oocyte maturation and competence in repeat breeder cows compared with unaffected cows.[55] Insulin has been shown to be an important mediator of follicular development, steroidogenesis, oocyte maturation, and subsequent embryo development,[56] and treatment with insulin has been shown to increase fertility in repeat breeder cows.[57] Workers in Japan have linked the repeat breeder syndrome with abnormal profiles of endometrial epidermal growth factor (EGF). Assays of EGF have been suggested as diagnostic tools, and EGF treatment has been suggested to restore fertility.[58,59]

Early embryonic death also contributes as a cause of infertility in repeat breeders.[48,50] The interval between heats may help distinguish between EED and failure of fertilization. Failure of fertilization usually does not affect the interestrus interval. However, EED may prolong the interestrus interval if the fetal wastage occurs after the time of maternal recognition of pregnancy. Maternal recognition of pregnancy occurs at approximately days 15 to 17 after estrus in the cow, days 11 to 14 in the mare, and days 12 to 13 in the ewe.[60] Animals experiencing EED after pregnancy recognition often have interestrus intervals corresponding to multiples of a normal cycle length. Luteal insufficiency is suspected to cause EED in some repeat breeder cows, and trials of exogenous progesterone supplementation have shown promise for maintaining pregnancy in young late-lactation repeat breeders.[61]

BOX 12.8

Causes of Repeat Breeding in Mares

Common Causes

Transition season
Endometritis
Poor timing of artificial insemination
Pneumovagina
Metritis
Endometrial fibrosis
Poor heat detection
Ovulation failure
Twins
Uterine lymphatic lacunae
Endometrial cysts
Early foal heat breed
Poor uterine clearance
Ventral uterine sacculation

Less Common Causes

Diestrus breeding
Urovagina
Rectovaginal fistula
Malnutrition
Pyometra
Heat stress
Poor semen quality
Old age
Endophyte-infested fescue

Uncommon Causes

Salpingitis
Hydrosalpinx
Oviductal adhesions
Oophoritis
Uterine neoplasia
Cervical neoplasia
Ovarian neoplasia
Parovarian cysts
Contagious equine metritis
Iodine deficiency
True hypothyroidism
Phosphorus deficiency
Zearalenone toxicity
Intersexuality
Gonadal dysgenesis, sex reversal, trisomy
Other karyotype abnormalities
Teratogenic factors
Vitamin A deficiency
Cervical trauma
Luteal insufficiency

Approach to Diagnosis

Clinical differentiation of EED from failure of fertilization is difficult. In addition to evaluation of heat detection and breeding techniques, it is important to obtain a detailed history. When dealing with a herd problem, the clinician begins by evaluating the male or males used or assessing the semen quality and techniques used for artificial insemination. When dealing with an individual repeat breeder, evaluation of the female is the first step.

Evaluation of the male should include evaluation of the animal's physical condition, including the genitalia. The quality of the semen should be checked. The male's libido and ability to mount should be determined by observation or through historic information. Examination of the male for venereally transmitted diseases, such as trichomoniasis and campylobacteriosis in the bull and contagious equine metritis in the stallion, may be warranted if other factors are ruled out. When dealing with an artificial insemination program, the semen quality should be

B, Bovine; *C*, caprine; *O*, ovine.

evaluated and the thawing, transporting, timing, and deposition techniques should be evaluated.

Errors in heat detection and the timing of breeding are major management causes of repeat breeding. Discussing and observing the methods used to determine when an animal should be bred are important in dealing with both the individual animal and the herd. Milk or serum progesterone determinations at the time of breeding have proved helpful in determining the accuracy of heat detection and timing of insemination. In some dairies 40% to 50% of the cows are bred at the wrong time.

Examination of the female or females should begin with evaluation of the body condition. Poor nutrition has been associated with repeat breeding.[62] The reproductive examination should include evaluation of the vulva, vagina, cervix, uterus, oviducts, and ovaries. Poor vulvar conformation may lead to pneumovagina and endometritis, resulting in EED. The spermicidal effect of urine may cause failure of fertilization in the mare or cow that pools urine in the vagina. Cervical canal occlusion can prevent fertilization. An abnormal uterine environment may also lead to repeat breeding. Endometritis with minimal intraluminal pus may cause failure of fertilization but often results in EED. Unlike ruminants, the mare may continue to display estrus while experiencing pyometra. The volume of pus present in the uterus will cause failure of fertilization. Hydrosalpinx or salpingitis may lead to failure of fertilization by blocking sperm or ovum passage. Ovulation abnormalities such as delayed ovulation or ovarian cyst formation may result in failure of fertilization. Whenever possible, including a uterine culture, cytologic smear, and endometrial biopsy as part of the examination is likely to help determine the cause of the infertility.

Differentiation of EED from failure of fertilization in repeat breeders has been facilitated by the use of embryo flushing techniques and ultrasonography. Collection of unfertilized ova indicates failure of fertilization; collection of degenerating embryos indicates early embryonic death. In ruminants, failure to collect ova or embryos may indicate oviductal blockage resulting in failure of fertilization. This is not the case for mares because they usually retain unfertilized ova in the oviducts.

Ultrasonic determination of pregnancy in the mare and cow has made early detection of pregnancy possible. Loss of an embryo after detecting it with ultrasound at 10 days of gestation confirms EED. Pregnancy wastage can be confirmed later in gestation with sequential rectal palpations of the reproductive tract or ultrasonic evaluation. Hormone assays are also helpful for confirming embryo or fetal loss.

An assay for eCG, previously called *pregnant mare serum gonadotropin* (PMSG), can be used to determine if a mare was pregnant long enough to stimulate formation of the endometrial cups and eCG production. eCG can be detected at about 40

days of gestation with these kits. The endometrial cups continue to produce eCG until 120 to 150 days of gestation even if the fetus dies. Therefore eCG can be used to confirm EED but not failure of fertilization. Progesterone determination cannot be used to confirm pregnancy in the mare or ruminants. However, it can be used to confirm nonpregnancy if the progesterone level is low early in the expected gestation. A bovine early conception factor test can be used to confirm fertilization, but it does not rule out EED later.

The fetally derived hormone-metabolite estrone sulfate has been used to determine the presence of a live fetus. It is detectable in the serum or urine of the dam if the fetus is alive after 45 days of gestation in the doe, 70 days of gestation in the ewe, 100 days of gestation in the mare, and 120 days of gestation in the cow.[63,64] Thus a decline in estrone sulfate indicates death of the fetus. Estrone sulfate is probably most helpful in confirming fetal loss in the doe and ewe because other techniques are available in the larger species.

Boxes 12.8 and 12.9 list the causes of repeat breeding in mares and ruminants. The causes have been divided into expected frequencies of occurrence.

Pregnancy Loss

Mats H.T. Troedsson

Pregnancy loss refers to the failure of a conceptus to be maintained successfully to term. Pregnancy loss may be classified as early embryonic death (EED), abortion, or stillbirth, depending on the gestational stage when the pregnancy loss occurred. *EED* is the death of a conceptus before organogenesis is complete (≈55 days in horses, 45 days in cattle, and 34 days in sheep).[65] *Abortion* refers to pregnancy loss after the completion of organogenesis. *Stillbirth* refers to the delivery of a nonviable fetus at or near term.

Early Embryonic Death

The exact incidence of EED in any species is difficult to determine because most losses occur before pregnancy can be routinely diagnosed. Embryonic death early in pregnancy usually results in reabsorption of the embryonic tissues and fluids. Consequently, EED cannot be distinguished from failure of fertilization in most instances. However, despite the lack of clinical evidence, EED probably accounts for the largest percentage of reproductive wastage in large animals. The incidence of EED has been estimated at 5% to 24% in mares,[66] 30% to 35% in cows,[67] and 20% to 30% in ewes.[68] The rate of EED is generally higher in subfertile or repeat breeder females and in older females.

Loss of the embryo before maternal endocrine recognition of the pregnancy (i.e., days 11 to 14 in the mare, days 15 to 17 in the cow, and day 12 in the ewe and doe) results in return to estrus at the normal time. Embryonic loss after this critical period may result in persistence of the CL in horses, pseudopregnancy in goats, or irregular returns to estrus in cattle.

Chromosomal and genetic defects of the oocyte, sperm, or embryo; a poor oviductal or uterine environment; endocrine dysfunction; and maternal stress are all considered important factors in the pathogenesis of EED.[66,69] Infectious agents such as *T. foetus* and *C. fetus* subsp. *venerealis* in cattle[69] and *Streptococcus zooepidemicus* and other bacteria in horses[70] can cause EED. Endogenous release of $PGF_{2\alpha}$ during the CL-dependent stage of gestation may result in luteolysis and subsequent embryonic loss or abortion in any large animal species. Primary luteal insufficiency associated with low plasma progesterone concentrations has been suggested as a possible cause of EED in horses, cattle, and sheep, although scientific evidence is limited.[67,71,72]

Abortion

The rate of abortion after pregnancy diagnosis at 60 days of gestation has been estimated to be approximately 10% in horses[73] and 3% to 4% in cattle.[74] Fetal death may result in abortion (expulsion of the fetus from the uterus) or retention of the fetus in the uterine lumen, with subsequent fetal maceration or mummification. In animals with a CL-dependent pregnancy for all or most of gestation (cows, goats, llamas), death of the fetus usually results in the abortion of an autolyzed fetus because of a delay between the time of fetal death and lysis of the CL. In species that do not depend on a CL for maintenance of pregnancy for most of gestation (e.g., mares and ewes), fetal death causes an immediate decrease in placental progestogen production and rapid expulsion of a relatively nonautolyzed fetus. *Mummification* is characterized by fluid reabsorption from a fetus retained in a sterile uterine environment. Fetal mummification is most common in multiparous species with a CL-dependent pregnancy (e.g., sows) and is rare in uniparous species that are CL independent for most of gestation (e.g., mares). *Maceration* refers to the degenerative changes that occur in a fetus after retention in a nonsterile uterine environment. Fetal maceration may be associated with significant maternal endometrial damage.

HORSES. Equine abortions may be characterized as infectious or noninfectious in origin. Most equine abortions occur secondary to placental dysfunction. One of the most commonly diagnosed infectious causes of abortion in horses is equine herpesvirus type 1 (EHV-1).[73] Abortion caused by EHV-1 usually occurs after 7 months of gestation as a result of exposure to the virus with subsequent viremia and damage to the placental vasculature. Exposure of pregnant mares to EAV may lead to abortion within 1 to 3 weeks after initial viral exposure. Abortion may be caused by vasculitis, edema, and necrosis in the endometrium and allantochorion.[75] Exposure to EAV at breeding will not cause a mare to abort later in gestation. Abortion rates may range from 10% to 70% during an outbreak.

Consumption of eastern tent caterpillars (larva of *Malacosoma americanum*) by mares causes abortion. The syndrome has been named *mare reproductive loss syndrome* (MRLS). Pregnancy loss before 150 days of gestation is characterized by hyperechoic amniotic and allantoic fluids on ultrasonographic examination along with a dead or dying fetus.[76,77] Near-term abortions are characterized by histologic lesions in the placenta and umbilical cord. In many cases, endometrial cultures are positive for non–beta-hemolytic streptococci and *Actinobacillus* species. Diagnosis of MRLS is based on four variable factors: placental lesions, culture of characteristic bacteria from fetal tissues, conformation of increased caterpillar exposure, and diagnostic elimination of other known causes of abortion (John Roberts, personal communication). The microscopic lesions observed in natural late-term MRLS cases are primarily the result of host response to bacterial infection, with the most common isolates being non–beta-hemolytic streptococci and actinobacilli.

During an outbreak in central Kentucky in 2001 and 2002, a variety of nonspecific lesions were reported that included placental edema, fetal pneumonia, and hemorrhages in the heart and placenta. During this outbreak, inflammation of the umbilical cord (funisitis), specifically the amniotic segment, was observed in 78% of cases.[78] Funisitis was also observed in necropsied cases during a 2006 Florida outbreak.[79] The lesion is initiated as a suppurative to pyogranulomatous response between the outer circumferential stroma and the outer tunica adventitia of major umbilical vessels and progresses outward to involve or ulcerate the amniotic surface of the umbilical cord.[79,80] Other causes of equine abortion such as noninfectious umbilical cord lesions, leptospirosis, and EHV should be ruled out by appropriate diagnostic tests. In addition, if a horse farm

VetBooks.ir

encounters unilateral endophthalmitis or pericarditis in the general population, MRLS should be elevated as a differential diagnosis for unsolved abortions.[81,82]

Crosiella equi, *Amycolatopsis* spp., and *Streptomyces* spp. have been associated with chronic placentitis and subsequent late-term abortion, stillbirth, and premature birth.[83,84] The condition is often termed *nocardioform placentitis* due to similarities of the causative agents to the *Nocardia* species. The pathogenesis, route of infection, or risk factors have not been identified for the disease. Lesions are typically located in the ventral aspect of the uterine body and base of the uterine horns. Gross lesions are easily recognized as a brownish, thick, and tenacious exudate on the chorionic surface. The causative bacteria have been isolated only from clinical cases and not from the environment.[85]

Leptospira species have also been identified as a significant cause of equine abortion in Kentucky.[86] *Leptospira interrogans* serovar Pomna type *Kennewicki* is most commonly causing abortion in horses in North America, but other serovars such as Grippotyphosa and Hardjo have also been implemented in equine abortions.[87,88] Environmental wet conditions are considered important to dissemination of *Leptospira* from wildlife to horses.

Bacterial and fungal abortions in mares are primarily caused by infections that ascend through the cervix, causing placentitis and subsequent fetal infection. The bacterial organisms most commonly cultured from aborted fetuses include *Streptococcus* species, *Escherichia coli*, *Pseudomonas* species, *Klebsiella* species, and *Staphylococcus* species. The most frequently recovered fungi are *Aspergillus* species.

The most common noninfectious cause of equine abortion is twin pregnancy.[73] Inability of the uterus to support two fetuses to term because of insufficient placental support may result in abortion at any stage of gestation but is most common after 7 months. Early diagnosis of pregnancy using ultrasonography allows for highly successful manual reduction of one twin if done before day 16 of pregnancy. This technique has significantly reduced the incidence of abortion caused by twin pregnancies.

RUMINANTS. Infectious bovine rhinotracheitis–infectious pustular vulvovaginitis (IBR-IPV) virus and bovine virus diarrhea–mucosal disease (BVD-MD) virus are two of the most common viral causes of abortion in cattle.[89] Bacterial abortions caused by *Brucella abortus*, *Arcanobacterium (Actinomyces) pyogenes*, *Bacillus* species, *Listeria monocytogenes*, *E. coli*, *Leptospira* species, and *Pasteurella haemolytica* and fungal abortions caused by *Aspergillus* species and *Mucor* species usually result from hematogenous spread and localization in the placenta.[90] Protozoal abortion, caused by *Neospora* organisms, has been recognized as a significant cause of abortion in cattle worldwide.[91] Epizootic bovine abortion (EBA) is a common cause of third-trimester abortion in susceptible heifers and cows inhabiting the foothills of the Sierra Nevada mountain range of California, Nevada, and Oregon.[92] The Pajaroello tick, *Ornithodoros coriaceus*, is responsible for transmitting the causative agent, which has been identified as a delta proteobacteria, unofficially named *Pajaroellobacter abortibovis* when it feeds on pregnant cows.[93,94]

Campylobacteriosis (vibriosis), caused by *C. fetus* and *C. fetus* subsp. *jejuni*, and enzootic abortion of ewes, caused by *Chlamydia psittaci*, are the most common infectious causes of abortion in sheep.[95] They are characterized by abortion in the last 4 to 6 weeks of gestation, premature births, stillbirths, and birth of weak, infected lambs. *C. psittaci* is also the most common cause of infectious abortion in goats in the United States.[96]

Noninfectious causes of large animal abortion include genetic or chromosomal factors, maternal stress, inadequate nutrition, vitamin or mineral deficiencies, ingestion of poisonous plants or other toxins, hormonal factors, environmental factors, physical factors, and certain medications.

Approach to Diagnosis of Abortion

A definitive diagnosis is reached in 20% to 40% of bovine abortions,[65] 50% to 60% of equine abortions,[73] and 30% to 40% of sheep abortions.[97] The generally low diagnostic success is a result of the complexity of the condition (Boxes 12.10 and 12.11). Abortion involves disease in the maternal, placental, and fetal compartments individually or together, and all these compartments have to be examined thoroughly. In addition, a "triad" of determinants for animal disease has to be considered: 1) the presence of a pathogenic organism, 2) the environment in which a host lives, and 3) the susceptibility of the host to the disease.[98] To enhance diagnostic success, information and samples must be collected from the fetus, placenta, dam, and herd. A thorough history should be obtained, including the gestational age of the fetus; reproductive, medical, and vaccination history of the dam and other individuals in the herd; previous abortions and diagnoses; new arrivals to the herd and contacts of the animal with other herds; potential causes of maternal stress; possible access to toxins and poisonous plants; and sources of water and nutrition.

A physical examination that includes all body systems should be performed on the aborting dam. Examination of the reproductive system should include palpation or ultrasonography of the reproductive tract per rectum, speculum examination of the vagina, and digital examination of the cervix. Samples should be collected from the vagina, uterus, or both, for culture and cytologic studies. Paired serum samples from the dam and other females in the herd (10 animals or 10% of the herd, whichever is greater) may also help demonstrate an immunologic response to an infectious agent. Maternal serologic testing is generally most useful if paired samples are submitted, combined with accurate information about the animal's vaccination history. However, postabortion titers from cows that aborted can be compared with titers from unaffected cows in the herd at a similar stage of lactation. Demonstration of a fourfold rise in titer between acute and convalescent serum samples suggests recent exposure to an agent, but the presence of antibodies does not necessarily indicate that the agent caused the abortion. An exception can be made for brucellosis, for which a high titer from a single sample can be diagnostic.

For optimal diagnostic efficiency, the entire aborted fetus and placenta should be submitted to a diagnostic laboratory for necropsy. If this cannot be done, a prompt necropsy should be performed and collections of fetal, placental, and maternal samples should be submitted to a diagnostic laboratory (Table 12.1).

A systematic necropsy must be performed on the aborted fetus. Fetal age and development may be assessed by measuring crown-rump length, hair patterns, and color. Meconium staining of the skin suggests uterine fetal distress. The condition of the fetus, including the degree of autolysis, should be noted. A careful examination for fetal anomalies (e.g., cerebellar hypoplasia, hydrocephalus, cleft palate, cardiac anomalies) should be performed. Histopathologic samples should be immersed in a volume of 10% buffered formalin (or Bouin fixative) equivalent to 10 times the volume of tissue. Samples for culture, virus isolation, and fluorescent antibody tests should be submitted on ice in separate sterile containers. A sample of abomasum and stomach contents should be aseptically collected for culture. Fetal heart blood or thoracic fluid may be collected for serologic evaluation. A late-term fetus is immunologically competent, and high titers may indicate activity of a pathogenic agent. Serologic testing of fetal fluids can be useful both in detecting a nonspecific active fetal immune response (total immunoglobulin [IgG]) and for titers against a specific antigen.

The fetal membranes should be examined for size, weight, degree of autolysis, condition, and completeness. Samples of

placental tissue, especially areas with lesions, should be collected for histologic examination, impression smears, bacterial culture, virus isolation, and fluorescent antibody tests. The equine placenta should be examined for integrity, lesions, and distribution of chorionic villi. The normal equine placenta is everted after expulsion, with the allantoic surface presented outward and chorioallantois ruptured at the site of the cervical star. Blood may be collected from the free end of the cord. The allantoic surface should be examined for abnormalities such as multiple allantoic pouches that may indicate compromised fetal circulation.[99] The chorionic surface of the placenta should be examined for lesions and distribution of chorionic villi. Areas of avillous chorion are normally observed in association with the cervical star, narrow folds over large vessels, and areas opposing endometrial cups. Absence of chorionic villi over a circumscribed area is characteristic of twins and represents the region where two placentas were in contact. The region of the placenta adjacent to the cervix should be examined for loss of chorionic villi and the presence of inflammatory exudate, a hallmark of ascending infection. In cases of nocardioform placentitis, a characteristic thick and sticky exudate often covers an avillous area of the chorion at the ventral part of the site of the uterine body and base of the horn.

The cotyledons and intercotyledonary spaces of the ruminant placenta should be carefully examined for lesions. Autolytic changes of the placenta may be difficult to interpret. Some normal features of the bovine placenta must be kept in mind.[73] Amniotic plaques are present on the inner surface of the amnion and on the umbilical cord. They are most prominent at 3 to 7 months of gestation. Necrotic areas of the chorioallantois in the tips of the uterine horns are also normal and caused by insufficient vascularization to that area. Mineralization of the placenta is normal during the first months of gestation but may reflect placental injury associated with infection at the end of gestation.

All aborted fetuses and placental tissues should be handled with care, and tissues not submitted to a diagnostic laboratory should be burned or buried. Dams that have aborted should be isolated from the remainder of the herd.

Fescue Toxicosis

Karen McDowell

Tall fescue (*Lolium arundinaceum* [Schreb.] Darbysh.) is one of the most widely grown perennial grasses in the world and covers approximately 14 million ha in the United States alone. It can be infected with an endophytic fungus, *Epichloë coenophiala* (previously classified as *Neotyphodium coenophialum* or *Acremonium coenophialum*), which, in a symbiotic relationship with the plant, produces a variety of potentially toxic alkaloids that may adversely affect grazing livestock.[100,101] It is the ergot alkaloids, a class of compounds including ergopeptines, lysergic acid amines, and clavines, that are the principle toxins responsible for fescue toxicosis in livestock.[102–104] Perennial ryegrass (*Lolium perenne* L.) may be infected with a similar endophyte, *N. Lolli*, and also produce ergot alkaloids, resulting in a toxicosis in livestock that is similar to fescue toxicosis.[105] Tall fescue toxicosis is the major grass-induced toxicosis in the United States,[106] and ergovaline is the most abundant ergot alkaloid in tall fescue.[103]

Clinical Signs of Fescue Toxicosis

Ergot alkaloids have an ergoline ring structure with a molecular architecture similar to various biogenic amines, including dopamine, serotonin, norepinephrine, and epinephrine, and this structural similarity allows them to bind to the respective biogenic amine receptors.[103] Clinical signs of fescue toxicosis in livestock have been well documented.[106–112]

TABLE 12.1

Tissue Samples to Be Submitted for Diagnosis of Cause of Abortion

Source	Preservation Method	
	Chilled or Frozen	Fixed[a]
Aborted fetus	Lung, liver, kidney, spleen, thymus, skeletal muscle, heart, heart blood, abomasum, and stomach contents	Lung, liver, kidney, spleen, thymus, skeletal muscle (diaphragm), heart, adrenal gland, lymph node, thyroid, brain, gonads
Placenta	Allantochorion (ruminants: cotyledons and intercotyledonary areas), allantoamnion, amniotic fluid, cord blood	Allantochorion (ruminants: cotyledons and intercotyledonary areas), allantoamnion, umbilical cord
Dam or herd	Paired serum samples, vaginal or uterine swabs	

[a]10% Formalin or Bouin fixative should be used.

Historically, the endocrine hallmark of fescue toxicosis in several species has been a decrease in circulating concentrations of prolactin.[112,113] Prolactin is secreted from the lactotrophs of the anterior pituitary gland, and control of its secretion is complex and not completely understood. However, inhibition by dopamine (from the hypothalamus) is a major regulator of its release.[114] Dopamine exerts inhibition of prolactin by interacting with the dopamine type-2 receptors (DRD2) of the lactotroph.[112] Ergovaline is a dopaminergic agonist, and it is through interaction with this DRD2 receptor that it inhibits release of prolactin. Dopamine receptors in ovarian tissues, including the CL, have been reported for a number of species, including horses[115] and cattle,[116] but the role of those receptors in fescue toxicosis, if any, has not been fully elucidated.

A second hallmark of fescue toxicosis is vasoconstriction, which has been reported in cattle,[117–119] sheep,[120,121] goats,[122]

and horses,[123–126] and this vasoconstriction may adversely affect reproductive performance.

Horses

In horses the most frequently reported problems associated with endophyte infected (E+) fescue consumption are in late pregnancy and include altered hormone concentrations, extended gestation, thickened placenta, premature placental separation, placental retention, dystocia, birth of dysmature foals, increased foal and placental weights, and agalactia.[109,113,127] Pregnancy may be prolonged as much as 2 to 4 weeks.[109,127,128] For pregnant mares grazing E+ versus E– (endophyte negative) fescue, Monroe[109] reported significantly reduced circulating prolactin concentrations throughout gestation, as well as reduced progesterone and estrogen concentrations at foaling. Gestation length averaged 360 days for mares on E+ fescue and 333 days for mares on E– fescue, and more mares grazing E+ fescue had retained and thickened placentas than in mares grazing E– fescue. Similarly, Cross[113] reported increased gestation length, agalactia, and weak and dysmature foals, as well as reduced concentrations of progesterone in pregnant mares grazing E+ versus E– fescue.

In addition to lactogenesis,[129] prolactin also exerts effects on steroidogenesis (estrogens, progesterone and testosterone)[130,131]; hair growth and shedding[132]; libido; and synthesis of surfactant by the fetal lungs,[133] so perturbations in prolactin secretion may affect a variety of systems. Importantly, prolactin may also exert an effect on the feto-placental unit by altering steroid synthesis and/or metabolism and maturation of the fetal adrenal-pituitary axis necessary for parturition.[107] Placental lactogens have not been identified in mares, and as such physiological effects related to inhibition of pituitary prolactin release associated with fescue toxicosis in pregnant mares may be severe.

Normally progestins in the maternal circulation of pregnant mares increase and estrogens tend to decrease in the last 60 days of gestation. Approximately 24 to 48 hours before parturition progestins decrease dramatically, thus causing an increase in the estrogen-to-progestin ratio.[134] However, studies have shown that late-gestation mares consuming E+ fescue do not have the decreased estrogens or increased progestins at the expected time of parturition.[107,109] In addition, the placental hormone relaxin tends to be lowered when pregnant mares graze E+ fescue.[135] Alterations in these hormone concentrations, along with the possibility that the ergot alkaloids from E+ fescue may interfere with the maturation of the fetal hypothalamic-pituitary-adrenal axis and the ability of the fetus to produce cortisol and thyroid hormone,[113,136,137] may contribute to the extended gestation exhibited by mares consuming E+ fescue.

Youngblood and coworkers[138] fed pregnant mares, between 65 and 100 days gestation, either E+ or E– fescue seed, added to their diet, for 10 days. Serum concentrations of prolactin were not different between the treatment groups. Mean concentrations of progesterone were greater in the mares fed E+ fescue seed, but there was no change in progesterone concentrations over time compared with pretreatment values, and there were no incidences of pregnancy loss. There was, however, a significant decrease in plasma concentrations of endogenous catecholamine activity (3,4-dihydroxyphenyl acetic acid) that occurred in the E+ treated mares, suggesting an endocrine disruptive effect of hypothalamic origin.

Recently, McDowell and coworkers (unpublished) allowed pregnant mares to graze and foal on pastures planted in a novel endophyte (NE) fescue versus those planted in a mixture of orchard grass and Kentucky bluegrass (OGBG). There were no differences in prolactin, progesterone, or estradiol concentrations; foaling rates; or placental weights among the mares on the different pasture types. In addition, foals from the mares grew at comparable rates regardless of pasture. The NE fescue pastures contained negligible ergovaline. Novel endophyte fescues have been developed to retain alkaloids that confer benefit to the plants but not those that are deleterious to grazing animals.[139,140]

Reports of the effect of E+ fescue on estrous cycles and/or early pregnancy rates in mares differ. Arns[141] reported no differences in pregnancy rates, cycles per pregnancy, or estrous cycle lengths in mares consuming E+ versus E– fescue seed, whereas Brendamuehl[142] reported prolonged luteal function, decreased pregnancy rates, and higher early embryonic death rates in mares grazing E+ versus E– fescue pastures. The Arns study reported decreased prolactin in the mares receiving E+ fescue seed, whereas when Hestad and McDowell[124] compared cycling, nonbred mares fed either E+ or E– fescue seed, the E+ seed resulted in reduced serum prolactin concentrations only associated with the periovulatory prolactin surge, but not during diestrus. Hestad also reported decreased blood flow to the corpus luteum (CL) in the mares receiving the E+ seed compared with mares receiving E– seed.

For pregnant mares, it is generally recommended that animals be removed from E+ fescue pastures 30 to 90 days before expected parturition. Both horses and cattle respond well to treatment with a DRD2 receptor antagonist, such as domperidone.[113,143,144] Further discussions and dosing recommendations have been given by Cross,[113,145] Evans,[107] and Jones.[146]

That E+ fescue causes vasoconstriction in horses has been demonstrated both in vivo[124,126,147] and in vitro.[123,148] This vasoconstriction likely contributed to the decreased blood flow in the CL in cycling mares reported by Hestad.[124] Decreased blood flow in the CL, while not affecting interovulatory intervals in the Hestad study, might have contributed to increased lengths of diestrus in the 1994 Brendemuehl study, by contributing to CL resistance to $PGF_{2\alpha}$.[149]

Responses of individual horses grazing the same pastures are variable, and there are currently no convenient and inexpensive laboratory assays to determine fescue alkaloid concentrations in the circulation of horses grazing E+ pastures. Even if there were, the minimal amounts of alkaloids necessary for an animal to develop premonitory signs of fescue toxicosis have not been established. It has frequently been reported that pastures with ergovaline concentrations below approximately 300 ppb do not cause detrimental effects in horses.[150] However, minimal "safe" levels of ergot alkaloids that do not result in fescue toxicosis in horses are not known, and animals grazing in the same pastures likely consume different amounts of fescue grasses. Thus a sensitive measure of biological responses to fescue toxicosis is necessary. To that end, McDowell and coworkers[124,126,147] proposed that monitoring vasoconstriction of the palmar artery in horses can provide a convenient, noninvasive, and satisfactory biomarker to determine premonitory signs of fescue toxicosis.

Ruminants

The most consistent deleterious health effects associated with fescue toxicosis in ruminants are due to vasoconstrictive properties of the ergot alkaloids. The vasoconstrictive effects of ergot alkaloids are well documented in cattle[151–153] and sheep.[154] Fescue toxicosis in ruminants is best characterized by the two maladies of "summer slump" in warm climates and "fescue foot" in cold climates.[110–112] Summer slump is associated with decreased weight gain, elevated body temperature and respiration rates, shade-seeking behavior, rough hair coat, excessive salivation, and reduced milk production. Fescue foot is characterized by tenderness and/or swelling around the fetlock, lameness, tissue necrosis, and potential sloughing of the hoof, tips of ears, or tail switch. Clearly the previously described conditions may directly and indirectly affect reproductive performance, particularly elevated body temperatures and decreased weight gain associated with summer slump.

Fescue toxicosis associated with decreased reproductive performance in ruminants has been reported.[111,155] Cattle grazing

VetBooks.ir

E+ fescue pastures, compared with nontoxic forages, typically have reduced dry matter intake, reduced body condition scores, and reduced calving rates.[155–158] However, reports of reduced reproductive performance have not been consistent. Pregnancy rates for cows consuming E+ fescue were reduced 7% to 39% compared with control cows,[159,160] but other reports showed no reduction in pregnancy rates.[161,162] Serum progesterone concentrations may be reduced in heifers[143] and ewes,[163] and age of the animal may influence the effect of E+ fescue consumption on reproductive performance in cattle.[162] Jones[143] reported that heifers consuming E+ diets had shorter estrous cycle lengths and lower midcycle progesterone concentrations than heifers on E– and commented that vasoconstriction in the ovary may result in decreased peripheral progesterone concentrations.

Consumption of E+ fescue causes decreased concentrations of prolactin in cattle and sheep. This decrease in prolactin causes a decrease in milk production,[164] but rarely complete agalactia, as ruminants have placental lactogens that are thought not to be affected by fescue toxicosis. In addition to decreased prolactin production, cattle grazing E+ fescue also have altered expression of over 500 different genes in the pituitary gland, including genes controlling growth hormone, GnRH and ACTH,[165] decreased glutamatergic neurotransmission capacity,[166] and altered expression of several liver genes, including those involved in immune responses, oxidative phosphorylation, and ATP synthesis.[167]

Male Reproductive Function

E+ fescue may negatively impact reproductive performance in bulls and rams. Looper[156] reported that bulls grazing toxic E+ fescue pastures had reduced sperm motility and morphology compared with bulls grazing NE (nontoxic) pastures and that semen quality in bulls grazing E+ pastures was decreased as ambient temperature increased. In other studies, ergot alkoids inhibited sperm motility[168] and reduced IVF embryo cleavage rates.[169] Jones[170] reported that bulls fed a diet containing E+ fescue seed had increased scrotal temperature, reduced scrotal circumference, and increased sperm concentration compared with bulls fed a control diet. In addition, studies using Doppler ultrasonography demonstrated constriction of blood flow to the testes of bulls fed E+ fescue seed or allowed to graze E+ fescue pastures.[171] However, it is difficult to differentiate between direct effects of fescue toxicosis on male fertility versus effects of increased core and/or testicular temperatures due to vasoconstriction.

There is little information on the effects of E+ fescue on stallion fertility. One study showed no adverse effects of E+ fescue seed consumption on sperm motility, number, morphology, or testicular size, but it did result in reduced gel-free semen volume compared with control stallions.[172] Clearly, much more information on potential effects of fescue toxicosis on male fertility is necessary.

Mitigating Fescue Toxicosis in Grazing Livestock

Approaches to ameliorating adverse effects of fescue toxicosis have been reviewed[113,145,173–175] and include, among other things, renovation to remove or reduce the amount of E+ fescue in pastures; chemical suppression of seedheads in fescue; removal of animals from E+ infected pastures during times of growth or reproductive performance that may be affected by E+ fescue, using NE or E– tall fescues; and treating the animals with domperidone. Interestingly, clover isoflavones have been demonstrated to relieve alkaloid-induced vasoconstriction in goats,[122] and a single polymorphism in the *DRD2* receptor gene has been associated with resistance to fescue toxicosis in cattle.[176,177]

Ergotism in Human Populations—in Medicine and Disease

For interesting discussions on ergotism in human populations, see Strickland,[112] van Dongen and Groot,[178] and Schiff.[179]

Approach to Diagnosis of Fescue Toxicosis

James P. Brendemuehl

Definitive diagnosis of fescue toxicosis involves identification of the causative endophytic fungus in forage or seed samples by microscopic examination (Boxes 12.12 and 12.13). Ergopeptine concentrations may additionally be determined by high-pressure liquid chromatography analysis or specific enzyme-linked immunosorbent assay (ELISA). A presumptive diagnosis of fescue toxicosis can be made in cattle on the basis of expression of the characteristic clinical signs of hyperthermia; excessive salivation; long, rough hair coat; necrosis of the tail

BOX 12.12

Manifestations of Fescue Toxicity in Mares

Agalactia, hypogalactia
Hypoprolactinemia
Decreased relaxin prepartum
Prolonged gestation
Early embryonic death
Cyclic irregularity
Dystocia
Premature allantochorion separation
Allantochorion edema
Increased placental weight
Retained placenta
Corpus luteum persistence
Decreased pregnancy rates
Decreased total progestagens prepartum
Poor neonatal viability
Reduced colostral immunoglobulin G (IgG) absorption
Neonatal hypoadrenalism
Neonatal hypopituitarism
Neonatal hypothyroidism
Fetal oversize
Hirsutism
Hyperhidrosis

BOX 12.13

Manifestations of Fescue Toxicity in Ruminants

Agalactia, hypogalactia
Reduced calf birth weight
Hypoprolactinemia
Reduced serum cholesterol
Reduced conception rates
Reduced pregnancy rates
Early embryonic death
Cyclic irregularity
Delayed return to cyclicity postpartum
Dystocia
Hyperthermia
Hyperpnea
Hirsutism
Reduced weight gain
Photosensitization
Necrosis of the digits
Necrosis of the ears and tail
Fat necrosis

and ear tips; and fat necrosis in association with consuming fescue forage. Hypoprolactinemia is supportive of the diagnosis, but the assay is not commercially available.

A presumptive diagnosis of fescue toxicity in the pregnant mare is based on the observation of failure of normal mammary development for gestational stage. Prolongation of gestation is commonly reported as well. An accurate breeding history should include dates of breeding, dates of confirmed pregnancy diagnosis, and absence of parturition at the anticipated time. A history of recent exposure to fescue pasture or hay is supportive. In tall fescue–endemic areas, pastures that contain tall fescue grass should be considered infected with the endophyte unless specific testing has confirmed otherwise. Determination of total plasma progestogen concentrations is a sensitive indicator of endophyte exposure after 300 days of gestation.[180]

Management of a mare suspected of endophyte exposure should consist of removing the mare from the suspected pasture or hay source and maintaining the mare in a stall or dry lot under close observation. High-quality hay, preferably legume, should be provided. Because of the increased incidence of dystocia in mares grazing endophyte-infected tall fescue, close monitoring of the mare and attendance at parturition is critical to minimize risk to the mare and loss of the foal. Removal of mares from infected fescue by day 300 of gestation has been demonstrated to alleviate the toxic effects on the mare and foal. Removal after day 300 carries an increased risk of prolonged gestation, agalactia, dystocia, and neonatal death. Induction of parturition is not recommended because of the high incidence of fetal dysmaturity, fetal oversize, and failure of pelvic relaxation associated with endophyte exposure. Elective cesarean section deliveries of postdate gestation mares have resulted in significantly higher foal survival rates than spontaneous deliveries.

Where removal of pregnant mares from infected fescue is not practical or mares are inadvertently grazed on endophyte-infected fescue beyond the recommended stage of gestation for removal, pharmacologic intervention is warranted. Several DA_2 dopamine receptor antagonists—perphenazine,[181] fluphenazine,[182] and domperidone[183]—and the dopamine depleter reserpine[184] have been investigated prophylactically to prevent or therapeutically to treat clinical fescue toxicosis. Perphenazine[181] and fluphenazine[182] have demonstrated mixed success in preventing toxicosis in restricted clinical trials. Reserpine[184] was ineffective in preventing prepartum agalactia and prolonged gestation but was sufficient to resolve postpartum agalactia. Domperidone[185] has demonstrated efficacy in both the prevention and treatment of clinical fescue toxicosis in clinical trials involving large numbers of mares in numerous locations.

Prolonged Gestation

Bruce W. Christensen

Many factors influence the duration of gestation in horses and ruminants. Normal variations in length of gestation have been attributed to genetic, nutritional, and environmental factors.[186,187] The species, breed, and sex of the fetus; ambient temperature; and length of photoperiod are among factors that, within normal variations, affect the duration of gestation.[20,186–188] The duration of pregnancy in Thoroughbred mares ranges from 310 to 374 days,[188] in dairy cows from 275 to 292 days, in beef cows from 271 to 310 days, in ewes from 143 to 155 days, and in does from 146 to 155 days.[189] Prolonged gestation periods are those that exceed the normal gestational variation attributable to genetic, nutritional, and environmental factors. In pathologic prolonged gestation there is an impediment to the mechanisms that terminate gestation and initiate parturition. Pathologically prolonged gestation has been attributed to genetic, infectious, and toxic factors,[190] as well as to manipulation of the embryo.[191,192]

Of the several forms of prolonged gestation with genetic causes in cattle, the best described forms have been observed in Guernsey and Holstein cattle.[20,187,190,193] In each the fetus fails to initiate parturition at term because of fetal adrenal hypoplasia. Prolonged gestation, from 3 weeks to 3 months beyond normal term, has been observed in a number of dairy cattle breeds.[194] Graves, Hansel, and Krook[193] described a Holstein fetus of 441 days' gestation in which the pituitary pars distalis was aplastic and the adrenal and thyroid glands were severely hypoplastic. Two different types of fetuses have been associated with prolonged gestation in cattle.[186] In the first type, fetuses had a large skeleton and excessive growth of epidermal organ structures such as hair and hooves but no obvious deformities. The second type of fetus was mature or immature and exhibited cranial and central nervous system anomalies; growth ceased at about 7 months of gestation. Both types of calves had hypoplastic or absent adrenal glands. These anomalies have been observed to be inherited as an autosomal recessive trait.[187,190]

Several infectious agents have been incriminated in prolonged gestation in ruminants. Bluetongue virus, bovine diarrhea virus, and border disease virus may cause severe cerebral lesions in the fetus, resulting in the absence of a hypothalamus and pituitary stalk. Again, by virtue of the lack of adrenocorticotropic hormone, the sequence of events necessary for parturition does not occur.[190]

The use of assisted reproductive techniques in cattle in the form of in vitro procedures and somatic cell nuclear transfer ("cloning") offers advantages for reproducing important genetic lines, but they have many accompanying complications that have yet to be overcome. Besides increased pregnancy loss, increased birthweight of calves, and increased incidence of dystocia and perinatal losses, another complication is prolonged gestation in recipient cows compared with embryo transfer recipient and artificially inseminated cows.[191] This technology has great potential for manipulating and preserving superior genetic potential.[195] The cow has been the most successfully cloned animal to date, but such cloning still has a low success rate.[196–198] This is an active area of research, and it is still hopeful that with further understanding the current pitfalls surrounding in vitro procedures and nuclear transfer will be overcome and use of the techniques will become more commonplace.[197]

Veratrum californicum contains the teratogenic agent cyclopamine. When pregnant ewes ingest cyclopamine on the 14th day of gestation, their fetuses lack a pituitary gland or have a malformed hypothalamic stalk. These defects result in prolonged gestation by virtue of secondary adrenal hypoplasia.[190]

Prolonged gestation in mares has been cited as an indication for induction of parturition.[199,200] However, the clinical significance of prolonged gestation in mares is undetermined because there is no apparent correlation between duration of gestation and readiness for birth. Dysmature neonatal foals have resulted from gestations of normal and longer than normal durations; alternatively, 399 days' gestation resulted in births of normal twin foals.[201] Prolonged gestation in the mare has not generally been associated with excessively large foals and dystocia.[202] Therefore in the absence of clinical signs that warrant induction of parturition in a high-risk pregnancy and the fulfillment of criteria for induced parturition, there is no reason to perform elective parturition induction in mares in which gestation is prolonged.

Approach to Diagnosis of Prolonged Gestation

Approach to the diagnosis of prolonged gestation in mares and ruminants is essentially similar (Boxes 12.14 and 12.15). If the client is concerned about what is apparently prolonged gestation in an otherwise normal dam, an accurate breeding history should be obtained. Because no pathognomonic clinical or laboratory findings are associated with prolonged gestation, the diagnosis is predicated on the history and a general physical

BOX 12.16

Causes of Dystocia in Mares

Common Causes

Malpresentation
Malposition
Malposture
Abortion
Arthrogryposis
Twinning

Less Common Causes

Fescue toxicity
Preterm parturition
Torticollis
Vaginal, vulvar obstructions (hematoma, callus, abscess, tumor)
Pelvic injury, fracture

Uncommon Causes

Fetopelvic disproportion
Congenital defects
Hydrocephalus
Uterine dorsoretroflexion
Uterine torsion
Hydrops of fetal membranes
Rupture of prepubic tendon
Fetal mummification, maceration
Vaginal prolapse
Abdominal, inguinal hernia
Uterine inertia
Induction of parturition
Premature separation of chorioallantois from endometrium
Uterine laceration

examination of the dam. The overall condition of the dam should be determined. In addition to the reproductive history, exposure to infectious agents and toxic plants should be determined. The most important anamnestic factors are breeding dates, dates of confirmed pregnancy examinations, and absence of parturition at the expected time. The reproductive tract should be examined for the gravid uterus and evidence, although tenuous, of the term or near-term fetus. Diagnostic ultrasonography can be incorporated into the workup to enhance the assessment of viability and fetal well-being by determination of fetal heart rates, fetal size and movement, uteroplacental thickness, and estimation of allantoic fluid volume.[203,204] Parturition should not be induced unless the objective is fetal survival in the face of a high-risk pregnancy.[205] Otherwise, the mare should be examined and, if appropriate, the owner assured that the gestation is probably normal and that patience will likely result in a normal foal with adequate colostrum and passive immunity.[206]

Dystocia

Mats H.T. Troedsson

Dystocia is defined as difficult parturition; it may be a sign of either maternal or fetal conditions that impede fetal passage through the birth canal.[20] Dystocia in mares and ruminants is more likely to be attributable to fetal causes such as malpresentation, malposition, and malposture than to maternal conditions[20,207] (Boxes 12.16 and 12.17). The overall incidence of dystocia and incidences of types of dystocia vary among the species and breeds within a species.[208] Cattle, especially first-calving heifers and larger breeds, are more commonly affected by dystocia; the overall incidence of bovine dystocia ranges from 3% to 25%.[20] The incidence of dystocia among Thoroughbred mares is 4%,[207] and in does it is 3% to 5%.[209] The incidence of dystocia is generally greater in sheep than in goats.[95] Dystocia represents an emergency situation that commands prompt resolution to afford the optimum prognosis for dam and fetus. Reposition, traction, fetotomy, and cesarean section are the obstetric procedures available for the management of dystocia.[210] The economics of large animal practice often play a significant role in determining which course to pursue in resolving dystocia. The lives of the dam and the fetus may be at risk. Although the objective should be the survival of both, unless otherwise advised by the owner and if conditions are not prohibitive, the well-being of the dam and her reproductive potential should have priority over the fetus.

Although parturition has been divided into three distinct stages for descriptive purposes, the stages overlap clinically and normal parturition is observed as a continuous process.[207] The equine fetus is lying in a ventral or ventrolateral position with head and forelimbs flexed during late gestation.[211] During the first stage of parturition the fetus plays an active role, along with myometrial contractions, in assuming correct extremity posture as it positions itself for delivery through the birth canal. The second stage of parturition commences with rupture of the chorioallantois and culminates in delivery of the fetus. Myometrial contractions continue during third-stage parturition, which ends with the expulsion of the placenta. In the mare, parturition is a forceful, explosive act. The time between rupture of the chorioallantoic membrane and delivery of the fetus is normally about 20 minutes.[20] Separation of the fetal membranes from the endometrium may occur within 1 to 2 hours after the second stage of parturition commences; therefore the retained fetus must be delivered quickly or it will asphyxiate. Fetal expulsion in the ruminant is not quite as explosive as in the mare; second-stage parturition in the bovine usually requires ½ hour to 4 hours.[20] Ewes and does require a range of ½ hour to 2 hours to complete the second stage, or

BOX 12.17

Causes of Dystocia in Ruminants

Common Causes

Fetopelvic disproportion (B, common; C, O, uncommon)
Malpresentation
Malposition
Malposture
Twins, triplets (B)
Uterine torsion
Periparturient hypocalcemia (B)
Failure of cervix to dilate (B, O; rare in C)
Lymphedema

Less Common Causes

Preterm parturition
Abortion
Congenital defects (fetal monsters)
Hydrops of fetal membranes (B, O)
Emphysematous fetus
Hydrocephalus (more common in B than O, C)
Extremity ankylosis (more common in B than O, C)
Breeding immature, young, small-for-age females
Obesity (B)
Pregnancy toxemia (O, C)
Uterine inertia
Fetal mummification, maceration
Uterine, cervical, vaginal obstruction
Retained fetus
Pelvic fracture
Vaginal prolapse

Uncommon Causes

Phytoestrogen toxicity (B, O)
Rectovaginal constriction of Jersey cattle (B)
Uterine rupture
Abdominal, inguinal hernias
Lipomatosis (B)
Lupine poisoning, arthrogryposis (B)
Polybrominated biphenyl toxicity
Bovine fetal tumors
Rupture of prepubic tendon (B)
Hereditary edema, lymphedema in Ayrshire calves
Prolonged gestation (B, O)
Chlorinated naphthalene toxicity

B, Bovine; *C*, caprine; *O*, ovine.

slightly longer if twins or triplets are present.[20] Primiparous animals generally require a longer time to expel the fetus than do multiparous dams.

Dystocia in large animals is often accompanied by forceful straining. The dam may attempt to lie down and stand repeatedly. This is characteristic of dams with dystocia that is caused by fetopelvic disproportion, malposture, or fetal impaction. Alternatively, the dam may stand quietly with minimal or no straining, as in cases of uterine inertia, uterine rupture, or exhaustion associated with prolonged dystocia of any cause. Whatever the presentation of the dam, the attending veterinarian must be prepared for unexpected behavior when attempting to perform obstetric examinations and procedures. General anesthesia followed by elevation of the hindquarter will facilitate safe manipulation and vaginal delivery of a foal in mares with dystocia. This technique, if applied correctly, will likely result in less damage to the mare's reproductive tract. If general anesthesia is not an option, the dam, fetus, attendants, and veterinarians must be protected from injury. The dam should be placed in open-ended stocks with movable sides or a straw-bedded box stall. During obstetric examination and manipulation, mares and cows may attempt to get up and lie down, or they may suddenly collapse. Such sudden movements may injure the dam and veterinarian if rigid, closed-end stocks are used. Minimum physical restraint should be used; however, restraint should be sufficient to permit completion of the obstetric examination and procedures with efficiency and safety.

Little is known about the pharmacokinetics of drugs in pregnant domestic animals. Accordingly, it must be assumed that sedative and anesthetic drugs will depress neonatal and fetal functions at least as much as those of the mare. The effects on myometrial activity of drugs administered to dams experiencing dystocia must also be considered. Acepromazine has little effect on the fetus and is generally considered safe for use in the pregnant mare. However, acepromazine was shown to have a suppressive effect on myometrial activity in cycling mares.[212] Xylazine causes significant fetal cardiovascular compromise in horses and has been reported to stimulate myometrial activity in cows and mares.[212–214] The fetal and myometrial effects of detomidine are similar but of longer duration compared with those of xylazine.[212,213] The effects of detomidine on myoelectrical activity in the uteri of cows and mares treated during the last trimester of pregnancy were dose dependent.[215,216]

As equipment is being organized and the process of evaluating the dam begins, a pertinent reproductive history should be obtained, including the dam's age, her previous breeding history, and the outcomes of previous pregnancies (i.e., abortion, normal parturition, dystocia). Her present gestational status should be determined; has parturition commenced at term, or is it a preterm or postterm delivery? Her udder should be examined to determine the stage of development. Information about the progress of the current parturition should be obtained. The time since rupture of the chorioallantoic membrane, the duration and intensity of labor, whether fetal membranes or parts have appeared at the vulva, and previous attempts to assist in delivery should be noted. If the dam is recumbent, the veterinarian should determine if she has attempted to or been able to rise. Although a complete examination of the dam is optimum, it should be postponed until after the delivery of the fetus. However, in obtaining the dam's reproductive history, questions about her current physical condition should be included. Such predisposing factors as recent weight loss, systemic disease, and trauma should be considered. She should be assessed for signs of hemorrhage, dehydration, and shock.

After the tail has been wrapped, the perineal area should be thoroughly and gently washed and rinsed. Examination of the dam's reproductive tract may cause some discomfort or pain. Caudal epidural anesthesia (1 to 1.25 mL/100 kg of 2% lidocaine or other anesthetic) is often an excellent means of facilitating examination and resolution of dystocia and at the same time minimizing trauma to the dam, fetus, and operator. Lidocaine epidural anesthesia, however, may cause hindlimb weakness and ataxia. Safe and effective analgesia can also be induced by epidural administration of xylazine (0.17 mg/kg diluted in 10 mL physiologic saline). A combination of lidocaine (0.22 mg/kg) and xylazine (0.17 mg/kg) resulted in an onset of analgesia within a few minutes and a duration of over 5½ hours.[217] Although both vaginal sensitivity and the Ferguson reflex are reduced by epidural anesthesia, myometrial contractions and abdominal press are not totally eliminated unless the dam is put under general anesthesia. This approach has to be combined with an elevation of the hindquarter of the dam, in order to provide sufficient space for safe manipulation of the fetus. Great care must be taken during the examination of the genitalia and fetus. In addition to the viability of fetus and dam, the dam's future reproductive potential is at risk and must be preserved. The vulva, vestibule, vagina, and cervix

VetBooks.ir

should be carefully examined. The location of the fetus in the birth canal, as well as its viability, presentation, position, and posture, should be determined. Schuijt and Ball[218] described a procedure to manually dilate the bovine birth canal before forced extraction is attempted. In the management of dystocia in any species, forced extraction should proceed only after maximal dilation of the caudal reproductive tract in order to minimize the potential for injuries to the dam during parturition (i.e., cervical, vaginal, and vulvar lacerations; hematomas; postparturient vaginal necrosis; and obturator, perineal, and gluteal paralyses).[20,219] Mares are especially susceptible to cervical lacerations, which may have detrimental consequences on the dam's future reproductive performance. Slow traction with continuous palpation of cervical stretching by the attending obstetrician is therefore recommended in equine dystocias.

The integrity of the birth canal, fluids, and fetal membranes serves as an indicator of the length of time the dystocia has persisted and the well-being of the fetus. Generous lubrication is required in all cases of dystocia and should be applied continuously during the management of dystocia to prevent damage to the dam's birth canal. Lubricating preparations consisting of methyl cellulose are superior to those consisting of mineral oil or soaps. Several liters of lubricants should be infused into the bovine and equine uterus by the use of a nasogastric tube.

Traction or forced extraction can usually be successfully implemented after correction of malpresentation, malposition, or malposture. Because of the length of the extremities of the foal, manipulation is more difficult in the mare than in the cow and requires extensive repulsion to provide adequate room for manipulation. Examination and manipulation can be greatly facilitated by elevating the mare's hindquarters under general anesthesia, enabling the fetus and viscera to recede cranially into the mare's abdominal cavity, thereby allowing more room for the operator.[220] If a nonviable fetus cannot be delivered by traction or forced extraction or if the owner is unwilling to select cesarean section, fetotomy can be performed.[210,220] Beyond the delivery of the nonviable fetus, fetotomy is indicated to save the mare and her subsequent fertility.[210] The advantages of fetotomy include avoiding major abdominal surgery (cesarean section) and its complications and preserving the birth canal because excessively large parts are not forced through it.[20,219–221] At the same time, the primary disadvantage of fetotomy, particularly if not properly performed by an experienced obstetrician, is trauma to the birth canal by instruments, wire, or bone.[20] The indications, equipment, procedures, and complications of fetotomy have been reviewed in several publications.[20,210,219–221]

Cesarean section is indicated for a dam with dystocia when attempts to deliver the fetus by reposition, traction, and fetotomy are unsuccessful or contraindicated, and continued attempts may compromise the fetus, the dam, or her subsequent fertility.[20,95,201,205,208,222–227] Cesarean section may be the only rational procedure for delivery of some fetuses (e.g., emphysematous fetuses, deformed fetuses, bicornuate fetuses). In addition, high-risk pregnancies caused by maternal conditions can be effectively and efficiently managed by cesarean section.[205] The specific indications, procedures, and complications of cesarean section have been reviewed in a number of publications.[20,201,205,208,222–227]

Management of a case of dystocia is not complete until a systematic examination, focusing on the dam's reproductive tract, has been conducted. Complications during dystocia involving the reproductive tract and other body systems can affect the outcome of the case.[20,202,228,229] As much as possible, examination of the dam's reproductive tract should rule out the presence of another fetus in the uterus or abdominal cavity.[20] The most common reproductive injuries incurred by dams during parturition include cervical, vaginal, and vulvar lacerations; hematomas; postparturient vaginal necrosis; and uterine hemorrhage.[206,219,229] Gastrointestinal complications, such as constipation associated with unwillingness to defecate, postpartum perineal inflammation, and bruising or rupture of entrapped or compressed segments of the gastrointestinal tract, can follow parturition in the mare.[229] Musculoskeletal and neurologic complications have been reported after parturition in cows and mares.[20] Retained placenta, delayed uterine involution, metritis, and laminitis may result from normal parturition but are more likely sequelae of dystocia.[20,229,230]

The signs associated with normal progression of each of the stages of parturition must be explained carefully to clients and farm managers. It is only through understanding the clinical signs associated with events of normal parturition that clients become proficient at recognizing abnormal events and know when to seek professional assistance.

Retained Fetal Membranes

Mats H.T. Troedsson

Retained fetal membranes represent the failure of the entire or partial placenta to be expelled within physiologic time limits. Although variation exists among species regarding the duration of time that must pass before a placenta is considered retained, the condition is one of the most common complications occurring in animals after parturition.

Retained Fetal Membranes in Mares

The anatomic structure of the equine placenta is described as diffuse, epitheliochorial, and microcotyledonary. It is composed of the allantochorion, the allantoamnion, and the umbilical cord.[231] During most normal foalings, the separation of fetal membranes from the endometrium and their subsequent expulsion occur within ½ hour to 3 hours of the delivery.[210,232,233] The incidence of retained fetal membranes is 2% to 10% in the mare, with a higher incidence in draft horses than in lighter horse breeds.[234] The cause of retained fetal membranes remains unclear, but it is believed that allantochorionic microcotyledons near the tip of the nongravid uterine horn have failed to separate as a result of an endocrine unbalance, a disturbance in normal myometrial contractions, or any swelling at the site of microcotyledons[235] (Box 12.18). Diagnosis of retained fetal membranes in the mare is straightforward when it is based on the observation of membranes hanging from the vulva beyond 3 hours after foaling. However, if the fetal membranes fall cranially over the pelvis, they remain within the uterus without being visible, and the diagnosis must be made using vaginoscopy or ultrasonography or by digital intrauterine examination. If an early diagnosis of complete or partial retention of fetal membranes has been missed, the diagnosis may be made 1 to 2 days after foaling. At this time, clinical signs indicative of metritis are often present (i.e., fever, depression, colic, and/or laminitis).

After their expulsion, the fetal membranes should be stored until they can be scrutinized to determine if they are complete. The clinician should rinse the fetal membranes with water and, on a flat surface, thoroughly examine them for completeness.[236] Evidence that a part of the placenta is retained in the uterus or that an area of microvilli has been sheared off and retained in the endometrial crypts is an indication for digital endometrial examination or ultrasonographic examination and institution of appropriate therapy (see Chapter 43).

Approach to Diagnosis of Retained Fetal Membranes in Mares

HISTORY. Many cases of retained fetal membranes follow episodes of dystocia, cesarean section, and fetotomy. An increased incidence of retained fetal membranes has been reported in mares that abort after the seventh month of gestation.[234] However, no increase in the incidence of retained fetal membranes associated with abortion, stillbirth, twinning, and

High milk production

delivery of a weak or diseased foal was observed if it occurred without dystocia.[237]

PHYSICAL EXAMINATION. Fetal membranes must be examined after their expulsion to determine their entirety and integrity. Tears, missing areas of tissue, and areas of chorionic surface devoid of microvilli should be considered evidence of partly retained fetal membranes, and immediate action should be taken to enhance expulsion of retained tissue and minimize complications.

Vital signs may be normal early in cases of retained fetal membranes. A rectal examination should be performed to determine the degree of uterine involution. Aseptic intrauterine palpation can be performed to determine the area and extent of retention and the integrity of involved tissues and fluid.[236] Systemic signs of dehydration, septicemia, toxemia, and laminitis may accompany fetal membranes retained for 24 to 36 hours.[229] Occasionally mares with retained fetal membranes show signs of colic. Therapeutic approaches for retained fetal membranes in mares are discussed in Chapter 43.

Retained Fetal Membranes in Ruminants

The anatomic structure of the ruminant placenta is described as cotyledonary and epitheliochorial.[233] It is composed of the allantochorion, allantoamnion, and umbilical cord. Fetal membranes are considered pathologically retained in the cow if they are not expelled by 8 to 12 hours after calving.[232,233] The incidence of retained fetal membranes in dairy cattle is 3% to 12% after normal parturition.[238] Dairy cows are more commonly affected than beef cows.[238] The incidence of retained fetal membranes may exceed 50% after abnormal parturition or abortion and in brucellosis-infected herds.[238] The retained placenta itself is relatively innocuous, but the condition is important because cows with retained fetal membranes experience an increased incidence of postpartum complications such as metritis, pyometra, ketosis, mastitis, delayed conception, and abortion.[214,239] The principal cause of retained placenta in cattle is a disturbance in the loosening process between the fetal cotyledons and maternal caruncles[240] (Box 12.19). The processes that lead to successful loosening and separation of the placentome occur during the months preceding parturition. Many infectious and noninfectious factors are believed to disrupt the separation and expulsion processes. An endocrine causal relationship does not appear to exist.[241]

Clinical signs of retained fetal membranes in the doe and ewe are similar to those in the cow. The placenta of the ewe and doe is considered retained if it is not expelled within 24 hours after parturition.[95] The incidence of retained placentas in does is 6.4%.[242] Placental retention for longer than 24 hours may cause metritis in ewes and does. Inadequate dietary selenium and inadequate nutrition and exercise during gestation have been seen as factors predisposing does to retained placentas.[242] There have been several reports on factors that predispose to retained fetal membranes.[210,232,233,238,240,243,244] Many infectious and noninfectious factors apparently contribute to the disruption of the process of loosening and separation of the placentome. Accordingly, it has been suggested that a retained placenta should be considered to be a sign of an underlying disease.[245]

Approach to Diagnosis of Retained Fetal Membranes in Ruminants

HISTORY. A review of accurate breeding records correlates retention of fetal membranes with the duration of pregnancy. Gestational periods of abnormal lengths result in a higher incidence of retained placenta than do normal-term parturitions. Induced parturition, twinning, and late-term abortions have been associated with retained fetal membranes in cows. Many periparturient diseases and conditions affect the incidence of retained fetal membranes.[210,232,233,238,240,243,244]

PHYSICAL EXAMINATION. In cows that have calved spontaneously and without problem after a normal gestation period, little illness tends to be associated with retained fetal membranes, and treatment may be unnecessary. Transient decreases in

appetite and milk production may be observed.[238] However, metritis, toxemia, and septicemia may be observed when retention of fetal membranes is associated with gestation of abnormal length, dystocia, nutritional deficiencies, or certain infectious diseases. Metritis affects up to 90% of cows with retained fetal membranes.[243] For considerations for the treatment of retained fetal membranes in cows, see Chapter 43.

Alterations in Lactation

Bruce W. Christensen

The mammary glands are modified cutaneous glandular structures considered accessory reproductive organs that function to secrete milk for the nourishment of the young.[246] The mammary glands are located in the prepubic region in the mare, cow, ewe, and doe. The cow's udder is composed of four mammary glands, whereas in the doe, ewe, and mare the udder has two mammary glands. One teat serves each mammary gland, and in the cow, ewe, and doe each teat has one streak canal. The mare has two streak canals per teat.

The mammary glands are ectodermal in origin, and most of their fetal development occurs during the first half of gestation.[247] Except for growth that occurs in association with some of the anomalous conditions of the mammary gland or as a result of the deposition of fat, there is little growth of mammary tissue between birth and puberty. Further mammary gland development occurs with each estrous cycle after the onset of puberty. Development of the duct system is primarily attributable to estrogen. Progesterone is the principal stimulant to development of secretory tissue. However, neither estrogen nor progesterone alone or in combination can cause optimum mammary gland growth and development.[248] Insulin, cortisol, thyroxine, prolactin, and growth hormone are necessary for full mammary gland development. During pregnancy the mammary gland attains maximum development under the control of pituitary, ovarian, adrenal, and placental hormones.[249] During parturition a process of interrelated neuroendocrine processes initiates lactogenesis, the production of milk. The secretion of milk and its release from the mammary gland after parturition depend on the availability of appropriate amounts of the hormones named previously, especially prolactin and oxytocin.

In addition to mastitis, conditions that manifest themselves as alterations in the mammary gland and lactation are fairly common in ruminants and horses. Problems caused by conditions that affect the mammary gland are often multifactorial in that they compromise the well-being of the patient, the nutrition of the offspring, and ultimately the economics, especially in commercial dairies.

Enlarged Mammary Gland

Many conditions and diseases of the mammary gland cause swelling or enlarging of the gland[250] (Boxes 12.20 and 12.21). Enlargement may involve one or more of the glands of the udder. However, the enlarged mammary gland is not necessarily inflamed. Several anomalies of the mammary gland cause noninflammatory enlargement of the gland (e.g., gynecomastia, precocious udder development).[250–252] It is important to determine whether the enlargement of the gland is attributable to an infectious or a noninfectious cause. Trauma is probably the most likely cause of noninfectious inflammation of the mammary gland. Mastitis, with which a large number of organisms have been associated, is the most common cause of mammary gland inflammation (see Chapter 36).

Evaluation of a patient with an enlarged mammary gland should include the medical and reproductive histories. The age and sex of the animal may limit the considerations. Gynecomastia is seen in young bucks, rarely in rams and bulls, and never in stallions.[250,252] Congenital anomalies such as stenotic or absent teat canals are not determined until parturition occurs and lactation commences.[250] The animal should be given a complete physical examination, with emphasis on the affected mammary gland. Examination of the gland should

include observation, palpation, and expression of its contents. Cytologic and bacteriologic examination of the secretion from the mammary gland may be helpful in determining the cause and establishing the prognosis of enlarged mammary glands. In postpartum cows the most common causes of enlarged mammary glands are periparturient udder edema and mastitis. Mastitis occurs most often in mares after weaning. Trauma to the udder is more likely to be problematic in cows and goats than in ewes and mares because the udder is more pendulous in the former.[250] Undesirable udder traits of genetic origin occur in the goat (e.g., hanging or saclike udder, polythelia, blocked teat).[253] Lacerations, superficial contusions, and seromas are detected by close examination of the affected gland. Diagnoses of other injuries may rely on examination of the gland's secretion for evidence of increased cellularity and hemorrhage. Mammary gland neoplasia is rare in mares, cows, and small ruminants.[250,254–256]

Udder Edema

Udder edema, one of the most common causes of enlarged mammary glands, results from the excessive accumulation of intercellular fluid in the mammary gland (Box 12.22). The disorder is observed during the late gestation and early postpartum periods and is common in both horses and ruminants, but it is probably more frequently seen in dairy cattle. One study reported an udder edema incidence of 18% in dairy cattle, of which less than 1% required veterinary treatment.[257]

Two forms of udder edema are seen in cattle.[258] In the physiologic or acute form, there is edema of the mammary gland during the late gestation and early postpartum periods.[258] The entire udder is usually symmetrically involved, and the edema may involve adjacent abdominal and perineal areas.[258] The condition is usually not obviously painful but may cause the cow some difficulty in lying down and walking because of the mammarian swelling. Chronic bovine udder edema differs from the acute form in that affected cows develop udder edema within 6 weeks after calving, and the edema may persist for several months.[258] The swelling may be localized in the form of plaques on the ventral aspect of the rear of the udder, or it may involve the ventral abdominal wall.[258]

Udder edema is a relatively common condition of dairy goats.[259] Two-year-old does kidding for the first time are most commonly affected; however, all ages can be affected. Affected does usually have colostrum at parturition, but within a few hours the udder is warm, hard, and agalactic.

Broodmares affected with udder edema have generalized ventral edema during the last 1 to 2 weeks of gestation and for as long as 2 to 3 days after foaling. The extent of ventral edema varies, ranging from local swelling of the udder and immediately adjacent subcutaneous tissues to a generalized swelling that may extend from posterior to the mammary glands forward, along the ventral abdomen and thorax, to the axillary or pectoral area. In the mare such edematous accumulations are referred to as *plaques of edema*. Affected broodmares seem to be uncomfortable and reluctant to move. Younger broodmares, especially primiparous mares affected with udder edema, appear to be in more pain than older mares, and some of the mares so affected refuse to allow their foals to suckle.

Agalactia

Any disease or condition that adversely affects the dam has the potential to compromise lactation. Agalactia, the failure of lactation after parturition, may be attributable to a primary endocrinologic or mammary gland problem, or it may be secondary to any of a multitude of systemic conditions and diseases (Boxes 12.23 and 12.24). True agalactia may be attributable to mammary gland anomalies or inadequacies among the numerous endocrinologic factors of development and pregnancy. Agalactia may be a complication of many conditions. In some animals the conditions to which agalactia is secondary manifest as alterations in a specific system, whereas other animals with agalactia may demonstrate such signs as fever, weight loss, anorexia, and anemia. Inadequate nutrition is rarely the cause of clinically observed agalactia. Fescue grass toxicity, caused by ingestion of the ergot alkaloid–producing *Acremonium coenophialum*, is an important cause of agalactia and hypogalactia[260,261] (see Clinical Signs of Fescue Toxicosis earlier).

Agalactia should not be confused with failure of milk ejection (milk letdown). Administration of oxytocin may enhance milk letdown but does not affect milk production. Oxytocin stimulates a release phenomenon that acts on previously secreted and stored milk. Although somatotropin may increase milk production in a normally lactating cow, its effect on agalactia has not been adequately studied.

Inexperienced or nervous mares with adequate milk are often reluctant to allow their offspring to nurse, in part because of the mare's inexperience. Such nervous mares need not necessarily be primiparous mares. Although not allowing their

APPROACH TO DIAGNOSIS OF AGALACTIA. An accurate reproductive history should be obtained. It should be determined whether the dam is primiparous or multiparous. If primiparous, is she manifesting anxiety in the presence of her offspring? If multiparous, has she been agalactic at previous parturitions? Has she sustained recent trauma, perhaps during parturition, or was there exposure during gestation to infectious diseases or toxic plants? After a history has been determined and the dam and neonate have been observed, attempts to facilitate the youngster's suckling might be indicated. Is the dam agalactic, or does she simply refuse to let the neonate suckle? Such measures as twitching or tranquilizing the nervous and inexperienced mare may resolve that problem. If assessing the dam's behavior toward her offspring does not resolve the problem, a thorough physical examination should be initiated. The objective now should be to rule out or incriminate infectious and inflammatory conditions contributing to the agalactic state. The dam herself may be systemically affected, or the problem may be localized in the udder or a mammary gland.

In listing causes of agalactia and hypogalactia in Boxes 12.23 and 12.24, the authors included only those that have a direct effect on the anatomic integrity of the mammary gland or its function. Abnormalities involving any system may compromise lactation.

Galactorrhea and Precocious Mammary Gland Development

Galactorrhea, the abnormal manifestation of lactation (not the secretion of true milk), occurs occasionally from the primordial mammary gland of young foals and ruminants, including neonates.[250] The secretion is popularly known as *witch's milk*.

Precocious mammary gland development and galactorrhea occur in pregnant and nonpregnant mares and in some of the ruminant species (Box 12.25). Such premature udder development and subsequent lactation have been observed in nonpregnant and nonsuckled doelings and heifers.[250,262] Udder development and subsequent lactation have been observed in young nonpregnant heifers and does being suckled by other young animals.[250] In addition to the continued stimulation of suckling, other causes of premature mammarian development and lactation may be trauma and diseases of the pituitary, ovarian, and adrenal glands.[250] Zearalenone toxicity has been implicated in precocious mammary gland development and lactation in heifers.[263] Milk production is nonphysiologic in that it is of insufficient quality and quantity and does not justify milking the affected animals. There is no evidence that such abnormal development compromises normal lactation after parturition.[250]

Inappropriate lactation has been observed at various stages of pregnancy in most domestic species.[250] The most common cause of galactorrhea is abortion. Lactation may commence before or even without expulsion of the dead fetus. Lactation during pregnancy has also been observed in association with multiple fetuses, placentitis, and ovarian tumors. Accordingly, premature mammary gland development during gestation should be considered a warning of impending abortion, and the dam should be examined. Occasionally, pregnant mares develop mammarian enlargement during middle to late gestation that spontaneously regresses.[261] Some of these mares begin to lactate before parturition. It must be kept in mind that premature lactation and subsequent loss of colostrum is one of the most important causes of failure of passive transfer of immunoglobulins.[264]

Gynecomastia, the abnormal development of the male's mammary glands, has been observed in bucks in which rudimentary mammary glands and associated teats underwent development.[250,262] The aberrant structures, located on both sides of the buck's scrotum, can secrete up to 1 L daily of a substance that resembles milk. The cause is presumed to be endocrine imbalance but has not been determined. Lofstedt and colleagues[265] reported adrenal neoplasia as a cause of lactation in a wether.

Musculoskeletal Abnormalities

CARTER E. JUDY and SAREL R. VAN AMSTEL, *Consulting Editors*
TROY HERTHEL, JAN K. SHEARER, and RICHARD ANDREW LECOUTEUR

Major Clinical Signs or Problems Encountered

Lameness and Stiffness

Randall B. Eggleston • John Maas • Carter E. Judy

Lameness is the term used to describe a condition in which an animal is incapable of normal locomotion. Generally, lameness is characterized by an inability to maintain a normal gait, manifested by asymmetry in movement, apparent incoordination or weakness, and inefficient or ineffective motion of the limbs. Lameness can usually be assessed only when the animal is moving under its own power, although lameness severe enough to cause an inability to bear weight can be assumed at a standstill. The onset of lameness can be acute (e.g., fracture), chronic (e.g., degenerative joint disease), or acute on chronic (e.g., catastrophic fracture secondary to stress fractures).

Mechanisms of Lameness and Stiffness

The ultimate effects of any cause of lameness are restricted movement of the limbs or body, reduced performance, and abnormal gait. Causes of lameness are generally associated with conditions of the musculoskeletal system or nervous system. Most causes of lameness have both a musculoskeletal component (e.g., atrophy of the supraspinatus and infraspinatus muscles) and a neurologic component (e.g., suprascapular neurapraxia). Some causes of lameness have only a musculoskeletal component (e.g., upward fixation of the patella) and are not principally associated with either afferent nerve signs (i.e., pain) or efferent nerve signs (i.e., motor dysfunction). Similarly, other causes of lameness are solely related to a motor nerve deficit (e.g., radial neurapraxia).

Unlike the usual definition of lameness, *stiffness* refers to a generalized restriction in freedom of movement in a limb, the neck, or back. Stiffness is manifested by a limited range of motion by a joint, reduced length of stride, or decreased flexibility during bending or turning. For example, cellulitis and soft tissue swelling in the area of the tarsocrural joint can cause restricted freedom of movement of the hind limb and an apparent lameness, yet there may be no specific musculoskeletal or neurologic cause. Stiffness may have either congenital or acquired causes, and the clinical signs may be mild and transient or severe and persistent. Stiffness may or may not be associated with pain.

Approach to Diagnosis of Lameness and Stiffness in Horses

The lameness examination is the most commonly performed assessment of the musculoskeletal system in the horse. The examination should be well planned, consistent, and thorough. Knowledge of all diseases capable of causing lameness is not required, as long as the examiner maintains an open mind and objectivity during the examination (Box 13.1). The goals of the lameness examination are to determine which limbs are affected, differentiate between supporting limb and swinging limb lameness, and establish the musculoskeletal and/or neurologic components producing the lameness.

1. History. The lameness examination begins with the client interview. A summary of the important historical features of the lameness should include answers to basic questions about the following:
   - Onset (e.g., When was the last time the horse was seen sound? Was the lameness acute in onset, or did it have a slow, insidious onset?)
   - Characteristics of the lameness (e.g., Is the lameness seen more in hand, at the lunge, or under saddle?)
   - Associated or inciting factors (e.g., injury) that may have contributed to or caused the lameness.
   - Changes in the characteristics, intensity, and duration of the lameness.
   - Responsiveness to treatment (e.g., Has the horse received any type of treatment, and, if so, what was the response?)
   - Time since the last hoof trimming and shoeing, and whether or not the horse's shoeing was changed.
   - In addition, the signalment and activity that the horse undertakes (e.g., jumping vs. racing) should be ascertained and may be a guide in determining potential causes of the lameness (e.g., stress fractures are more common in racing Thoroughbreds, and osteochondrosis is more commonly diagnosed in young animals).
2. Observe from a distance—stationary phase. Observing the horse from a distance while it is stationary permits an assessment of the horse's conformation, position, and posture. The horse should be viewed from the front, from behind, and from both sides. Special note should be made of any abnormality in the following:

VetBooks.ir

BOX 13.1

Causes of Lameness and Stiffness in Horses

Common Causes

Infections of the foot
Bruised or punctured sole
Hoof wall defects
Fractures
Septic (infectious) arthritis
Laminitis
Secondary (degenerative) joint disease
Navicular disease
Osteomyelitis
Fibrotic or ossifying myopathy
Rhabdomyopathy (tying up)
Sprain
Strain
Tenosynovitis
Contracted tendons (flexural deformity)
Ankylosis or arthrogryposis
Osteochondrosis or bone cyst
Cruciate or meniscal rupture
Luxation or subluxation (dislocations)
Upward fixation of the patella (locking patella)
Sesamoiditis
Muscle injury, soreness, bruise, trauma, compartment syndrome
Subcutaneous abscess, cellulitis
Angular limb deformities
Disruption of the suspensory apparatus (broken down)
Postanesthetic equine myasthenia
Tendon rupture, damage, tendonitis (bowed tendon)
Osteomalacia, osteodystrophy (rickets)
Bucked shins
Epiphysitis (physeal injuries)
Purpura hemorrhagica

Less Common Causes

Shivers (shivering)
Borreliosis (Lyme disease)
Equine monocytic ehrlichiosis (Potomac fever)
Chronic selenium toxicity
Hemangioma, hemangiosarcoma, angiosarcoma
Skeletal neoplasia
Rabies
Spondylitis, diskospondylitis
Spinal or vertebral neoplasia
Vertical column malformation
White muscle disease (nutritional myodegeneration)
Gunshot injury
Corynebacterium pseudotuberculosis
Hypothyroidism (goiter)
Actinobacillosis
Hyperparathyroidism
Ulcerative lymphangitis
Myotonia congenita
Vesicular stomatitis
Fistulous withers (*Brucella abortus* or other organisms)
Sporadic equine lymphangitis
Acute necrotizing equine vasculitis (with or without thrombocytopenia)
Peripheral arteriovenous fistula
Hypertrophic osteopathy or osteodystrophy

Uncommon Causes

Nocardiosis
Cutaneous blastomycosis
Pemphigus foliaceus
Tuberculosis
Multisystemic postexhaustion syndrome
Generalized steatitis
Cutaneous vasculitis
Sterile nodular panniculitis
Multiple clotting defects in ill foals
Salmonellosis
Factor VIII deficiency (hemophilia A)
Idiopathic equine aplastic anemia
Idiopathic equine thrombocytopenia
Hemimelia (radial, tibial, ulnar hypoplasia, agenesis)
Lupus erythematosus (rheumatoid arthritis)
Phycomycosis
Bone fragility disorder

Poisons, Toxins, Deficiencies, and Excesses

Moldy sweet clover poisoning
Strychnine toxicity
Tetrachlorodibenzodioxin (dioxin) toxicity
Warfarin (dicumarol) toxicity
Vitamin K–induced renal toxicity
Calcinosis resulting from plant poisoning
Zinc toxicity
Phosphorus toxicity
Phosphorus deficiency
Vitamin D toxicity
Locoweed-associated limb deformities or stringhalt-like gait
Chronic fluoride toxicity

- Conformation. A number of conformational abnormalities have been associated with lameness. For example, upright pastern conformation predisposes to pastern disease and foot lameness; offset or bench knees predispose to carpal disease; and straight through the hocks or post-legged conformation predisposes to upward fixation of the patella, suspensory desmitis, and fetlock disease. Poor conformation can affect the young horse when it is put into training or can cause a slow insidious onset of lameness. Recognizing these conformational abnormalities at the time of examination can be helpful in diagnosing potential causes of lameness. When a horse is evaluated for purchase, recognition of poor conformation should be noted and discussed as a source of future lameness problems.
- Position of the head (e.g., tilted, turned).
- Distribution and equality of muscle mass along the neck and trunk.
- Topographic symmetry of the front limbs, from the dorsal region of each scapula to the hoof. From the rear, the height and mass of the hip musculature and the symmetry between the hindlimbs should be assessed. From each side, abnormalities in stance (e.g., camped out in front) or load bearing (e.g., dropped elbow) and the position of the head and neck (e.g., hyperflexed poll) should be compared.

3. Physical examination and palpation. Palpation enables a closer inspection of the horse and identification of abnormalities that may or may not otherwise be noticed. A thorough examination of the musculoskeletal system allows for identification of palpable abnormalities and also offers the opportunity for the practitioner to refine the identification of normal structures; subtle abnormalities cannot be appreciated unless the examiner is skilled at recognizing normal anatomy. There are also many instances in which normal structures palpate abnormally but are not necessarily associated with lameness (e.g., flexor tendon sheath [windpuffs, windgalls] and palmar or plantar metacarpophalangeal joint [MCPJ] pouch effusion [wind puffs]). The examination

VetBooks.ir

should be conducted consistently and thoroughly starting with the cervical neck and concluding at the tail. Abnormal findings should be described to identify their location on the limb, their size, and their orientation relative to normal anatomic landmarks. Palpation of the upper limb is often limited to the overlying muscle mass, with identification of any atrophy, hypertrophy, pain, or fibrosis. Articular structures and surrounding ligamentous structures can be difficult to palpate because of the overlying muscle. Deep palpation of the thoracolumbar and gluteal musculature can provide clues to potential hindlimb lameness and tack or rider issues. The pelvis, iliac arteries, and sublumbar musculature can be evaluated by rectal palpation while the horse is standing quietly; movement or crepitation can be assessed while swaying the horse from side to side.

Particular attention should be directed toward palpation of the limbs. The majority of lameness will originate from the carpus distally in the front limb. Common sources of lameness in the hindlimb can be identified from the stifle distally. All palpable structures should be evaluated, including skeletal structures, synovial structures, and soft tissue structures (tendons and ligaments). This portion of the examination can be performed using different methods, by either palpating each tissue in one pass of the limb or making multiple passes of the limb, palpating each tissue structure separately. Regardless of the preferred technique, a consistent and complete examination should be performed. Once the limbs have been palpated in the weight-bearing position, the examiner should palpate them in the non–weight-bearing position. This allows for separation of the soft tissue structures and facilitates deep palpation of the suspensory apparatus. Comparing limbs is often useful for distinguishing an abnormality from an unusual or unique conformation.

The relative size, shape, and condition of the feet (e.g., contracted heel, scuffed toe); length of heel; and pattern of shoe wear (e.g., thinner branch on the outside of the shoe than on the inside) give clinically significant but often overlooked clues to the site and cause of lameness. Evaluation of the feet with hoof testers is mandatory; most lameness arises from problems in the forefeet.

Certain signs indicating trauma (e.g., wounds, swelling, hair loss, pain) may lead to more important findings such as underlying evidence of a fracture (e.g., bony crepitus, warm or cold areas, bony protuberance). Observe from a distance—the mobile phase. Observations made from a distance while the horse is moving can be evaluated critically once clues provided by the history, as well as observations made of any postural deformities, direct the practitioner's attention to a specific area of the horse's body. This part of the examination is conducted while the horse is moving in at least two gaits, the walk and the trot. Sometimes it is also helpful diagnostically to observe the horse move at other gaits (e.g., canter) or while under saddle. It may also be beneficial to observe the horse on different surfaces to amplify different lameness issues. If possible, the horse should be evaluated under conditions similar to those under which it performs. At a walk, the horse should be observed moving toward and away from the examiner. The breakover point of the foot at the toe, the arc of the foot flight, the distance covered by the foot in the swing phase, and the placement of the foot should be evaluated for each limb and should be compared between pairs of limbs. Although many abnormalities can often be observed only during a trot, some conditions may cause a subtle alteration in gait that can be observed only at a walk (e.g., fibrotic myopathy, stringhalt).

If a fracture is suspected or if there is the possibility of exacerbating preexisting trauma, this part of the examination should either be abbreviated or not performed at all to preclude further damage or trauma. In such cases, immediate radiographic or other definitive diagnostic tests should be performed (Box 13.2).

BOX 13.2

Causes of Spontaneous Fractures in Horses and Ruminants

Pathologic fractures
Subclinical stress fractures
Tumors
Infection
Inflammation
Osteoporosis
Copper deficiency
Molybdenum excess
Phosphorus deficiency
Protein deficiency
Osteomalacia
Osteodystrophy (rickets)
Rapid growth
Lactation
Advanced pregnancy
Bone fragility disorder

Recognizing the asymmetric movement of the head and neck for frontlimb lameness and the asymmetric movement of the pelvis for hindlimb lameness is a common method of lameness identification. Hindlimb lameness issues often present the greatest diagnostic challenge.

Sound horses at a trot show a perfect sinusoidal pattern for all midline body locations, including the head, withers, and tubera sacrale. The height of these structures falls from the beginning of the diagonal stance phase, reaching the lowest position at midstance, and then rising to the highest level at or shortly after the end of the stance phase (suspension). Correlating head and neck movement with the correct frontlimb lameness is relatively easy. It is well recognized that the head is elevated during the stance phase of the lame limb, with an increase in downward motion during the stance phase of the sound limb—"down on sound." Lameness can also be recognized by changes in the distal limb, including changes in the motion of the MCPJ. During the stance phase, the hyperextension of the MCPJ is decreased with increasing lameness in the lame limb, whereas in the contralateral sound limb an increase is seen. With respect to stride length and foot flight, with forelimb lameness the caudal phase of both the lame and the sound limbs becomes shortened, whereas the cranial phase remains unchanged. In the hindlimbs the opposite is seen; the cranial phase is shortened and the caudal phase remains unchanged. This may be explained by the significantly decreased suspension phase following the lame diagonal. In the forelimbs the arc of the lame front foot is unchanged, but there is an increase in the arc of the sound front foot. In the hindlimbs, the arc of the foot flight in the lame hindlimb is lower than the sound limb in most cases. The change in maximal hoof height during the swing phase appears to be the result of changes in trunk height and is no indication for reduced flexion in the upper joints or an effort to reduce the pain when the hoof lands. Medial (winging) or lateral (paddling) deviation of the distal limb during the flight phase can result in interference and trauma to other limbs and potential lameness. Conformational abnormalities, most commonly toeing in or toeing out, give rise to an alteration in the point of breakover and a change in the flight of the distal limb. Poor foot balance caused by either poor conformation or poor trimming can result in similar flight patterns.

Plaiting describes adduction of the lame limb directly in front of or lateral to the opposite limb. In the front limbs,

VetBooks.ir

plaiting is commonly the result of faulty conformation, but in the hindlimbs it is more commonly associated with lameness. This pattern of travel is often associated with upper limb lameness but can also be seen with distal hock or proximal metacarpal disease.

A dampening effect also appears to occur as an adaptation to lameness. This effect is more pronounced in the hindlimb than the frontlimb. Flexion of the shoulder and hock joints actually increases during weight bearing in the lame limb. This is probably an increase in the function of the shock-absorbing mechanism. The increased flexion cannot be related to increased loadings but has to be attributed to a gentler braking of the flexion by the extensor muscles. In such a way the loading of the lame limb with the body weight occurs more gradually, reducing the peak forces in the hoof.

The tubera coxae are typically the landmark of choice in evaluating hindlimb lameness. Because the tubera coxae are more laterally located, the pattern is different from that seen in the head. Also, because the hindlimbs lack closely located segments, such as the neck and head, an enhancement of the vertical movements must be found in a rotation of the back around a longitudinal axis. Such a rotation is indicated by different vertical displacements of one tuber coxae during both stance phases. The vertical movement of the tuber coxae exhibits a characteristic pattern of a double-waved, slightly asymmetric line during one stride. The lowest point of the hip is reached in the middle of the stance phase of the contralateral limb. The highest point of the hip is reached shortly after the stance phase of the contralateral limb.

Kinematic studies have more clearly defined the notion of "hip hike" and "hip drop" and have recorded regular patterns of pelvic movement in lame horses. Consistent findings in the overall pelvic movement in the lame horse include less downward movement during the midstance phase and less upward movement at the end of and after the stance phase of the lame limb. This can give the appearance of an overall pelvic elevation during the stance phase of the lame limb as compared with pelvic height during stance of the sound limb; a similar exaggerated pattern is seen in the tubera coxae. The tubera coxae also exhibit less downward movement during the midstance phase and less upward movement at the end of the stance phase in the lame limb. More notably, there is more downward movement during midstance of the sound limb (midflight of the lame limb) and more upward movement at the end of stance of the sound limb (impact of the lame limb), giving rise to the notion of a "hip hike." These changes result in an increase in the overall vertical movement of the tuber coxae on the lame side as compared with the sound side. Clinically, many find it easier to identify the exaggerated excursion of a tuber coxae to identify the side of the lameness.

Lateral movement or drifting of the hind end can also be seen in horses with unilateral hind limb lameness. Horses tend to drift or move away from the side of the lameness. Subtle lameness with an absence of asymmetric pelvic movement may present with a consistent drifting to one side or the other.

Thorough and useful systems for grading the severity of lameness are available. Most systems are designed to enable the practitioner to compare how lameness changes with time, assess the characteristic of lameness among horses, and accurately record information and communicate information to other veterinarians. Simple and consistent schemes that are easy to remember and modify can be developed (Table 13.1).

Once the initial standing and mobile examinations are completed, the affected limb is identified, and the lameness is graded, identification of the specific region of the limb is the next goal. Manipulative tests or stressing of articulations and associated soft tissue structures can provide additional information as to the location of the source of lameness. Flexion and extension tests are designed to stress selective regions of the limb and observe the effects of the manipulation on the lameness. These tests are also commonly performed on the sound horse to reveal potential areas of concern, particularly during prepurchase examinations. Flexion and extension manipulations also enable an assessment of range of motion. Interpretation of these tests should be approached with caution. They are seldom specific for one particular joint. For example, the fetlock flexion test not only stresses the fetlock joint but also places stress on the proximal and distal interphalangeal joints; the hock flexion test also flexes and stresses the stifle joint because of the presence of the stay apparatus. If a flexion test results in a positive response, the horse should be walked out of the response and observed before additional manipulations. Occasionally exacerbation of the lameness will persist for an extended period of time, which changes the baseline lameness and clouds the interpretation of additional manipulations.

It is common for horses to be presented with multiple lameness issues. Secondary lameness or compensatory lameness is the result of increased stress or overloading of the other limbs in response to the primary lameness. This most commonly occurs in the contralateral limb but can also occur between frontlimbs and hindlimbs. The secondary lameness can also be the result of shifts in body mass that produce an apparent or phantom lameness. Phantom lameness is less severe than the primary lameness. The following guidelines can be used to aid in the differentiation between a real or compensatory and an apparent or phantom lameness.

- Address the most severe lameness first.
- Horses with primary hindlimb lameness and apparent or phantom contralateral frontlimb lameness: Each lameness should be considered as real.
- Horses with a primary forelimb lameness and apparent or phantom ipsilateral hindlimb lameness: Each lameness should be considered as real.
- Primary forelimb lameness may produce asymmetric pelvic movement causing the perception of a contralateral hindlimb lameness. Example: left foreleg lameness (head elevation) causing apparent or phantom right hindleg lameness (hip drop).
- Horses with a primary forelimb lameness and apparent contralateral hindlimb lameness: Isolate out the front limb lameness first.
- Primary hindlimb lameness (>3 to 5/5) can mimic ipsilateral forelimb lameness. Example: A horse shows a cranial load shift during the stance phase of the lame limb that causes the head and neck to shift forward and nod down, giving the perception of ipsilateral forelimb lameness—"down on sound."
- Horses with a primary hindlimb lameness and apparent ipsilateral forelimb lameness: Isolate the hindlimb lameness first.

TABLE 13.1

Five-Grade Lameness Scheme

Grade	Description
1	An inconsistently observable lameness visible under special circumstances (e.g., in a circle, flexion tests, hard surface)
2	A consistently observable lameness visible only under special circumstances (e.g., in a circle, flexion test, hard surface)
3	A consistently observable lameness at a trot in a straight line
4	A consistently observable lameness at a walk
5	A non–weight-bearing lameness; horse is unable to use the leg

Modified from the *Am Assoc Equine Pract Newsl*, March 12, 1983.

VetBooks.ir

TABLE 13.2

Structures Desensitized by Commonly Performed Nerve Blocks

Nerve Block	Nerve(s) Affected	Structures Desensitized[a]
Palmar (plantar) digital	Palmar (plantar) digital	Heel bulbs; frog; bars; navicular bone and bursa; palmar regions of the third phalanx, distal interphalangeal joint, sole, and soft tissues
Abaxial sesamoid	Palmar (plantar)	Coronary band, interphalangeal joints, lamellar and solar corium
Low palmar (volar)	Palmar, palmar metacarpal[b]	Skin of medial and lateral pastern, metacarpophalangeal joint, proximal sesamoids, flexor tendons, tendon sheath
High palmar (volar)	Palmar, palmar metacarpal[b]	Skin and deep structures of palmar cannon region (flexor tendons, suspensory ligament except origin, interosseous ligaments of splint bones)
High 2-point	Lateral palmar, medial palmar	Origin of suspensory ligament

[a]Includes all structures listed up to and including the particular block; first structure listed in each block is also the area that can be tested with point pressure to evaluate the effectiveness of the block.

[b]For hindlimbs, additional anesthetic (i.e., ring block) is necessary at the level of the particular perineural block to achieve the desired effect.

Assumptions as to the cause of a horse's lameness based solely on the physical examination and visual inspection should be avoided unless obvious signs are present, such as severe swelling or crepitus. After the physical and visual examination, evaluation of the horse with perineural analgesia is mandatory for accurate isolation and diagnosis. The clinician must possess a thorough knowledge of anatomy and the structures desensitized by blockade of the appropriate peripheral nerves or synovial structures (Table 13.2). *When performing perineural analgesia, it is important to remember to block from distal to proximal.* Perineural anesthesia of proximal structures first may inadvertently anesthetize more distal pathology, resulting in misinterpretation of the region of pain affected. An improvement in gait indicates a favorable response to a nerve or joint anesthesia; complete elimination of gait asymmetry is unusual and generally should not be expected after intraarticular or peripheral nerve analgesia. If necessary, improvement in gait can be confirmed by repeating the successful block the next day. By that time residual effects from multiple blocks performed previously should be absent.

Common local anesthetics used in horses include solutions of lidocaine, mepivacaine, and bupivacaine. These solutions all share a common mechanism of action, specifically the ability to block or inhibit nociceptive nerve conduction by preventing the increase in membrane permeability to sodium ions. Lidocaine and mepivacaine are considered to be fast acting and have a duration of action of ½ to 3 hours and 2 to 3 hours, respectively. Bupivacaine, on the other hand, is intermediate in onset and has a much longer duration of action of 3 to 6 hours. Mepivacaine is reportedly less irritating to tissues than lidocaine.

Intrasynovial analgesia can be used to more specifically isolate lameness to a joint, tendon sheath, or bursa. It can be used in combination with perineural analgesia or alone depending on the suspected source of the lameness. Proper patient restraint and strict aseptic technique, including aseptic preparation of the skin, wearing sterile gloves, and use of a new bottle of anesthetic, are imperative to avoid iatrogenic synovial sepsis. Lameness may be erroneously associated with a joint if intraarticular analgesia of several joints is performed within a short period of time; ample time (30 to 60 minutes) must be allowed between joint blocks to allow for adequate articular desensitization. Some intraarticular and intrasynovial anesthetic techniques may mimic the results of perineural anesthesia. An example is that of the coffin joint, where intraarticular anesthesia of the joint has the same regions of anesthesia as that of the palmar digital nerve block. It is important not to overinterpret the results in such cases.

When performing intrasynovial analgesia, it is not necessary to follow the distal-to-proximal rule. If intraarticular analgesia of a proximal joint results in no improvement in the lameness, immediate follow-up with distal limb perineural blocks is still possible. Exceptions to this rule exist with intrasynovial analgesia to the foot. When performing intrasynovial analgesia of the distal interphalangeal joint (DIPJ) or navicular bursa, it is important to take into consideration the volume of anesthetic used and the timing at which the lameness is reevaluated. The recommended volume of anesthetic for the DIPJ is 4 to 5 mL, and for the navicular bursa 3 to 4 mL. Once injections into these structures have been performed, the horse should be evaluated at 5-minute intervals to help with the interpretation of the response to the block because they may result in inadvertent anesthesia similar to the palmar digital nerve block.

Significant improvement in experimentally induced lameness to the navicular bursa can be seen at 5 minutes after intraarticular anesthesia of the DIPJ with 5 mL of 2% mepivacaine hydrochloride. Amelioration of bursal lameness is most likely caused by diffusion of the anesthetic into the bursa via an indirect or functional communication, or by diffusion of anesthetic into the periarticular tissues. The proximal palmar pouch of the DIPJ lies in close proximity to the palmar digital (PD) neurovascular bundles as they course along the medial aspects of the collateral cartilages, making it possible for anesthetic diffusion to block nerve conduction at that level.

Experimentally induced solar toe pain can also be ameliorated by intraarticular blockade of the DIPJ with 10 mL of 2% mepivacaine hydrochloride. The structures innervated by the deep branch of the PD nerves include the DIPJ, navicular bursa, distal navicular ligament, laminar corium, and corium of the sole. The DIPJ capsule contacts the PD neurovascular bundle, and a local anesthetic injected into the DIPJ likely desensitizes the PD nerves below the level of the coronary band, as well as the structures innervated by them.

Variable responses are also seen with blockade of the DIPJ when different volumes of anesthetic are used. Blocking the DIPJ with 6 mL of 2% mepivacaine results in significant improvement in lameness originating from the dorsal margin of the sole; however, lameness originating from the palmar sole shows no improvement. Using 10 mL of mepivacaine reduces lameness originating from the dorsal margin of the sole, as well as the palmar heel regions of the sole, but only after 30 minutes. The difference in response to analgesia of the DIPJ in attenuating pain at the dorsal margin of the sole versus the angles of the sole may be because these regions are innervated by different branches of the PD nerve. This may help distinguish between pain arising from the DIPJ or the navicular apparatus and palmar solar pain.

In contrast to the responses seen with blocking the DIPJ in the presence of navicular bursa disease, blocking the navicular bursa with 3.5 mL of mepivacaine hydrochloride in the presence

VetBooks.ir

of experimentally induced DIPJ lameness results in a significant improvement in lameness but only after 30 minutes. Experimentally induced lameness from the dorsal sole is improved by blockade of the navicular bursa; lameness originating from the palmar sole does not show significant improvement.

Knowledge of the previously described responses to intrasynovial analgesia of the DIPJ and the navicular bursa is helpful in localizing and interpreting lameness commonly seen in the horse. Similar responses can be encountered with intraarticular analgesia of the carpus and distal tarsal joints. Instillation of anesthetic into the middle carpal joint and the tarsometatarsal joints can result in desensitization of the proximal suspensory ligament, a common site for soft tissue injury and lameness in the horse.

Recently, objective methods of lameness evaluation have become prevalent in equine veterinary practice. The development of a body-mounted inertial sensor system using accelerometers and gyroscopes to measure acceleration and angular velocity of the head and torso during locomotion has been shown to facilitate lameness evaluation. Results of a recent study indicated that lameness evaluation of horses obtained by use of a body-mounted inertial sensor system was significantly associated with results obtained via subjective lameness evaluation by expert clinicians. The objective measurements provided by this system may be beneficial for evaluation of horses with mild, intermittent lameness; difficult, multi-limb involvement; and for documentation of response to regional or intraarticular anesthetic blocks.

Once the lameness has been described and localized, a radiographic or ultrasonographic examination can be performed as the next step to confirm a clinical diagnosis. Radiography should be performed using proper technique, an ideal film/screen combination, and multiple views to construct a thorough study (Table 13.3). Comparing radiographs of affected and unaffected limbs can help confirm or refute a suspected abnormality, evaluate the severity of the disease, and identify possible bilateral limb involvement.

Although standard radiographic techniques are well documented and described, ultrasound examination has become a mainstay in musculoskeletal imaging. Indications for ultrasonographic evaluation of a lameness include diagnosis of soft tissue injuries, including muscular, vascular, tendon, tendon sheath, ligament, joint capsule, or bursal defects; evaluation of articular surfaces (articular cartilage thickness, osteochondritis dissecans lesions); assessment of fluid accumulation (synovial effusions, seromas, or infection); evaluation of bony surfaces; monitoring of the progression of healing; and monitoring of the effects of training on soft tissue injuries such as tendonitis or desmitis.

When radiographic or ultrasonographic techniques are nondiagnostic, other methods such as thermography, nuclear scintigraphy, treadmill evaluation, computerized videographic gait analysis, force plate evaluation, body-mounted inertial sensors examination, computed axial tomography (CAT), or magnetic resonance imaging (MRI) may be useful.

TABLE 13.3

Recommended Radiographic Views of Extremities

Radiographic Series	Minimum Radiographic Views
Distal extremity (navicular)	45 degrees DP, 65 degrees DP (2), LM, flexor tangential[a]
Pastern	45 degrees DP, LO, MO, LM
Fetlock	45 degrees DP, LO, MO, LM, flexed LM
Metacarpal or metatarsal	DP, LO, MO, LM
Carpus	DP, LO, MO, LM, flexed LM, flexed skylines (distal radius, proximal and distal rows of carpal bones)
Tarsus	0 degrees DP, 10 degrees DP, LO, MO, LM
Radius-ulna or tibia-fibula	Cr-Cd, LO, MO, LM
Elbow	Cd-Cr, LO, LM
Shoulder	ML
Stifle	Cd-Cr, LM, flexed LM, Cd 30° L-CMO, patellar skyline

[a]View to highlight the flexor cortical margin of the navicular bone (50 degrees proximal palmarodistal oblique).

Cd-Cr, Caudocranial; *Cd 30° L-CMO*, caudal 30-degree lateral-craniomedial oblique; *Cr-Cd*, craniocaudal; *DP*, dorsopalmar (dorsoplantar); *LM*, lateromedial; *LO*, lateral oblique; *ML*, mediolateral; *MO*, medial oblique.

Approach to Diagnosis of Stiffness, Lameness, and Abnormal Gait and Posture in Ruminants

Sarel R. Van Amstel • Jan K. Shearer

Clinical signs can be caused by neurologic deficits, pain, and muscular or skeletal disorders. Diagnosis requires a complete history, including review of information on lameness in dairy records; careful observation during standing and walking, including locomotion scoring; and examination and palpation of the foot and upper limb.

History

Historical details should be obtained in terms of duration, severity, onset of clinical signs, and previous treatment. Past history may help establish if the condition is acquired or congenital. This is particularly important in order to distinguish among conditions with similar signs such as spastic paresis, upward patella fixation, and spastic syndrome. History should also include information regarding management and housing such as free stall size and bedding; evidence of overcrowding; types of walking surfaces; number of times a day milking; and accumulation of mud, manure, gravel, and stones on tracks in cases of pastured cattle. Finally, historical information regarding nutrition including the use of supplements, water source, and potential toxin exposure should be included.

Observation

Detection of lameness may present a challenge because cows are adept at disguising discomfort. Therefore careful observation both during standing and walking is important. Changes in weight bearing, posture, and conformation may be indicative of both the presence and type of lameness. Nearly 90% of lameness involves the foot; thus particular attention should be paid to alterations in weight bearing between claws. Observation is best conducted on a flat, hard surface because subtle lameness may not show when the animal is walking on a softer earthen surface. Stiffness and rigidity may be major components of altered gait and posture. Common causes in which stiffness may be an important component are shown in Box 13.3.

Palpation

For upper leg conditions, hands-on examination includes palpation during standing and walking, as well as manipulation of the leg with the animal in lateral recumbency. For examination of the hip, the examiner attempts to detect crepitation in the joint by placing both hands over the greater trochanter while an assistant abducts, adducts, and rotates the affected limb. For the stifle, examination in the standing animal involves palpation of the joint for fluid effusion and stability. Stability of the joint can be assessed in the following ways: (1) Standing

VetBooks.ir

BOX 13.3

Alterations in Gait in Ruminants in Which Stiffness Can Be a Major Component

Chronic hypophosphatemia
Chronic fluorosis
Tetanus
Lupine alkaloid intoxication
Copper deficiency or molybdenosis
Acute laminitis
Nutritional myodegeneration (white muscle disease)
Locoweed toxicity
Sweet clover poisoning
Rickets, osteomalacia, osteodystrophy
Bovine virus diarrhea (coronitis and cerebellar atrophy) (B)
Sarcocystis
Vesicular stomatitis (B)
Overgrown claws
Bluetongue (coronitis) (O)
Degenerative joint disease
Muscle trauma
Ionophore toxicity
Hemlock poisoning
Generalized calcinosis
Fescue intoxication (fescue foot)
Frostbite
Contracted tendons
Selenium toxicosis
Clostridial myositis
Claviceps spp. mycotoxicosis (ergotism; Bahia grass and Dallis grass staggers)
Mycoplasma bovis polyarthritis and tenosynovitis (B)
Mycoplasma mycoides subsp. *mycoides* polyarthritis (C)
Caprine arthritis encephalitis virus (CAE) (C)
Muscle abscess
Ruptured anterior cruciate ligament or torn collateral ligament of stifle
Luxations and subluxations
Upward fixation of the patella
Epiphysitis

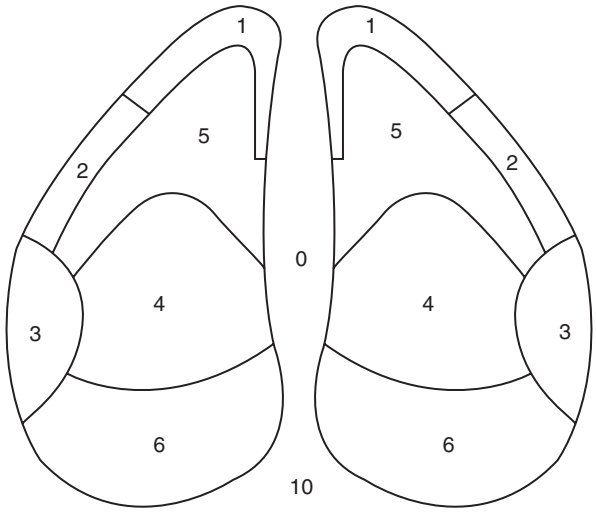

FIG. 13.1 Zones of ruminant claw.

behind the animal, the examiner reaches around the leg with both hands locking the fingers over the tibial crest while leaning into the back of the thigh. The leg is stabilized against that of the examiner while the tibia is pulled caudally (Video 13.1). (2) Alternatively, the examiner stands in front of the affected leg and attempts to demonstrate laxity by pushing on the tibial crest. It is important to stabilize the foot during this procedure. Distention of the joint capsule can cause swelling between the patellar ligaments despite the presence of the fat pad (see Video 13.1). One should also note that there are extensions of the joint capsule between the quadriceps femoris muscle and the femur and distally around the tendons of the peroneus tertius and the long digital extensor muscle.

When evaluating the tarsus or hock, one should always assess the degree of flexion possible in this joint. Overflexion of the hock indicates gastrocnemius rupture, whereas overextension may be indicative of rupture of the peroneus tertius.

Swelling of joints and legs should be palpated for heat, pain, and consistency. Peritarsal bursitis causes a soft, nonpainful swelling on the lateral side of the hock, whereas a hard, painful swelling may be associated with septic arthritis or degenerative joint changes. In cases of septic arthritis, a discharging tract may also be present.

In some cases it may be difficult to distinguish upper from lower leg problems. This can be done by placing a tourniquet at or slightly above the level of the fetlock joint followed by an intravenous injection of 20 mL of 2% lidocaine into a vein below the tourniquet (Video 13.2). Remove the tourniquet after a few minutes or so, and immediately allow the animal to walk. In cases of an upper leg problem, the lameness will persist. Pain and lameness associated with upper leg problems tend to become worse after a period of flexion.

Foot and claw conditions are diagnosed by visual appearance after appropriate restraint. The claw including the interdigital space is thoroughly cleaned. Claw horn and foot lesions should be identified, taking into consideration the location and the claw zone affected (Fig. 13.1). The presence of pain should be investigated if no lesions are visible. This can be done with a hoof tester. Important areas in which to apply pressure include the sole ulcer site in the axial region of zone 4 and the toe ulcer site in zone 5. Sole hemorrhages occurring in zone 4 should also be tested for pain.

The skin of the interdigital space and interdigital cleft (zones 0 and 10, respectively) should also be carefully examined for evidence of fissures or lesions indicative of digital dermatitis.

Postural Deformities

Carter E. Judy • John Maas

A postural deformity in horses or ruminants is an abnormal stance caused by neurologic deficit, pain, or a musculoskeletal problem. Postural deformities can range from subtle conformational faults such as broken forward foot axis to severe and unusual positions, such as when the animal is camped out in front. Inability to bear weight on a limb, asymmetric angles between joints, and lateral or medial deviations in the alignment of limbs are examples of postural deformities. Often the postural deformity itself is specific for certain diseases and conditions (Table 13.4).

Mechanisms of Postural Deformities

Postural deformities can be either congenital or acquired and result from maldevelopment, trauma, or disease. Congenital deformities may be caused by tendon contracture or laxity, osseous malformation, and hypoplasia or aplasia of osseous structures or soft tissues. Acquired deformities are most often caused by trauma or disease. Disuse atrophy secondary to an unrelated musculoskeletal abnormality can result in abnormal posture. Occasionally diseases affecting proprioception and consciousness may cause an abnormal stance that appears as

VetBooks.ir

TABLE 13.4

Examples of Postural Deformities and Possible Origins for Horses

Postural Defect	Likely Site of Origin
Contracted heels	Foot; flexor tendons
Bucked knees	Suspensory ligament
Dropped elbow	Motor nerves to forelimb; olecranon
Tiptoe stance	Foot; flexor tendons; interphalangeal joints
Non–weight bearing	Foot; any long bone; any limb articulation
Broken down (hyperextension) fetlock; dropped fetlock	Suspensory apparatus
Toe-out hindlimb and elevated hip	Coxofemoral joint; femoral neck
Basewide behind	Coxofemoral joint; femoral neck
Hyperextension of stifle and hock	Patella
Camped out in front	Bilateral forefeet
Carpal valgus	Distal metaphysis, physis, epiphysis, or carpal bones
Stiffly elevated head	Withers; cervical spine
Shifting weight between forefeet	Bilateral forefeet
Recumbency	Any long bone; feet; spinal cord; myopathy

a postural deformity (e.g., head pressing) but is unrelated to neurologic pain or a musculoskeletal problem.

Approach to Diagnosis of Postural Deformities in Horses

A history can help the examiner determine if a postural deformity is congenital, as with arthrogryposis, or acquired. Because most postural deformities in horses (Box 13.4) arise from traumatic injuries or overuse, a complete lameness examination is essential. Occasionally a postural deformity does not cause lameness; in these instances the veterinarian must consider nontraumatic causes associated with abnormal development, improper nutrition, and seemingly unrelated disease such as carpal valgus deformity.

Diagnosis of the cause of a postural deformity begins with a detailed description of the deformity and assessment of the position and asymmetry of the anatomic structures involved. If the nature and severity of the deformity cannot be determined by direct observation, palpation and manipulation of the affected structure are required. Radiography and ultrasonography can also assist in the diagnosis and provide information on which to base treatment recommendations and prognosis.

Approach to Postural Deformities in Ruminants

Sarel R. Van Amstel • Jan K. Shearer

The causes of postural deformities in cattle vary widely and may be congenital, nutritional, environmental, traumatic, and infectious. History, visual inspection, manipulation, and palpation are important in the diagnosis of postural deformities in ruminants. Postural deformities in ruminants including the origin are shown in Box 13.5.

Overall symmetry of the limbs may be changed because of swellings originating from muscle, bones, or joints and muscle atrophy. Swellings could be caused by dislocations of joints or fractures of any long bone caused by trauma or metabolic bone disease. Other swellings of joints include septic arthritis in which the joint is swollen and painful and there is a palpable effusion in the joint. In cases of degenerative joint disease, the

BOX 13.4

Causes of Postural Deformities in Horses

Common Causes

Infections of the foot
Hoof wall defects
Fractures
Septic (infectious) arthritis
Secondary (degenerative) joint disease
Laminitis
Angular limb deformities
Osteomyelitis
Sprain
Strain
Tenosynovitis
Contracted tendons (flexural deformity)
Laxity of flexor tendons in foals
Tendon rupture, damage, tendonitis (bowed tendon)
Upward fixation of the patella (locking patella)
Epiphysitis
Septic tenosynovitis
Muscle injury, soreness, bruise, trauma, compartment syndrome
Navicular disease
Cuboidal bone hypoplasia

Less Common Causes

Disruption of the suspensory apparatus (broken down)
Lateral or medial patellar luxation
White muscle disease (nutritional myodegeneration)
Brucellosis
Sesamoiditis
Hypertrophic osteopathy or osteodystrophy
Ankylosis or arthrogryposis
Luxation or subluxation
Snakebite
Equine monocytic ehrlichiosis (Potomac fever)
Spondylitis, diskospondylitis
Spinal or vertebral neoplasia
Tick paralysis
Vertebral column malformation
Nigropallidal encephalomalacia (star thistle poisoning)
Postanesthetic equine myasthenia
Abscess caused by *Clostridium perfringens*
Hyperparathyroidism
Osteomalacia, osteodystrophy (rickets)

Uncommon Causes

Lupus erythematosus (rheumatoid arthritis)
Osteochondrosis
Cruciate or meniscal rupture
Patellar ligament injury
Malnutrition
Splenic rupture
Neonatal maladjustment
Subcutaneous abscess, cellulitis, foreign body
Vesicular stomatitis
Bucked shins (dorsal metacarpal disease)
Hemimelia (radial, tibial, ulnar hypoplasia, agenesis)
Botulism (shaker foal)
Myotonia congenita
Skeletal neoplasia
Shivers (shivering)
Borreliosis (Lyme disease)

Osteomalacia
Locoweed-associated limb deformities
Epiphysitis
Chronic selenosis
Primary/secondary copper deficiency
Calcinosis caused by plant poisoning

Acquired

Secondary contracted tendons
Fractures
Degenerative joint disease
Ruptured gastrocnemius
Septic tenosynovitis
Peroneal neuropathy
Radial neuropathy
Suprascapular neuropathy
Obturator neuropathy
Severed or ruptured tendons
Luxations
Arthritis (septic)
Ruptured peroneus tertius
Muscle atrophy caused by denervation
Tibial neuropathy
Femoral neuropathy
Sciatic neuropathy
Myopathies

swelling is hard and often not painful to pressure. Swellings of the muscle could be hard (vitamin E/selenium deficiency); soft and fluctuant, such as with subcutaneous hematoma or abscesses; or crepitant, such as with subcutaneous emphysema or gangrenous myositis (e.g., blackleg).

Leg Angles

Straight hocks in excess of 175 degrees may predispose to degenerative joint disease. Bilateral excessive hock angle (sickle hock) is often associated with shallow toe angles and low heels. Cow hocks (inward hock rotation), on the other hand, are often associated with unbalanced weight bearing and overgrowth of the outer claws. Abduction of a single leg usually indicates pain in the outer claw, whereas a basewide stance in the front legs is indicative of pain in the outer claws. In the rear legs, a basewide stance may also be due to obturator nerve paralysis, which affects the adductor muscles of the inner thigh of the rear legs. Apart from a basewide stance, animals affected by obturator nerve paralysis appear ataxic and are predisposed to splaying their back legs. With a "camped under" posture, more weight is shifted to the rear legs and is often associated with pain in the front feet due to laminitis. Laminitis and pain may also cause the animal to cross the front legs in an effort to remove weight from the medial claws. Partial flexion of the front leg with inability or difficulty in advancing the leg may be associated with suprascapular or radial nerve injury or bicipital bursitis. The leg is held in semiflexion, and the elbow is dropped in case of damage to the radial nerve at the level of the brachial plexus.

POSTURAL CHANGES ASSOCIATED WITH STIFLE JOINT. Instability within the stifle joint associated with cranial cruciate rupture is often seen when the animal is walking and may be accompanied by an audible sound (Video 13.3). This is caused by sliding of the femoral condyles over the tibial plateau. The animal tends to stand with the fetlock slightly flexed and the heel raised. Weight bearing is on the tip of the toe. In cases of medial collateral ligament instability, the leg is held in an abducted position to relieve weight bearing on the medial side of the stifle and weight is placed on the medial claw when walking. With upward fixation of the patella the limb will "lock" while in full extension. This is followed by a stringhalt-type exaggerated motion during flexion. The animal may have a normal gait in between steps. Rarely the leg may become locked in extension.

POSTURAL CHANGES ASSOCIATED WITH HOCK JOINT. Dropping (overflexion) of the hock during standing, but more so during walking, is often indicative of gastrocnemius rupture (Video 13.4). Tibial nerve paralysis also results in a dropped hock and slight knuckling of the fetlock. The hock remains dropped while the animal is walking but does not sink during weight bearing, in contrast to rupture of the gastrocnemius muscle. Overextension of the hock is associated with peroneal nerve damage, peroneus tertius rupture, upward fixation of the patella, flexor tendon contracture, and advanced degenerative joint disease. Intermittent spastic contracture of both legs with flexion of the hocks is caused by spastic (spasmotic) syndrome (Video 13.5). In contrast, spastic contracture of one or both hind legs with overextension of the hock is due to spastic paresis. Cattle with damage to the peroneal nerve will stand with the foot knuckled over onto the dorsum of the pastern and fetlock joint. At the same time the hock joint will appear to be overextended. In mild cases, the fetlock tends to knuckle over intermittently when the cow walks.

POSTURAL CHANGES ASSOCIATED WITH FETLOCK AND INTERPHALANGEAL JOINTS. Knuckling of the fetlock joint is associated with neuropathy of the sciatic nerve and its branches, the peroneal and tibial. Other causes include lesions of the palmar or plantar aspect of the foot or sole, as well as conditions of the spinal cord (e.g., lymphosarcoma) or vertebral column.

POSTURAL CHANGES ASSOCIATED WITH NERVES, TENDONS, AND JOINTS OF FRONT LEGS. Postural changes and clinical signs of suprascapular nerve injury include stumbling, inability to support weight in severe cases, inability to support and extend the shoulder, a shortened stride, and abduction of the leg. Reflexes and sensation in the lower limb remain normal if the suprascapular is the only nerve affected, and atrophy of the supraspinatus and infraspinatus muscles can become visible in 5 to 7 days after injury.

In calves, contracture of the flexors may cause flexion of both the carpus and fetlock. In such cases, the leg usually cannot be straightened. Semiflexion of the knee can also be due to abnormal conformation or metabolic bone disease.

VetBooks.ir

Depending on the level of contracture of the flexors, only the fetlock may be affected. In more severe cases, the carpus may also be affected because of contracture of the flexor carpi radialis and ulnaris or, additionally, because of fibrosis of the joint capsule. In milder cases, the animal may be able to walk on its toes and knuckle forward during weight bearing. In more severe cases, the animal bears weight on the dorsum of the foot or is unable to walk.

POSTURAL CHANGES ASSOCIATED WITH CONDITIONS OF FOOT (DEFINED AS PART OF LIMB BELOW FETLOCK). A symmetric swelling of the foot sometimes extending to and above the fetlock is usually associated with foot rot, whereas a unilateral swelling of the digit is more often associated with a septic tenosynovitis, retroarticular space abscess formation, or sepsis of the distal interphalangeal joint. This can be confirmed through an aspirate of the distal interphalangeal joint and ultrasound of the flexor tendons and structures in the heel. Toe ulcers may cause a heel-first foot placement or weight bearing toward the heel when standing; these can be seen in the apex of zone 5 (see Fig. 13.1). The proximal interphalangeal joint may become subluxated with superficial flexor tendon contracture, resulting in knuckling of the joint.

Septic arthritis of the distal interphalangeal joint results in severe lameness with little to no weight bearing during both standing and walking. White line disease in zone 3 of the rear outer claw often prompts the animal to abduct the limb to move weight bearing to the medial claw. Ulcers or hemorrhage in zones 4 and 6 could also be responsible for changes in gait and posture, which may include inward rotation of the hocks to reduce weight bearing on the outer claws of the rear legs, knuckling of the fetlock, crossing of the front legs, and abduction or adduction of the leg. White line disease in zones 1, 2, and 3 could also result in postural change.

Swellings and Enlargements (Soft and Hard Tissue)

Carter E. Judy • John Maas

Swellings and enlargements consist of soft tissue (e.g., tendon) or hard tissue (e.g., osseous) and can occur anywhere on an animal's body. Typically, swellings and enlargements that are clinically relevant are located on the limbs.

Swellings and enlargements can be further divided into two principal groups: those associated with a specific musculoskeletal anatomic structure and those that are not. For example, a soft fluctuant swelling in the region of the left carpus may be caused by an abnormality of the antebrachialcarpal joint (e.g., septic synovial effusion) or may not involve the joint at all (e.g., subcutaneous abscess). Although lameness can be associated with such a swelling, clearly it is important to determine the cause of the abnormality because the one involving the joint may require the more immediate treatment.

Mechanisms of Swellings and Enlargements

The mechanism by which swelling or enlargement develops depends on the tissue involved. Soft tissue swelling is often produced by trauma, inflammation, infection, or neoplasia; it can consist of interstitial fluid (e.g., edema), fluid within an open space (e.g., synovial hernia), or a localized accumulation of cells or fibrous tissue. Localized edematous swelling is commonly caused by inflammation and/or obstruction of venous blood or lymph flow. Generalized edema is usually the result of increased hydrostatic pressure caused by circulatory failure or an altered capillary-tissue osmotic gradient stemming from hypoalbuminemia. Fluctuant swellings such as hematoma, synovial effusion, a purulent abscess, or a plasma-filled cyst contain free fluid. Granulation tissue, fibrous scar tissue, and tumor cells are the most common constituents of firm soft tissue swellings. Rupture of supporting or confining structures (e.g., prepubic tendon rupture) can result in unusual forms of soft tissue swelling caused by herniation of internal organs.

Many factors influence new bone formation. Trauma and infections initiate bony enlargement (e.g., callus) by disrupting the periosteum, producing inflammation and eventually ossification. The extent of periosteal new bone formation depends on the cause of the stimulus and size of the affected area. Remodeled bone may also arise from nontraumatic events, usually associated with altered metabolism or neoplasia. Bony enlargements associated with the metaphysis and physis in young, growing animals are usually secondary to a combination of nutritional and traumatic factors. For example, dietary calcium, phosphorus, and vitamin D imbalance can lead to abnormal bone growth. A bony swelling develops gradually and may become noticeable only after it enlarges, interferes with normal function, or becomes a source of lameness.

Approach to Diagnosis of Swellings and Enlargements in Horses

For causes of swellings and enlargements in horses see Box 13.6.

1. History. A history should determine the number of horses involved, duration of clinical signs, and possibility that traumatic events or environmental factors are responsible for causing a swelling or enlargement. In addition, changes over time in the appearance and size of the swelling or enlargement can be informative.

BOX 13.6

Causes of Swellings and Enlargements in Horses

Soft Tissue

Septic (infectious) arthritis
Secondary (degenerative) joint disease
Sprain
Strain
Hygroma

Epiphysitis
Luxation or subluxation
Osteochondroma
Osteomalacia (rickets)
Bucked shins (dorsal metacarpal disease)
Hypertrophic osteopathy
Ankylosis or arthrogryposis
Calcinosis caused by plant poisoning
Selenium toxicity

VetBooks.ir

2. Inspection and palpation. The location of the swelling and its proximity to anatomic structures often reveal the tissue involved and the probable cause of the condition. For example, swelling around a joint may indicate arthritis, periarthritis, or hygromas. Tendon swelling may indicate tendonitis or ruptured tendons. Swelling over ligaments may indicate rupture, subluxation, or inflammation around a ligament. Muscle swelling results from abscesses or fascial tears. Subcutaneous swelling may indicate hematomas, edema from inflammation around a ligament, or cellulitis. Bony enlargements can often be localized to the shaft of a bone (e.g., periosteal callus) or ends of a bone (e.g., metaphyseal flaring). Periarticular new bone may be readily apparent (e.g., ringbone) or may not be found even on deep palpation. New bone formation can also be found associated with the axial skeleton and head. Palpation of a swelling can determine its consistency and association with anatomic structures. Osseous swelling indicates calcification, proliferation of bone, or fracture. Firm soft tissue swelling indicates inflammation, abnormal proliferation of soft tissue (e.g., granulation, tumor), or herniation. Warmth, redness, and pain associated with swelling indicate active inflammation. While new bone is forming, the swelling may be soft and sensitive to palpation. Cold and insensitivity to palpation suggest inadequate blood supply and possibly ischemia (e.g., gangrene). Lameness caused by an injury or condition that results in a hard swelling or enlargement may be accentuated by performing a stress test, such as trotting the horse in hand after direct pressure on the swelling. Intraarticular anesthesia may substantially reduce lameness caused by joint effusion associated with periarticular new bone.
3. Radiography, ultrasonography, and alternative imaging techniques. In addition to identifying definitively the nature of an osseous swelling or enlargement, radiography can gauge the severity and progression of the disease and help establish a therapeutic plan and prognosis. Ultrasound can often determine the position (e.g., depth, area) and volume of a soft tissue swelling and the optimum site for aspiration or biopsy. Thermography may help identify subtle heat production secondary to inflammation and increased blood flow, before onset of a swelling, allowing for early treatment. Nuclear scintigraphy may help localize the cause of swellings and identify whether they are bony or soft tissue in origin. CAT scanning is useful for evaluating bony swellings, especially of the head when swellings of the mandible and maxilla may be related to infected teeth. MRI may prove useful for accurate imaging of soft tissue masses that cannot be accurately characterized with other diagnostic techniques.
4. Cytology, microbiology, and histology. A fine-needle aspiration, using aseptic techniques, should be performed to obtain samples for microbiologic culture (e.g., bacterial and fungal) of soft tissue swellings. If the material is very viscous, a large-gauge needle may be required. Fluid collected for cytology should be placed in tubes containing ethylenediaminetetraacetic acid (EDTA) to prevent clotting before analysis. Tissue samples obtained by biopsy should be placed in 10% buffered formalin.

Swellings and Enlargements in Ruminants

Sarel R. Van Amstel • Jan K. Shearer

Swellings and enlargements can originate from soft tissue (muscle or tendons) or hard tissue (bone). Those associated with lameness usually occur on the limbs.

Approach to Swellings and Enlargements in Ruminants

History

History will indicate whether it is congenital or acquired, as well as the duration. Historical information should also include type of pasture, presence of lameness, and progression of the lameness signs, possibility of trauma, vaccination history, appetite, and presence of systemic signs, as well as the number of animals affected.

Examination Including Palpation

The anatomic location of the swelling may give an indication as to its origin. Palpation will provide information about the nature and possible cause of the swelling. Soft fluctuant swellings on the upper leg are usually due to abscess formation following a small penetrating wound, or they may occur after an intramuscular injection. Cattle on sweet clover may develop hematomas due to the presence of warfarin sodium, which inhibits vitamin K and thus vitamin K–dependent factors.[2,7,9,10] Fluid effusion into a joint capsule will result in a soft fluctuant swelling. Those associated with septic joints are usually less fluctuant and warm and painful on palpation. Joint swelling associated with degenerative joint disease may be hard on palpation due to new bone formation and nonpainful. Fluid effusion into the joint space is usually present. Degenerative joint disease may be hereditary, typically incited by abnormal conformation. Acquired degenerative joint disease is common after traumatic injury to supporting ligaments or menisci. Unilateral swelling of the foot is often associated with sepsis of the distal interphalangeal joint and sheath of the flexor tendons. Bilateral swelling of the foot is typically associated with foot rot. Swelling immediately above the dew claws may be due to tenosynovitis, septic inflammation of the fetlock joint, rupture of the flexor tendons, or suspensory ligament. Generalized soft and nonpainful swelling of the leg that pits on pressure may be due to lymphatic obstruction, increased hydrostatic pressure, decreased oncotic pressure, or increased capillary permeability.

Radiology, Ultrasonography, and Cytology

CARPAL JOINT. Ultrasound carried out in the longitudinal plane over the dorsal surface of the joint will facilitate arthrocentesis. Individual joint recesses that can be visualized include the radiocarpal, intercarpal, and carpometacarpal joints. In the absence of ultrasound, joint fluid can usually be obtained from the radiocarpal pouch with the carpus in slight flexion. A high white cell count in the presence of degenerate neutrophils confirms septic arthritis. Bacteria may not always be visible on cytologic examination. In chronic cases of septic arthritis, the joint looks and feels thicker with a reduced range of motion. In such cases, chronic degenerative changes will be visible radiographically. These changes can first be detected over the cranial surfaces of the proximal carpal row. The radiocarpal joint space is widened, and subchondral bone destruction may be present, which is eventually followed by new bone formation.

COXOFEMORAL JOINT. Ultrasound-guided arthrocentesis can be carried out in cases where an increase in joint fluid can be visualized. Radiographs are useful in establishing the cause of lameness and may be accomplished by anesthetizing the animal and positioning it in dorsal recumbency for a ventrodorsal radiograph. The size of the musculature will greatly influence the detail visible in the radiograph.

STIFLE JOINT. The following should be considered with arthrocentesis of the stifle. There is communication between the femoropatellar and medial femorotibial joint cavities. These compartments do not always communicate with the lateral femorotibial space. To enter this compartment, a needle is introduced behind the lateral patellar ligament and directed

caudally. To enter the femoropatellar and the femorotibial compartments, the needle is inserted between the medial and middle patellar ligaments and directed slightly down and toward the medial lip of the trochlea. Use of ultrasound will confirm the presence of increased joint fluid and facilitate collection.

Paresis and Weakness

Richard Andrew LeCouteur

Paresis may be defined as a deficit of voluntary movement. It may be monoparesis (paresis of a single limb), paraparesis (paresis of both pelvic limbs), tetraparesis (paresis of all four limbs), or hemiparesis (paresis of a thoracic and pelvic limb on the same side). Paresis results from disruption of the voluntary motor pathways that extend from the cerebral cortex, through the brainstem and spinal cord, to the motor unit (peripheral nerve, neuromuscular junctions, and muscle fibers). Complete loss of voluntary movement is referred to as *paralysis (plegia)*. Voluntary movements must be differentiated from reflex movements on the basis of neurologic examination findings.

Weakness may be defined as impairment of strength and power. Most authors use the terms *paresis* and *weakness* synonymously; however, this may be confusing in some circumstances. For example, weakness may occur in the absence of paresis in some disorders of the nervous system, and weakness may result from many disease processes that do not primarily involve the nervous system (e.g., heart failure, respiratory insufficiency). The clinical signs of weakness may vary considerably and may include paresis, gait abnormalities, dysphagia, regurgitation, dyspnea, and dysphonia. Weakness may be present at rest or may occur after exercise. The distribution of involvement may be local, regional, or generalized. In addition, there may be gross deformities of muscle mass (e.g., atrophy, hypertrophy, skeletal deformities) associated with weakness.

This section focuses on paresis and weakness caused by conditions that affect the motor unit (Box 13.7). Diseases of other systems (e.g., respiratory and cardiovascular diseases or central nervous system disorders) that may result in paresis and weakness are discussed separately in other sections.

Mechanisms of Paresis and Weakness

Voluntary movement is initiated by the cerebral cortex. Muscular activity occurs subconsciously after activation of successively lower levels of the nervous system: basal nuclei, midbrain, pons and medulla, cerebellum, brainstem, spinal cord, and motor unit. The function of these lower levels is vital, and without their input voluntary movements become impossible.

Monoparesis (or monoplegia) is a common problem in horses and ruminants. It may be caused by dysfunction of the lower motor neuron or neuromuscular junction. Monoparesis is commonly caused by trauma to a nerve or plexus, although neoplasia (e.g., lymphoma, neurofibroma) and inflammation or infection (e.g., early stages of rabies) of peripheral nerves have been reported to cause monoparesis.

Bilateral pelvic limb paresis, ataxia, or paralysis may occur as a result of a neurologic disorder localized to the spinal cord caudal to the T2 spinal cord segment. Various congenital vertebral and spinal cord malformations may result in pelvic limb paresis. Equine protozoal myeloencephalitis and equine degenerative myeloencephalopathy may result in lameness, weakness, and ataxia that may progress to tetraparesis. Musculoskeletal disorders resulting only in bilateral pelvic limb weakness and paresis are unusual. Possible causes include trauma (e.g., postcalving or postfoaling paralyses caused by lumbosacral nerve root compression or contusion), vascular disorders (e.g., thrombosis), and early stages of an infectious disorder that may progress to tetraparesis.

The causes of tetraparesis are numerous and include progression of many of the disorders mentioned previously. Outbreaks of intoxication with *Clostridium botulinum* occur sporadically in horses and ruminants; the condition results in a flaccid paralysis that starts with the pelvic limbs and progresses cranially. Depending on the amount of toxin involved, large numbers of animals may be affected. Polyneuropathies (congenital and acquired) and polymyopathies (congenital, metabolic, infectious, and immune-mediated) are causes of tetraparesis.

Muscle weakness may result either from a primary neuromuscular disease or disorders that affect muscle secondarily. In the latter category, problems of horses and ruminants that commonly result in weakness include poor diet, underfeeding, toxicoses, and anorexia. Systemic diseases and disorders such as dehydration, low circulating blood volume, anemia, and metabolic abnormalities (e.g., acidosis or alkalosis) also may result in weakness. Disorders of bones and joints affecting one limb also may affect the contralateral limb through overuse or misuse, and weakness of the contralateral limb may result.

Primary neuromuscular diseases are usually classified on the basis of the anatomic component of the motor unit that is involved. Such diseases are broadly subdivided into neuropathies (disorders of the neuron, its cell body, axon, and/or Schwann cells [myelin]); junctionopathies (disorders of the neuromuscular junction); myopathies (disorders of muscle fibers); and neuromyopathies (disorders of both neurons and muscle fibers).

Dysfunction of the motor unit results in lower motor neuron signs, seen clinically as muscle weakness. The expression of this weakness may vary considerably, and the distribution of involvement may be local, regional, or generalized. Atrophy, hypertrophy, and skeletal deformities may accompany the muscle weakness. Any patient with some form of clinical weakness should be viewed as potentially having a motor unit disorder. That the patient is "weak merely because it is sick" should not be readily assumed without meticulous evaluation of the motor unit.

BOX 13.7

Causes of Paresis and Generalized Weakness in Horses and Ruminants

Anemia
Cardiovascular disease

Approach to Diagnosis of Paresis and Weakness in Horses

Establishing a diagnosis requires an informed and coordinated approach to defining a problem list through associations and direct observations (i.e., a diagnostic plan) (Box 13.8).

1. Signalment. Breed, age, sex, and use of the horse.
2. History. Feeding program, vaccination and deworming schedules, course of complaint, response to treatment, and possibility of exposure to toxins or trauma.

BOX 13.8

Causes of Paresis and Weakness in Horses

Degenerative
Equine degenerative myeloencephalopathy

Anomalous or Congenital
Hydrocephalus
Vertebral and spinal cord malformations

Metabolic
Exertional rhabdomyolysis
Hyperkalemic periodic paralysis
Hypothyroidism
Hyperthermia
Hypocalcemia
Hypokalemia
Equine hepatic lipidosis
Vitamin A deficiency

Nutritional
Macronutrient malnutrition
Vitamin E (selenium) deficiency

Neoplastic
Brain or spinal cord tumor
Lymphosarcoma
Melanoma
Leukemia

Infectious or Inflammatory
Encephalitis, myelitis
Equine protozoal myeloencephalitis
Diskospondylitis
Botulism
Rabies
Ehrlichiosis
Tuberculosis
Rhinopneumonitis
Hepatoencephalopathy
Tick paralysis
Cerebrospinal nematodiasis
Equine protozoal myeloencephalitis

Toxic
Snakebite
Plant poisons (star thistle poisoning, oleander, moldy corn poisoning, white snakeroot, locoweed, larkspur, delphinium, onion, moldy sweet clover)
Vitamin D
Phosphorus
Heavy metals (lead, arsenic)

Traumatic
Vertebral fracture or luxation

Vascular
Postanesthetic hemorrhagic myelopathy

3. Physical examination. The clinician must rely on clinical signs of abnormal function to identify the location of the neurologic dysfunction. The first step in locating a neurologic lesion is to determine the level of the abnormality along the longitudinal plane of the neuraxis (i.e., brain, spinal cord, or motor unit). The second step is to further localize the lesion within an anatomic region (e.g., motor unit should be further localized to peripheral nerve, neuromuscular junction, or muscle). The third step is to determine the location of the lesion in the transverse plane at the appropriate longitudinal level (e.g., left or right side).
4. Minimum database. Complete blood count, serum biochemistry panel (including electrolyte determinations), fecal analysis, and urinalysis may be considered. Measurement of muscle-specific serum enzymes such as creatine kinase (CK), as well as aspartate aminotransferase (AST) and lactic dehydrogenase (LDH), may be helpful in identifying neuromuscular disorders in which myonecrosis is a principal pathologic feature. Urine can be tested for the presence of myoglobin released from damaged skeletal or cardiac muscle.
5. Specific diagnostic tests: Electrodiagnostic testing. Electromyography (EMG) involves the detection and characterization of electrical activity (potentials) recorded from a patient's muscles. A systematic study of individual muscles permits an accurate determination of the distribution of muscles affected by a pathologic process.
6. Nerve and muscle biopsy examination. This procedure evaluates the morphology of portions of the motor unit and may differentiate neuropathies, junctionopathies, and myopathies. In some instances, results of muscle biopsy analysis may provide a definitive diagnosis (e.g., polysaccharide storage myopathy of horses).

Approach to Diagnosis of Paresis and Weakness in Ruminants

Sarel R. Van Amstel • Jan K. Shearer

The approach to the diagnosis of disorders causing paresis and weakness in ruminants (Box 13.9) is essentially the same as that for horses. The following should be included:

Signalment
Age, sex, breed, use (pet, dairy, beef)

History
Feed composition and storage, calving difficulty, exposure to trauma or toxins, recent purchase of new animals or new introductions into an established social group, vaccinations, housing

Physical Examination
Observe the animal from a distance to evaluate posture, signs of weakness or neurologic signs such as stumbling, and ataxia. Observe for knuckling, muscle fasciculation, and limb dragging. Look at mucous membrane color (conjunctiva or vulva). Look at the position of the eye (degree of retraction) and skin elasticity above the eye, the presence of dry mucous membranes, and capillary refill time to assess degree of dehydration. Palpate the rumen to assess rumen filling. In cases of acute rumen acidosis, the rumen is usually fluid filled. Take a rumen sample to measure pH. Do a rectal examination and palpate the spine and pelvic bones to determine the presence of fractures or any bony prominences or lymph node enlargements.

Other Diagnostic Tests
A hematocrit and total protein will give an indication of the degree of anemia or dehydration. A complete blood count including fibrinogen may indicate the presence of inflammatory disease. A blood smear should be examined for the presence of blood parasites and type of anemia present. Blood chemistry including electrolytes and the animal's blood gas status should be evaluated. A neurologic examination should be carried out. Reduced lower jaw and tongue tone, as well as dysphagia, may be indicative of botulism, rabies, polioencephalomalacia, or listeria. Other common cranial signs may include ptosis, anisocoria, delayed or absent pupil light response, dropped ears, facial asymmetry, delayed or absent sensory response to

Vertebral fracture or luxation
Calving paresis

Parasitic

Parelaphostrongylus tenuis

Toxic

Lead poisoning
Ionophore toxicity

the face, head tremors, blindness, and star gazing. Intension tremors may indicate cerebellar disease, whereas head pressing may indicate problems with the cerebral cortex.

The degree of ataxia and weakness can be tested by walking the animal in a tight circle and observing the proprioceptive response or pulling the tail (laterally) while walking next to it. Spinal reflexes can be done if the animal is recumbent. Box 13.9 lists causes of paresis and weakness in ruminants. A spinal tap should be considered, particularly in small ruminants including camelids where an eosinophilic pleocytosis is suggestive of meningeal worm infestation.

Muscle Spasms and Myoclonus

Richard Andrew LeCouteur

Muscle spasms are sudden, transient, and involuntary contractions of a single muscle or group of muscles, attended by pain and loss of function. Often all the muscles affected by a spasm are supplied by a single nerve. A painful, tonic, spasmodic muscular contraction is often referred to as a *cramp*.

Myoclonus may be defined as a disturbance of neuromuscular activity characterized by abrupt, brief, rapid, jerky, arrhythmic, asynergic, involuntary contractions involving portions of muscles, entire muscles, or groups of muscles, regardless of their functional association. The movements may be single or repetitive (10 to 50 per minute) and are similar to those that follow stimulation of a muscle. Myoclonus is seen primarily in muscles of the limbs, where involvement is often diffuse or widespread. Myoclonus may also be present in facial or masticatory muscles and muscles of the tongue, larynx, and pharynx. Myoclonus usually disappears during sleep.

This section describes muscle spasm and myoclonus as specific clinical signs associated with dysfunction of the musculoskeletal system.

Mechanisms of Muscle Spasms and Myoclonus

Spasms are usually of reflex origin and may result from irritation or stimulation at any level of the nervous system from the cerebral cortex to the muscle fibers. In most cases, however, spasms are caused by peripheral irritation affecting either muscles or nerves. Pain may cause either tonic or clonic spasms of muscles, especially if the painful stimulus is focal or discrete. Mechanical irritation may cause a localized spasm. There may be prolonged and characteristic muscle spasm associated with hyperirritability of nerves and muscles in tetany or tetanus. Spasms may follow injury or irritation of peripheral nerves, particularly during the process of regeneration. Spasms may also result from irritation or diseases affecting cortical centers in the brain, motor nuclei in the brainstem, or descending motor pathways in the spinal cord.

There has been much discussion regarding the pathologic process underlying myoclonic movements. Although it was originally thought that the neural discharge that excites the muscular contraction of myoclonus was confined to the motor unit, it is now known that myoclonus may also result from dysfunction of the brain (e.g., cerebral cortex, brainstem, basal nuclei, thalamus), spinal cord, peripheral nerve, neuromuscular junction, or the muscle itself, alone or in combination. A variety of processes evidently lead to hyperexcitability of the cerebral cortex, subcortical structures, or even the lower motor neurons alone. Myoclonic movements or muscle spasms may occur in a variety of conditions. They have been observed in association with encephalitis, meningitis, toxic and postanoxic states, metabolic disorders, degenerative diseases, and vascular and neoplastic conditions. Myoclonus has also been reported in association with lesions of peripheral nerves, nerve roots, and spinal cord.

Specifically, disturbances in plasma electrolyte concentrations, certain drugs, and toxins may elicit involuntary muscle activity. In general, the mechanism that is common to all causes of spasm or myoclonus involves inappropriate stimulation of a nerve or muscle cell, causing the cell to fire a series of action potentials, resulting in muscle contraction. For example, toxins may act directly on the muscle cell membrane to stimulate the release of calcium into the cell from the sarcoplasmic reticulum, thereby causing involuntary muscle contraction. Alternatively, some toxins may cause efferent neurons to release

neurotransmitter across the neuromuscular junctions, thereby stimulating receptors on the muscle cell membrane.

Approach to Diagnosis of Muscle Spasms and Myoclonus in Horses

A broad spectrum of diseases may be associated with muscle spasms or myoclonus in horses (Box 13.10). A thorough investigation is necessary to achieve an accurate diagnosis.

1. History. A comprehensive history should include evaluation of the environment and stablemates, description of any traumatic episodes, and any potential drug or toxin exposure.
2. Physical examination. Complete lameness and neurologic examinations should be done as extensions of a thorough physical examination.
3. Minimum database. Complete blood count, serum biochemistry panel (including muscle enzyme determinations), and cerebrospinal fluid analysis should be considered. In the case of muscle spasm and myoclonus, elevation in muscle enzymes may indicate secondary muscle damage rather than a primary muscle disease. A tetany panel, including serum calcium, phosphorus, and magnesium determinations, may be completed. Hypocalcemia may be a cause of muscle spasms in lactating horses, exhausted endurance horses, or horses transported long distances.
4. Specific diagnostic tests: Electrodiagnostic testing. A systematic study of individual muscles using EMG permits an accurate determination of the distribution of muscles affected by a pathologic process.
5. Nerve and muscle biopsy examination. This procedure evaluates the morphology of portions of the motor unit and may differentiate neuropathies, junctionopathies, and myopathies.

TABLE 13.5

Causes and Pathogenesis of Muscle Spasms in Ruminants

Sign	Pathogenesis
Posterior paralysis of Danish Red calves	Single Mendelian recessive factor from 1 bull
Inherited congenital myoclonus of polled Herefords and their crossbreeds	Decrease in inhibitory glycine receptors
Maple syrup urine disease in polled Herefords and their cross breeds	Deficiency of activity of mitochondrial enzyme branched-chain alpha-keto acid dehydrogenase
Lethal spasms in Jersey and Hereford calves	Autosomal recessive gene from 1 bull
Congenital brain edema in Herefords	Autosomal recessive gene
Hypomagnesemia (lactation tetany; grass tetany; grass staggers; wheat pasture poisoning)	Stress; transport; dietary deficiency (lush pasture, high potassium and nitrogen); inclement weather; lactation and pregnancy; individual susceptibility
Hypocalcemia	Onset of lactation, vitamin D deficiency, starvation, metabolic alkalosis, stress (sheep and goats), prepartum diets high in calcium, individual and breed susceptibility, IV oxytetracycline administration
Hypoglycemia	Failure to nurse, sepsis, bacterial meningitis, enterotoxigenic colibacillosis, cold exposure, twin or triplet lambs
Tetanus	Disinhibition of gamma motor neurons
Rabies	Encephalitis
Pseudorabies	Encephalitis
Meningitis	Bacterial infections, viral encephalitides
Coccidiosis	Possible labile neurotoxin
Chlorinated hydrocarbons	Cause repetitive discharge of motor and sensory neurons
Strychnine	Antagonist of glycine and acetylcholine and mainly affects the motor nerves in the spine
Organophosphates	Inactivation of cholinesterase
Cocklebur	Carboxyatractyloside (CAT)
Buckeye	Glycoside saponin (aesculin)

Approach to Diagnosis of Muscle Spasms and Myoclonus in Ruminants

The approach to diagnosis of muscle spasms and myoclonus in ruminants is essentially the same as that described for horses. The cause and pathogenesis of muscle spasms in ruminants are outlined in Table 13.5). In ruminants a tetany panel (consisting of serum calcium, phosphorus, and magnesium determinations) should be completed in any animal exhibiting these signs. In lactating cattle on grass pasture and in sheep transported long distances, hypomagnesemia and hypocalcemia are likely. Several infectious (e.g., rabies, pseudorabies), toxic, and inherited causes of muscle spasms and myoclonus should be suspected in ruminants. In postparturient animals and animals with wounds or bites, or animals recently castrated or tail docked, tetanus should be considered as a possible cause of muscle spasms and myoclonus.

Collapse and Sudden Death

STAN W. CASTEEL, *Consulting Editor*
PHILIP J. JOHNSON

■ MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Collapse versus sudden death, 227

Causes of collapse and sudden death, 228

Collapse Versus Sudden Death

Collapse is easily identified as a state of extreme prostration and depression. However, sudden death has a somewhat tenuous meaning, lending itself to subjective impression. The timing parameter used to define sudden death ranges from 1 to 24 hours from the onset of the fatal episode. Some veterinarians restrict the definition to a narrower time span. The 12- to 24-hour interval is sometimes selected to coincide with the frequency of owner observation of the livestock. For our purposes, sudden death means clinically unanticipated, rapid death (12 to 24 hours) occurring during normal activity in animals that had been regarded as healthy. As a rule, a condition of this nature results from fatal dysfunction of the cardiovascular, nervous, respiratory, or gastrointestinal (GI) systems. In addition, disruption of cellular metabolism (such as is associated with cyanide or hydrogen sulfide intoxication) may result in peracute death.

Approach to Diagnosis of Sudden Death

The causes of sudden death are investigated in much the same way as for any disease. The accompanying tables of differential diagnoses include infectious, metabolic, nutritional, physical, cardiovascular, toxic, and miscellaneous causes of sudden death. Diagnostic laboratories provide an array of tests and analytic procedures on the basis of veterinarians' needs in their service areas. Use of these facilities to support a definitive diagnosis is essential in sudden death cases.

Recently, a specific postmortem examination protocol intended to identify etiology in instances of sudden death and exercise-associated sudden death (EASD) in racehorses was developed and described by the California Animal Health and Food Safety Laboratory System–University of California, Davis.[1] The three principal goals of that protocol include performance of a complete postmortem examination for each case to attempt to establish the cause of EASD, standardization of histopathologic examination of the heart in cases of EASD (so that results would be compared over time and between institutions), and description of the toxicology screens performed at that institution for cases of EASD.[1]

Diagnosis is rarely based on a single item of evidence and usually requires input from multiple testing procedures. Unless the cause of death is apparent, some important considerations required for effective use of a diagnostic laboratory include the following:

1. A detailed history, which consists of the herd incidence, management changes, past medical problems, vaccination records, new additions to the herd, a complete description of the environment (e.g., recent lightning, flooding?), and assessment of the frequency of animal observations. Owners and managers may not be candid for fear of being considered negligent. Inconsistencies among involved parties should be carefully evaluated. Recent changes in management practices should be scrutinized, including feeding habits and whether there have been any illnesses in comingled animals. Animals trailed or transported for long distances or introduced onto unfamiliar ranges may be poisoned by plant species normally avoided by indigenous livestock or infected by a novel locally endemic infectious agent against which the animal had insufficient immunity. The likelihood of foul play should be considered without creating undue alarm. Assigning blame should be left to the discretion of owners. Consideration of disgruntled former employees and equine insurance claims are particularly critical situations that may have legal implications. The precise cause of death is crucial for insured livestock (mostly horses) because of exclusion clauses in many insurance policies. Heavily insured horses should be subjected to a detailed, documented, and witnessed diagnostic evaluation by an unbiased specialist, wherever possible. Toxicologic testing is especially critical in these cases. Scrutiny of the environment before the carcass is moved is necessary to eliminate questionable procedures in insurance claim cases. Evidence of struggling in the immediate area indicates a more protracted illness in contrast to collapse and death without a struggle. Suspicions should be aroused when evidence suggests that the carcass may have been dragged or carried to the current location.
2. Communication with the diagnostic laboratory before specimen collection should be undertaken to ensure that

VetBooks.ir

necessary samples are identified, correctly handled, and transported in accordance with the laboratory's current standard operating procedures. In light of the fact that many cases of sudden death result from central nervous system dysfunction, it is necessary to remove the brain for examination. Busy practitioners frequently do not take the time to remove this organ. Furthermore, there is a higher-than-normal probability of a poison being involved in sudden death cases, especially in equine insurance claims. For toxicologic examination, toxicants remaining in the GI tract must be considered, together with those in the major excretory organs, liver, and kidneys. Again, an active dialogue with laboratory personnel should facilitate appropriate specimen collection and handling in order to maximize the probability of a positive diagnostic outcome.

3. The correct quantity and method of preservation of the sample depends on the specific test. Medicolegal cases demand that stringent photographic and written documentation, witnessing, and chain-of-custody protocol be followed during necropsy and sample collection. The quantity of the sample is particularly important for chemical analysis. Sending insufficient quantities of sample may preclude multiple testing procedures. In general, 100 to 200 g of tissue or ingesta, 50 mL of urine, all fluid from both eyes, and 5 to 10 mL of blood or serum suffice for most analytic procedures. A midsagittal cut through the brain is performed to allow freezing of one half for chemical analysis and formalin preservation of the other. When poisoning is suspected, samples from possible sources such as feed, water, baits, poisonous plants, and suspect materials should be submitted. Usually 1 kg of each is adequate. Samples submitted for chemical analysis should be frozen in individual containers and labeled with patient identification data, date, location, and specific identity of the specimen (type of tissue). Specimens for bacteriology and virology must be packaged separately and chilled. Dry ice should be avoided because gaseous carbon dioxide may kill some infectious agents. Tissues for histopathologic examination require fixing in 10% formalin with tissue slices only 4 to 5 mm thick (excessively large blocks of tissue will not be properly fixed in 10% formalin). Suspected poisonous plants are properly preserved by placing them in a plastic bag with wet paper towels or drying them between sheets of paper.

Causes of Collapse and Sudden Death

Infectious Causes of Sudden Death in Horses

Foal actinobacillosis is an acute fulminant septicemia caused by *Actinobacillus equuli*, a gram-negative bacterial pathogen found in the upper respiratory tract, feces, and genital tract of normal adult horses (Box 14.1). Many other bacteria can also cause bacteremia/septicemia. Predisposing factors to foal septicemia with any agent include prematurity/dysmaturity, failure of passive transfer, maladjustment, dam malnourishment/illness during gestation, and adverse environmental conditions. A characteristic histopathologic finding is multiple bacterial emboli in renal glomerular capillaries without inflammatory infiltrate in neonatal foals. Acute hemorrhagic necrotizing enterocolitis, sometimes associated with Clostridial infection, may cause sudden death in foals in the absence of other clinical signs.

Acute anthrax may be rapidly fatal to horses (following a period of excitement, depression, convulsions, and coma). Isolating the causative agent from blood confirms the diagnosis. Babesiosis/Theileriasis is caused by an intraerythrocytic parasite that may cause death within 24 hours. Identification of the organism in blood smears, complement fixation testing for parasite antibodies, or polymerase chain reaction (PCR) testing confirms the diagnosis.

Death may result from clostridial myonecrosis associated with infection at intramuscular injection sites by *Clostridium septicum*, *Clostridium chauvoei*, *Clostridium novyi*, or *Clostridium perfringens;* various parenteral agents such as ivermectin, vitamin B complex, vitamin E, prostaglandin, antihistamines, and flunixin meglumine have been implicated in this regard. Clostridial myopathies are also associated with deep stab or puncture wounds. Toxicoinfectious botulism (shaker foal syndrome) is caused by *Clostridium botulinum* (usually type B or C) and is more common in specific (endemic) geographic locations. *Clostridium botulinum* spores can be identified in approximately 80% of affected foals. The neurotoxin may sometimes be demonstrated in gut contents. Although rapid death (within a few hours) was attributed to *Clostridium sordellii* enteritis in foals with colic and bloody diarrhea in one study,[2] *C. perfringens* type C is a more common cause of hemorrhagic enteritis, enterotoxemia, and peracute death in foals as young as 4 days.[3] Diagnosis may be supported by bacteriologic culturing, the demonstration of alpha and beta toxins in fresh intestinal samples, and identification of large numbers of clostridia (large gram-positive bacilli) in smears of intestinal contents. *C. perfringens* type D also induces sudden death in the most aggressive foals in group-feeding situations. Similar enterotoxemia has also been associated with toxin-producing *Clostridium difficile*[4] and *Bacteroides fragilis*.[5] Death of foals resulting from hemorrhagic necrotizing enterocolitis as a result of infection by *C. difficile* has been increasingly reported in recent years.

Peracute death may result from severe disease associated with infection by *Neorickettsia risticii* (Potomac horse fever or Shasta River Crud). More commonly, *N. risticii* infection results in severe colitis, fever, systemic inflammation, diarrhea, dehydration, ileus, colic, and laminitis in adult horses. Diagnosis of *N. risticii* infection is based on PCR testing to demonstrate *N. risticii* DNA in whole blood and feces. Salmonellosis is responsible for many cases of acute enterocolitis, especially when several animals are involved. Peracutely affected horses may die within 6 to 12 hours. Horses may die before signs of colic or diarrhea are recognized. Confirmatory postmortem diagnosis is based on characteristic histopathologic findings, microbiological isolation of *Salmonella* spp. from bowel contents, bowel wall, and/or associated lymph nodes, or demonstration of Salmonella deoxyribonucleic acid using PCR. Tyzzer disease is a rapidly developing fatal hepatitis of foals caused by *Clostridium piliforme*. The incidence is sporadic, and, because of the peracute development, clinical signs may not be observed before death. Diagnosis is based on histopathologic demonstration of bacilli in bundles within hepatocytes surrounding necrotic areas using a silver stain (such as Warthin-Starry) or PCR.

BOX 14.1

Infectious Causes of Collapse and Sudden Death in Horses

Peracute typhlocolitis (any cause)
Babesiosis/Theileriasis
Botulism[a]
Clostridial myopathy
Clostridium difficile enterocolitis
Clostridium perfringens enterotoxemia
Clostridium sordellii dysentery
Guttural pouch mycosis
Hemorrhagic enterotoxemia in foals
Neonatal septicemia
Neonatal diarrhea
Neorickettsia risticii infection (Potomac horse fever)
Salmonellosis[a]
Theiler disease (serum hepatitis)
Tyzzer disease

[a]Likely to involve several animals.

VetBooks.ir

Guttural pouch mycosis often results in nonfatal intermittent unilateral epistaxis or dysphagia. Occasionally a single episode of severe epistaxis from hemorrhage from the internal carotid artery may result in unanticipated death from exsanguination. Necropsy reveals blood in the nasal passages and guttural pouch with fungal plaques on the surface of the affected artery, usually at the dorsocaudal aspect of the medial compartment. In fatal cases, the local exterior environment of the carcass will be contaminated with blood that has clearly issued from one or both nostrils.

Acute infection of the central nervous system by either West Nile virus (WNV) or equine herpesvirus 1 (EHV-1) may simply present as unexpected death in susceptible individuals. Diagnostic corroboration for these conditions is based on histopathologic characterizations, immunohistochemistry (WNV), and PCR testing.

Infectious and Parasitic Causes of Sudden Death in Ruminants

Infectious causes of sudden death range from acute septicemia and toxemia to rupture and release of abscess contents into the systemic circulation (Box 14.2). A liver abscess rupturing into the caudal vena cava; endocarditis, especially of the right atrioventricular valve, with subsequent pulmonary thromboembolism; and the rupture of a pituitary abscess are occasional causes of sudden death in individual animals. Acute anthrax and the clostridial infections, as well as ingestion of their preformed toxins, are more common causes of sudden death in ruminants. Anaplasmosis may cause sudden death in mature cattle under stress, without apparent icterus. In these cases, anthrax may be mistaken for anaplasmosis because of the gross enlargement of the spleen. *Anaplasma* organisms may be demonstrated in blood smears, whereas newer diagnostic methods involve indirect fluorescent antibody and PCR testing. Of all domestic animals, cattle are the most susceptible to clostridial infections in which tissue invasion is present (blackleg). Therefore it is important to ascertain the vaccination status of affected animals. In addition, a fluorescent antibody test and isolation of the bacterium confirm the diagnosis. *C. perfringens* of various types is responsible for heavy losses caused by enterotoxemia in calves, lambs, kids, and feedlot cattle in apparent good health and on full feed. *C. perfringens* type D has been associated with focal symmetric encephalomalacia in lambs.[6] Coliform mastitis may result in peracute systemic disease and rapid death if not treated early. Diagnosis is based on culture of the organism from the affected gland. *Leptospirae* may cause an acute septicemia with hemolytic anemia and rapid death in young ruminants. Demonstration of leptospires in fresh urine, immunohistochemical staining of tissues, or PCR testing may assist in making the diagnosis. The course of listeriosis in sheep and goats is rapid, and death may occur in 4 to 48 hours after the appearance of clinical signs.[7] Bacteriologic culture (isolation) or immunohistochemical staining of the organism in tissues is diagnostic. Acute fascioliasis *(Fasciola hepatica)* occurs seasonally in sheep and may cause sudden death within 6 weeks of initial infection. Anaerobic conditions induced by flukes in hepatic parenchyma predispose ruminants to the highly fatal clostridial hepatopathies such as *Clostridium hemolyticum* infection. Evidence of fluke infection is grossly visible. Individual animals with chronic or severe endoparasitism may present as acute collapse or sudden death if they are maintained in a herd/flock. This is especially true for South American camelids. Peracute malignant catarrhal fever (MCF) is a sporadic cause of sudden death in cattle that is usually associated with contacting ovine carriers, but most animals with MCF have diarrhea, keratitis, and other obvious clinical signs for days before death occurs. A septicemic form of mycoplasmosis was reported to cause rapid death in kids.[8] Isolation of the causative organism is diagnostic. Sudden death is the usual manifestation of septicemic pasteurellosis in lambs. Pseudorabies is a consideration in sudden death cases of ruminants having contact with infected swineherds and feral hogs in the Midwestern United States. Brain for microscopic examination and virus isolation should be submitted to confirm the diagnosis. Acute septicemic salmonellosis mainly affects young ruminants and may result in death within 24 hours. Acute septic metritis usually occurs secondary to complications of parturition. Endotoxic shock and rapid death may occur in severe cases. Thromboembolic meningoencephalomyelitis caused by *Histophilus somni* is a peracute septicemic disease of young calves. Many cattle die without showing clinical signs. It may be associated with prior respiratory problems in the herd or feedlot. Typical lesions or isolation of the causative organism is diagnostic. Adult lymphosarcoma associated with bovine leukemia virus can be a cause of sudden cardiac death when neoplastic cells infiltrate the cardiac conduction system.

BOX 14.2

Infectious and Parasitic Causes of Collapse and Sudden Death in Ruminants

Abscess rupture at liver hilus or pituitary
Anaplasmosis[a] (B)
Anthrax[a]
Black disease, infectious necrotic hepatitis
Blackleg
Botulism[a]
Bovine lymphosarcoma
Clostridium hemolyticum, bacillary hemoglobinuria, redwater[a]
Clostridium perfringens, enterotoxemia
Coliform mastitis
Endocarditis
Leptospirosis
Listeriosis (C, O)
Liver flukes (O)
Malignant catarrhal fever (B)
Mycoplasmosis (C)
Neonatal septicemia
Neonatal diarrhea
Pasteurellosis, septicemic[a] (O)
Pseudorabies

Metabolic and Nutritional Causes of Sudden Death in Horses

Hypocalcemia is commonly associated with lactation ("lactation tetany"), transport ("transit tetany"), and exhaustion during or following endurance work. Affected animals develop tetany, synchronous diaphragmatic flutter ("thumps"), muscle tremors, sweating, and ileus. Diagnosis is based on demonstration of hypocalcemia in the face of typical clinical signs. White muscle disease (nutritional myodegeneration) is associated with selenium and vitamin E deficiency. Sudden death in affected adult horses after severe exercise may be attributed to degenerative lesions in cardiac and skeletal musculature. Death in foals may occur within hours of birth as a result of heart failure and pulmonary edema. Diagnosis of nutritional myodegeneration is based on histopathologic findings and measurement of whole blood and/or liver selenium and vitamin E concentrations. Unanticipated death may result from cardiotoxic hyperkalemia in Quarter Horses (and related breeds) affected with hyperkalemic periodic paralysis (HyPP). HyPP is a genetic disease that more commonly results in episodes of muscle weakness and/or stertorous breathing.

VetBooks.ir

Diagnosis of HyPP status (unaffected/heterozygous/homozygous) is straightforward and based on genetic testing. However, the determination as to whether unexpected death resulted specifically from hyperkalemia is less straightforward and may be based on a combination of genetic testing (tissue obtained postmortem), ruling out other plausible etiologies (including postmortem examination), and the demonstration of elevated potassium concentration in ocular fluids (compared with controls).[9]

Metabolic and Nutritional Causes of Sudden Death in Ruminants

Metabolic and nutritional diseases are not often considered in cases of sudden death. The primary lesion in a disorder of cattle known as "falling disease" is progressive fibrosis of the myocardium. Sudden deaths characteristic of the disease are attributed to exercise-induced heart failure.[10] Rapid development of hypocalcemia is usually associated with the onset of lactation in cattle, with stressful circumstances in older lactating ewes, or with transport associated with fasting and weather stress. Hypomagnesemia may also develop under similar conditions, especially in ewes and cows in heavy lactation and on lush grass pastures. Polioencephalomalacia occurs most commonly in animals raised under intensive production techniques and can sometimes be traced to excessive sulfates in the diet and/or water. The clinical course tends to be most rapid in sheep. Severe cases of ruminal lactic acidosis, especially in animals unaccustomed to high levels of soluble carbohydrate in the diet, may induce death within 24 hours. Nutritional myodegeneration of the heart is a frequent cause of sudden death in young ruminants born to dams fed selenium-deficient diets during gestation. Diagnosis is based on histopathology and measurement of liver selenium concentration. Some cases of sudden death associated with myocardial necrosis are idiopathic.[11]

Cardiovascular Causes of Sudden Death in Horses

As a category, cardiovascular conditions likely represent the most common cause of unanticipated death in horses. Diagnosis of sudden death caused by cardiovascular failure depends on a careful and organized methodological approach (Box 14.3).[1] In most instances, a single animal is affected. Necropsy is necessary to identify the location and characteristics of the lesion, and further analysis may be necessary to establish the exact cause of death.

Disorders of the equine cardiovascular system that might lead to unanticipated death may be categorized into those conditions in which death results from a fatal rhythm disturbance (ventricular tachycardia, ventricular flutter, ventricular fibrillation, complete atrioventricular block, or asystole); conditions in which death results from acute myocardial failure (acute decompensation of chronic heart failure, acute onset of severe valvular insufficiency [e.g., chordal rupture], or acute myocardial ischemia/necrosis); and conditions in which heart function is compromised by tamponade (viral, bacterial, or idiopathic pericarditis, trauma).[12] Cardiac-related death may result suddenly from several intoxications (myocardial plant toxicities including yew (*Taxus* spp.), oleander *(Nerium oleander)*, foxglove (*Digitalis* spp.), summer pheasant's eye *(Adonis aestivalis)*, box elder (*Acer* spp.), and marsh mallow *(Malva parviflora)*. Cardiac death may also result from intoxication by ionophore antibiotics (as contaminants from the bovine feed industry), cantharidin toxicity (blister beetle poisoning), and snake envenomation (*Crotalus* spp. *Viperidae*).[12] In rare instances, marked hyperkalemia (hyperkalemic cardiotoxicity) may be responsible for death in horses affected with HyPP. Penetrating chest wounds or iatrogenic damage to the equine heart (cardiac catheterization) may provoke fatal arrhythmia or cause severe hemorrhage with fatal outcomes. External or internal exsanguination represents an important cause of unanticipated death, and several specific syndromes have been described: cardiac rupture (with cardiac tamponade); rupture of either the pulmonary artery or aorta (with or without tamponade); carotid artery rupture in the guttural pouch may lead to the unanticipated death of horses affected with guttural pouch mycosis; and rupture of the cranial mesenteric artery at its origin consequent to damage resulting from *Strongylus vulgaris* larval migration is presently a rare cause of fatal internal hemorrhage following widespread use of ivermectin. Peripartum uterine arterial rupture involving ovarian, utero-ovarian, uterine, or external iliac arteries is sometimes observed in older mares, with death ensuing in 30 minutes to 20 hours. Pulmonary artery rupture may lead to death in horses that are affected with exercise-induced pulmonary hemorrhage or pulmonary hypertension for any cause. Brain hemorrhage may cause death, especially in horses that have "flipped over backwards" and fractured the basioccipital/basisphenoid bones at the base of the skull.

Aortic sinus of Valsalva aneurysms or tears in the aortic root are well-recognized conditions in breeding stallions, often leading to sudden death, especially early in the breeding season, often occurring immediately after servicing a mare.[12] Rupture of the aorta may occur just distal to the aortic valve, resulting in cardiac tamponade and rapid death. Aortopulmonary fistulation in conjunction with aortic rupture is quite common in the Friesian breed; aortic rupture and aortopulmonary fistulation should be included in the differential diagnosis when Friesian horses are presented with a history of recurrent false colic, coughing, sustained tachycardia, and/or peripheral edema.[12,13] Cardiovascular diseases including myocardial lesions (hemorrhage, swelling, fibrosis, and infarction), aortic root rupture, and abdominal large artery rupture were identified as common explanations for sudden/unexpected death in Japanese stallions.[14]

Acute central nervous system embolism results from detached thromboemboli originating from vegetative lesions on heart valves affected with bacterial endocarditis or from accidental intracarotid injection. Cerebral hematoma may also result from inadvertent intracarotid injections. Endocarditis, especially of the aortic valve, may result in coronary thromboembolism and myocardial infarction, albeit rarely. Coronary artery occlusion resulting from damage induced by migrating *S. vulgaris* larvae is diagnosed by the presence of the larvae in the coronary thrombus. Massive abdominal or thoracic hemorrhage is found at necropsy, and the cause may be difficult to ascertain.[15] Myocarditis in horses up to 4 years of age resulting from recent respiratory infection may be diagnosed with histopathologic examination. Pericardial rupture and the associated heart damage may result from violent trauma. Splenic rupture with fatal hemorrhage occurs rarely because of the protection afforded by the thoracic wall. Massive thrombi of verminous origin have been observed in young horses that die suddenly while exercising.

BOX 14.3

Cardiovascular Causes of Collapse and Sudden Death in Horses

Physical Causes of Sudden Death in Horses

Fatal air embolism can result from any open vein above the heart. Open needles or catheters and severe head wounds involving teeth and sinuses have resulted in sudden death from air emboli. Air is aspirated into the vein by the *Venturi* effect from blood surging past a portal and creating the necessary negative pressure to aspirate air into the vein. Between 700 and 6000 mL of air may produce a fatal air embolus in the right ventricle, where it obstructs the pulmonary artery. Cecal or colonic rupture in periparturient mares may lead to death within 8 hours.[16]

Physical Causes of Sudden Death in Ruminants

Physical causes of sudden death typically display gross evidence indicative of the diagnosis. Abomasal bloat occurs in calves and lambs drinking excessive quantities of warm milk replacer at infrequent intervals. Abomasal ulcers may occasionally perforate and cause rapid death in calves or adult cattle. Ruminal bloat is one of the more common physical causes of sudden death in intensively raised ruminants. When differentiating postmortem from *antemortem* bloat, note that bloat is the primary cause of death when there is congestion and hemorrhage in the anterior parts of the carcass and edema in the scrotal and ventral perineal areas. Bloat and hypersalivation are the most consistent clinical signs seen in cases of choke. Attempts to swallow firm fruits, tubers, or green ears of corn may occlude the esophagus and result in rapid ruminal tympany and death.

Sudden death is a major concern in feedlots because most such deaths occur in cattle near market weight. GI disturbances are seen with a high frequency in cattle in the late stages of the feeding program. Sudden death is the result of interactions among factors such as rumen acidosis, bloat, and endotoxemia.

Exposure to high-voltage currents in the form of lightning or electrical transmission wires may cause instantaneous death. The diagnosis of lightning strike is based on a history of an electrical storm, linear singe marks, food in the mouth, several animals being found dead in the vicinity, and evidence of lightning damage in the immediate environment. Gunshot wounds may be deliberate or accidental; death resulting from gunshot injury typically involves either the head or heart. Bullets may pass through or lodge in obscure locations, making retrieval difficult. Radiography can assist in confirming and locating a bullet. Heatstroke is a sporadic condition characterized by hyperthermia and collapse. High humidity, dehydration, obesity, and poor heat tolerance associated with young or old age are all factors that predispose animals to overheating. Fleeced animals such as sheep and South American camelids often succumb to heatstroke if the time of shearing is not appropriate. "Summer slump" induced by consumption of endophyte-infected fescue potentiates the heat intolerance. Internal bleeding may cause sudden death when a uterine artery is ruptured during parturition. This is readily apparent on necropsy. Tracheal edema, or "honker" syndrome, of feeder cattle is seen sporadically in feedlot cattle of the southern plains during hot weather. The pathoanatomic basis of this syndrome is extensive edema of the mucosa and submucosa of the lower trachea, with attendant dyspnea and obstructive asphyxiation. Increased respiratory movements stimulated by hot weather or exercise trigger the clinical illness, especially in heavy cattle during the latter part of the feeding period.[17] Traumatic reticuloperitonitis or reticulopericarditis result from poor oral discrimination behavior in cattle. Sudden death in these cases may result from acute hemorrhage or dysrhythmia if the heart is affected by foreign body migration (cardiac puncture may occur).

Toxic Causes of Sudden Death in Horses

Toxic causes of sudden death are frequently related to management practices. An increase in specific disease syndromes or sudden death in a population of livestock with common potential exposures suggests involvement of a toxicant. Investigation of the premises and a familiarity with poisonous plants and pesticides used in the practice area should help narrow the list of possible causative agents (Box 14.4).

BOX 14.4

Toxic Causes of Collapse and Sudden Death in Horses[a]

- 4-Aminopyridine (Avitrol), an avicide
- Arsenic
- Black flies
- Cantharidin*
- Ferrous fumarate
- *Fusarium moniliforme*–associated mycotoxicosis
- Insulin and potassium
- Monensin[a]
- Nitrogen dioxide
- Organophosphate and carbamate insecticides
- Toxic plants
  - *Acer rubrum* (red maple)
  - *Acer negundo* (female box elder)
  - Blue-green algae[a]
  - *Cicuta* spp. (water hemlock)
  - *Conium maculatum* (poison hemlock)
  - Cyanogenic plants
  - *Melilotus* spp. (sweet clover)
  - *Nerium* spp. (oleander)
  - *Nicotiana* spp. (tobacco)
  - *Ricinus communis* (castor bean)
  - *Taxus* spp. (Japanese yew)

[a]Likely to involve several animals.

Horses ingesting a lethal dose of the avicide 4-aminopyridine have died within 2 hours of the onset of clinical signs. Diagnosis is based on chemical analysis of stomach contents. Fatal doses of arsenic-containing pesticides may induce cardiovascular collapse and death in horses within hours of ingestion. The presence of edema and fluid in the GI tract suggests arsenic toxicosis, and chemical analysis of GI tract contents, liver, or kidney confirms it. Black flies swarm where swiftly flowing water provides the aeration necessary for the development of larvae. Massive attacks of these blood-sucking insects can rapidly kill livestock because a toxin present in the saliva of the flies increases capillary permeability.[18] Cantharidin poisoning can occur after ingestion of 4 to 5 g of blister beetles. Lesions suggestive of cantharidin toxicosis include blistering and ulceration of mucous membranes of the GI and urinary tracts and myocardial degeneration and necrosis. Sustained hypocalcemia and hypomagnesemia are features of the clinical pathology consistent with blister beetle poisoning. Identification of blister beetles in the hay and chemical analysis of urine and GI contents are suitable for diagnostic confirmation. In the past, ferrous fumarate, present in digestive inoculate and administered to foals immediately after birth, resulted in death in some cases in 12 to 96 hours. This illustrates the acute toxicity of iron to young animals in particular. Lesions induced were those of gross liver damage. *Fusarium moniliforme*–contaminated corn causes rapid death in horses after the sudden onset of bizarre neurologic deficits and behavioral effects. The lesion of this mycotoxin-induced leukoencephalomalacia is liquefactive necrosis in the subcortical white matter.

High intravenous doses of insulin[19] and potassium[9] induce sudden death without significant lesions. Chemical detection is often overlooked and difficult to perform and interpret in cases of deliberate poisoning. Immediate analysis of blood and circumstantial evidence of needle punctures (blood stains) in the jugular furrow may be of diagnostic value. Monensin is

quite toxic to horses, and fatal poisoning can occur within 12 hours of ingestion of poultry feed containing 100 g/ton or cattle premixes containing 300 g/ton. Lesions related to heart failure are seen on postmortem examination. Tissues collected for microscopic examination should include heart and diaphragm. Chemical analysis of feed samples and stomach contents will confirm exposure. Toxic gases such as nitrogen dioxide, hydrogen sulfide, and carbon monoxide may be responsible for sudden death in horses housed in poorly ventilated buildings with associated gas sources nearby. Organophosphate and carbamate insecticides may induce acute intoxication and death within hours. Diagnosis is based on a history of exposure, determination of acetylcholinesterase activity in the caudate nucleus of the brain, and chemical detection of specific compounds in gut contents.

Circumstances surrounding toxic plant ingestion and diagnosis of intoxication are described in the ruminant section of this chapter. Ingestion of wilted *Acer rubrum* (red maple) leaves and other *Acer* spp. may induce massive methemoglobinemia, causing marked tissue anoxia and death.[20] Red maple poisoning usually occurs during the late summer and early fall when trees are in full leaf. Ready access to wilted leaves follows windstorms. *Ricinus communis*, or castor bean, is also unique. Seeds of this plant contain a phytotoxin called *ricin*, which causes severe enteritis and rapid death in horses. About 150 beans (50 g) are sufficient to kill a 450-kg horse. Diagnosis can be verified by finding a toxic amount of ingested seeds in the gut contents.

Toxic Causes of Sudden Death in Ruminants

Intoxication of livestock is frequently suggested as a simple explanation for complex situations involving sudden death. Suspicions are warranted when a large number of animals die suddenly within a short time. Toxicants should be considered when the appearance of a disease or sudden death is temporally associated with a change in the environment (Box 14.5). An accurate diagnosis in many of these cases requires qualitative and quantitative analyses for suspect poisons. Selecting toxicants for which to analyze requires reasoned judgment supported by an extensive investigation of the environment and postmortem findings.

The avicide 4-aminopyridine is usually formulated with corn, making it a palatable poison for nontarget herbivorous livestock. Diagnosis is confirmed by chemical analysis of rumen contents or urine. Anticoagulant intoxication may induce sudden death when hemorrhage occurs in the cranial vault, abdominal cavity, pericardial sac, mediastinum, or thorax. The antemortem or postmortem sample for chemical analysis is whole blood or liver. Failure to detect an anticoagulant is not unusual because of the time lag between consumption and presence of the clotting defects, as well as the metabolism of the compound. Arsenic derivatives are a significant hazard to ruminants, especially in areas where such chemicals are widely used as cotton desiccants. Postmortem findings are consistent with microvascular injury to the GI tract. Diagnosis is confirmed by chemical analysis of rumen contents, liver, or kidney. In rare cases, large doses of botulinum toxin may cause sudden death in ruminants. Sources of the toxin include the bones of dead animals eaten by osteophagic livestock, poultry carcasses in manure fed to cattle, stagnant pond water, animal tissues in silage or baled hay, and improperly ensiled silage or haylage.

Acetylcholinesterase-inhibiting agents such as the carbamate and organophosphate pesticides can kill livestock within hours. When agricultural strategy results in the deployment of these pesticides in close proximity to livestock, the situation may be disastrous. Acetylcholinesterase activity in the caudate nucleus of the brain is readily determined and interpreted, and specific compounds may be identified in rumen contents. Toxic gases such as carbon monoxide, hydrogen sulfide, and nitrogen dioxide become important differentials for sudden death in ruminants housed in poorly ventilated buildings, particularly over waste pits. Chlorinated hydrocarbon pesticides do not enjoy the widespread use they once did; however, old containers remain in obscure locations on many farms. When acute intoxication with these compounds is suspected, samples for analysis should include liver, brain, and rumen contents. In subacute cases, fat and milk are appropriate samples. Copper toxicosis is a frequent cause of sudden death in sheep and has been reported in cattle fed chicken litter.[21] Cattle feeds normally contain twice as much copper as sheep feeds and may cause copper toxicosis in sheep. Copper from treated fence posts also may poison

VetBooks.ir

sheep that either chew the posts or ingest contaminated forage in the vicinity. Samples required for chemical confirmation consist of whole blood or serum and liver. Close proximity of livestock to petroleum exploration and production activities in the major oil-producing states results in a variety of clinical problems, including sudden death.[22] Consumption of the more volatile petroleum constituents may induce rapid bloating and coating of the respiratory membrane when these substances are aspirated into the lungs. Gossypol toxicosis reportedly causes death without premonitory signs in calves (occasionally cows) and lambs fed cottonseed products containing this toxic pigment.[23,24] Poisoning appears abruptly after livestock have been fed the gossypol-containing ration for a period of weeks to months. Sudden death is attributed to heart failure. Postmortem examination reveals edema, centrilobular hepatic necrosis, and an enlarged heart. Ionophores may induce sudden death in species exposed to large overdoses, but delayed death is the usual course. Conditions conducive to lethal overdose include insufficient mixing or top dressing with monensin- or lasalocid-supplemented mineral. Degenerative-to-necrotic lesions in the heart are compatible with a diagnosis of ionophore poisoning.

Acute lead intoxication is another differential from the list of possibilities in sudden death cases. Lead poisoning is the most common toxicosis in cattle. Blood, liver, and kidneys are suitable specimens for lead analysis. Metaldehyde is an uncommon poison for ruminants; however, intoxication in cattle has occurred in low wetland areas where the chemical is used as a molluscicide. The palatability of metaldehyde baits promotes ingestion. Ammoniation of high-quality forage such as forage sorghum and Sudan grass, cereal grain, brome, and fescue hays is responsible for bovine bonkers syndrome, reportedly caused by the formation of 4-methyl-imidazole.[25] This sporadic intoxication causes central nervous system derangement and rapid death in cows and nursing calves. Ruminants may be poisoned by nicotine sulfate from ingestion of solution, treated foliage, and food or water from contaminated containers. The onset and progression of the syndrome are rapid, and death may occur within hours. Detection of nicotine in urine is easily performed by most toxicology laboratories. Iatrogenic selenium toxicosis and death in young ruminants can result from parenteral administration of excess doses. Rapid onset of violent tetanic seizures ending in death characterizes strychnine toxicosis. Samples suitable for chemical analysis include rumen contents, liver, and urine.

Urea toxicosis is a frequent cause of sudden death in feedlot livestock. In one particular case, 48 feedlot steers died within 2 days of delivery of a new lot of feed supplemented with urea.[26] Unusually high rumen pH, excess ammonia in serum, rumen contents, and eyeball fluid support the diagnosis. Water deprivation, with attendant sodium ion intoxication, is a known cause of sudden death in ruminants.[27] Some cases occur in hot weather, but frozen water supplies in cold weather can be equally as devastating.

Poisonous plant problems frequently present a unique set of circumstances associated with their ingestion. Overgrazing of pastures is probably the most significant factor affecting the ingestion of toxic plants. Other situations conducive to poisonous plant ingestion include lack of suitable forage in periods of drought and the incorporation of toxic forbs in hay or green chop. Plants normally avoided because of poor palatability may become acceptable when frosted or sprayed with herbicide. Toxic plants may also be the first green plant available early in the spring, when livestock are hungry for anything green and succulent. Livestock trailed or transported for long distances without food or water and then suddenly introduced to new pasture may fail to avoid toxic plants and often will eat anything within immediate reach. In general, diagnosis of plant poisoning is based on availability, grazing evidence or presence in the hay, and the existence of plant parts in the rumen contents. Diagnostic lesions are usually lacking, and analytic methods for toxic components are severely limited.

Aconitum spp. (monkshood) are rarely a cause of sudden death because of their limited availability. *Delphinium* spp. (larkspur), however, are closely related to monkshood and are responsible for more cattle losses in the western United States than any other poisonous plant. Larkspur grows in dense stands in the mountainous West and is readily consumed, especially during an early stage of growth. Mature stands are less palatable and not as toxic. Cattle poisoned by larkspur are often found close to a stand, collapsed, and bloated. Death from the cardiotoxic and neuromuscular blocking effects may occur within a few hours of ingestion. Sheep are less susceptible to larkspur and are seldom poisoned by it, partly because of their different grazing habits.[28] *Asclepias* spp. (milkweed) contain either cardioactive glycosides or neurotoxic compounds.[29] The most toxic species reside in the western and southwestern United States. These plants are not very palatable but are somewhat less objectionable when dried. Livestock will graze them in a drought, but the biggest problem is contamination of hay or green chop. Blue-green algae may cause sudden death in all classes of livestock within minutes of ingestion of toxins from certain neurotoxic species. Toxins from other hepatotoxic species may require 24 hours to induce death. Toxic blooms occur sporadically during certain environmental conditions of late summer and fall. Diagnosis is usually based on a history of exposure to a concentrated bloom, but some laboratories perform chemical and biological assays.

Calycanthus spp. (bubby bush) contain an alkaloid similar in structure and mechanism of action to strychnine. These species are of minor importance to the livestock industry in the Southeast and West but have induced death in cattle. Seeds and other plant parts may be identified in rumen contents. *Cicuta* spp. (water hemlock) may induce violent convulsions and death within an hour of consumption. Intoxication is most common in early spring, when plants growing along waterways are easily uprooted and the tuberous parts are eaten. A single root system from a large plant can kill a cow. This is one of the most toxic plants in North America, and it has been responsible for the deaths of numerous livestock and humans. *Conium maculatum* (poison hemlock) grows throughout the United States. Cattle are most sensitive, and sheep are relatively resistant. Poisoning is usually associated with heavily grazed pastures.

Cyanogenic glycosides are present at toxic concentrations in more than 250 plant genera, including *Sorghum*, *Prunus*, *Triglochin*, and *Linum*. Ruminants are especially susceptible to these glycosides because they possess the microorganism enzyme systems necessary for rapid liberation of hydrocyanic acid. Death may occur within 15 to 30 minutes of ingestion. Hyperoxygenated venous blood will be cherry red and slow to clot, and rumen contents may have the odor of almond extract. Samples of forage, blood, and rumen contents should be collected immediately, placed in airtight containers, and frozen for analysis. Negative results are often questionable because of the highly volatile nature of hydrogen cyanide. *Drymaria pachyphylla* (inkweed) has caused sudden death in cattle in the southwestern United States. The differential diagnosis in this part of the country includes anthrax. Diagnosis is based on examination of rumen contents for plant parts.

Halogeton glomeratus is a soluble oxalate-containing plant that grows best in disturbed soil along roadsides in the western intermountain states. *Sarcobatus vermiculata* (greasewood) grows in semiarid regions of the West. It also contains toxic levels of soluble oxalate. Unadapted sheep are most frequently intoxicated by these plants, and death may occur within 9 to 11 hours of onset of intoxication. Sudden death results from hypocalcemia and inhibition of cellular respiration. Postmortem findings include hemorrhagic rumenitis, hydrothorax, ascites,

VetBooks.ir

and the presence of oxalate crystals in the kidney and rumen wall. *Kalmia* spp. (laurel) are an occasional problem in winter or early spring, when they are the only conspicuously green plant available. Laurel grows in the wild in the eastern and western regions of the United States. Death may occur in 12 to 14 hours. Fragments of glossy, leathery leaves may be visible in rumen contents. *Kochia scoparia* (summer cypress or burning bush) sporadically causes a thiamine-responsive polioencephalomalacia in cattle. *Laburnum anagyroides* (golden chain tree) is a large ornamental shrub considered to be the second most poisonous plant in Great Britain. It also grows in much of the United States. The shrub contains quinolizidine alkaloids that may induce rapid death from respiratory failure. *Lupinus* is a genus with about 200 species in North America. There is considerable seasonal variation in toxicity, with the toxic species presenting a problem when plants are immature or when they have reached the seedpod stage. Acute intoxication and rapid death are likely only when large quantities of seeds are ingested within a short time. Toxic species cause more deaths in sheep than any other plant in Montana, Idaho, and Utah. Improperly cured hay and silage derived from *Melilotus* spp. (white and yellow sweet clover) may cause sudden death in cattle when hemorrhage occurs in the cranial vault, pericardial sac, mediastinum, or thorax. Induction of the disease requires consumption of the moldy forage for several weeks to allow sufficient depletion of vitamin K–dependent clotting factors. *Nerium* spp. (oleander) are widely cultivated in the South and West. Toxic in the green or dry state, these plants may border hay fields, and significant mortality of livestock may occur when dropped leaves or trimmings are incorporated into forage. Livestock are often poisoned when prunings are mixed with grass clippings and the bitter taste is disguised. Diagnosis is based on evidence of consumption and identification of plant parts in rumen contents.

The genus *Nicotiana* contains toxic species of wild and cultivated tobacco. Poor palatability usually hinders consumption; however, opportunities for intoxication and death sometimes occur in areas of the West where forage is scarce and in parts of the country where tobacco is cultivated. Nitrate-accumulating plants include certain annuals, weeds, and cool-season crops and grasses. Notable examples include pigweed, lamb's quarters, Sudan grass, and oat hay. Under the right environmental conditions most plants can accumulate toxic concentrations of nitrate. Plant-associated nitrate poisoning is a serious problem only in ruminants because of the nitrate-reducing ability of rumen microbes. Onset of nitrate intoxication is rapid, and death may result within 6 to 24 hours of rapid ingestion of a toxic dose. Diagnosis is based on a brownish cast to the viscera and blood, together with chemical analysis of serum, aqueous humor, and forage for nitrate concentration.

Acute bovine pulmonary emphysema is associated with an abrupt change from dry range forage to lush green pasture high in L-tryptophan concentration. Less commonly, the pulmonary toxins of *Perilla frutescens* (perilla mint) can induce dyspnea and death in a few hours. Necropsy reveals incomplete collapse of lungs that are heavy and firm, with froth-filled airways. Histologic examination shows a proliferation of type II pneumocytes. *Phalaris* spp. (canary grass) have been reported to have caused sudden collapse and death of sheep in California.[30] Sheep that had been grazing a field containing canary grass were herded a short distance when six ewes collapsed and died. Bilaterally symmetric, greenish-gray discoloration was seen in the midbrain. The same gross discoloration was also seen in the renal cortex. Microscopic examination confirmed the presence of intracytoplasmic accumulation of this granular pigment. *Solanum* spp. (nightshades) grow throughout the United States, especially in waste areas and overgrazed pastures. Rapid ingestion of large quantities of highly toxic fruit can result in coma and rapid death. *Taxus* spp. (yew) poisoning in ruminants commonly results in sudden death. Poisoning is most likely to occur when ruminants are pastured adjacent to residential areas where yew is a common ornamental shrub. Diagnosis is based on evidence of exposure and identification of yew leaves in rumen contents. *Xanthium* spp. (cocklebur) are most toxic at the cotyledonary stage of growth. These species may induce death in calves within 12 hours of onset of clinical intoxication. Hypoglycemia and centrilobular hepatic necrosis are consistent findings. *Zigadenus* spp. (death camas) are of major importance to sheep grazing on western ranges. These plants begin growth in early spring, presenting a significant hazard at this time.[31]

Miscellaneous Causes of Sudden Death in Horses

Allergic reactions capable of causing sudden death include rupture of warble fly larvae. Warble fly larvae are seldom able to penetrate equine skin, and the fully matured larvae either die or are killed when the horse is saddled or harnessed. The ruptured larvae induce anaphylactic shock and pulmonary edema. Foam in the airways is found on necropsy. Penicillin or other antibiotics may cause an anaphylactic reaction with a similar outcome.

Perinatal sudden death may occur in foals as a result of meningeal hemorrhage caused by birth trauma. The sudden onset of profuse, watery diarrhea and rapid development of hypovolemic shock characterize colitis-X. A severe necrotic typhlitis is seen at necropsy, with destruction of colonic and cecal mucosa. Diaphragmatic rupture and hernia are associated with violent exercise or trauma, with or without bowel herniation. Electrocution occurs when a horse chews through or comes into contact with an uninsulated hot wire while well grounded. Death is instantaneous, usually with negative necropsy findings. Lightning strike may reveal burning or singeing of skin, hair, or underlying tissue. GI conditions that may cause sudden death include volvulus, intussusception, torsion, strangulation, tympany, and small intestine rupture from ascarid impaction (in foals). Gastric rupture may cause sudden and unexpected death; in one study, rupture of the stomach was predominantly attributed to either idiopathic causes or as a complication of gastric impaction.[32]

Gunshot wounds may be another cause of sudden death that is surprisingly difficult to verify, because bullet retrieval is necessary to establish the diagnosis. Tracking and finding a small metal object lodged in tissue is a time-consuming task at best. Heat or work stress is seen in horses in hot, poorly ventilated quarters, or in poorly conditioned horses overworked in hot, humid weather. Collapse and coma are followed by death in a few hours. Necropsy reveals skeletal and cardiac muscle damage, GI ulceration, and renal necrosis. In pregnancy, unrecognized and untreated torsion of the gravid uterus may result in sudden death.

Exercise-induced respiratory tract injury may cause sudden death in well-conditioned horses.[33] Exercise-induced pulmonary hemorrhage occurs during race training or competition, with most cases being of little acute concern. In severe cases, horses may die during or immediately after exercise with extensive hemorrhage (especially the caudal lung lobes) evident at necropsy.

Serum hepatitis (Theiler disease, viral hepatitis) may result from administration of biologics of equine origin 50 to 90 days before the onset of clinical signs, including fever, jaundice, and hepatoencephalopathy. In severe cases, death may occur within 12 to 48 hours. The main lesion seen is liver necrosis with discoloration and accentuation of the lobular pattern on the cut surface. Recently, several viral pathogens have been implicated in the etiology of Theiler disease.[34,35] Fracture of the junction between the basisphenoid and the basioccipital bone usually results from rearing over backward and striking the poll on the ground.

Sudden and Unexpected Death in Equine Athletes

Emphasis placed on the postmortem diagnosis of cause of death and risk factors for death in racehorse communities has led to several retrospective studies on this topic in recent years.[36-38] Consistently, most racehorse deaths result from catastrophic musculoskeletal injuries (serious accidents) with limb fracture being the most common circumstance leading to death among all racehorses. Other fatalities are classified as unexpected or sudden death, in association with exercise (racing or training) or occurring spontaneously in the absence of physical exertion. The pathologist may or may not be able to conclude definitively that any observed lesions are necessarily the cause of death (e.g., observed abnormalities may represent unrelated comorbidities or could even result from agonal breathing). Although often presumed to result from acute cardiac, cardiovascular, or cardiorespiratory failure, the importance of a complete and structured postmortem examination cannot be overstated.[1] Results and conclusions from postmortem examinations at different institutions (and over time within the same institution) will be easier to compare if a recently described standardized protocol gains broad acceptance.[1]

In one recent study, postmortem findings and cause of death were retrospectively reported over a 13-year period for 963 horses examined for the Ontario Racing Commission Death Registry.[36] In that study, unexpected or sudden death that occurred during or immediately following exercise accounted for 31% of performance-related deaths, most commonly resulting from cardiopulmonary lesions (pulmonary hemorrhage was the most common explanation). The most frequent causes of death or significant postmortem findings in horses dying suddenly during exercise were classified as respiratory (50%), cardiovascular (22%), and undetermined (20%). Less frequently, skull fracture, sepsis, encephalitis, dyshemostasis, and hemorrhage were reported in a handful of cases. Pulmonary hemorrhage (such as exercise-induced pulmonary hemorrhage) represented 93% of respiratory explanations. Acute heart failure and pulmonary hypertension resulting from postexercise arrhythmia may lead to pulmonary hemorrhage, cardiopulmonary failure, and sudden death in racehorses.[39] Hemopericardium (pericardial tamponade), hemothorax, and hemoabdomen represented 82% of cardiovascular cases. For example, aortic rupture is a well-recognized cause of sudden death in this species and likely results from increased aortic pressure during strenuous physical activity, as reported previously.[40]

As mentioned earlier, a cause of death was not established for 20% of sudden death cases because explanatory lesions could not be identified postmortem. In those cases, it was speculated that cardiac arrhythmia may have led to death. Injection-associated death was identified in 4% of the study population.[36] The proportional mortality rate for exercise-associated sudden death among all breeds was 9% (157 of 1708). Death resulting from injected drugs occurred in 38 of 377 horses (10%) whose deaths were unrelated to exercise and in 38 of 963 of all horses (4%) horses in that study.[36] In most instances, collapse followed by seizure or death occurred *during or immediately following* the injection. Untoward clinical reactions led to euthanasia for a number of other injected horses that died. Various drugs and combinations of drugs were implicated in this study and included amino acid supplements; antibiotics (penicillin, trimethoprim–sulfadiazine, gentamicin); unspecified iron preparations; dimethyl sulfoxide (DMSO); mannitol; vitamin E–selenium preparations; other nonspecified vitamins; testosterone; other anabolic steroids; estrogen; calcium; pentosane polysulfate; Sarapin; trichlormethiazide–dexamethasone acetate; n-butyl alcohol; and prednisone.[36] Although specific necropsy-identified lesions that satisfactorily explained death in these cases were not identified, both pulmonary edema and/or congestion with variable hemorrhage were often identified. Suspicion of an inadvertent intracarotid injection was based on the presence of cerebral edema, malacia, and vasculitis in one case. Furthermore, evidence of sepsis identified during postmortem examination implied that death may have resulted from the intravenous administration of contaminated solutions in three additional cases.

Bit-induced asphyxia (partial or complete) was recently suggested to contribute to the risk of sudden death in racehorses.[41] In that work, the author contended that both sudden/unexpected death and catastrophic musculoskeletal injury result from bit-induced asphyxia, a potentially preventable situation in racehorses.[41]

Miscellaneous Causes of Sudden Death in Ruminants

Fatal anaphylaxis occurs in sensitized animals after parenteral administration of drugs or vaccines. This is most common with the penicillins. Vaccines containing gram-negative bacteria or cell walls may cause an endotoxemic reaction that looks similar to anaphylaxis. Anaphylactic shock may also be an outcome of blood transfusion reactions. Immune-mediated hemolytic anemia (neonatal isoerythrolysis) from ingestion of colostrum-containing alloantibodies against a neonate's erythrocytes may induce sudden death if the specific antibody concentration is sufficiently high. A sudden death syndrome occurs in feeder cattle on high-concentrate diets. It usually occurs in warmer months and is limited to cattle fed high-concentrate rations for several weeks.[42] A malignant tumor that has been associated with sudden death is the thymoma, or thymic lymphosarcoma, seen most commonly in old goats. It appears as a large, pale, fleshy mass in the cranial mediastinum.[43]

Assessment of the Mare During Late Gestation

The per-cycle pregnancy rate in mares has been reported between 60% and 69%, with increasing mare age, breeding at foal heat, and overuse of stallions reported as negative factors at one Thoroughbred stud.[1] Approximately 79% and 87% of pregnancies detected at days 15 and 40, respectively, result in a live foal.[2] With additional losses in the perinatal period, it has been estimated that between 22% and 40% of mares that are bred do not produce a live foal.[2–5] Factors that contribute to this outcome include mare age, infertility, early fetal loss, abortion, and perinatal death.[1,4] During late gestation, common causes of reproductive loss are fetoplacental infection, placental dysfunction, maternal illness, and complications of delivery.[4,6,7] As mares age, their pregnancy and foaling rates decline and their foals experience higher morbidity and mortality rates and decreased athletic ability.[1–3,5]

The 2015 National Animal Health Monitoring System (NAHMS) reported that 3.3% of foals died within the first 48 hours after birth. This compares to the 1998 and 2005 NAHMS studies, where mortality rates of 1.7% and a 2.6% were reported, respectively.[8] This includes an estimate of euthanasia and spontaneous deaths. Sepsis, asphyxia, and dysmaturity, including prematurity and postmaturity syndromes, are the leading causes of neonatal foal mortality during the first 2 weeks of life.[9] Despite advances in neonatal intensive care, many foals still die, not because their primary problem is untreatable, but because veterinary intervention was delayed, delivery was unattended, neonatal compromise was not recognized in a timely fashion, or critical care was unavailable or not economically feasible. Foals surviving severe peripartum illness often experience increased morbidity associated with chronic infections, suboptimal growth, or developmental orthopedic disease. The three periparturient events that have the most devastating effect on neonatal survival are hypoxia, infection, and derangement of in utero development.

Many of the periparturient events associated with increased fetal/neonatal morbidity and mortality have been identified in the mare (Box 15.1).

There are several clinical indications for evaluating the late-term fetus, including a larger than expected maternal abdomen, premature lactation, vaginal discharge, maternal illness, or prolonged gestation.[7] Mares that have a history of reproductive failure in late gestation are also candidates for close monitoring in future pregnancies. Biochemical and biophysical techniques for monitoring fetoplacental well-being have been developed for use in the pregnant mare.[10–14] Mares with high-risk pregnancies should be identified early, treated appropriately, and monitored closely through the perinatal period. Accurate assessment of fetal well-being is complicated and handicapped by the size of the dam and fetus.

Mares experiencing problem pregnancies can be assigned to one of three categories: (1) mares with histories of abnormal pregnancies, deliveries, or newborn foals; (2) mares at risk for a problem with the current pregnancy due to systemic illness or reproductive abnormality; and (3) mares with no apparent risk factor, which experience an abnormal periparturient event.[13] A list of important risk perinatal risk factors is presented in Box 15.2. Ideally, mares with high-risk pregnancies should receive some type of late-gestation fetal monitoring or at least be carefully watched during late gestation and attended at the delivery. Personnel attending the delivery of a high-risk foal should be trained in resuscitation techniques (see later).

The hormones associated with pregnancy and fetal well-being can be divided into several categories.[15] These include hormones that control uterine myometrial activity, including quiescent and contractile states, and those that induce fetal maturation. Progestagens, including progesterone and its metabolites, are important in maintaining uterine quiescence during pregnancy. Progesterone is produced by the ovary until days 120 to 150 of gestation. After this time progestagens are synthesized by the uteroplacental tissues from pregnenolone, which is derived from fetal adrenal glands.[16] Pregnenolone is metabolized to

BOX 15.1

Common Causes of Abortion, Stillbirth, and Perinatal Death in Horses

- Infectious problems (in order of frequency)
  - Fetoplacental infection
    - Bacterial
    - Viral
    - Fungal
    - Unidentified
- Noninfectious problems (in order of frequency)
  - Neonatal asphyxia not associated with dystocia
  - Neonatal asphyxia associated with dystocia
  - Placental edema
  - Premature placental separation
  - Twin pregnancies
  - Contracted foal syndrome
  - Other congenital malformations
  - Umbilical cord abnormalities
  - Placental villous atrophy
- Eastern Tent *(Malacosoma americanum)* or Processionary caterpillars *(Ochrogaster lunifer)* ingestion

From Giles RC, Donahue JM, Hong CB, et al: Causes of abortion, stillbirth, and perinatal death in horses: 3527 cases (1986-1991). *J Am Vet Med Assoc* 203:1170, 1993.

BOX 15.2

Conditions Associated With the High-Risk Foal

Maternal Conditions

- Past history of:
  - Foals with neonatal isoerythrolysis, perinatal asphyxia syndrome, congenital malformations
  - Prematurely born, post-term foals that appear premature or asphyxiated foals
  - Dystocia or premature placental separation
  - Foal rejection
  - Recent exposure to infectious diseases associated with abortion and stillbirths, such as equine herpesvirus, viral arteritis, *Leptospira* spp.
- Systemic problems such as:
  - Fever
  - Anemia or hypoproteinemia
  - Endotoxemia
  - Gastrointestinal crisis, such as large bowel torsion
  - Malnutrition
  - Severe systemic infection
  - Laminitis
  - Prolonged recumbency from a variety of neurologic or musculoskeletal problems
  - Excessive medication administration
  - Prolonged transport before parturition
- Reproductive, mammary gland, or localized problems, such as:
  - Severe endometrial fibrosis
  - Hydrops allantois or amnii
  - Purulent vaginal discharge
  - Prepubic tendon rupture
  - Pelvic injuries
  - Agalactia, such as from grazing on fescue pastures
  - Failure to produce good-quality colostrum
  - Premature lactation

Abnormalities of Labor or Delivery in Current Pregnancy

- Premature parturition
- Abnormally long gestation
- Prolonged labor
- Induction of labor
- Dystocia
- Early umbilical cord rupture, umbilical cord abnormality
- Cesarean section
- Premature placental separation

Neonatal Abnormalities

- Meconium-stained fluid or neonate
- Placental disease (e.g., placentitis, villous atrophy, edema)
- Twins
- Orphan
- Delay in or lack of intake of colostrum
- Dysmaturity or prematurity
- Exposure to infectious diseases, such as influenza
- Trauma (birth, predators, mother)
- Adverse environmental conditions
- Failure to be up and nursing by 2 to 3 hours of age
- Congenital abnormalities
- Weakness, poor appetite

progesterone in the placenta, which is further converted to 5 α-pregnane,3,20,-dione (5 α-DHP) in the endometrium. 5 α-DHP is metabolized to other progestins in the fetus, while some is passed into the maternal circulation, where it can be measured using commercial progesterone assays, due to endogenous progestagen cross-reactivity with progesterone antibodies. Maternal progestagen concentrations are relatively low and stable between days 150 and 315 of gestation, with concentrations typically between 2 and 12 ng/mL, depending on the assay used. These values rise sharply over the final 15 to 21 days of the pregnancy, before a large fall in the last 1 to 2 days before parturition. The rise is associated with mammary gland development and changes in the electrolyte concentrations of mammary secretions.[15]

Monitoring progestagen concentrations can provide useful insight into fetoplacental abnormalities, although maternal changes typically lag the early stages of disease. Measurement of progestagens may therefore be indicated to determine the need for progestin supplementation.[17] Three abnormal progestagen patterns have been described, and multiple samples collected at 48- to 72-hour intervals are recommended in high-risk mares.[18–21] Precipitous falls in progestagen concentration are seen in circumstances of fetal death and/or imminent expulsion.[22] In acute maternal illnesses, such as colic or uterine torsion, the progestagen concentration declines hours to days before abortion. In these mares the concentration may fall to less than 2 ng/mL.[21] A premature rise in the plasma progestagen concentration can occur in response to fetal stress and/or placental pathology and can persist for days or weeks before abortion or premature delivery.[18] A premature increase in maternal progestagens could reflect hastened or precocious fetal maturation. Removal of the initiating stressful event can lead to normalization in progestagen concentrations and the subsequent delivery of a healthy full-term foal. A third abnormal maternal progestagen profile is found in mares exposed to tall fescue grass infected with an endophyte fungus, where there is a failure in the concentration rise seen in normal mares.

Relaxin is a marker of fetoplacental well-being and periparturient complications in the mare.[23] The placenta is the sole source of circulating relaxin in mares.[24] In healthy pregnant mares, relaxin concentrations increase from about day 80 to a peak of 80 to 100 ng/mL at day 175, which persists until birth.[25,26] There are breed differences in relaxin concentrations during normal pregnancy.[27] A study of mares with normal pregnancies reported slightly lower values over the final 7 weeks of gestation.[23] Plasma values drop at delivery and are cleared within 48 hours of passage of the fetal membranes. In mares with problematic pregnancies, low relaxin levels during late pregnancy have been indicative of placental insufficiency

associated with a variety of causes including twinning, fescue toxicosis, oligohydramnios, placentitis, and pituitary disease.[23] The variability in values and breed differences make it difficult to rely on relaxin concentration as a marker of treatment efficacy in problem pregnancies.[23]

Estrogens regulate contractile properties of the myometrium. The precursors for estrogen formation are derived from fetal gonads, and metabolism takes place in the placenta. Precursors include estrone, estradiol-17α and estradiol-17β, and the equine-unique compounds equilin and equilenin.[15] Removal of the fetal gonads does not affect gestational length, implying that estrogens are not required for maintenance of pregnancy. However, labor is lengthened, foals are growth restricted, and maternal concentrations of prostaglandin F are decreased. It is likely that a prepartum increase in estrogens is associated with increased prostaglandin production and increases in oxytocin receptors, similar to that of other species.[15] Measurement of total maternal estrogens may reflect fetal health, with low concentrations associated with fetal compromise or death, but clinical data are lacking.

Several studies have demonstrated that ultrasound-guided transabdominal and allantocentesis can be used relatively safely in the late-gestation mare as long as the procedure is performed aseptically and multiple attempts are not made.[13,28,29] However, the clinical usefulness of fetal fluid analysis in the horse remains to be determined. Studies attempting to relate the phospholipid profile in amniotic fluid with equine fetal lung maturation have been inconclusive.[13,30,31] Transabdominal-guided ultrasound amniocentesis has also been used to detect experimentally induced equine herpes virus (EHV-1) fetal infection in utero.[32] The technique holds promise as a diagnostic aid to detect specific fetal diseases and as a potential therapeutic avenue to deliver medication in utero. Preliminary data demonstrated that mares that delivered healthy foals had a significantly higher amniotic fluid lactate concentration at the time of delivery than mares that delivered sick foals.[33] The significance of this finding is not known.

Electrolyte concentrations in prepartum mammary secretions may be monitored to predict impending parturition in the mare. As parturition approaches, the mammary concentration of sodium decreases and concentrations of potassium and calcium increase. An elevation in calcium concentration to over 40 mg/dL (400 µg/mL; 10 mmol/L) is a reliable indicator of readiness for birth and can be used to help determine whether elective induction or cesarean section should be performed. The increase in calcium occurs over the last 72 hours of gestation.[34,35] Test strips are commercially available to measure calcium and magnesium concentrations in a field setting (Predict-A-Foal Kit [Animal Health Care Products, Vernon, Calif.] and FoalWatch Kit [Chemetrics, Calverton, Calif.]). The milk calcium test better predicts mares that are not likely to foal rather than accurately determining the timing of foaling.

There are increases in the mammary concentration of potassium and a decrease in the mammary sodium concentration over the final 7 days of the gestational period. The mammary concentration of potassium typically exceeds that of sodium between 1 and 5 days before foaling. This has been used by some as a predictor of birth, although a recent study concluded that the use of mammary electrolyte concentrations was not reliable due to individual variability in both raw concentrations and percent changes.[36] The reversal of the milk sodium-to-potassium ratio was more accurate at predicting the day of birth than the milk calcium concentration in Martina Franc jennies, a breed that has longer mean gestational length.[37] The ratio reliably reversed 48 to 24 hours before parturition.

An arbitrary scoring system using calcium, sodium, and potassium concentration in the mammary secretions to assess fetal maturity has been described.[35] False-positive results (i.e., a value that inaccurately predicts imminent foaling) have been associated with vaginal discharge, placentitis, and premature lactation. False negatives occur commonly in mares with systemic illness or animals that have undergone general anesthesia. In many mares the changes in the electrolytes occur only within hours of delivery, so if monitoring is not performed frequently, the changes will be missed.[36,38] Recently, a comparison was made among milk calcium carbonate concentration, refractometry index, and pH with respect to prediction of foaling in healthy Thoroughbred mares.[39] Milk pH declines from a mean of approximately 7.4 to 6.4 over the final week of parturition. The positive predictive value (PPV) of foaling within 72 hours and the negative predictive value (NPV) of foaling within 24 hours for calcium carbonate concentration (using a water hardness test kit) were 93.8% and 98.3%, respectively. The PPV with 72 hours and NPV within 24 hours for mammary secretion pH (using pH paper 6.2 to 7.6) were 97.9% and 99.4%, respectively. Both techniques were superior to handheld refractometry. The authors used cutoff values of 400 µg/g for calcium and 6.4 for pH. The decision on whether or not to induce parturition in a mare should not be based solely on the results of this type of testing.

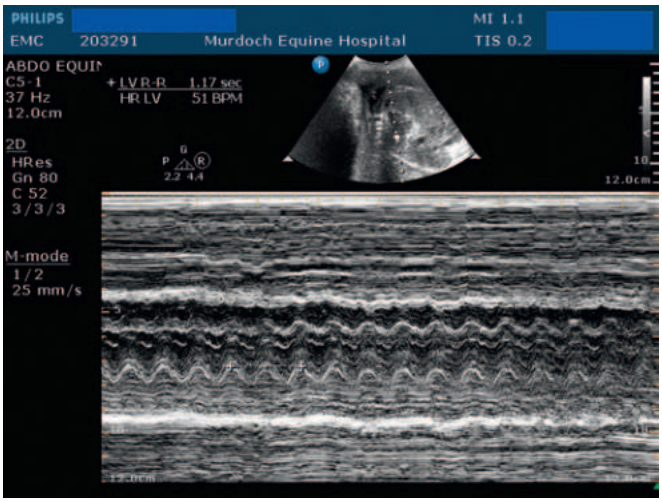

FIG. 15.1 M-mode assessment of a fetal heart to determine fetal heart rate. In this example the rate was calculated using two successive heart beats, resulting in a rate of approximately 102 beats per minute. *(Courtesy Dr. Emma McConnell.)*

Fetal heart rate (FHR) and fetal heart rate variability (FHRV) are useful tools to assess fetal well-being. The most commonly used technique for assessing FHR is M-mode echocardiography (Fig. 15.1). This requires access to suitable ultrasound equipment including a low-frequency probe and appropriate software. This technique does have several limitations, including difficulty in locating the fetal heart in some cases due to maternal and fetal movement. Also, the heart rate at any time point is influenced by fetal activity, and a single time point observation may not accurately reflect the upper and lower FHR extremes.[40]

A fetal electrocardiogram (ECG) can be used to assess FHR and FHRV after day 150 of gestation.[40–44] The left arm electrode is placed on the dorsal midline of the mare at the lumbar region, and the left leg electrode is placed 15 to 20 cm cranial to the udder on the ventral midline. The hair should be clipped, and ample gel or alcohol should be placed to ensure good contact of the electrodes. Poor fetal signals may result from poor electrode contact or placement, fetal movement, or electrical interference. An alternative method involves placement of the left leg lead on the left neck, the left arm lead in the left flank at the height of the hip, the neutral lead on the mare's croup, and the right arm lead over the linea alba cranial to the udder and then connecting the leads to a Televet 100 Holter ECG (Engel Engineering Services GmbH, Heusenstamm, Germany) recording system. This configuration allows

VetBooks.ir

for simultaneous determination of the maternal and fetal ECG. Calculation of the fetal HRV has merits but remains essentially a research tool. It requires acquisition of a minimum of 5 minutes of good-quality recording and export of an R-R interval file, which is then processed using a dedicated software product (Kubios HRV software [Biosignal Analysis and Medical Imaging Group, Kuopio, Finland]). From a practical perspective, gross examination of the beat-to-beat variability can be done using a standard ECG trace; an absence of variability is a concerning sign, assuming no maternal sedation.

The fetal heart rate peaks around 196 beats per minute at 3 months' gestation, before decreasing over the reminder of the gestational period.[11] Heart rate decreases from greater than 120 beats per minute before day 160 of gestation to between 60 and 90 in late gestation.[12,40–43,45,46] In late gestation FHRs below 60 bpm are common and are not of concern unless they persist and occur without accelerations.[47] Conversely, rates greater than 120 bpm are also common in active foals and are normal unless they do not return to healthy baseline levels. Cardiac accelerations in response to fetal movement are an indicator of fetal well-being. An early study reported an average of 10 heart rate accelerations (25 to 40 beats per minute) in a 10-minute period; 95% of these were associated with fetal movement.[48] Another study reported that the number and duration of cardiac accelerations and decelerations remained relatively constant over the last 2 months of pregnancy. There were approximately 22 accelerations per hour lasting around 29 to 42 heart beats and around 24 decelerations per hour lasting 24 to 60 heart beats.[43]

There is an increase in FHRV over gestation.[43,46] HRV describes the variability in R-R intervals between successive beats and reflects the influence of the neuroendocrine system. A frequency-domain analysis, reported as a low frequency (LF)/high frequency (HF) ratio, is an indicator of sympathetic activity and is used as a marker of stress. In stressful states the HF component decreases, producing a lower LF/HF ratio.[43] Therefore a healthy state is typically associated with a high HRV.[40] The FHV and FHRV are relatively constant over the final 10 days of gestation and are not useful indicators of foaling.[43]

The fetal response to hypoxia is persistent bradycardia and a reduction in movement. If reduced oxygen delivery persists or worsens, tachycardia and arrhythmias result, again with an absence of movement. Ultimately myocardial exhaustion leads to a return of persistent bradycardia immediately before fetal death. Although persistent fetal tachycardia and bradycardia suggest fetal compromise, a normal FHR alone does not guarantee that the fetus is healthy. Prolonged periods of fetal inactivity, in the absence of maternal sedation, are also suggestive of poor fetal health.

Transabdominal ultrasonography allows noninvasive evaluation of the intrauterine environment and fetal well-being. In the mare, transabdominal ultrasonography can be used to evaluate the equine fetus after day 90, when the gravid uterus contacts the ventral abdominal wall. This technique is used more commonly during the second and third trimesters. After 9 months of gestation, most fetuses are in an anterior presentation and are unlikely to change that presentation before delivery.[49]

Transabdominal scanning has been used to detect twins, document fetal position, estimate fetal size using fetal aortic diameter, evaluate fetal activity, evaluate placental integrity, determine fetal fluid clarity and volume, and monitor FHR and fetal breathing. Phased array or convex transducers with lower frequencies (2 to 4 MHz) are required due to the deep tissue penetration needed (up to 25- to 30-cm depth). Higher-frequency probes provide a clearer assessment of the uteroplacental unit, with depths less than 10 cm typically required. The mare's ventral midline must be cleaned from the level of the umbilicus (xiphoid in late pregnant mares) caudally to the mammary gland, and isopropyl alcohol is applied with or without coupling gel. Clipping provides a better image but is usually not required. Chemical sedation should be avoided because drugs such as xylazine and detomidine induce fetal bradycardia and retard fetal movement. The abdomen should be scanned in both sagittal and transverse planes. The examination typically begins at the front of the udder, moving cranially to detect the characteristic shadowing of the fetal ribs (Fig. 15.2) The aorta is identified and measured as close to the heart as possible (Fig. 15.3). A fetal heart rate is typically calculated using M-mode ultrasound. The position of the foal is verified, and as discussed earlier, after 9 months' gestation the head is directed toward the pelvis and the fetus lies in dorsal recumbency with vertebrae closest to the ventral abdominal wall.[12] Abnormal positioning after this time heightens the risk of dystocia. Fluid depths are assessed for both the allantoic and amniotic fluid compartments using multiple measurements from the lateral aspect of the ventral abdomen of the mare.[14] The most prominent region of fetal fluid is around the thorax in the area of the elbows.[12] In healthy mares the maximum depth of the allantoic fluid has been reported as 13.4 ± 4.4 cm, and the maximal depth of the amniotic fluid as 7.9 ± 3.5 cm. The amniotic membrane is a thin, hyperechoic structure that appears to float freely in between the amniotic and allantoic sacs.

FIG. 15.2 Characteristic rib markings overlying the thorax in a 5-month gestational age pony fetus.

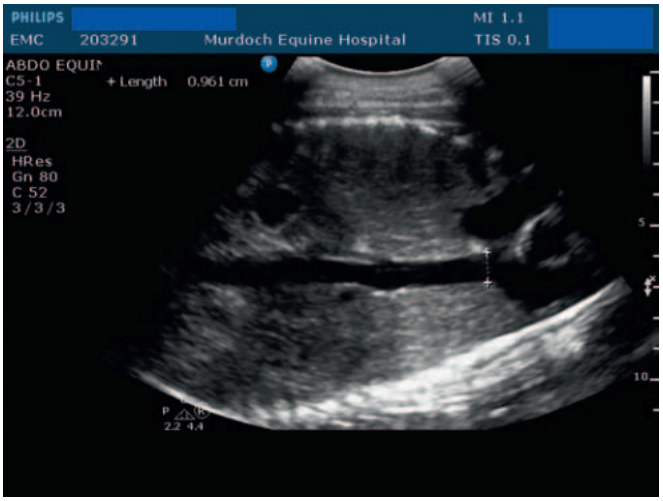

FIG. 15.3 Measurement of the aortic diameter is ideally made close to the heart.

Biophysical profiles that use several parameters to establish an idea of the size and overall health of the equine fetus have been developed.[10,11,14,45,48] There is evidence that these profiles are important in high-risk mare pregnancies[50] but fall short of similar profiles in human medicine in predicting outcome.[14,47] The six parameters typically assessed using transabdominal ultrasonography include fetal weight, as estimated by the fetal aortic diameter in relationship to the mare's weight (mean 2.1 cm at 300 days' gestation to 2.7 cm at full term), FHR (decreases with advancing gestational age), fetal activity (increases with advancing age; graded from 0 to 3), uteroplacental contact and thickness, and maximal amniotic and allantoic fluid depth. Similar to human biophysical profiles, a maximum score of 2 is given to each parameter if it is normal. Low scores predict poor outcomes, but high scores do not guarantee a healthy foal.

Qualitative assessment of the fluid appearance is also useful. The fluid within the allantoic and amniotic spaces is characteristically anechoic, although small floating particles can be observed in the allantoic compartment in late-term mares.[45] During late gestation the equine fetus should demonstrate moderate activity (grade 2 to 3/3) with only brief episodes of inactivity (<20 minutes). Assessment of fetal breathing should be an important component on any biophysical profile, but it is difficult to assess in mares.[47] Breathing is characterized by excursion of the diaphragm between the thorax and the abdomen with accompanying rib cage expansion. Regular breathing movements are observed intermittently in most late-term fetuses. It can be difficult to differentiate fetal from maternal breathing movements. Ideally, a minimum of 20 seconds of continuous breathing is observed.

Assessment of the combined thickness of the uteroplacental (CTUP) unit is limited to ventral and lateral views using transabdominal ultrasound (Fig. 15.4). Combined measurements are used because it is difficult to accurately demarcate the junction of the placenta and uterus. The average CTUP viewed transabdominally ranges between 8 and 15 mm.[11] One study reported mean values across normal Paints, Quarter Horses, and Thoroughbreds between 270 and 330 days' gestation of 8 to 12 mm.[51] Measurements may vary between breeds with reports of mean CTUP values of 12.7 ± 3.1 mm in Lipizzaner mares between 280 and 315 days.[14] Thicker measurements may indicate placental edema, hemorrhage, or placentitis. Areas of separation between the uterus and chorion appear as black anechoic areas. The maximum ventral fetal fluid pocket depths average 8 cm for amniotic fluid and 13 cm for allantoic fluid.[11]

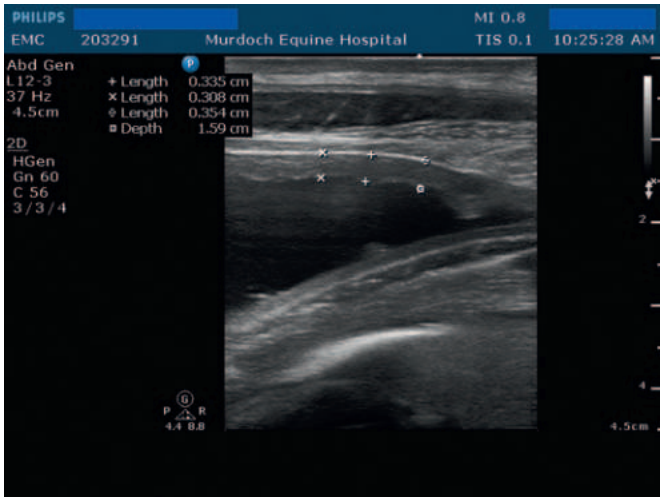

FIG. 15.4 Measurement of the combined thickness of uteroplacental unit. This measurement is taken from a 150-day gestation age pony fetus.

Excessive fetal fluid accumulation is observed in cases of hydrops. Markedly decreased amounts of fetal fluids have been associated with placental dysfunction and the birth of a dysmature, hypoxic foal. As gestation advances, fetal fluids increase in turbidity. Sudden increases in turbidity may be associated with meconium passage, hemorrhage, or inflammatory debris. Given the frequency of ascending placentitis, transrectal ultrasonography has been added to the assessment of mid- and late-term pregnant mares.[51]

Uterine blood flow changes can by assessed with rectal ultrasound using pulsed wave and color flow Doppler settings.[52] Monitoring changes in uterine artery diameter, blood flow (pulsatility index, blood flow volume), and the presence of an early diastolic notch may have a role in monitoring high-risk mares, although evidence is currently lacking.

Effects of Placental Insufficiency

The effects of uteroplacental vascular insufficiency on the newborn depend on the severity of placental compromise and the severity and duration of prenatal and perinatal asphyxia. Conditions associated with chronic asphyxia include chronic placentitis, villous atrophy, twin and post-term pregnancies, and ingestion of endophyte-infected fescue grass. If decreased uteroplacental blood flow is long-standing, growth is concomitantly inhibited in the fetus. The pattern of growth retardation associated with chronic placental insufficiency is usually asymmetric, characterized by visceral wasting with relative preservation of fetal length and head circumference. It has long been recognized that twin equine neonates and other abnormally small foals tend to have heads that are disproportionately large for their small bodies.[53]

In placental vascular insufficiency, the fetus has the ability to avoid overgrowing its nutrient supply and to maximize organ growth. Under metabolic stress, there is a fetal anti-insulin response with loss of fat and glycogen stores and muscle mass. Associated with the decrease in uteroplacental blood flow is an increase in uterine and fetal vascular resistance and redistribution of cardiac output, with a greater percentage of blood flow going to organs such as the brain and heart. Unless uteroplacental insufficiency is severe, brain growth continues at a relatively normal rate. In the human fetus, the redistribution of cardiac output also results in decreased blood flow to the lung and kidney and decreased production of fetal urine and lung liquid, two major components of amniotic fluid. A decrease in amniotic fluid volume is therefore associated with chronic fetal asphyxia.[54,55]

Repeated episodes of hypoxemia during gestation slowly deplete cardiac glycogen stores and impair the ability of the heart to effectively pump blood during subsequent hypoxemic episodes, such as during labor. The newborn with depleted glycogen stores may also be at increased risk of developing hypoglycemia and hypothermia. Meconium aspiration and persistent arterial hypertension in the newborn period are secondary to chronic fetal hypoxia. Immature skeletal ossification, particularly of the carpal and tarsal bones, has also been associated with growth retardation in the foal.[53]

There are certain advantages associated with adaptation to chronic placental insufficiency. Growth-retarded premature human infants have a lower incidence of hyaline membrane disease than babies of the same gestational age that are appropriately sized.[56] Presumably, fetal hormones, such as the corticosteroids and catecholamines that are released in response to nutrient deprivation, stimulate early maturation of the lung and surfactant system. Accelerated neurologic maturity has also been documented along with accelerated pulmonary maturity.[57] Therefore the fetus that has been chronically exposed to an adverse in utero environment may be in some ways more tolerant of premature delivery and independent life outside

VetBooks.ir

the uterus than the "normal" fetus that is abruptly displaced through induction of labor or cesarean section. The low-birth-weight fetus therefore represents a successful adaptation to a nutrient-deprived environment. Its smaller size, decreased metabolic needs, and early organ maturation actually place it at lower risk of hypoxic injury at birth and aid its transition to independent life after delivery.[55] Further discussion of the characteristics, treatment, and prognosis of growth-retarded premature foals may be found in Chapter 17.

Premature lactation, purulent vaginal discharge, previous history of growth-retarded foals, advanced maternal age, and prolonged gestation are problems that should raise the suspicion of chronic uteroplacental insufficiency. The birth should be attended to minimize the chances of acute asphyxia. The newborn animal should be examined for evidence of growth retardation; infection, particularly in utero–acquired pneumonia secondary to placentitis; and metabolic and acid-base derangements. Ample colostrum should be administered, and body temperature and blood glucose should be monitored closely.

Human infants that display characteristics of asymmetric growth retardation commonly "catch up" by late infancy or early childhood. Similar observations have been made in the foal. Many mildly to moderately growth-retarded newborn foals have also done well following discharge from the hospital and have grown to a normal size. Problems secondary to an immature musculoskeletal system are the most common complications noted in these individuals, but careful orthopedic management can result in a successful outcome.

Placentitis

Placentitis is a common cause of reproductive losses in horses, with an estimated 30% of pregnancy losses attributable to the disease.[4] The most common cause of placentitis is ascending infection from the lower urogenital tract via a relaxing cervix. This leads to thickening of the fetal membranes and separation from the uterus. Infection via this route is typically localized to the cervical star region. A far less common route of infection is the hematogenous avenue resulting in a diffuse or multifocal placentitis.

Mares with ascending placentitis are typically pluriparous, and many have anatomic defects, including vestibule-vaginal reflux, pneumovagina, and damage to the cervix, including fibrosis, tears and adhesions.[15] Most cases of placentitis are the result of bacterial infection caused by typical equine pathogens including *Streptococcus equi* subspecies *zooepidemicus*, *Escherichia coli*, *Enterobacter agglomerans*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*. In some regions a slightly different form of placentitis has been recognized and is characterized by focally extensive placentitis located predominantly at the base of the placental horns at the junction of the horns and body of the placenta.[58] The affected area is covered with thick, tenacious brown mucoid exudate, and the underlying chorionic villi are necrotic and absent or reduced in size. This form is associated with infection by a group of gram-positive, branching, filamentous Nocardioform actinomycetes, including *Crossiella equi*, *Amycolatopsis* species, and less commonly *Cellulosimicrobium cellulans* and *Streptomyces* species.[59] There is link between some of these bacteria, which are part of the normal intestinal flora, and ingestion of Eastern Tent caterpillars *(Malacosoma americanum)* or Processionary caterpillars *(Ochrogaster lunifer)*.[60,61] The Eastern Tent caterpillar is linked to Mare Reproductive Loss Syndrome (MRLS) in the United States, and the Processionary caterpillar is a causal agent of Equine Amnionitis and Fetal Loss (EAFL) syndrome in Australia.[62] It is likely that the barbed setae (hairs) penetrate the intestinal mucosa, thereby facilitating bacterial translocation.

*Chlamydophila (*formerly *Chlamydia) psittaci* infects a wide range of wild bird and poultry species around the world. The organism has been documented as a cause of placentitis in mares with associated foal mortality.[63] It has the potential to spill over into humans, with clusters of human cases documented after handling of diseased fetal membranes.[63,64] The likely modes of transmission in these cases from fetal membranes to humans are either via the airborne route or direct inoculation of the eyes or nose. There is some limited evidence that respiratory protection (P3 mask) and eye protection reduces the risk of disease.[65] The potential avian reservoir for equine chlamydiosis is not known, but a pigeon-like variant was isolated in New South Wales.[66]

Clinical signs of placentitis include vaginal discharge, premature udder development, and precocious lactation. The discharge may be evident on the vulva, tail, or inner thighs. Premature udder development is the result of placental compromise, fetal stress, a precocious increase in maternal progestagen concentration, and enhanced fetal adrenocortical activity. Despite even voluminous vaginal discharge, most mares with placentitis do not become febrile and do maintain a normal appetite. The dam's hematology and fibrinogen concentration usually remain within normal limits. Untreated mares with experimental placentitis due to *S. equi* subsp. *zooepidemicus* had significant increases in serum amyloid A (SAA) within 96 hours of inoculation that persisted through to birth or abortion.[67] The increase in SAA was prevented in most treated mares.

Transrectal ultrasound is used to identify placental separation and utero-placental thickening of the caudal uterine body. This region is most commonly involved in mares with ascending placental infection. Measurement of the combined thickness of the uterus and placenta (CTUP) is established. The rectal transducer is placed at the cervical-placental junction, where a branch of the uterine artery is seen between the uterus and bladder. This measurement increases from around 4 to 6 mm at 7 months' gestation to 10 to 12 mm at term.[45,51] Mare parity has an impact on CTUP during midpregnancy (100 to 250 days), with primiparous mares having a greater thickness than multiparous mares.[68] The difference is lost in late pregnancy. A measurement greater than 12 mm at 9 months, or greater than 15 mm at 11 months, is consistent with placental pathology.[45,69] Measurement of CTUP alone can be misleading, and monitoring of the CTUP by ultrasound along with determination of the maternal progestagen concentrations has been recommended.[18] Fetal membranes commonly disunite from the uterus, separated by fluid of variable echodensity.

Transabdominal ultrasonography is used to evaluate other areas of the placenta to detect loss of placental integrity or increased uteroplacental thickening. Using transabdominal ultrasound, the uteroplacental unit should be less than 16 mm during late gestation. Other signs suggestive of placentitis include increased fetal fluid echogenicity, which might result from hemorrhage or purulent exudate. If placentitis is severe enough to alter placental function, reduced fetal movement, loss of heart rate variability, and absolute fetal bradycardia collectively indicate fetal compromise.

Samples of vaginal discharge should be cultured, and Gram stains should be performed. The goal of maternal therapy is to treat the placental infection and maintain the pregnancy, provided there is no evidence of severe fetal distress or demise. In many cases, because the infection is of long duration, the fetus has been chronically stressed and therefore is relatively mature for its gestational age and better prepared to tolerate preterm birth. If placentitis is suspected, following delivery, the foal should be considered a high-risk individual. Commonly encountered problems in the newborn foal that was exposed to placentitis are pneumonia, uveitis, growth retardation, incompletely ossified bones, and sometimes systemic sepsis.

Systemic Disease in the Mare

Colic and colic surgery are risk factors for fetal death or premature delivery. Foal survival rates after medical colic are

VetBooks.ir

superior to rates after colic surgery, which are reported as between 54% and 80%.[70–73] Specific risk factors have varied among studies but have included the duration of anesthesia, intraoperative hypotension, intraoperative hypoxemia, perioperative toxemia, stage of gestation, and age of the mare. A retrospective study reported that pregnant mares older than 15 years of age undergoing colic surgery were less likely to produce a live foal than mares aged 15 years or younger.[72] In the same study mares that had colic surgery at 16 to 39 days of pregnancy were less likely to produce a live foal (49%) than mares that were older than 40 days in foal. The management of mares postoperatively typically includes supplementation with a progestin, although no clear benefit has been reported.[71] Likewise, the tocolytic agent clenbuterol hydrochloride has been recommended, but again without significant evidence.

In acute colic, the progestagen concentration declines hours to days before abortion. The concentration may fall to less than 2 ng/mL.[21]

Laminitis is often a chronic condition that is exacerbated in pregnant mares because of added body weight. The condition is associated systemic hypertension, and a recent study of pregnant laminitic mares reported hypertension, shorter gestational periods, and lower placental and foal birth weights than a control group of normal mares.[74] The authors reported a number of vascular abnormalities in the placenta, including reduced vascular lumen and capillary area in microcotyledons, and thickened vascular walls.

There have been several retrospective studies of uterine torsion in mares. Survival rates of mares have varied between 60% and 90.5%.[75] Survival of the mare and the foal is determined, in part, by gestational age at the time of the torsion, degree of rotation, and method used for correction. Foal survival is also related to the interval from torsion to correction. A multicenter retrospective study reported an overall foal survival rate of 82.3%; positive foal outcomes were highest when torsion occurred before 320 days' gestation (90.6%) and when corrected by standing flank laparotomy (88%).[75] The authors suggested that improved outcomes at earlier stages of gestation were likely due to lighter foals exerting less pressure on uterine vessels by crossed broad ligaments. This is coupled with reduced oxygen demands in younger fetuses. Avoidance of general anesthesia and dorsal recumbency must also have comparatively less impact on placental blood flow.

Management of the High-Risk Late-Gestation Mare

Each mare should receive a complete physical examination, and foaling histories should be obtained. Signs of impending parturition (sacroiliac ligament and perineal relaxation, mammary development, and mammary secretion electrolyte concentration) should be assessed daily. The reproductive tract may be evaluated by rectal palpation, and transabdominal ultrasonography may be performed at regular intervals to detect changes in the fetus, fetal fluids, or placenta. Prolonged periods of feed restriction should be avoided to prevent maternal hypoglycemia.[13] Estimation of progestin concentrations in the maternal circulation, using a commercial progesterone assay, is recommended.[18]

When treating a pregnant mare for any medical or surgical condition, consideration must also be given to the fetus. Any illness or disease that affects the mare's cardiovascular system has the potential to affect placental perfusion and the integrity of the fetoplacental unit. Hypotension, toxemia, and hypoxemia are examples of conditions that can alter uteroplacental blood flow and jeopardize the pregnancy. Diseases that stimulate prostaglandin production have the potential to initiate labor and delivery. Illnesses that produce prolonged periods of anorexia in the late-term mare can also contribute to premature delivery. The effect of various drugs on the placenta and fetus should be considered when treating the pregnant mare. If delivery is not imminent, then many drugs will pass through the placental and fetal circulation and be cleared by the maternal liver and kidneys. Due to the epitheliochorial nature of the equine placenta, some drugs will not cross the placental barrier at all. If drugs are administered to the mare and the fetus is delivered shortly thereafter, then the neonate must rely on its renal and hepatic function to process, degrade, and excrete those drugs. In most instances, as long as fetal well-being and placental integrity are closely monitored, the goal of most therapies is to treat the maternal condition and maintain the pregnancy as long as possible to achieve an acceptable degree of fetal maturation.

The use of antibiotics in placentitis should be based on knowledge of common pathogens and the likelihood of achieving therapeutic concentrations at the site of infection. Studies using microdialysis probes inserted into the allantoic fluid of normal mares reported therapeutic concentrations of penicillin and gentamicin in the allantoic fluid after 22,000 IU/kg of potassium penicillin G (IV q6h) and 6.6 mg/kg gentamicin (IV q24h), albeit with peak concentrations in allantoic fluid 80% of that achieved in maternal serum.[76] Studies in two mares with experimentally induced bacterial placentitis again confirmed passage of both drugs across the placenta. The combination of trimethoprim and sulfadiazine (30 mg/kg PO bid) and the phosphodiesterase inhibitor pentoxifylline (8.5 to 10 mg/kg PO bid) also readily crosses the fetal membranes in both healthy mares and in animals with experimental placentitis.[17] In many cases, medical treatment of the placental infection and prolongation of pregnancy is associated with a good outcome. Maternal treatment includes systemic antibiotics, flunixin meglumine, pentoxifylline, and altrenogest.[13,77] In an experimental model of placentitis, induced through inoculation of *S. equi* subspecies *zooepidemicus*, the combination of trimethoprim sulfamethoxazole, pentoxifylline, and altrenogest was highly effective at prolonging gestation and improving foal viability when contrasted with mares that received no treatment.[77] Because of the usual presence of mixed gram-positive and gram-negative placental and fetal infections, a broad-spectrum antibiotic that reaches therapeutic levels in the fetus and fetal fluids should be selected. Therapeutic options include penicillin and gentamicin, trimethoprim-sulfonamide, or ceftiofur. Trimethoprim-sulfonamide combinations or doxycycline have in vitro activity against several nocardioform actinomycetes.[59] Low doses of flunixin can be administered to decrease inflammation and prevent prostaglandin-mediated induction of delivery.

Altrenogest (Regu-Mate, 0.044 to 0.088 mg/kg, 10 to 20 mL of 0.22% solution for 500-kg mare, PO q24h) is commonly used in late pregnancy to prevent preterm delivery, possibly through interference with prostaglandin regulation and oxytocin receptors.[17] The rationale for altrenogest use in late pregnancy has been questioned, as plasma progestagen concentrations are typically raised in mares with placental disease.[78] The evidence for altrenogest use in mares with placentitis is not strong, with studies using a model of experimental placentitis failing to document an advantage of the drug over antimicrobials alone.[79,80] Altrenogest readily crosses the placenta and reaches relatively high concentrations in the fetal fluids and the newborn foal.[81] Concentrations in the healthy foal decline rapidly over the first 6 hours postpartum. The effects of altrenogest on the foal are largely unknown, but a reduced neutrophil-to-lymphocyte ratio in foal blood has been reported.[82] It has been recommended to withdraw altrenogest after 320 days' gestation.

In a group of mares with experimentally induced ascending placentitis after inoculation with *S. equi* subspecies *zooepidemicus*, the authors reported that estrogen supplementation (estradiol cypionate 10 mg IM q3d for 3 treatments), coupled with trimethoprim sulfamethoxazole (30 mg/kg IV q12h for 10d) and

VetBooks.ir

flunixin meglumine (1.1 mg/kg IV q24h for 10 days), resulted in a normal gestation period and foal survival rates similar to control animals.[79] This was a superior result than that of mares treated with antibiotics, flunixin, and altrenogest.

If there are large areas of placental thickening, IV DMSO (0.5 to 1 gm/kg) can be administered to decrease placental edema, although direct evidence is lacking. Pentoxifylline has also been administered in attempts to improve placental perfusion.

If premature delivery appears unavoidable, then one to three doses of maternal corticosteroids can be used with the hope of stimulating and accelerating fetal lung maturation through enhanced surfactant production. This is done with the knowledge that corticosteroids are anecdotally associated with a heightened risk of laminitis, particularly in mares with underlying disease. Normal Thoroughbred mares given 100 mg of dexamethasone intramuscularly on gestation days 315, 316, and 317 delivered foals around 2 weeks earlier than saline-treated control mares.[83] The interval between the last dose and parturition was only 1 to 8 days. Resultant foals were smaller but appeared mature and had normal neutrophil-to-lymphocyte ratios. There was evidence of lingering adrenal suppression in some foals.

In the high-risk mare, it is important that the delivery be attended by knowledgeable personnel and that all supplies, drugs, and equipment required for diagnosing and correcting a dystocia and stabilizing the mare and foal be organized and close at hand. A spontaneous, vaginal delivery is generally preferred in the high-risk mare, both because of the profound problems associated with the untimely delivery of a premature foal and the complications sometimes associated with induced labor or cesarean section. (See the Maturity section in Chapter 17). There are instances, however, when an induced birth or cesarean section is indicated or preferred.

Induction of parturition should be considered with the following:

- Severe fetal distress noted on prenatal assessment
- Evidence of premature placental separation or a history of premature placental separation associated with dead or asphyxiated foals
- Hydrops allantois and/or amnion
- Unproductive stage I labor
- Uterine inertia
- Impending prepubic tendon rupture
- Life-threatening maternal illness

Indications for cesarean section may include the following:

- Pelvic injury or abnormality resulting in obstruction of the birth canal
- Gastrointestinal crisis requiring surgery
- Severe dystocia
- Insufficient, thickened placenta associated with fescue toxicity in the mare
- Catastrophic and terminal illness or injury in the mare, such as gut rupture or fractured limbs

If induction of parturition or cesarean section is elected, every effort should be made to ensure that the fetus is mature and ready to be born; the usual result of induction at an inappropriate time is a nonviable newborn. Three essential criteria are a gestation of longer than 330 days, good-quality colostrum in the udder, and softening of the cervix.[84] The scheduling needs of the veterinarian or owner should never be the only criterion used for determining the timing of delivery. A slow, continuous oxytocin infusion administered at a rate of 1 unit/minute usually results in delivery within 20 to 40 minutes.[13] Alternatively, multiple intravenous or intramuscular injections of 10 to 20 units of oxytocin every 10 minutes have been recommended.[84,85] Other investigators have shown that smaller intravenous doses of oxytocin (2.5 IU administered every 15 to 20 minutes until rupture of the chorioallantois or a total of 20 IU of oxytocin has been administered) is an effective, and perhaps more physiologic, method of induction.[86]

Induction of parturition in the mare has been associated with more violent, painful contractions than spontaneous labor and a higher incidence of premature placental separation and neonatal asphyxiation. Cesarean section also predisposes to neonatal peripartum asphyxia. Maternal hypotension secondary to general anesthesia and the weight of the maternal abdominal contents on the aorta and vena cava both compromise uteroplacental circulation. For further details concerning anesthesia of the late-term mare, the reader is referred to other texts.[87] Abdominal support with nonsteroidal antiinflammatory drugs and altrenogest has been used to maintain the pregnancy in a mare with hydrous amnion until day 321, when spontaneous delivery occurred.[88] The delivery was complicated by uterine inertia, maternal postpartum hypovolemic shock, and cardiac arrhythmia, but both mare and foal survived.

Foal Resuscitation

The veterinarian attending or assisting in the birth should be prepared in the event that cardiopulmonary cerebral resuscitation (CPCR) of the foal is required. Detailed descriptions of CPCR are published elsewhere.[89–92] Foals born by Cesarean section or assisted vaginal delivery are at increased risk of cardiac or pulmonary arrest. Mares suffering from systemic illness, hydrops, prepubic tendon rupture, placentitis, placental insufficiency, or premature placental separation are also at heightened risk for delivering foals with serious complications.

After delivery the at-risk foal should be positioned on a firm, flat surface with the withers against a wall to prevent movement if thoracic compressions are needed.[92] Quickly palpate the thorax for evidence of rib shaft fractures or costochondral dislocations. If fractures are detected, the affected side should be in contact with the ground. Initially place a nasal insufflation tube into one nasal passage to the level of medial canthus of the eye, and deliver oxygen at 10 L/min. Assess the foal's breathing and circulation over the following 30 seconds, noting rates and effectiveness. The nasal passages should be examined for meconium staining, and any fetal membranes should be removed. Remaining fluid can be cleared using gentle postural drainage and a bulb syringe and soft catheter. Hanging foals from their pelvic limbs must be avoided.

Spontaneous breathing is stimulated by vigorous rubbing of the body and head with a dry towel. Gentle thoracic compression is also helpful. Other techniques used to improve breathing include tactile stimulation of the nasal mucosa or the ear canal. In other species, pouring of cold water into the ear canal or application of acupuncture needles to the nasal philtrum (absent in the foal) has been suggested.[93] If the foal fails to breathe or is making irregular gasping movements, then positive pressure is urgently required.

The attendant can provide positive pressure using mouth-to-nostril resuscitation. The opposite nostril is occluded along with gentle pressure over the proximal esophagus, and breaths are delivered with the foal's head in extension. During each forced breath, the rise in thoracic wall should be observed to ensure an appropriate tidal volume is delivered. Exhaled air is only 16% to 18% oxygen, but this is considered adequate in the face of failing perfusion.[92] Alternatively, a pump and face mask resuscitator can be used (McCulloch Medical Products, Glenfield, New Zealand). This device can be connected to a nasotracheal tube or a face mask and delivers a set volume of 780 mL, thereby avoiding volutrauma. The resuscitator device can also be easily adapted to suction the airway.

Cuffed nasotracheal tubes (7-mm, 9-mm, and 12-mm diameter; 55 cm long) should be available as part of the

resuscitation kit, along with a self-inflating resuscitation bag (the bag component of a commercial air mask bag unit [AMBU; Ambu Inc., Linthicum Heights, Md.). Intubation provides the most effective method for ventilation support. A 9-mm tube will suit most foals, although a large tube may be needed in foals larger than 55 kg. Passage of the nasotracheal tube is facilitated by keeping the head in extension. The tube is passed through the ventral meatus into the nasopharynx to the larynx. Rotation of the tube can aid in passage through the arytenoid cartilages and into the trachea. The tube is inserted fully to reduce dead space, such that the tube end is positioned in the midtracheal region and the cuff is inflated. An adult resuscitation bag (typically 1600-mL capacity with 2600-mL oxygen reservoir bag) is connected to the tube and manually compressed to provide positive-pressure ventilation at an initial rate of 10 breaths/minute. The bag has an adjustable escape valve that prevents barotrauma. The valve is typically set at 35 to 45 cm H_2O.[90] The thoracic wall should rise appropriately without air leaks around the cuff. Ideally, the bag is connected to an oxygen cylinder using a flow rate of 8 L/min, but ventilation with room air is acceptable. The oxygen flow rate can be adjusted on the basis of the minute volume that is delivered.[92] Assisted ventilation should be ceased every 3 minutes to monitor for spontaneous ventilation. The use of chemical respiratory stimulants, such as doxapram hydrochloride, is no longer indicated in the treatment of secondary apnea.

If there is asystole or the heart rate is persistently less than 40 beats per second, then cardiac compressions are indicated without delay. It has been recommended that compressions occur at a rate between 100 and 120 per minute, with complete thoracic wall recoil between each compression.[89,91] The compressions should be forceful and contribute around 25% to 30% of normal cardiac output. Ideally, compressions are continuous and there should be a compression-to-ventilation ratio of 30:2.[91]

Drugs are indicated if the heart rate fails to increase with supported ventilation and thoracic compressions. The drugs can be administered intravenously via the jugular vein or intraosseously, using a 12-gauge intraosseous infusion needle.[89] The most popular medications for cardiovascular resuscitation include epinephrine and vasopressin. Epinephrine can initially be administered using a bolus dose of 0.01 to 0.02 mg/kg (1 mg/mL, 0.5 to 1.0 mL/50-kg foal), repeated every 3 to 5 minutes due to a short half-life. A higher dose is recommended if the foal fails to respond to other therapies (0.1 mg/kg; 1 mg/mL, 5 mL/50-kg foal). Vasopressin is a peripheral vasoconstricting agent that can be administered at a bolus dose of 0.6 U/kg IV.[92] It can be used alone or in combination with epinephrine.[91] The effects last approximately 10 to 20 minutes. The use of sodium bicarbonate in CPCR continues to be controversial, but evidence indicates a potentially deleterious effect of myocardial function, and in the absence of any positive survival data it is no longer recommended in human CPCR.[91,94]

Defibrillation is indicated in ventricular arrhythmias, including ventricular fibrillation and ventricular tachycardia without palpable pulse pressure.[90] The technique should not be used in the management of bradyarrhythmias or asystole. Recommendations include an initial defibrillation of 2 J/kg, followed by a discharge of 4 J/kg 30 to 60 seconds after treatment with epinephrine or 1.5 mg/kg, repeated in 5 minutes for lidocaine, and continued cardiac compressions.[89] Amiodarone has been used in adult horses with refractory ventricular tachycardia; the recommended dose is 5 mg amiodarone/kg/h for 1 hour, followed by 0.83 mg amiodarone/kg/h during 23 hours, although boluses over 2 minutes have been used safely in normal adult horses.[95,96]

Resuscitation should be discontinued in the absence of spontaneous cardiac output within 10 minutes of initiating CPCR. Successful resuscitation is associated with spontaneous ventilation at a normal rate, depth, and effort and a regular cardiac rhythm with a rate greater than 60 beats/min. The foal should be monitored closely over the following 60 minutes and then at a lower level for a further 48 hours, as there is a heightened risk of postasphyxia complications.

Perinatal Asphyxia Syndrome

Perinatal asphyxia syndrome (PAS), also termed *hypoxic ischemic syndrome* (HIS), describes the clinical consequences of reduced oxygen delivery to tissues. The clinical effects of asphyxia can be widespread and can involve many systems including the nervous system, kidneys, gastrointestinal tract, and cardiopulmonary system. The nervous system is the most commonly affected. The pathophysiology and clinical features of nervous system disease can be found in the Neonatal Encephalopathy section in Chapter 17. The renal system is the second most common system affected by asphyxia. In most affected foals the impact is relatively small, with reduced glomerular filtration and mild tubular disease, resulting in few abnormal clinical or laboratory findings. The most common laboratory derangement is persistent elevation in creatinine concentration or an increased level that is slow to normalize. In a small number of animals there is significant acute tubular necrosis resulting in anuria or oliguria, widespread edema, persistent and worsening elevation in serum creatinine concentration, and abnormal fractional excretion of electrolytes. Tissue edema can develop quickly, particularly if high rates of sodium-rich fluids are used. It is recommended to err on the side of fluid restriction rather than fluid excess when managing foals at risk for complications from PAS.[97] See Chapter 17 for fluid therapy guidelines in neonatal foals. Nephrotoxic drugs such as gentamicin or amikacin should be avoided if possible, unless therapeutic drug monitoring is available.

The management of oliguria or anuria can be difficult. Strategies to promote diuresis include a constant rate infusion (CRI) of dopamine at a rate of 2 to 5 μg/kg/min or furosemide at a CRI (0.25 to 2.0 mg/kg/h) or frequent boluses (1 mg/kg). The two treatments can be used concurrently.[98] Use of mannitol remains controversial but can be considered if oliguria persists. Once urine flow is established, the use of diuretics and vasoactive drugs should be revised and serum electrolyte concentrations and blood pH monitored. Overuse of diuretics can promote excessive fluid and electrolyte losses.

The gastrointestinal tract is another common target for asphyxial injury. The clinical signs are often related to gastroparesis and intestinal ileus. These include colic, recurrent gastric reflux, abdominal distention due to accumulation of intestinal gas and fluid, intestinal impaction, and diarrhea. In severe cases there is marked edema of the bowel wall, epithelial necrosis, and hemorrhage into the lumen. Damage to mucosal integrity can lead to translocation of bacteria with generalized peritonitis and systemic sepsis. The syndrome of necrotizing enterocolitis (NEC) is a significant cause of morbidity and mortality in preterm human infants.[99] The disease involves intestinal coagulative necrosis, bacterial overgrowth, *Pneumatosis intestinalis*, and a marked inflammatory response. Although controversial, intestinal hypoxia or ischemia and infection with certain bacteria, such as *Clostridium perfringens*, may be important contributing factors.[99] A similar syndrome has been reported in foals associated with birth hypoxia and *Clostridium* species.[100,101]

The recognition that intestinal complications of asphyxia should promote preventative strategies, including avoidance of overfeeding, monitoring of gastric and intestinal volume and wall movement with ultrasound, monitoring for increases in abdominal circumference using a soft tape measure, and avoidance of antiacid medications. Decreased gastric acidity may be a partial explanation as to why preterm human infants are at heightened risk of NEC.[99] A small volume of milk is often fed to at-risk foals to promote intestinal health (so-called

VetBooks.ir

"trophic feeding"), but this falls short of what is required in terms of minimal caloric requirements.[102] Trophic feeding is often around 12 to 24 mL/kg/day in human neonates, with full enteral feeding described as 150 to 180 mL/kg/day.[103,104] Other strategies that have been used to reduce the risk of NEC in human preterm infants include recombinant erythropoietin (rEPO), probiotics, and lactoferrin[105]; none of these have been described in at-risk foals. Recombinant EPO was originally used to treat anemia of prematurity but also exerts a trophic effect on the intestine.[105] Calorie supplementation of foals with parenteral nutrition is strongly recommended, particularly when gastric reflux or hemorrhagic diarrhea is present and no enteral feeding can be used.

Foals that have experienced an episode of hypoxia or ischemia are at increased for secondary infection and should be on broad-spectrum antibiotics. The use of aminoglycosides should be reconsidered if therapeutic monitoring is not available due to likely altered renal function. Immunoglobulin prophylaxis is recommended when serum IgG concentration is less than 800 gm/dL (8 gm/L), although there are no data that document decreased infection or improved survival with plasma therapy in at-risk foals. Plasma does have benefits in addition to immunotherapy, including improvement of osmotic pressure and provision of coagulation factors and a buffer base.[97] Glucose homeostasis is commonly disturbed in postasphyxiated foals, and concentrations should be monitored frequently. Hypoglycemia is frequently noted at the time of admission, but hyperglycemia is also common in responsive to modest replacement therapy. In some foals glucose intolerance can be managed by insulin therapy (see Chapter 17).

Respiratory failure is uncommon in PAS foals, but periods of hypoxemia and/or hypercapnia are not uncommon. Intranasal delivery of humidified oxygen is often helpful in the early stages of treatment. Rates of 2 to 5 L/min are commonly used with the goal of raising the arterial oxygen concentration (PaO_2) above 80 mm Hg. This should be achieved along with maintenance of tissue perfusion, using judicious fluid therapy and vasopressive agents as needed. Hypercapnia should be treated only if there is a poorly compensated respiratory acidosis. This can be managed using positive pressure ventilation or respiratory stimulants, such as doxapram or caffeine.

The short-term prognosis for foals with PAS is dependent on several factors, including the degree and duration of oxygen deprivation, as well as the organ systems involved, and the preparedness and training of attending personnel. The prognosis for most foals is good to excellent with survival rates commonly reported around 75%.[106,107]

Colostrum management and assessment of FPT, 258, 259
Hematology and biochemistry values, 259, 260
Hypoglycemia, 259, 260

Neonatal Behavior

Most spontaneous births (≈80%) occur between 8 p.m. and 6 a.m., with a peak foaling time between 10 and 11 p.m.[1] A normal foal should have righting reflexes and sufficient muscle tone to be able to right itself to sternal recumbency within 2 to 3 minutes of birth. By 5 minutes the foal should be bright, alert, and responsive to visual, auditory, and tactile stimuli. Over the next 20 to 25 minutes the normal foal will be restless, alternating periods of sternal recumbency with lateral recumbency before beginning lurching attempts to stand. During this period the foal will often vocalize in response to maternal sounds or contact. Once standing, the initial posture is an unsteady basewide rocking stance, but this slowly improves such that by 60 minutes most foals should be standing securely without assistance. The mean time to stand in a recent study of Thoroughbred foals was 52 minutes (±30 minutes standard deviation).[1] Colts typically take slightly longer to stand than fillies. The suckle reflex is present within minutes of birth in most foals and should be present in all foals by 30 minutes. Once standing, the foal will seek the udder, a process that is initially very clumsy but improves once the foal has successfully sucked. There will be repeated nudges of the udder in order to facilitate milk letdown. The foal should be nursing from the mare by around 2 hours (mean reported times of 111 and 125 minutes; ranges 35 to 420 minutes and 30 to 600 minutes), and most have nursed twice by 2.5 hours of age.[1,2] Sucking periods vary in duration between 1 and 5 minutes and are interspersed with periods of sleep that last around 7 minutes. It is important to watch the foal during sucking to confirm appropriate teat contact and swallowing movements. A foal that spends long periods at the udder may do so because of inability to nurse from the mare or inadequate milk from the mare. The daily milk consumption of most newborn foals is estimated between 21% and 25% of their body weight.[3] This equates to around 12 to 12.5 L/day for a 50-kg foal. On the basis of the caloric density of milk, this reflects a daily intake of 120 to 150 kcal/kg body weight, half used for basal metabolism and thermoregulation and half for growth.

Sleep periods first occur between 90 minutes and 4 hours after birth and last for about 7 minutes.[4] The foal spends one-third of its time lying down during the first 2 months of life, compared with 5% to 10% for adults, most of which occurs overnight. Foals do not learn to follow their dams to the exclusion of any other moving object for the first 1 to 2 weeks of life. Foals identify their dams by sight and smell and during the first week of life spend 85% of the time within 1 m of the dam, 94% to 99% within 5 m, and only rarely more than 10 m away from the dam.[5] Loss of affinity for the mare in a foal that seems otherwise healthy may be an early sign of the neurologic form of hypoxic ischemic syndrome.

Recommendations to clients as to when veterinary intervention should be sought vary from practice to practice. The "1-2-3" rule states that foals should be standing unassisted by 1 hour, sucking from the mare by 2 hours, and the mare should have passed her fetal membranes by 3 hours. Clients may adopt a similar "2-4-6" rule to seek veterinary attendance, where intervention should be sought if the foal has not stood by 2 hours, not sucked by 4 hours, or the fetal membranes are still in place by 6 hours. These recommendations are only used as a rough guide and will obviously be influenced by peripartum conditions and client experience. A recent study from New Zealand reported that 95% of mares had passed the fetal membranes within 4 hours of parturition.[1]

TABLE 16.1

Apgar Score: Assessment of Neonatal Asphyxia

Parameter	0 Points	1 Point	2 Points
Appearance	Gray or blue mucous membranes	Pale pink mucous membranes	Pink mucous membranes
Pulse (beats per minute)	Absent	<60, irregular	>60, regular
Grimace			
Nasal stimulation	No response	Grimace	Strong grimace, sneeze
Ear tickle	No response	Head and neck motion	Ear tickle, head shake
Thoracolumbar stimulus	No response	Head and neck motion	Attempt to stand with head, neck, limb motion
Activity (muscle tone)	Limp, lateral recumbency	Semisternal, some limb flexion	Sternal
Respiration (breaths per minute)	Absent	<30, irregular	>30, regular, can whinny

A modified Apgar score (Table 16.1) has been used in foals to semiquantitate the severity of signs that occur in response to peripartum asphyxia.[6] The acronym used in equine practice differs from that used in human medicine and refers to appearance, pulse, grimace, activity, and respiration. Appearance refers to oral mucous membrane color; pulse uses 60 beats per minute (bpm) as a cutoff; grimace is assessed in response to stimulation of the nasal mucosa, inside of the pinnae, and over the thoracolumbar area adjacent to the spine; attitude reflects the degree of muscle tone; and respiration refers to ventilation rate and rhythm with 30 breaths/min as the cutoff. Each category is scored from 0 to 2 points with a score of 10 being optimal. A score of 0 to 3 indicates marked depression; 4 to 6, moderate depression; 7 to 8 reflects mild asphyxial injury; and normal foals have a score of 9 or 10. Ideally the modified Apgar calculation should be made within the first minute after birth, but certainly within 15 minutes of delivery. Repeating the score 4 minutes later is recommended. Foals with low scores typically require aggressive resuscitation, whereas mildly affected foals may respond to vigorous rubbing, stimulation of the nasal mucosa, and limb movement.

Maternal Behavior

The mare's behavior is critical and must be closely monitored. A good dam will pay close attention to its foal, avoiding stepping or lying on it, protecting it from real or perceived threats, and facilitating the nursing process. The mare and foal will be in close contact over the first few days of life, within 5 m of each other for more than 95% of the time. Signs of concern are mares that are ambivalent about the foal, avoid or fear their foal, do not allow the foal to nurse, demonstrate extreme protection ("foal proud"), or are outwardly aggressive toward the foal.[7,8] Some mare behavior may be viewed as aggressive but may actually be normal. This may occur in response to excessive bumping of the udder or overly enthusiastic sucking. It has been reported that maiden mares, older mares, mares with a history of rejecting foals, and Arabian mares of Egyptian lineage are at greatest risk of rejecting their foals.[9] The health of either the foal or mare can contribute to a failure to bond. For example, foals that are unable to stand or suck are less likely to form a normal bond, and mares with painful mammary glands or that are experiencing strong postpartum uterine contractions are less tolerant of foals trying to suck. The benzodiazepine drug alprazolam has been used to treat maternal aggression with apparent success.[10] A dose rate of 0.035 mg/kg, PO, q8-12h has been recommended. Some cautions are recognized, including slight mare sedation at q8h dosing; the likelihood that the drug is passed in milk (although no foal sedation has been observed); and there may be increased risk of congenital defects when used in the first trimester by pregnant women.[10]

Physical Assessment

Numerous factors influence a foal's body weight at birth, including breed, gender, gestational age, and intrauterine environment. Estimates of body weight for newborn Thoroughbred foals for the purpose of drug calculation range between 40 and 55 kg, although many healthy foals may well exceed this range. Birthweight of Thoroughbred foals was positively correlated with mare body condition score.[11] The average daily weight gain for healthy foals is breed dependent but is typically between 1.3 and 1.7 kg/day for Thoroughbred-type foals.[12] Daily weight gain in hospitalized foals is determined by disease, calorie intake, and a lack of exercise and is almost always less than that of healthy, active foals.

The degree of physical development should be considered in relation to the estimated gestational age. This assessment should be made in light of the variable gestational length in horses. Typically gestational length is calculated from the time of insemination through birth, a figure that overestimates the true gestational period by as much as 7 days. The mean gestational period in Thoroughbreds is around 340 to 342 days with 95% of mares foaling between 327 and 357 days.[13] A number of factors influence this period, including breed, gender, and time of year. Colts on average have a gestational length that is approximately 1.5 to 2.5 days longer than that of fillies; they are slightly heavier, slower to stand, and have a heavier placenta.[14] Mares that conceive early in the breeding season have pregnancies that may be up to 10 days longer than those that become pregnant late in the season.[13,15] The role of dam, sire, and the dam's sire in determining gestational period has been suggested in some but not all breeds.[16]

Physical characteristics of immaturity include low birth weight, small body size, short and shiny hair coat, doming of the head, periarticular laxity, and droopy ears. Foals with a shortened gestational period and signs of physical immaturity are termed *premature*, while foals that are physically immature in the face of an appropriate gestational length are termed *dysmature*. Foals born after 356 days should be regarded as post-term. This is distinguished from foals that are post-mature, a condition of increased morbidity as a consequence of failing placental function.[16] Post-mature foals tend to have a lean and lanky physical appearance.

Rectal Temperature

Rectal temperature in normal foals ranges between 99° F and 102° F (37.2° C and 38.9° C) during the first 4 days after birth.[2] The upper end of the normal range, which is around 1° F (0.6° C) above the upper end of the adult range, is strongly influenced by environment and exercise. Temperature can be variable in foals with systemic sepsis; in the early stages of sepsis the rectal temperature is commonly within the normal

range or mildly elevated. Foals in septic shock will usually have a low rectal temperature, and those with localized infection will often be afebrile.

Ears

The ears of a normal foal are typically erect at the time of birth. Drooping of the ear pinnae is most commonly associated with prematurity or dysmaturity and, as such, is often accompanied by other physical signs of immaturity, such as small body size, short silky hair coat, and a domed head. Examine inside the ear pinnae for evidence of dermal hemorrhages. These can be a manifestation of systemic sepsis (see Chapter 17) or thrombocytopenia caused by disseminated intravascular coagulation (DIC) or alloimmune thrombocytopenia.

Eyes

The neonatal foal may not be able to close its eyelids completely (lagophthalmos), has reduced production of tears, and lacks a menace response. The menace response is a learned one and is usually acquired in the first 14 days of life. The pupil is oval-shaped, and pupillary light reflexes are present from birth but are slower. Other normal ocular findings include persistence of the hyaline artery remnants, the blood supply to the developing lens, and a pale pink to red optic disc with smooth margins. Newborn foals also have very prominent lens "Y" sutures. Lens suture lines are apparent in most foals and can persist into adulthood. An ophthalmic survey of healthy Standardbred foals conducted within 48 hours of birth reported abnormalities in 36% of foals.[17] Most were acquired and included retinal and subconjunctival hemorrhages; these had resolved in all foals by 1 (retinal) and 2 weeks (subconjunctival) of age. All foals in that study had hyaloid system remnants of various degrees.[17] In an ophthalmic survey of older foals (mean age of 9.4 weeks), suture lines were observed in 95% of animals.[18] The anterior suture was predominately Y-shaped, but the authors reported that posterior sutures were more variable, from "Y-shaped to sawhorse, to stellate." Posterior lens sutures are reportedly more difficult to recognize in Thoroughbred foals. The suture patterns are not consistently symmetric between eyes. Prominent lens sutures can be confused with congenital cataracts. Congenital cataracts are amenable to surgery in the absence of uveal tract inflammation, a normal retina, and an appropriate demeanor. Other abnormalities that can occur include atresia of the nasolacrimal system, dermoids, retinal dysplasia, and optic nerve hypoplasia.

The neonatal foal may have significant corneal ulceration without tearing, blepharospasm, or photophobia due to reduced corneal sensitivity when compared with older foals and adult horses.[19] Consequently, special attention is required to monitor for ocular disease. It is recommended to fluorescein stain the cornea daily in sick recumbent neonatal foals. The combination of lagophthalmos, recumbency, and seizure predisposes foals with encephalopathy to a high incidence of corneal ulceration.

Entropion (inward rolling of the eyelid margin) is a common ocular problem of newborn foals. This usually occurs as a complication of dehydration and/or malnutrition and may lead to corneal abrasion and ulceration. Treatment is placement of vertical mattress sutures or staples to evert the offending lid while the primary condition is corrected. An alternative strategy is to inject procaine penicillin G subcutaneously into the lower lid to cause temporary eversion. It is extremely rare that surgery is required to correct entropion.

Examine the conjunctiva and sclera for signs of hemorrhage. This is commonly associated with birth trauma, and affected foals should be monitored closely for development of more classical postasphyxia complications. These hemorrhages resolve by week 2 of postnatal life.[17] Episcleral injection (engorgement and proliferation of scleral vessels) is a prominent feature of systemic sepsis. Iridocyclitis is usually associated with systemic sepsis and can include hyphema, hypopyon, and fibrin. These changes are not uncommon in foals with in utero–acquired infection and may be present at birth. Iridocyclitis is also seen in older foals with *Salmonella* or *Rhodococcus equi* infection.

Oral Cavity

Oral mucous membranes in healthy newborn foals should be pink and moist and have a capillary refill time (CRT) of 1 to 2 seconds. Bright pink to red mucous membranes, accompanied with injected scleral vessels and hyperemia of the coronary bands, are consistent with the early stages of sepsis. During this early hyperdynamic phase the CRT may be shorter than normal. Darkening of mucous membranes with a delay in the CRT may indicate sustained sepsis. In severe cases this is accompanied by petechial or ecchymotic hemorrhages.

Icteric mucous membranes are most commonly associated with systemic sepsis but are also a feature of neonatal isoerythrolysis, liver disease, internal hemorrhage, meconium retention, or infection with equine herpesvirus type 1. Pale membranes suggest anemia and can occur with external umbilical cord hemorrhage, internal hemorrhage from torn umbilical vessels, fractured ribs, or hemorrhage within gastrointestinal or urinary tracts. Pallor with icterus would normally indicate neonatal isoerythrolysis or internal hemorrhage. Petechial or ecchymotic mucosal hemorrhages suggest advanced sepsis when associated with darkened membranes and a prolonged capillary refill time, or alloimmune thrombocytopenia when the membranes are pink (Fig. 16.1). Blue to gray discoloration of the membranes is consistent with hypoxemic circulatory shock. Overt cyanosis is uncommon and should prompt close examination of the cardiovascular and respiratory systems.

In term foals the central incisors usually erupt during the first 5 to 7 days of postnatal life. The middle incisors rise between 4 and 6 weeks of age, but the corner incisors do not erupt until around 6 to 9 months. In miniature horses and ponies the eruption of the middle and corner incisors is delayed at 4 months and 12 to 18 months, respectively. The 12 temporary molars are present at birth or erupt within the first week of life. These teeth are replaced by permanent premolars at 2.5, 3, and 4 years of age. The three molar teeth do not erupt until 1, 2, and 3.5 years of age for molars 1, 2, and 3, respectively.

Dental problems are uncommon in foals with the exception of those associated with facial deformities such as maxillary prognathism, mandibular prognathism, and campylorrhinus. Maxillary prognathism (parrot mouth; bird face; overbite;

FIG. 16.1 Spontaneous mucosal hemorrhages and ulceration in a foal with alloimmune neonatal thrombocytopenia.

VetBooks.ir

brachygnathism; brachygnathia) describes the condition where the mandible is shorter than the maxilla, producing an overjet or overbite. The condition may affect the incisors, cheek teeth, or both, and is the most common congenital oral malformation of foals. The majority of foals with maxillary prognathism suffer little impact to their quality of life, and the defect simply represents a cosmetic problem. In moderate to severely affected foals the lack of incisor contact results in excessive growth of the lower teeth and secondary soft tissue trauma to the palate caudal to the upper incisors. The premaxilla and incisive bones tend to bend forward and downward as growth continues due to the lack of an opposing force, normally provided by the mandible. This can lead to difficulty in grazing. Mandibular prognathism (sow mouth; monkey mouth; brachygnathia superior; underbite) describes the condition where the maxilla is shorter than the mandible, producing an underbite. The condition occurs much less commonly than the maxillary equivalent and is most frequently seen in pony and small horse breeds. The defect in its most severe form can be associated with deformity of the nasal passages and nares, and there may be difficulty in breathing and an inspiratory stridor. Mandibular prognathism is commonly associated with congenital hypothyroidism.[20] Campylorrhinus lateralis (wry nose, wry face) describes the condition where the premaxilla and nasal septum are deviated laterally. It may occur singularly or in combination with other deformities, such as wry neck, cleft palate, and maxillary or mandibular prognathism. If the deviation is severe, the foal may have great difficulty in sucking from the mare. There may also be problems with breathing. In most foals the deviation is mild and represents a simple but obvious cosmetic defect. Close attention must be paid to dental wear as maxillomandibular malocclusion occurs commonly.

Cleft palate is an uncommon congenital defect of foals that results from incomplete fusion of the lip and/or secondary palate during the early gestational period. Previous reports estimate the incidence between 0.1% and 0.2% of all horse births.[21] Almost all clefts occur in the secondary palate, the horizontal partition dividing oral and nasal cavities. The secondary palate includes all of the soft palate and most of the hard palate, with the majority of defects restricted to the soft palate. The basis of this congenital defect is not known but could include a heritable component and/or exposure of the developing fetus to infection, toxins, or nutritional disturbances. The diagnosis is usually straightforward and centers on an appropriate history and signalment. Confirmation is through palpation using the third finger of an upturned hand or by direct inspection of the oral cavity. It is important that the hand is clean before direct palpation. Endoscopic examination of the nasal passages or through the oral cavity under anesthesia may be required to detect small defects. Oral palpation is recommended for all sick neonatal foals before commencing potentially costly treatment. A cleft in the secondary palate permits the oral contents to pass directly into the nasopharynx and nasal passages. Consequently, the most common complaint is nasal regurgitation of milk immediately after sucking. As the foal matures, feed particles will also appear at the nares. Foals with small palate defects may have intermittent milk drainage from the nostril and consequently escape diagnosis during the neonatal period. Rarely, cases are initially diagnosed in adult horses. Most will develop an aspiration pneumonia, which can be difficult to identify in its early stages due to immaturity of cough receptors. Surviving foals will typically be poorly grown and ill-thrifty. The presence of milk at the nares after feeding does not definitively indicate that a cleft is present and is more commonly associated with pharyngeal/laryngeal weakness or incoordination. The tongue should be examined for evidence of candidiasis, appearing from small white plaques up to a diffuse tan coloration of the tongue. The condition can be local or systemic and is common in debilitated foals and those that have been on chronic antibiotic therapy. In severe cases the condition will cause reduced nursing and salivation.

Thyroid Gland

Hypertrophy of the thyroid gland (goiter) can occur in response to deficient or excess dietary iodine. One of the more common reasons for thyroid gland enlargement in neonatal foals is excess iodine supplementation during pregnancy.[22] There are reports of neonatal goiter when seaweed was incorporated into the diet of broodmares or when pellets were fed to mares that had been formulated with excessive iodine.[23,24] Dysmature foals with thyroid hyperplasia and concurrent musculoskeletal problems have been identified in Western Canada and northwest United States.[25,26] The syndrome results in hypothyroidism and may be related to the feeding of diets that are high in nitrate or low in iodine to mares during pregnancy. Thyroid hormone is an important cofactor in maturation of the respiratory system, and hypothyroidism has been linked to respiratory failure in a newborn foal.[27] In older foals enlargement of the thyroid has been associated with dietary iodine deficiency and low circulating levels of T4.[22] Newborn foals have baseline T3 and T4 levels that are considerably greater than that of adult horses.[28,29] These levels decline over the first 12 days after birth.

Neck and Back

A number of congenital anomalies affect the alignment of the vertebral column. These include atlantoaxial malformations, scoliosis, kyphosis, lordosis, and combined anomalies, such as kyphoscoliosis. Atlantoaxial malformations may occur with or without cervical scoliosis or signs of spinal cord compression. Arabian foals are most commonly affected, and a familial predisposition has been suggested.[30] There may be palpable abnormalities of the atlas and axis and altered head carriage. The diagnosis is confirmed using radiography where a range of abnormalities is seen, including atlantooccipital fusion, hypoplasia of the dens, and axis malformation. Prognosis is poor as many have signs of ataxia and paresis involving all four limbs at birth. Some animals may have normal neurologic function. Foals with severe kyphosis or kyphoscoliosis often have underlying malformation of the thoracic vertebrae.[31]

Gastrointestinal System

Most foals display abdominal straining within a few hours of birth and pass most of the meconium within the first 1 to 4 hours after delivery, but passage may be delayed without concern for up to 12 hours. Differentiating straining to defecate from straining to pass urine can be difficult in some foals. Typically foals straining to pass feces will have an arched appearance to their hindquarters (Fig. 16.2). A change in the color and consistency of the feces from a dark brown to black pasty material to a lighter brown, less tenacious material indicates that the meconium has been passed. The routine administration of an enema is performed commonly in healthy newborn foals in an attempt to reduce the straining associated with passage of meconium. A variety of methods are used, with commercial glycerine phosphate–based products the most common. These are relatively easy to administer, although care should be taken to avoid direct trauma to the rectal mucosa with the applicator tip. Many veterinary practices probably use gravity enemas using 400 to 800 mL of warm soapy water delivered through a soft tube, such as a canine stomach tube or male urinary catheter. Acetylcysteine retention enemas are not administered routinely, but rather in foals with resistant meconium impactions.

Auscultation of the abdomen can provide an indirect assessment of intestinal contractility. The technique should be interpreted with caution as the presence of borborygmi does not equate to propulsive motility or ingesta transit. The changes

FIG. 16.2 A foal demonstrating a classical hunched appearance while straining to pass feces.

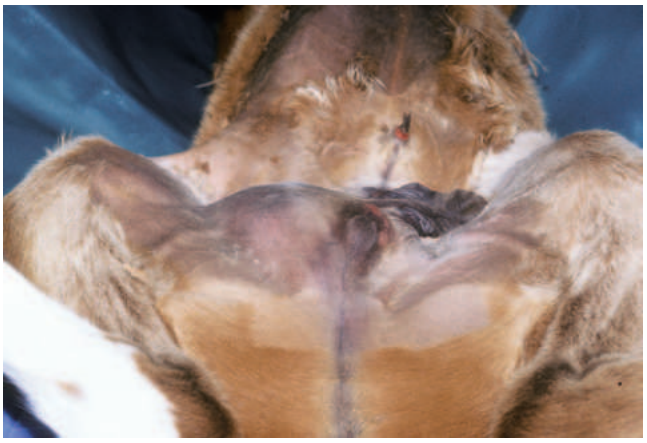

FIG. 16.3 A dissecting scrotal hernia before surgical repair.

FIG. 16.4 Coprophagy is an important behavior in establishing hindgut flora.

in gastrointestinal sounds over time may be more useful in determining a diagnosis. For example, a silent abdomen that progresses to a hyperactive one could be indicative of inflammatory intestinal disease, whereas an abdomen with normal sounds that changes to silent could be consistent with a surgical lesion. Percussion and ballottement are used to differentiate abdominal distention caused by gas or fluid accumulation. A tympanic sound on percussion is consistent with intraluminal or free peritoneal gas, and ballottement can detect waves of free abdominal fluid. Progressive abdominal distention, irrespective of the underlying cause, can be monitored using a soft measuring tape repeatedly positioned over small clipper marks. Gastric distention can cause a "sprung rib," a swelling that projects beyond the 18th rib.

Firm structures can be detected using transcutaneous abdominal palpation, assuming the foal is suitably relaxed. It is possible to palpate bowel impacted with meconium, fecoliths, intussusceptions, the urinary bladder, or enlargement of the internal umbilical remnants caused by infection or hemorrhage. The external umbilicus should also be palpated for enlargement or herniation, and, in colts, the inguinal rings and scrotum should be assessed for bowel herniation. These are typically soft and fluctuant swellings that are easily reduced when the foal is placed on its back and are managed by manual reduction and strapping. Incarceration is rare, but bowel integrity can be assessed using ultrasound; devitalized bowel lacks motility and has thickened and edematous wall. In some colts the intestine can protrude through a rent in the parietal vaginal tunic and migrate subcutaneously in what is described as a direct inguinal hernia[32] (Fig. 16.3). This is often associated with preputial swelling and requires surgical intervention.

Digital rectal examination is indicated in a colicky foal or in any foal where meconium passage has not been observed. Distal meconium impaction is typically apparent on rectal examination, but high impactions are not. Intestinal atresia should be suspected if there is no history of fecal passage and there is clear or white mucous on the glove.

Passage of a nasogastric tube is an often-overlooked diagnostic procedure in colicky neonatal foals. Removal of gastric fluid can reduce or eliminate colic signs, as well aid in the localization of disease. Gastric distention may also be present in sick neonates showing no signs of colic. The condition occurs with primary gastric outflow problems or mechanical or functional small intestinal obstruction. Functional obstruction caused by small intestinal ileus occurs more commonly in neonates secondary to a range of diseases including hypoxic ischemic syndrome, sepsis, prematurity, enteritis, electrolyte derangements, and overfeeding.

Coprophagy is observed in normal foals from birth through 5 to 6 months of age.[33–35] Most foals demonstrate coprophagy by 7 days of age (Fig. 16.4). The consumption of feces is not driven by hunger, and foals have a selective preference to consume feces of their dams. The most likely basis for coprophagy is as a mechanism to populate the intestinal tract with bacteria, fungi, and protozoa essential for digestion of a herbivorous diet. Coprophagy precedes the passage of protozoa in foal feces and the development of the syndrome known as "foal heat diarrhea." This is a benign diarrheal disease of newborn foals and should not require treatment.

Abdominal Ultrasound

Ultrasound is a key component in the examination of a foal abdomen. Numerous conditions are recognized on ultrasound, including uroperitoneum, bacterial peritonitis, hemoperitoneum, strangulating intestinal obstructions, meconium impaction, gastric enlargement, enteritis, necrotizing enterocolitis, and hernias. The foal can be scanned in lateral recumbency or standing; the latter is preferred as thickened or heavy structures will move to the dependent region of the abdomen, gas-filled structures will migrate dorsally, and visualization of peritoneal fluid is improved. Clipping is not essential if the hair is dampened with alcohol. The stomach is identified in the mid to ventral abdomen on the left side between the 6th and 12th

VetBooks.ir

intercostal spaces and lies medial to the spleen. In contrast to adults, the stomach is commonly in contact with the ventral body wall during the first week of life and the contents are readily imaged.[36] Gastric wall thickness is typically around 2.0 mm during the first week of life. The duodenum is readily located in normal foals on the right side of the abdomen between the ventral and caudal aspect of the liver and the dorsal margin of the right dorsal colon, as well as ventral to the caudal pole of the right kidney. The remainder of the small intestine is also easily identified throughout the abdomen and should have a wall thickness less than 2.5 mm. The large intestine is differentiated from the small intestine by increased luminal diameter, bowel sacculations, and greater likelihood of gas. The colon wall should be less than 2.8 mm during the first week of life. The neonate with acute colic should be assessed with ultrasound for small intestinal intussusception. These are readily identified, are typically jejunojejunal, and are often located in the ventral abdomen when the foal is standing. They have a characteristic appearance with the intussusceptum surrounded by fluid and the intussuscipiens creating a "target" sign. Some will resolve spontaneously, but most require surgical reduction. Meconium impactions have an echogenic ball or log appearance when in the small colon or a more varied appearance when present in the large colon, a hypoechoic to hyperechoic mass that may be surrounded by fluid.[37] Thickening of the wall with intramural gas echoes is consistent with a strangulated obstruction or necrotizing enterocolitis. Abdominal hemorrhage results in a classical "smoke swirl" appearance to the peritoneal fluid.

Abdominal Radiography

Radiography has been displaced as the principle imaging modality of the foal abdomen but still can provide essential information.[38] Contrast radiography remains an important technique to assess gastric outflow problems, intestinal transit, intestinal atresia, and high meconium impaction. The abdomen of most neonatal foals can be captured on a 35 cm × 43 cm cassette. A grid should be used to minimize film fogging. For a standing foal weighing around 50 kg, using a 400-speed film-screen system, a grid with a 10:1 grid ratio, and a focal spot-film distance of 100 cm, the appropriate technique should be in the range of 80 to 90 kV (peak) and 15 to 20 mA. This technique can be reduced slightly lateral projections in the recumbent foal. The beam should be centered on the last rib. For upper gastrointestinal contrast studies, 5 mL/kg of 30% wt/vol barium suspension is administered through a nasogastric tube; ideally foals are fasted for 4 hours before the procedure and should not be sedated. Barium typically empties rapidly from the stomach, allowing examination of the stomach and duodenum on initial films. The contrast should clear the small intestine by 3 hours and be completely cleared by 36 hours. The cecum should be visible by 1 to 2 hours post administration. A barium enema can be used to evaluate the lower intestinal tract, specifically intraluminal obstruction and atresia. Sedation can be used as the procedure is not defining a dynamic problem. A 30-French Foley catheter with a 30-cm^3 balloon is inserted 6 to 10 cm into the rectum, the cuff is inflated, and 300 to 500 mL of 30% wt/vol barium sulfate suspension are infused. Volumes up to 20 mL/kg have been described; colonic or rectal rupture is a rare but fatal complication of the procedure. Computed tomography (CT) is an underused tool in the assessment of the foal abdomen, with most applications involving examination of limbs, head, or neck.[39]

Abdominocentesis

Peritoneal fluid can also be evaluated by abdominocentesis. The technique has a greater complication rate in neonates, and ultrasound should be used to identify pockets of fluid for sampling. Most complications arise due to a combination of hypodermic needles, a moving patient, and a relatively thin bowel wall. If no fluid is identified, then the procedure should not be performed. For small volumes it is recommended to use a blunt, small bovine teat cannula; for larger volumes a hypodermic needle can be used. Peritoneal fluid nucleated cell counts are lower in foals than in adult horses.[40] Nucleated cell counts above 1.5×10^9/L may be considered abnormal in foals up to 4 months of age,[41] although another study suggested a value of 3.0×10^9/L as a cutoff for foals younger than 75 days of age.[42] Cytologic evaluation is similar to adults with a predominance of large mononuclear cells (macrophages and mesothelial cells) with smaller numbers of lymphocytes and neutrophils. The relative percentage of neutrophils (15%) may be less than that seen in normal adult peritoneal fluid. The protein concentration of foal peritoneal fluid is similar to that of adults, below 20 gm/L, and therefore values above this are considered abnormal. An increased total nucleated cell count, increase in the percentage of neutrophils with cell degeneration, and intracellular and extracellular bacteria would be expected in foals with septic peritonitis. This would be accompanied by a low pH (<7.2), increased lactate concentration, and a discrepancy between serum and peritoneal glucose concentrations (>2.7 mmol/L).[40]

Cardiovascular System

Physical assessment of the cardiovascular system includes examination of visible mucous membranes, palpation of peripheral arterial pulses, assessment of extremities for warmth, detection of limb or ventral edema, and cardiac auscultation. The heart rate in newborn foals in the minutes after birth is influenced by vagal tone and varies between 36 and 80 bpm. As the foal becomes active and struggles to stand, the heart rate will increase to 120 to 150 bpm before stabilizing in a range of 80 to 100 bpm over the first week of life.[43] Tachycardia is an important mechanism in neonates to improve cardiac output and blood pressure, and it is expected during periods of asphyxia and in response to hypovolemia, sepsis, anemia, or hypoxemia. A sustained increase in heart rate may also accompany pain or stress or reflect a primary cardiac problem. Bradycardia can be due to hypothermia, electrolyte abnormalities, or hypoglycemia.

Cardiac arrhythmias are rarely recognized but occur in most foals during the immediate postpartum period with supraventricular premature contractions and sinus arrhythmia predominating.[44,45] Other arrhythmias include supraventricular (atrial) tachycardia, atrial fibrillation, second-degree atrioventricular block, ventricular premature contractions, ventricular tachycardia, and idioventricular rhythm. These rhythm disturbances typically only last for 5 minutes and in most foals have disappeared by 15 minutes of age. Rarely they may persist up to 2 hours of age. The more severe arrhythmias are associated with a lower arterial oxygen concentration, suggesting a role for hypoxemia in the pathophysiology of these events. Arrhythmias that persist beyond this timeframe should be investigated by electrocardiogram. Causes include electrolyte abnormalities, persistent hypoxemia, and sepsis. Foals with sustained and rapid ventricular tachycardia need treatment with intravenous quinidine, gluconate, lignocaine, or propranolol.[46]

Cardiac murmurs are expected in the early neonatal period. A patent ductus arteriosus (DA) can result in a continuous machinery murmur with a point of maximal intensity high over the left heart base in the third intercostal space.[46,47] These are typically audible up until 3 to 4 days of age.[48] As the DA begins to close, the systolic component of the murmur often remains audible. Low-intensity, left-sided systolic murmurs are commonly heard through the first months of postnatal life. Some may be associated with flow across the foramen ovale, but most are likely due to turbulence in the great vessels created during left ventricular ejection.[46] Others have suggested

VetBooks.ir

that flow through the DA may persist for weeks to months.[49] Loud murmurs that persist beyond 7 days of age or any murmur that is accompanied by signs of cardiac disease, such as poor growth, cyanosis, lethargy, or exercise intolerance, should be referred for echocardiography. Auscultation of both sides of the thorax is important as right-sided cardiac murmurs are a feature of several congenital cardiac anomalies. Occasionally serious cardiac defects may not be associated with audible murmurs. Although most congenital cardiac diseases are detected in foals or young horses, some defects do not become apparent until the horse is required to perform or may occur simply as incidental findings in older horses.

Distal extremities should be free of edema and warm to the touch. Limb edema can occur for several reasons, but most commonly secondary to asphyxia or in response to inappropriate fluid therapy in oliguric or anuric foals. Limbs that are cool or cold are poorly perfused and will typically have weak arterial pulses. However, the relationship between peripheral pulse pressure and hypotension is not consistent; hypotension is not always associated with weak pulses and, conversely, weak pulses do not always indicate hypotension.[50] Arterial thrombosis should be suspected if a single limb is cold, although an aortic thrombosis could result in decreased perfusion to both hind limbs.[51] Pulse quality can be assessed in the distal limbs using the great or dorsal metatarsal arteries on the lateral aspect of the hind cannon bone. In the forelimbs the brachial artery can be palpated at the level of the medial collateral ligament of the elbow joint. Several methods are available to assess arterial blood pressure. Direct blood pressure monitoring is ideal because it is accurate and continuous, but it is invasive and difficult to maintain and can be complicated by vessel thrombosis or sepsis. More commonly, blood pressure is monitored indirectly using oscillometry or Doppler-based devices over the coccygeal, brachial, or great metatarsal arteries. An infant-sized inflatable cuff (bladder 52 mm) placed snuggly around the base of the tail yields data that are comparable to mean arterial measurements taken directly from a catheterized great metatarsal artery in a day-old foal weighing between 44 and 69 kg.[52] The technique tended to underestimate systolic and overestimate diastolic values, although the differences were not large. The mean arterial pressure of a healthy Thoroughbred foal using an oscillometric device was reported to be 95, 100, and 101 mm Hg at days 1, 2, and 3, respectively.[53] Other noninvasive methods to measure cardiac output, such as volumetric echocardiography, have shown good correlation with more robust but invasive techniques in anesthetized foals. The question remains if this correlation will be sustained in critically ill foals.

Respiratory Tract

In newborn foals the nasal passages are examined for meconium staining and, if present, the passages should be suctioned using a dose syringe and soft catheter or other portable or fixed suction device. The early stages of pulmonary disease are difficult to recognize, as cough and nasal discharge are typically absent. Immature cough receptors also contribute to a lack of awareness of ongoing milk aspiration into the major airways. Auscultation of the lung fields can also be misleading in young foals. Fluid sounds are normally present immediately after birth, as are end-inspiratory crackles due to simple atelectasis of the dependent lung during or after lateral recumbency. These crackles should resolve when the foal has been standing for several minutes. Conversely, foals with bronchopneumonia may have minimal abnormal lung sounds until the pathology becomes severe. In the absence of advanced diagnostics the clinician must rely on clinical signs, such as restlessness and agitation, increased respiratory rate and depth, or respiratory distress, to diagnose lower airway disease.

The normal response after delivery is an increase in minute ventilation, with elevations in both rate and tidal volume. The respiratory rate is usually rapid for the first hour of life, around 60 to 80 breaths/min, but should decline to a steady rate of 30 breaths/min thereafter in normal foals. Persistent elevations in the respiratory rate can be caused by a range of pulmonary and extrapulmonary causes. Pulmonary causes include meconium aspiration, bacterial or viral pneumonia, atelectasis due to recumbency, congenital pulmonary disease, rib fracture or dislocation, or pleural effusion. Nonpulmonary causes include fever, pain, excitement, exercise, brain disease, a compensatory response to metabolic acidosis, or idiopathic or transient tachypnea syndrome. An increase in the effort of breathing may be the first sign of respiratory disease. As the disease progresses, the foal can develop paradoxical thoracic wall motion due to muscular fatigue where the thoracic wall paradoxically moves inwards during inspiration and outwards during expiration. This is more commonly seen in premature foals with lung disease and is a sign of impending respiratory failure. Another sign of failure is an expiratory "grunt"; foals will keep their glottis closed until the end of the breathing cycle in order to maintain sufficient pressure in the respiratory tract to prevent airway collapse.

Respiratory rhythm should be regular in awake foals but may be irregular in normal foals during rapid eye movement (REM) sleep. This can also include body and limb movements and vocalization. Irregular or erratic breathing patterns in conscious foals, or in foals that are in coma or semicoma, are consistent with central nervous system disease or, less commonly, metabolic or electrolyte disorders, hypothermia, or prematurity or dysmaturity. Patterns include periodic breathing, ataxic breathing, tachypnea, hypopnea or intermittent apnea, and apneustic breathing. Hypopnea or apnea in foals with central nervous system disease may result in severe respiratory acidosis, prompting the use of respiratory stimulants or mechanical ventilation. Doxapram administered as a constant rate infusion was more effective than oral caffeine at reducing the arterial carbon dioxide concentration ($PaCO_2$) in affected foals.[54]

Respiratory distress or stertorous breathing can be caused by several uncommon conditions in the newborn foal. A range of congenital cardiac or respiratory tract malformations should be considered if abnormalities are present at or shortly after birth. Those involving the respiratory system include stenotic nares, choanal atresia, subepiglottic cysts, collapsing trachea, and lung lobe agenesis. Tearing of the diaphragm during birth with herniation of abdominal contents can also result in immediate respiratory distress. Similar distress can be seen with a dorsally displaced soft palate caused by neurologic or anatomic dysfunction. Soft fluctuant swelling in the parotid region could be consistent with guttural pouch tympany. The condition is more commonly seen in older foals but has been reported in the early neonatal period, often associated with pharyngeal/laryngeal weakness and altered ostia function. This may also result in milk entering the pouch. There is a reported predisposition in fillies and certain breeds, including Arabians and Paints.[55]

Localized or widespread crepitus of the subcutaneous tissues could be consistent with air leakage from respiratory tissues, most commonly from ruptured pulmonary bullae.[56] The thoracic wall should be palpated for evidence of rib shaft fractures or costochondral dislocation. Thoracic trauma and rib fracture occur most commonly as a complication of the birthing process. They are identified by observation of thoracic wall symmetry and synchrony, palpable crepitus, and localized edema. In addition, there may be an audible "click" on auscultation of the thorax. Affected foals may grunt on expiration and prefer to lie on the unaffected side. Diagnosis is confirmed by ultrasound or radiographic examination. On ultrasound examination there is disruption of the cortical surface and associated soft tissue edema. Management includes recognition and treatment of potential complications and avoidance of further

thoracic trauma. Potential clinical complications of rib fracture include hemothorax, lung laceration and pneumothorax, and pericardial/myocardial puncture.

Arterial Blood Gas Collection and Analysis

Due to the limitations of physical examination in accurately assessing the respiratory system, arterial blood gas (ABG) analysis is commonly performed at referral practices during the initial assessment. It is a sensitive indicator of respiratory function.[57] The sample is usually collected from the dorsal metatarsal artery. Alternative sites include the brachial artery, located at the level of the medial collateral ligament of the elbow joint, or the carotid artery, but hematoma formation is a common sequel to aspiration from this site. The sample will remain useful for up to 90 minutes in a capped plastic syringe at room temperature. Contamination of the sample with room air will artificially increase the arterial oxygen concentration (PaO_2) and decrease the $PaCO_2$. Interpretation of blood gas values of venous blood can be deceptive and should be restricted to evaluation of metabolic conditions and not pulmonary gas exchange.

Normal ABG values for neonates of different postnatal and gestational ages are presented in Table 16.2. Interpretation of the ABG sample involves consideration of the amount of struggling and position of the foal during sample collection. Foals that require considerable restraint to obtain a sample probably do not require sampling. Lateral recumbency can reduce the PaO_2 by as much as 30 mm Hg. Supplemental oxygen affects ABG values; a flow rate of 10 L per minute (lpm) delivered by nasal insufflation increased the PaO_2 from 84 ± 6 mm Hg to 298 ± 69 mm Hg in healthy, full-term newborn foals.[58] This flow rate approximates to a fraction of inspired oxygen (FiO_2) of 1.0.[59] If the respiratory rate is rapid and the depth shallow, supplemental oxygen will be diluted by room air because of the large quantity of room air entering the upper respiratory tract, and the concentration of alveolar oxygen will be less than expected. A general guide for supplemental oxygen use is to set an initial flow rate of 5 lpm. Oxygen should be humidified if delivered at high flow rates or for long periods of time.

Hypoxemia (PaO_2 < 70 mm Hg) can occur with hypoventilation, ventilation/perfusion mismatching, or right-to-left shunting of blood.[57] The two most common respiratory-derived derangements are hypoxemia with normocapnia or hypocapnia and hypoxemia with hypercapnia. Treatment of the former involves supplemental oxygen. The latter is usually indicative of severe respiratory disease but could reflect primary hypoventilation, as may occur in cases of botulism. Acute hypercapnia is associated with a more substantial drop in blood pH and may lead to circulatory collapse and coma, particularly if accompanied by hypoxemia. Chronic exposure to elevated CO_2 permits adaptation and subtle clinical effects. The change in pH is less dramatic because of enhanced bicarbonate reabsorption in the proximal tubules of the kidney, a process that begins within 6 to 12 hours and is maximal by 4 days. Hypercapnia can be exacerbated by fever or the administration of carbohydrates or bicarbonate. The latter is often clinically relevant and highlights the danger of giving large amounts of sodium bicarbonate to foals with pulmonary disease, potentially taking a primary metabolic acidosis and creating a more severe respiratory or mixed acidosis. Hypercapnia is also an expected response to metabolic alkalosis.[60]

Airway sampling either by transtracheal aspiration (TTA) or bronchoalveolar lavage is rarely performed in sick neonates, as the added stress of the procedures on an already compromised neonate can have fatal consequences. The TTA procedure is more likely to cause additional complications in foals with high ventilation rates, including pneumomediastinum and subcutaneous emphysema.

Pulmonary Imaging

Radiography can provide additional information that can assist in establishing a diagnosis, assessing the type and distribution of disease, and monitoring the response to treatment.[38] Radiographs are particularly useful in the diagnosis of rib shaft fractures, pneumothorax, pleural effusion, and diaphragmatic hernia. Radiographic changes associated with pulmonary disease tend to lag behind clinical changes, and it is difficult to differentiate atelectasis from pneumonia. Infiltrate tends to settle or move ventrally as the foal becomes ambulatory. Unfortunately, capturing diagnostic thoracic images in the field is difficult because of the amperage of portable machines and the limitation in plate size. The relatively low amperage results in long exposure times, which in a poorly compliant patient with high respiratory rate leads to motion artifact and a false interpretation of disease. Images tend to be limited to standing or recumbent lateral projections as positioning for ventrodorsal views can further compromise the cardiopulmonary system. Pleural and parenchymal diseases have a similar ultrasonographic appearance in newborn foals to that seen in adults. Anechoic pleural fluid

TABLE 16.2

Normal Blood Gas Values for Foals[a]

	Arterial					Venous			
Age Group	O_2 (mm Hg)	CO_2 (mm Hg)	pH	Base Excess	HC^-_3 (mEq/L)	O_2 (mm Hg)	CO_2 (mm Hg)	pH	HC^-_3 (mEq/L)

can be seen with some infectious processes, in foals with uroperitoneum, or with some congenital anomalies. Echogenic or cellular fluid is seen with other infectious processes, and in hemothorax cases there will be characteristic "smoke whirls" present.

Urogenital System

As the foal begins to move after birth, it causes stretch and breakage of the umbilical cord, typically around 3 cm beneath the abdomen. This can also occur when the mare rises after foaling.[61] Early separation of the cord has no detrimental effect, provided the cord is severed by stretch rather than sharp dissection. The volume of placental blood available for transfer to the foal under normal circumstances is relatively small, typically well below 200 mL.[62] Greater volumes may be lost if the cord is cut, preventing contraction of vascular smooth muscle. Hemorrhage should therefore be controlled with a commercial clamp or umbilical tape. Prolonged attachment of the cord is unlikely to be a significant problem, although blood flow between the placental membranes and the foal is partly gravity dependent, such that blood could flow preferentially from foal to membranes if the foal is above the level of the placenta. Manual breakage of the umbilical cord is recommended if it remains attached for more than 8 minutes. The preferred method for manual cord breakage is to grasp the placental side of the cord while holding the foal side of the cord with your other hand to prevent excessive traction on the abdominal wall. Gently twist and pull from the placental side such that the breakage will occur at the natural site of detachment. Intraabdominal umbilical arteries may continue to pulse for several days after delivery; this may result in a palpable pulse in the umbilical stump, but it is not associated with blood flow.[62] The umbilical stump should be treated once or twice daily until it becomes dried and sealed. A 0.5% chlorhexidine solution is preferred; however, it may cause delayed drying of the stump. Iodine solutions can also be used, but the concentration should be limited to 2% to prevent tissue necrosis.

Urine is one of the most important indicators of health in foals. As a consequence of a milk diet, normal neonatal foals produce a large volume of urine relative to their body weight, estimated at 148 mL/kg/day, or 7.4 L for a 50-kg foal. This value is approximately 5-fold to 10-fold greater than that of a healthy adult horse on a per-kg body weight basis.[63] The first passage of urine after birth occurs around 12 hours of age in normal foals, with colts passing urine earlier than fillies. The first urination in normal foals is concentrated with a specific gravity greater than 1.030, which will gradually decrease with subsequent urinations. The urine will become light in color and be very low in specific gravity, typically 1.001 to 1.008. Any foal observed to pass thick, concentrated urine should be assessed closely. Disruption to the urinary tract occurs relatively commonly and can be difficult to diagnose early in the clinical course. Rupture of the urinary bladder during delivery occurs more commonly in colts than fillies, although postpartum disruption to the tract in sick or hospitalized foals has no gender bias.[64,65] Signs often include prolonged straining, passage of small volumes of urine, progressive abdominal distention, lethargy, and weakness. Patency of the urachus is a common complication in sick newborn foals. Surgery is rarely required as most will close spontaneously by 2 weeks of age. Techniques to hasten closure generally involve chemical cautery, such as application of silver nitrate around the external opening. However, some believe that the resultant inflammation could predispose to infection or damage to internal structures and therefore limit their therapy to local disinfectants and systemic antibiotic therapy. Surgery would generally be recommended if the urachal leakage continued beyond 3 weeks of age.

In male foals the inguinal and scrotal region should be palpated for swelling and testicular descent. Inguinal and scrotal hernias occur relatively commonly but rarely result in clinical signs. Preputial edema may be present. Most congenital hernias are indirect, unilateral, and easily reducible and spontaneously resolve by 3 to 4 months of age. Positioning the foal on its back facilitates manual reduction. A figure-8 support wrap can assist in keeping the hernia reduced. Surgical correction is recommended if spontaneous resolution is delayed, if the hernia increases in size, or if signs of colic develop. Certain breeds appear to be at increased risk for herniation, including Tennessee Walking Horses and Standardbreds. A rent in the parietal vaginal tunic can lead to subcutaneous dissection of intestinal loops; this requires surgical reduction, herniorrhaphy, and unilateral castration.[66] Although extremely uncommon in foals, signs of colic can occur if herniated loops of intestine strangulate.

At the time of birth most testes lie within the inguinal canal. The extraabdominal gubernaculum, which can be easily mistaken for a testicle, typically limits movement into the scrotum. Monorchidism has been reported in foals, and affected colts are usually mistaken as cryptorchids.[67] Congenital abnormalities of the penis are rare. Failure to drop the penis during urination can occur as a consequence to preputial edema, a common complication in colts that are straining to defecate or urinate. The free part of the penis is normally fused to the internal lamina of the prepuce for up to 1 month of age. This can make exteriorization of the penis difficult. "Kinking" of the penis has been described, resulting in stranguria or pollakiuria.[68] Correction was achieved through manual straightening of the penis.

Umbilical Hernias

Umbilical hernias occur commonly in foals. The condition is generally considered to be a congenital defect with a likely hereditary basis, although umbilical infection may be an important postnatal predisposing factor. In a study of Dutch Warmblood foals, 19 of 44 had a palpable abdominal wall defect between 2 and 6 cm at the time of birth.[69] In all but one of these foals the defect had closed by 4 days of age; however, 28% of the foals developed a defect between 5 and 8 weeks of age. These were considered to be true umbilical hernias in that a hernial sac with contents was palpable in addition to the abdominal wall defect. The group included both foals with or without a palpable abnormality at birth. In a study of hospitalized foals it was concluded that the defect was more likely to occur in fillies than males and that the condition was more common in Thoroughbreds than Standardbreds.[70] Most clinicians recommend delay in treatment, as some defects will close spontaneously. Several techniques have been described for repair and vary from external clamps to surgical herniorrhaphy. Rarely, complications associated with umbilical hernias or their repair occur. These include colic, enterocutaneous fistulae, umbilical abscessation, and intestinal incarceration.[71]

Ultrasound Examination of Umbilical and Related Structures

The examination can be performed with the foal either standing or in lateral recumbency using a mid- to high-frequency linear transducer. The preferred probe is a high-frequency (10 to 14 MHz) linear transducer, although diagnostic scans can be performed with a 5- to 7.5-MHz linear rectal probe. Dorsal recumbency affords the best access, but care should be taken as this positioning has an adverse effect on ventilation. Clipping is helpful but not necessary, and most examinations are adequately performed using alcohol with or without coupling gel. Images are obtained in the transverse (short-axis) plane with the probe orientated perpendicular to the vertebral column and in a long-axis (sagittal) plane with the probe parallel to

the spine. The external umbilical stump can be assessed for size and echodensity; there are no published normal dimensions for size of the stump (Fig. 16.5). The umbilical vein runs cranially from the umbilical stump to the liver. It is located 1 to 2 cm deep to the skin and is a thin-walled ovoid structure that is 5 to 10 mm in maximal diameter (Fig. 16.6).[72] The paired umbilical arteries originate from the internal iliac arteries and run adjacent to the urinary bladder and urachus before emerging at the umbilical stump. The arteries atrophy postpartum and become the round ligaments of the bladder. They appear as thick-walled hyperechoic structures, which should measure less than 13 mm in diameter (Fig. 16.7).[72] Asymmetry in size is common, and there may be an echogenic core if filled with clot (Fig. 16.8). Pulsation may also be noted in very young foals. The urachus connects the apex of the bladder to the umbilical stump. It can be difficult to image unless it is fluid filled, as would occur during patency. At the level of the bladder apex the combined diameter of the urachus and arteries in transverse view should be less than 25 mm. The bladder wall should be examined for defects because a full appearance to the bladder does not preclude a leak (Fig. 16.9).

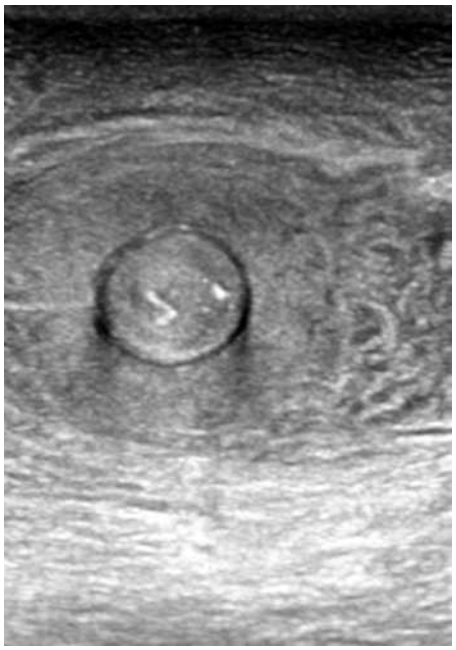

FIG. 16.5 An ultrasound image of an enlarged umbilical stump external to the body wall. The entire stump was 34 × 43 mm. Note the central core surrounded by thickened tissue.

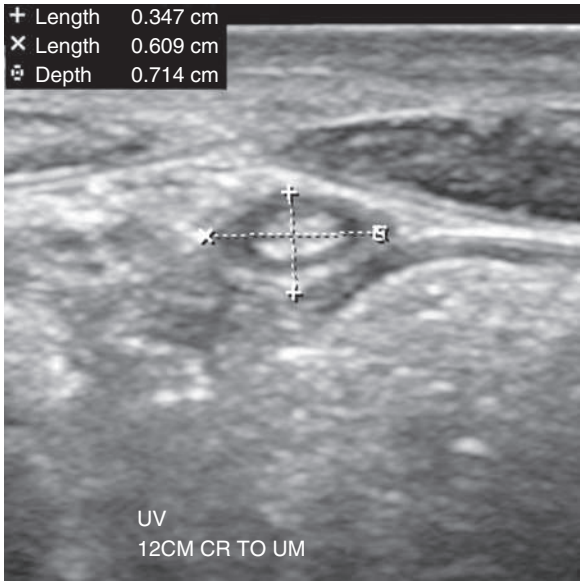

FIG. 16.6 A normal umbilical vein imaged transversely 12 cm cranial to the umbilicus.

Neurologic System

Differentiation of primary neurologic disease from systemic illness can be difficult as many critically ill foals are somnolent, recumbent, and unable to suck. Neurologic examination of the neonatal foal has several features that are unique to animals of that age.[73] While a domed skull could be consistent with hydrocephalus, it is also a physical feature of immaturity. Furthermore, hydrocephalus and other congenital brain abnormalities may occur with a normal skull shape and size.

FIG. 16.7 A transverse image taken 2 cm caudal to the umbilicus showing the normal paired umbilical arteries and the apex of the bladder. The arteries measured 4.2 and 4.7 mm in diameter.

FIG. 16.8 A transverse image demonstrating asymmetry in size and echodensity between the two umbilical arteries. Both were considered normal, and the combined measurement was within normal limits.

VetBooks.ir

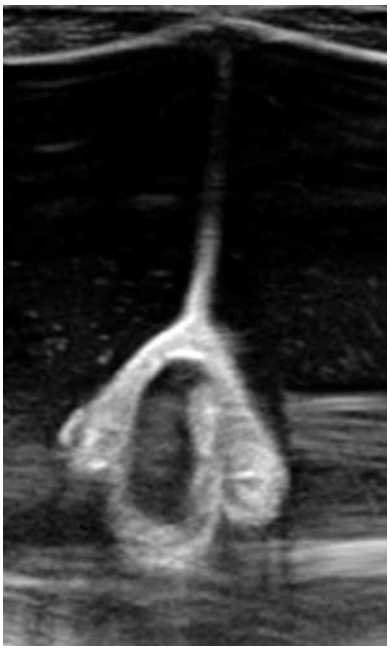

FIG. 16.9 A collapsed bladder attached to the body wall with a large-volume effusion consistent with uroperitoneum. The arteries give the collapsed bladder a classical shape.

FIG. 16.10 Collection of cerebrospinal fluid at the atlanto-occipital site using a hypodermic needle.

Examination of the head should be done with the foal standing or in sternal recumbency. The eyes have a normal slight ventromedial rotation in young foals. As described earlier, pupillary light responses are present but sluggish and the menace response is typically absent in the first week of life, although the foal should withdraw its head in response to a threatening gesture. Further assessment of vision can be through observations of behavior and navigation through obstacles.

The ability to suck and swallow milk should be evaluated. The suckle reflex should be evaluated using a clean and preferably gloved finger. Dysphagia can be recognized by nasal regurgitation of milk or milk coming out of the mouth. Although a cleft in the palate should be an important rule-out, it occurs less commonly than pharyngeal/laryngeal weakness and incoordination due to neonatal encephalopathy or systemic weakness. Dysphagia commonly resolves spontaneously but may take days to weeks.[74] Uncommon causes include persistent dorsal displacement of the soft palate, subepiglottic cyst, esophageal disease, or nutritional myodegeneration. Esophageal diseases are rare in the newborn foal. Reported conditions include congenital dilatation or ectasia, tubular or cystic esophageal duplication, megaesophagus, motor dysfunction, and stricture. Most descriptions are in foals outside of the neonatal period. Aspiration of milk into the airway may be difficult to identify due to immaturity of cough receptors; auscultation over the trachea after nursing may identify fluid sounds.

Limb reflexes can be evaluated with the foal loosely restrained in lateral recumbency. Spinal reflexes, such as the patellar, sciatic, and cranial tibial reflexes, are hyperactive in the newborn foal and therefore easily elicited. The neonatal foal can have strong thoracic and pelvic limb crossed extensor reflexes, where a stimulus to the distal limb causes flexion (withdrawal) of the affected limb and extension in the contralateral limb. This reflex is typically only seen in adults with severe or chronic upper motor neuron lesions.[75] The painful stimulus should also be recognized centrally.

The gait should be evaluated for evidence of paresis or ataxia. The normal gait is hypermetric and bouncy but should be precise and symmetric and be free of circumduction and toe-dragging.[73] Generalized hypotonia is seen with hypoxic-ischemic syndrome, sepsis, prematurity, botulism, white muscle disease, or heritable muscle disorders. A "bunny hopping" gait could be suggestive of a myelodysplasia, and examination of the anus, tail, and perineum is indicated. Peripheral nerve damage can occur with birthing trauma, particularly brachial plexus or radial nerve injury from forelimb traction. Affected limbs are weak, are hyporeflexic, and may have regions of anesthesia.

Seizures can vary from localized or partial to generalized. As described earlier, normal foals in REM sleep can be active, including galloping actions, neck extension, and vocalization. These can last for several minutes and be confused with seizures. Narcolepsy/cataplexy should be suspected in foals that collapse, remain laterally recumbent for several minutes in a sleep state, and then recover uneventfully. The condition has been reported in American Miniature Horses, Morgans, Shetlands, and Suffolks.[73] It is possible to induce collapse and flaccidity by applying pressure to the thorax in normal newborn foals. The response is referred to as squeeze-induced somnolence.[76] There is a decrease in respiratory and heart rate and activation of the hypothalamic-pituitary-adrenal axis. The response was originally thought to be a form of narcolepsy or cataplexy, but electroencephalogram data in a small number of foals was not consistent with REM sleep, a feature of true narcolepsy.[76] An exaggerated head nod, a base wide stance with truncal sway, and dysmetric gait without weakness may indicate cerebellar dysfunction. The most common cause would be cerebellar abiotrophy, an inherited condition of Arabian horses and Gotland ponies.

Cerebrospinal Fluid Collection

Samples of cerebrospinal fluid (CSF) can be obtained from the atlanto-occipital (AO) or lumbosacral (LS) sites. The procedure is helpful in differentiating neonatal encephalopathy from bacterial meningitis. An AO CSF tap is a relatively straightforward procedure (Fig. 16.10). In comatose or profoundly somnolent foals, an AO tap can be performed using diazepam (0.05 to 0.2 mg/kg IV), local anesthesia, and adequate restraint. In more active foals general anesthesia should be used. In most neonatal foals the tap can be performed using a 3.8-cm, 18- to 20-ga hypodermic needle; in larger foals (>55 kg) a styletted spinal needle will be required. The needle is inserted at the intersection of a line drawn from the anterior wings of the atlas and midline. The poll is flexed tightly, and the needle is directed to the mandible. Alternatively, CSF can be collected from the lumbosacral (LS) site in the standing foal or in foals that are laterally recumbent without the need for general

FIG. 16.12 Rupture of the gastrocnemius muscle has a guarded to poor prognosis in foals.

anesthesia. The landmarks for LS are the cranial borders of the tuber sacrale. A 3.5-inch styletted needle is inserted on midline approximately 5 mm cranial to a line intersecting the borders of the tuber sacrale after local anesthesia and a stab incision with a No. 15 blade. The sample should be analyzed within 30 minutes because of rapid cell degeneration. Normal CSF has 1 to 5 cells/μL with cells restricted to monocytes and lymphocytes. There should not be any neutrophils in normal foal CSF. Yellow discoloration (xanthochromia) and slight turbidity of the sample can be normal. Similarly, CSF protein concentration can be elevated in foals during the first 2 days of life.[77]

Musculoskeletal System

The hoof wall of the newborn foal is covered by soft horn, or perionychium, a protective layer that is rapidly worn away when the foal begins to ambulate.[78] The coronary bands should be examined for hyperemia, an early indicator of systemic sepsis. Changes in hoof capsule temperature could also indicate regional or generalized perfusion problems. The limbs should be assessed for flexural laxity or contracture (Fig. 16.11). Mild to moderate limb contraction can make it difficult for the foal to stand and ambulate. In response to pain, foals with contracted tendons may have elevated heart and respiratory rates, as well as diffuse muscular tremor. In severe cases the foal may not be capable of standing. Treatment involves a combination of analgesia, splinting, and intravenous oxytetracycline. Repeated dosing of oxytetracycline is discouraged due to the risk of renal complications.[79] Extensor tendon rupture is a complication of flexural contraction and is recognized by discrete soft fluctuant swelling on the lateral aspect of the carpus.[80] The condition is often mistaken as septic synovitis. Foals usually respond well to conservative management. Fetlock laxity is common and can often be managed using heel extensions taped to the foot.

As part of the physical examination, all peripheral joints and physes should be palpated for swelling, heat, pain, and edema. Although trauma is often implicated as the source of any lameness, infection should always be considered as the most likely cause until proven otherwise. Other problems that may be identified in the neonate include rupture of the gastrocnemius muscle (Fig. 16.12) or associated muscle and patellar luxation. Foals are unable to bear weight when there is complete rupture of gastrocnemius muscle and cannot stand when bilateral rupture occurs.[81]

Premature or dysmature foals have joint laxity and delayed ossification. Joint laxity can predispose affected foals to angular limb deformities. These are managed through a combination of hoof trimming, exercise restriction, and splinting. Delayed ossification is assessed using radiography, centering on the cuboidal bones of the tarsus and carpus. The management of delayed ossification is difficult, and collapse or crush of cuboidal bones can sometimes be unavoidable. Preventative strategies include restricted exercise and splinting.

Supplementation of foals with selenium is recommended for those born in known selenium-deficient regions where mares have not been supplemented during pregnancy. Severe rhabdomyolysis has been reported in newborn foals, usually associated with selenium deficiency.[82] Glycogen branching enzymes deficiency is an inherited cause of mortality in Quarter Horse foals.[83] Clinical signs are variable and include seizure, persistent recumbency, respiratory failure, and cardiovascular collapse. The generalized nature of the clinical signs would likely lead to a false diagnosis of other more common neonatal diseases.

Dermis

A short, silky hair coat is consistent with immaturity. Skin abrasions occur in foals with prolonged recumbency or as a consequence to seizures, colic, or frequent unsuccessful attempts to rise. Lesions are commonly seen on the elbows, around the eyes, or on other skeletal prominences. They usually begin as focal regions of moisture. A syndrome of ulcerative dermatitis with widespread crusting and erythema has been seen in foals with alloimmune thrombocytopenia.[84] Edema can form on the ventrum, axilla, perineum, and periorbital region with fluid overload and renal dysfunction. Swelling under the axilla can also result from cellulitis, trauma, or fractured ribs. Ventral swelling over or around the umbilicus can occur with tearing of the urachus and urine leakage into tissues (Fig. 16.13).

Immunoglobulin G and Colostrum

There is an association between low serum immunoglobulin G (IgG) and morbidity and mortality, most commonly due to sepsis. Measurement of serum IgG should be made between 12 and 18 hours of age. A normal foal that has consumed adequate amounts of colostrum will have a serum IgG measurement substantially greater than 8 g/L (800 mg/dL). Failure of passive transfer is generally defined as a serum IgG less than

4 g/L (400 mg/dL); partial failure of passive transfer is used when the serum IgG is between 4 and 8 g/L. Foals that have been exposed to chronic in utero infection can be born with IgG concentrations greater than 8 g/L. Furthermore, septic foals may catabolize immunoglobulins, resulting in lower concentrations than originally assessed. Tetanus prophylaxis, in the form of antitoxin (1500 IU), should be administered to foals with untreated failure of passive transfer.

Good-quality colostrum is typically yellow and highly viscous, but physical properties alone do not result in significant differences in foal IgG levels at 24 hours of age.[85] There is a strong linear correlation between colostral specific gravity and IgG concentration.[86,87] A modified hydrometer, the Equine Colostrometer (Jorgensen Laboratories, Colo.) is used to estimate the specific gravity of equine colostrum. It is important to accurately add the recommended volume of colostrum to the chamber. The temperature of the distilled water will also influence the final reading, and corrective tables are available. Handheld refractometers that measure sugar or alcohol content are also suitable for assessing colostral quality. The test can be performed rapidly by placing a single drop of mixed colostrum onto the glass prism of the refractometer. Values greater than or equal to 16 on the alcohol scale, or 23% on the BRIX sugar scale, correspond to a colostral IgG content greater than or equal to 60 gm/L.[85,88] The following guidelines have been recommended for evaluating BRIX readings: (1) 0% to 15% BRIX, 0 to 28 gm/L IgG, poor quality; (2) 15% to 20% BRIX, 28 to 50 gm/L IgG, borderline quality; (3) 20% to 30% BRIX, 50 to 80 gm/L IgG, adequate quality; and (4) greater than 30% BRIX, greater than 80 gm/L IgG, very good quality.[88]

A minimum dose of 60 to 90 gm/L of IgG has been recommended in the first 6 hours after birth.[89] This represents 1 to 1.5 L of good-quality colostrum, as defined by an IgG content of greater than 60 gm/L. Foals that received a minimum of 1.0 to 1.25 gm/L IgG/kg body weight within this time period should achieve a serum IgG above 8 gm/L.[90] The total IgG content in mammary secretions is highly variable but was reported to be 183 ± 58 gm/L (range 112 to 336 gm/L), equating to a mean volume of colostrum of 2.3 ± 0.5 L.[90] The specific gravity declines to below 1.040 by an average of 7 hours after parturition, reflecting a reduction in IgG concentration from a mean of 113 gm/L to 35 gm/L. Several factors influence colostral quality. Mares that are stressed or ill are less likely to produce good-quality colostrum, as are animals with adrenal hyperplasia secondary to pituitary dysfunction or those receiving exogenous glucocorticoids. Aged mares, particularly those older than 15 years of age, tend to produce colostrum with a lower IgG concentration.[89]

FIG. 16.13 Swelling around the umbilicus caused by tearing of the urachus within the tissues of the body wall.

Laboratory Data

Hematology and biochemistry can provide a critical insight in identifying foals at risk of developing clinical disease, in assessing the magnitude of clinical problems, and in monitoring response to treatment. Normal hematology, biochemical, and electrolyte data are reported in Tables 16.3 and 16.4. Foals that have been exposed to an abnormal in utero environment will frequently have abnormalities on routine blood work that can predict future clinical problems. Several important variations

to adult values must be considered when interpreting laboratory data. In addition, there are some differences between horse foals and donkey foals and readers are directed to an appropriate reference.[91]

White Blood Cell Count and Differential

The total white blood cell (WBC) count at birth is similar to that in adult horses, but the proportion of neutrophils and lymphocytes is more variable. An elevated count at birth reflects a fetal response to placental infection with or without infection of the foal. Premature or dysmature foals with incomplete adrenal maturation will have low total white cell and neutrophil counts and a neutrophil-to-lymphocyte ratio that is characteristically less than 1:1.[92] It is important to determine if sepsis is present as neutropenia is also a common feature of this condition. Evidence of shifting toward immature cell types, and neutrophil toxicity should indicate primary sepsis or prematurity/dysmaturity complicated by sepsis. Premature foals that fail to improve their total white blood cell and neutrophil counts over the initial 24 to 48 hours of treatment have an even poorer prognosis for survival. Persistent decreases in lymphocyte counts (<1000/μL) in Arabian foals could be consistent with severe combined immunodeficiency. Alloimmune neonatal neutropenia has been reported in foals and can persist for 2 to 4 weeks after ingestion of colostrum.[93] Affected foals are often outwardly normal but are considered to be at risk for sepsis and are therefore managed with prophylactic antibiotics.

Red Blood Cells and Platelets

The packed cell volume (PCV) at birth is 40% to 52% but decreases to 32% to 46% after colostrum and milk intake by 24 hours of age.[94] Increases in PCV can reflect dehydration, whereas decreases can be caused by blood loss, either internal or external, hemolysis, DIC, or prematurity. Platelet numbers are unaffected by age, but decreases are seen with alloimmune thrombocytopenia, DIC, and viral infection (equine herpesvirus–1, equine viral arteritis).

Plasma Protein and Acute Phase Proteins

Plasma or serum protein concentrations are low at birth but increase with globulin ingestion from colostrum. The albumin concentration should remain constant.[40] Plasma protein levels are 40 to 60 gm/L at birth and increase to 50 to 80 gm/L at 24 hours of age.[94] Levels increase with dehydration and chronic infectious processes and are decreased with whole blood loss, gastrointestinal disease, renal disease, or failure of passive transfer.

Fibrinogen concentrations are relatively low in newborn foals (2.16 ± 0.72 gm/L <12 hours of age; 3.10 ± 0.74 gm/L at 3 days of age), before increasing to a maximum at around 5 months of age (4.97 ± 0.91 gm/L), and then reducing to adult levels.[95] Hyperfibrinogenemia at birth is indicative of in utero sepsis and inflammation. Serum amyloid A (SAA) as determined by latex agglutination immunoturbidimetric assay in normal foals yielded median values of 0.9, 4.0, and 2.5 mg/L for days 1, 2, and 3, respectively.[96] These were contrasted against median values of 279.9, 195, 5.1, and 3.1 mg/L for systemic sepsis, localized sepsis, failure of passive transfer, and neonatal isoerythrolysis cases, respectively. The authors concluded that values greater than 100 mg/L were suggestive of local or systemic sepsis in young foals.

Glucose

Blood glucose concentrations are relatively low in newborn foals but increase after nursing. Baseline values are typically 50% of maternal values at birth and reach a low approximately 2 hours after birth.[40] Many diseases of foals can directly or indirectly affect blood glucose concentrations, but the change in glucose can be difficult to predict. Hypoglycemia commonly occurs in foals with decreased milk intake. Conditions that may be associated with increased metabolic demands, such as systemic inflammatory response syndrome (SIRS) and sepsis or reduced gluconeogenesis, can contribute to hypoglycemic states. Gluconeogenesis is also impacted by SIRS and sepsis, as well as prematurity or in utero stress. Hyperglycemia is a consequence of overzealous glucose supplementation or can occur in conditions with slow or reduced insulin responses, insulin resistance, or with inappropriate sustained gluconeogenesis. This can occur in foals with hypoxic-ischemic syndrome (HIS), SIRS, sepsis, and prematurity.

Blood L-lactate Concentration

Lactate levels reflect peripheral perfusion and tissue oxygenation. Increased concentrations are expected after hemorrhage, in foals with systemic sepsis, neonatal isoerythrolysis, or HIS. Increases can also occur in hypermetabolic states where oxygen demand is increased; examples include seizures, increased muscle activity, and shivering. Lactate is cleared by the liver and kidney, and therefore decreased perfusion to those organs can contribute to increased systemic values. Reference ranges will vary slightly with different analyzers, but normal values should be less than 2.5 mmol/L in horse and donkey foals 24 to 48 hours of age or older.[50,97–99] Values during the first 24 hours after birth in normal foals are higher. The venous lactate concentration 20 to 140 minutes after birth (2.38 ± 1.03 mmol/L) was greater than at 24 hours (1.24 ± 0.27 mmol/L) in a small group of normal foals.[100] A second study reported mean values at birth, 12, 24, 36, and 48 hours of 3.8, 2.8, 2.1, 2.0, and 1.7 mmol/L, respectively.[98] There is a suggestion that lactate values in "healthy" premature or dysmature foals may be higher than in term foals.[101] Lactate concentrations at admission are correlated with outcome; foals with a value ≥5 mmol/L were 5.63 times more likely to die than foals with a value <5 mmol/L.[98] When the cutoff value was set at 7.94 mmol/L, the odds of

VetBooks.ir

nonsurvival increased to 15.98. Other studies have identified lactate concentration cutoff points of 4.4, 5.5, and 6.9 mmol/L to predict survival.[101–103] As important as the initial concentration is the change in lactate concentration in response to treatment.[98,101] In nonsurviving foals elevated lactate levels typically persist beyond 24 hours of hospitalization. Samples should be analyzed within 10 minutes of collection, as erythrocytes can continue to produce lactate in lithium heparin tubes stored at room temperature.[104] If sampling is delayed, then samples should be collected into sodium fluoride-potassium oxalate and stored at 0° C to 4° C. In some point-of-care analyzers a high hematocrit can interfere with lactate measurement.[104] Anion gap can be used to approximate lactate, although direct measurement is preferred.

Creatinine and Blood Urea Nitrogen

Concentrations of both creatinine and blood urea nitrogen (BUN) can be elevated due to prerenal, renal, and postrenal causes. Marked elevation in creatinine concentration in newborn foals typically reflects problems with the fetoplacental unit; these foals are at risk of postnatal complications due to in utero compromise. Serum creatinine concentration is higher in foals with grossly abnormal placentas and in foals with a clinical diagnosis of perinatal asphyxia syndrome (PAS).[105] Assuming normal renal function, these elevated values should halve within 24 hours and approach normal levels by 72 hours. Failure to drop or a delay in decrease should suggest concurrent renal disease or other causes of azotemia. BUN is not typically elevated in cases of placental dysfunction. It can increase in conditions of increased catabolism.

Bilirubin, Hepatobiliary Enzymes, and Bile Acids

Relative to adult horses, newborn foals have increased total bilirubin concentrations that are attributable to the unconjugated component. The basis of the discrepancy is not known but could relate to accelerated breakdown of fetal and neonatal red blood cells or decreased uptake and conjugation of bilirubin. Concentrations peak shortly after birth before declining to adult levels by 2 weeks of age.[106] Increases in bilirubin above normal are seen with hemolytic conditions, such as neonatal isoerythrolysis, primary liver disease (including equine herpesvirus-1 infection, Tyzzer's disease, and cholangiohepatitis), sepsis, meconium impaction, and after internal hemorrhage or blood transfusion. Large increases in bilirubin can lead to the neurologic complication of kernicterus.

Gamma glutamyl transferase is normal at birth but increases between 5 and 14 days of age before decreasing to adult levels by 4 weeks of age. The increase is thought to be due to hepatic enzyme induction associated with normal maturation. The hepatocellular enzyme, sorbitol dehydrogenase, is not affected by age. Glutamate dehydrogenase concentration has not been well described in healthy newborn foals. These enzymes are increased in a range of conditions, particularly sepsis.[107]

The concentration of aspartate aminotransferase increases slightly after 7 days of age; an increase attributed to enhanced muscle activity rather than hepatobiliary changes. Serum alkaline phosphatase (ALP) concentrations are substantially increased over adult levels in the first few days of life, remaining elevated through the first week. The initial increases are attributed to intestinal activity, including the pinocytosis of maternal immunoglobulin, and to the osteoblastic activity in growing and adapting bones. Premature or dysmature foals with incomplete ossification will have ALP concentrations that are higher and persist for longer than levels in term foals.[40]

Serum bile acid concentrations are also greater in foals during the first 6 weeks and are 6 to 7 times greater than adults during the first 2 days of life.[108] Increased concentrations of bilirubin or triglycerides or hemolysis may interfere with serum bile acid measurement under certain methodologies. Serum cholesterol is also elevated during the first 2 weeks of life.

Trigylcerides

Triglycerides increase from birth to the first day of life, peaking early in the first week, and then gradually declining to adult levels by 3 months of age.[106,109] Increases in lipids, reflected through serum hypertriglyceridemia, are commonly reported in sepsis in foals, presumably secondary to altered fat metabolism.[110,111] Serum triglyceride concentrations are higher in foals with positive blood cultures and higher in nonsurviving foals (survivors: 116 mg/dL median [41 to 379, range] versus nonsurvivors: 55 mg/dL, median [10 to 311, range]).[109]

Electrolytes

As with adult horses, serum electrolyte concentrations in foals are maintained within a relatively narrow range. Disruption of the urinary tract or primary renal disease classically produces a hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and hyperkalemia. Many of these changes reflect the electrolyte intake associated with a milk diet and are less likely to occur when foals have received intravenous fluid therapy. Rhabdomyolysis due to selenium deficiency can cause a similar electrolyte profile to that of uroperitoneum in milk-fed foals.[82] Although both conditions may be associated with increases in creatinine and BUN, concurrent and substantial increases in creatine kinase and aspartate aminotransferase are expected with rhabdomyolysis.

Hyponatremia, hypochloremia, and hypokalemia are commonly seen with diarrheal disease in foals. Severe hyponatremia is more commonly seen in older foals with diarrhea that are allowed to replenish fluid losses by consumption of plain water. Hyponatremia is also a feature of renal disease, but hypernatremia can occur when affected foals are treated with relatively high volumes of sodium-rich intravenous fluids in the face of inadequate urine output.

Elevated total and ionized calcium concentration can be present in foals born to mares with marked placentitis.[40] Clinical hypocalcemia results in signs of tachycardia, sweating, tremor, muscular rigidity, and a stiff gait or recumbency. The syndrome is rare, but euthanasia is common due to failure to respond to calcium supplementation.[112] Parathyroid hormone concentrations may be elevated, decreased, or normal, suggesting differing syndromes.

General Principles of Treatment and Care of the Abnormal Foal

Guy D. Lester • Jane E. Axon

Frequent monitoring of the ill newborn foal is essential, as early recognition of subtle clinical changes can have a significant impact on outcome. This includes observations of behavior and repeated structured physical examinations. Assessment of the foal is described in Chapter 16. It is important that the clinician develops a routine method of examination that is consistently followed, irrespective of the perceived level of illness. This ensures that the assessment is complete and no abnormalities are missed. Delivering detailed and potentially expensive therapy to a foal with a significant congenital defect is potentially avoided by adopting this approach.

By the time that many sick newborn foals are examined by veterinarians, they are critically ill and require emergency therapy to restore circulation, tissue perfusion, and oxygenation. This approach is conserved across many diseases. After fluid resuscitation there can be an investigation into underlying diseases, and directed therapy can be instituted.

Catheter Selection and Placement

If high-volume fluid resuscitation is anticipated, then a large-bore (14- or 16-gauge) catheter should be placed into the jugular vein. Identification of the vein can be facilitated by elevation of the hindquarters in lateral recumbency and by placing a rolled towel under the neck. Teflon catheters (Abbocath, Abbott Hospitals, North Chicago, Ill.) are more thrombogenic than Silastic or polyurethane catheters but are usually easier and quicker to place. Short catheters placed in peripheral veins can be difficult to maintain and are not suitable for large-volume, rapid fluid replacement. Most referral hospitals use polyurethane catheters as they reduce the incidence of thrombophlebitis and eliminate the need for frequent catheter replacement. Using strict aseptic technique, the catheter is typically inserted using the "over-the-wire" (Seldinger) technique. Once positioned, the catheters can often be left in place for up to 3 weeks. A combination of superglue and sutures are effective in keeping the catheters in place. Catheter sites are covered but monitored frequently for signs of infection. Insertion site swelling is not uncommon for 24 hours after placement of some catheters. Blood samples for culture, hematology, and biochemistry can be collected at the time of catheter placement if the condition of the foal is not highly critical.

Fluid Resuscitation

After placement of an intravenous catheter, warmed fluid can be delivered at a rate of 20 mL/kg over 15 to 20 minutes.[1,2] Typically the initial fluid of choice is a multielectrolyte replacement solution, such as lactated Ringer's solution (LRS) or Hartmann's solution. After the initial or subsequent fluid boluses, the patient is reassessed, specifically noting changes in mucous membrane color, capillary refill time, pulse quality and rate, mentation, warmth of peripheral tissues, intestinal sounds, and urine production.[3] If there is minimal or no improvement, then the bolus can be repeated a further three times, to a maximum of 80 mL/kg, or 4 L for a 50-kg foal. During this time, essential laboratory data can be collected, including the packed cell volume, total plasma protein (TPP), and blood glucose concentration. Ideally, an arterial or venous sample is obtained for blood gas, electrolyte, and lactate determination. Factors that influence the rate or total volume of fluid used during resuscitation include a low TPP concentration (<35 gm/L); preexisting limb, body, or head edema; or spontaneous hemorrhage.

Colloids are indicated in low-protein states. Plasma is the most commonly used colloid in foal practice but is expensive and

VetBooks.ir

requires thawing and the use of an in-line filter. However, the benefits of fresh or fresh frozen plasma are numerous, including improvement of osmotic pressure, provision of coagulation factors, to provide buffer base, and immunotherapy.[2] The administration of plasma has been associated with anaphylactic or anaphylactoid reactions, which can be fatal. It is for this reason that plasma is not routinely used for acute fluid resuscitation. Plasma should be administered at an average rate of 10 mL/kg/h. Give the first 100 mL slowly and monitor the foal's pulse, respiratory rate, and temperature. Synthetic colloids are less expensive and do not require special storage conditions or use of a special filter, but they do not have the range of benefits of plasma. The use of synthetic colloids in foals has been questioned.[1–3] Hydroxyethyl starch (hetastarch) has, however, been used successfully for rapid fluid resuscitation in foals with few adverse reactions (3 mL/kg at a rate of 10 mL/kg/h).[4]

Correction of Dehydration

Once critical hypovolemia has been rectified, assessment can be made of residual dehydration.[3] Foals have a relatively greater proportion of extracellular fluid when compared with adults[5] and, in contrast to adults, can appear thin or emaciated when dehydrated. Traditional clinical parameters used to assess hydration in adult horses, such as moisture of oral mucous and skin tenting, are less reliable when used in foals. The volume of fluid is, however, calculated in a manner similar to that used in adults. A foal with moderately to severely sunken eyes is estimated to be 8% to 10% (of body weight) dehydrated. The estimated fluid deficit in a 40-kg animal that is 10% dehydrated would be approximately 4 L. The calculated deficit should be replaced over the following 12 hours, along with consideration of maintenance fluid requirements and any ongoing losses.

If an animal is mildly dehydrated and the gastrointestinal tract is not seriously compromised, fluid requirements can be provided by the enteral route, using milk or commercially available dextrose and electrolyte mixtures.

Maintenance Fluid Therapy

When using intravenous fluid therapy for maintenance of hydration, the Holliday-Segar formula has been advocated for calculation of fluid delivery rates in foals with impaired renal function, or in foals younger than 3 days of age where renal function is not known.[2,3] It employs a principle that slight fluid deprivation is less critical than overhydration, particularly when sodium-rich fluids are used. For the first 10 kg of body weight the foal receives 100 mL/kg/day; for 11 to 20 kg of body weight the foal receives 50 mL/kg/day; and for each kg over 20 kg the foal is assigned 25 mL/kg/day.[2] For a 50-kg foal this is calculated as 1000 mL/day for the first 10 kg, 500 mL/day for the second 10 kg, and 750 mL/day for the remaining 30 kg of body weight, for a total daily volume of 2250 mL or an hourly flow rate of 94 mL.[2] For older foals, or foals with normal renal function, higher flow rates can be used, typically in the range of 2 to 5 mL/kg/h.[3,6]

Use of Inopressor Drugs

If hypotension persists in the face of fluid resuscitation, inopressor therapy may be indicated. It has been recommended that the aim of therapy is to raise the mean arterial pressure (MAP) above 60 mm Hg, although this does not imply that tissue perfusion is adequate.[7] Agents that are commonly used include dobutamine, dopamine, norepinephrine, and vasopressin.[7] Dobutamine is a positive inotrope that improves cardiac output primarily by improving stroke volume. The drug is administered as a constant rate infusion (CRI) with a wide dose range of 3 to 20 μg/kg/min, but it is recommended to commence therapy at the low end of the range.[3] It is not common to administer a vasopressor with dobutamine to improve tissue perfusion. Norepinephrine acts at α_1- and α_2-receptors to mediate vasoconstriction, as well as acting at β_1-adrenergic receptors causing positive inotropic and cardiotropic effects.[7] The drug has a short half-life and is given by CRI at a highly variable dose range, from 0.05 to 5.0 μg/kg/min. Again, starting at the low end of the range is recommended.

Dopamine also has some combined α- and β-adrenergic effects, in addition to moderate to strong affinity for dopamine receptors (DA-1 and DA-2 receptors).[7] Activity at dopaminergic receptors primarily mediate vasodilation, particularly renal, cerebral, and splanchnic vascular beds. Lower infusion rates are used to improve renal and splanchnic perfusion (0.5 to 5 μg/kg/min), whereas higher infusion rates (10 to 25 μg/kg/min) will be required for patients in severe septic shock.

Vasopressin (0.25 to 1.0 mU/kg/min) acts at V1a receptors in the peripheral circulation causing vasoconstriction and at V2 receptors in the kidney to facilitate water reposition.[7] Low-dose vasopressin is commonly used in conjunction with norepinephrine infusion and is reported to be effective in the management of the hypotensive neonatal foal. Beneficial effects included an increase in MAP, a reduction in heart rate, and increased urine output.[8]

Glucose Supplementation

The fluid rate is in part dictated by the need to provide glucose supplementation. A rate of 5 mg/kg/min has been suggested as an initial CRI flow rate on the basis of the estimated placental supply in late gestation (6.8 mg/kg/min).[3,9] This equates to an hourly flow rate of 3 mL/kg (150 mL/h for a 50-kg foal) of a 10% glucose solution. Blood glucose concentrations should be monitored closely and the rate adjusted as required. Boluses of glucose solutions should be avoided as the resultant glucosuria will result in urinary losses of fluid, electrolytes, and glucose. It can produce a marked rebound hypoglycemia.

Electrolyte Management

In most foals, electrolyte concentrations will normalize over time, assuming adequate renal function and milk intake. However, there are several conditions where specific electrolyte supplementation or avoidance is important. Foals with uroperitoneum can develop life-threatening hyperkalemia. Specific management is discussed elsewhere in this chapter, but fluid therapy is typically based on 0.9% saline supplemented with glucose. Potassium supplementation may be required for critically sick neonates, anorexic foals, foals with diarrhea, or those receiving diuretic therapy. If serum concentrations fall below 2.5 mEq/L, intravenous supplementation is recommended. Potassium requirements are difficult to estimate from serum concentrations, but the following equation has been recommended:

$$\text{Replacement K (mEq)} = 0.4 \times \text{Body weight (kg)} \times \text{K deficit (mEq)}$$

Potassium can safely be added to fluids at a rate of 10 to 40 mEq/L, although when delivering fluids at a maintenance rate using the Holliday-Segar formula, concentrations up to 60 mEq/L may be used.[2] At higher concentrations it is important not to exceed recommended rates of administration. Potassium supplementation should not exceed 0.5 mEq/kg/h, or 25 mEq/h for a 50-kg foal.

Sodium overload is a problem associated with prolonged use of salt-rich replacement solutions.[2] The problem is avoided by using specially formulated low-sodium, high-potassium replacement solutions that are supplemented with glucose, or using 5% dextrose in water as the base solution for fluid therapy. The principles of hyponatremia or hypernatremia treatment are discussed in Chapter 32).

VetBooks.ir

Sodium bicarbonate is commonly given to foals that are acidemic, assuming that that it is metabolic in origin. The initial approach to management should be rehydration and improvement in tissue perfusion. This is achieved using crystalloids, colloids, and inopressor agents. When bicarbonate is administered to foals where the acidosis has originated from poor tissue perfusion, the results are often disappointing. Bicarbonate supplementation is indicated in conditions where there has been loss of buffer, such as diarrhea or renal tubular acidosis. If bicarbonate deficits are greater than 10 mEq/L (serum [HCO_3^-] < 15 mEq/L) after rehydration, then supplementation can be given using the following equation:

$$\text{Bicarbonate deficit (mEq)} = 0.6 \times \text{Body weight (kg)} \times \text{Base deficit (mEq)}$$

Isotonic bicarbonate can be made by adding 150 mL 8.4% bicarbonate solution to 850 mL sterile water, or 200 mL 5% bicarbonate solution to 800 mL of sterile water. Bicarbonate solutions should be given slowly. Bicarbonate solution should not be combined with any calcium-containing solution or precipitation will occur. The effect of the bicarbonate replacement therapy should be monitored closely and the dose adjusted accordingly. Neonates with severe diarrhea because of ongoing losses of bicarbonate through the feces may need considerably more than the calculated deficit to maintain an adequate blood pH until the diarrhea subsides.

Plasma Transfusion for Failure of Passive Transfer of Immunoglobulin

Plasma is administered through an aseptically placed catheter using a blood administration set with an in-line filter. The rule of thumb for plasma administration for FPT is 20 mL/kg or approximately 1 L for a 45-kg foal. In healthy foals, 1 L of plasma with [IgG] of 1200 mg/dL (12 g/L) raises the serum IgG 200 to 250 mg/dL (2 to 2.5 g/L). For foals with total failure of passive transfer, it may be necessary to provide 2 or 3 L of commercial plasma if the goal is to reach a serum IgG concentration of 800 mg/dL (8 g/L). The same amount of plasma has less effect in septic foals. Ill foals require relatively more plasma because the serum half-life of IgG is less, IgG may be sequestered in intravascular spaces or at sites of inflammation, and IgG may catabolize more readily.

Maintenance of Body Temperature

The thermoneutral zone describes an ambient temperature range in which heat production and heat loss are at a minimum.[10] The lower level of the range (Tlc) defines a temperature cutoff, below which the metabolic rate rises and the rate of evaporative heat loss increases. For 2-day-old pony foals the Tlc was estimated to be 25° C,[10] a value much higher than the typical ambient temperature that many foals experience. However, healthy foals are able to maintain their core body temperature down to an ambient temperature of 5° C, but premature or sick newborn foals are often unable to maintain their body temperature and frequently require external heat sources during treatment. Foals on phenobarbital therapy are also susceptible to a reduction in body temperature.

It is critical to dry the foal and remove it from drafts to reduce convective heat loss. If the rectal temperature is less than 100° F (37.7° C), efforts should be made to warm the foal by raising the environmental temperature. Rewarming the periphery only with high external heat without simultaneously warming the body core can produce peripheral vasodilation and accentuate cardiovascular collapse. Warming can be achieved using forced air warmers (Bair Hugger, 3M), radiant heat lamps, applying blankets, or careful use of heating pads. A heat pack can be made by placing a wet towel inside two rectal sleeves and microwaved to the desired temperature. It is important to address hypotension using warmed fluid therapy.

FIG. 17.1 Sternal recumbency is facilitated by use of a V-pad.

Bedding and General Environment

It is important that the environment for housing the sick foal is clean. A temporary barrier between the mare and recumbent foal facilitates treatment of the foal yet keeps the dam within sight, sound, touch, and smell of her foal, which facilitates bonding. Many of these foals are recumbent, making them further vulnerable to contagious or opportunistic pathogens. Recumbency increases the risk of pneumonia, predisposes to ileus and constipation, increases the risk of milk aspiration, and exacerbates musculoskeletal weakness. Recumbent foals are also at risk for the development of decubital ulcers and should be bedded on a soft and absorbent surface. They should be carefully turned and assisted to stand every 2 hours. Placement into custom-made V-pads (Dandy Products, Goshen, Ohio) can help the foal rest in sternal recumbency, improving oxygenation and reducing the risk of lung atelectasis and secondary pneumonia (Fig. 17.1).

Special Considerations of Drug Therapy

Differences between neonatal and adult animals in drug effects generally can be attributed to differences in drug distribution, metabolism, or excretion. Some general characteristics of the neonatal period include better absorption of drugs from the gastrointestinal tract, less drug binding to plasma proteins, increased apparent volume of distribution of drugs that are distributed in the extracellular fluid volume, increased permeability of the blood-brain barrier, and slower elimination (i.e., longer half-life) of many drugs.[11]

Some of these responses are attributed to differences in body water between neonates and adult horses. Total body water (TBW) in day-old foals was 744 ± 24 mL/kg, compared with 670 ± 60 mL/kg in adult horses.[5,12] During growth, the intracellular fluid compartment remains relatively consistent relative to size, while the extracellular fluid (ECF) compartment decreases as a percentage of body weight, with an increasing body fat percentage. The ECF volume was estimated at 381 ± 18 and 394 ± 29 mL/kg, in 1- and 2-day-old foals, respectively.[5,13] This compares with reported values in adult horses

VetBooks.ir

of 214 to 253 mL/kg. Plasma volume is around 96 mL/kg in neonates, again much greater on a per-kg body weight basis than reported values in adults, 53 to 63 mL/kg.[5] Although the neonate has a higher percentage of TBW than the adult, it is more vulnerable to water loss because of increased basal metabolic rate and relatively greater surface area (both predisposing to increased heat and water losses), as well as reduced urine concentrating ability.

Nutritional Support

Provision of adequate nutritional support to the compromised neonate is an essential component of critical care. Common reasons for not providing adequate nutrition include failure to estimate the nutritional requirements of the sick neonate, the need to use alternate methods and routes of delivery, and a gastrointestinal tract that is often compromised and intolerant of nutrient intake. The nutritional requirements for optimum growth of the normal-term foal are poorly defined, let alone for the premature, growth-retarded, or debilitated animal whose caloric, protein, mineral, and vitamin requirements might be very different.

Measurements of milk production of mares combined with data concerning the free-choice milk intake of normal orphan foals and premature and sick foals recovering from various illnesses suggest that a figure of 125 to 150 kcal/kg/day, or even higher, is close to the normal caloric intake.[14] Healthy full-term foals nurse an average of 2 minutes, seven times an hour, and consume between 20% and 30% of their body weight in milk daily, resulting in weight gain of 1.3 to 1.7 kg/day.[15–17] On this diet, a 50-kg foal would therefore consume 10 to 12.5 L of milk daily to provide 120 to 150 kcal/kg/day, 50% of which is used for growth and 50% for basal metabolism and thermoregulation. Factors that influence weight gain include caloric intake, the level of exercise, and the resting energy expenditure (RER). Weight gain is reduced in hospitalized newborn foals. RER is, however, less in ill foals, approximately 44 to 49.5 kcal/kg/day, compared with 65 kcal/kg/day in healthy foals.[18] The general recommendation is to provide a minimum of 50 kcal/kg/day and aim for a positive growth rate of 0.6 to 1.0 kg/day.

If there is no medical contraindication for oral feeding and the gastrointestinal tract is functional, then enteral nutrition is the preferred and most effective route of nutritional supplementation. Enteral feeding stimulates normal gut maturation, growth of intestinal villi, production of crypt cells, hepatic and biliary secretions, and brush border disaccharidase enzyme activity. Therefore, even in foals that must be fed parenterally, small volumes of enteral feeds are given to prevent gut atrophy.

Foals that are not nursing from the mare can be fed by bottle, bucket, or nasogastric tube. If an effective swallow reflex is present, bottle-feeding can be used. Bucket feeding allows the foal to drink with its head and neck in a flexed position and is helpful for foals with a weak swallow reflex or foals destined to be hand raised. Milk should be introduced in a shallow handheld bowl and the foal encouraged to suckle the finger or nipple as its head is lowered into the milk. Foals younger than 7 days of age should ideally be fed every 1 to 2 hours. Nasogastric intubation is required if ineffectual swallowing and sucking are present. A styletted small-bore flexible silicone tube (5 to 7 mm internal diameter) with a weighted tungsten end is preferred. Individual choice dictates whether the tube is passed for each feeding or left indwelling. Indwelling tubes can be sutured to the nares using a Chinese finger-trap suture technique[19] or taped to half a tongue depressor, which is then taped to the foal's muzzle and/or fleece halter. Tubes should be sealed between feedings to prevent aerophagia. Recumbent foals should be maintained in sternal recumbency using a V-pad immediately after tube feeding to reduce the risk of gastroesophageal reflux and aspiration. If the dam is available and milk production is adequate, free-choice nursing is optimal. A nurse mare is the next best substitute. Popular enteral formulas include mare's milk, goat's milk, and artificial milk replacers. Goat's milk is acceptable and is higher in fat, total solids, and gross energy than mare's milk. Foals raised on goat's milk occasionally become constipated and can develop a mild metabolic alkalosis. Cow's milk is not as digestible and can cause diarrhea, but it can be used if additional sugar is added and some of the fat is removed. This can be accomplished by using 2% skim milk and adding 20 g of dextrose per liter of milk. A variety of artificial milk replacers are available. The ideal replacer should have approximately 22% crude protein, 15% fat, and less than 0.5% fiber on a dry matter basis. Calf milk replacer can be used if it is mixed with mare's milk. Complications associated with enteral feeding include colic, abdominal distention, diarrhea, constipation, flatulence, misplacement of the nasogastric tube, aerophagia, nasal and pharyngeal irritation from the tube, and aspiration pneumonia.

Parenteral nutrition (PN) is used to supply at least a portion of the daily nutritional requirements to critically ill foals. PN is indicated whenever feeding via the gut is inadequate or contraindicated. Candidates for partial or total PN include those individuals with diarrhea, postsurgical patients, foals with botulism, premature and septic animals, and other individuals with gastrointestinal tracts poorly tolerant of enteral feedings. PN involves administration of hypertonic solutions containing dextrose, amino acids, lipids, vitamins, electrolytes, and trace minerals. These PN solutions must be administered continuously through a jugular catheter. Complications include metabolic disturbances such as hyperglycemia/hypoglycemia, glucosuria/osmotic diuresis, insulin resistance, hypertriglyceridemia, azotemia, and imbalances of trace minerals, vitamins, and electrolytes.[20,21] Catheter-related problems include thrombosis, phlebitis, and sepsis. Commonly used stock solution for PN includes 50% dextrose, 8.5% or 10% amino acids, and 10% or 20% lipid emulsion. Various PN worksheets are available, some of which are complicated.[22]

A simplified formula for 50 kg that is well tolerated in most foals is 2.5 L of 8.5% amino acids, 1 L of 20% lipid, and 1.5 L of 50% dextrose added to an empty 5-L bag. This mixture contains 750 g dextrose, 212.5 g amino acids, and 200 g lipids, and it provides 2550 kcal from dextrose (3.4 kcal/g), 850 kcal from amino acids (4.0 kcal/g), and 2000 kcal from lipids/glycerol (10.0 kcal/g). The PN solution has 47% of total calories from glucose, 16% from protein, and 37% from fat. It is recommended that foals should not receive more than 50% of nonprotein calories from lipid. The solution can be run at 104 mL/h over 48 hours, providing approximately 54 kcal/kg/day. It is common to supplement the solution with multivitamin concentrate, trace minerals, and KCl (to a final concentration of 20 to 40 mEq/L). The PN solution is hypertonic (1233 mOsm/L), so it is common to run concurrently with low-tonicity solutions or free water.

Foals receiving PN should have their blood and urine glucose monitored. Serum glucose concentration should remain greater than 80 mg/dL (4.4 mmol/L) and less than 180 mg/dL (10 mmol/L). Serum should be checked for gross lipemia. Heparin can be administered at 10 units/kg as an IV bolus to treat lipemia. Foals must be weaned onto and off of PN slowly. All IV lines must be checked and changed routinely. Most commonly, parenteral and enteral nutrition has been used in combination; parenteral nutrient delivery is used to supplement, not totally replace, oral intake. Details concerning the use of parenteral nutrition compounds can be found in Chapter 50.

Weakness and/or Somnolence

Numerous conditions in the newborn foal can produce a primary complaint of weakness and/or somnolence. The gestational

VetBooks.ir

and postnatal age of the neonate should be established. If weakness has been present since birth, in utero acquired bacterial or viral infections, birth asphyxia and trauma, chronic placental problems, and congenital anomalies should be placed higher on the list of differential diagnoses. Lethargy and loss of suckle are often the first signs of neonatal illness. A full udder on the dam accompanies poor nursing behavior in the neonate. If the neonate is depressed and has injected mucous membranes and hyperemic coronary bands, then sepsis is the primary differential and the most life threatening. If the neonate is relatively bright but is becoming progressively weaker, consider peripartum hypoxia and early signs of neonatal encephalopathy. If the newborn shows signs of physical immaturity such as tendon laxity and silky hair coat, then weakness may be due to fatigue, hypothermia, hypoxia, and/or hypoglycemia. Unfortunately, many weak foals begin to fade as a result of multiple problems. Glycogen branching enzyme deficiency in certain Quarter Horse and Paint lineages is an example of a genetic mutation that is associated with a range of abnormal signs that could include persistent recumbency.[23]

If weakness is present without accompanying somnolence, then several other differentials should be considered, including trauma. If weakness is detected in one or more limbs immediately after birth, peripheral nerve and muscle damage associated with vigorous extraction from the birth canal should be ruled out. Affected limbs are weak and hyporeflexic, and there may be regions of cutaneous anesthesia.[24] The diagnosis is based on history and neurologic assessment and confirmed using electrodiagnostics after 10 to 14 days.[25] The prognosis for recovery is dependent on the severity of the neural lesion. Where axon continuity is preserved, the outlook is generally good with resolution within days to weeks; where there has been disruption to axons or whole nerves, the outlook is guarded. Regrowth and reinnervation of muscle is possible; axonal regrowth is estimated at 1 inch per month.[25] Foals with rupture of the gastrocnemius muscle will be unable to rise or stand unsupported.[26] The treatment includes limb stabilization and exercise restriction, with a guarded prognosis for an athletic career.

Neuromuscular diseases causing weakness without somnolence include botulism, nutritional myodegeneration (NMD, white muscle disease), and congenital myopathies. Botulism is an infection acquired via the gastrointestinal tract or through wounds or the umbilicus. Consequently, signs appear in neonates that are typically 10 days or older. Most cases of NMD associated with selenium and/or vitamin E deficiency occur during the first year of life among rapidly growing large animals, but an in utero form of NMD may occur, resulting in clinical signs in affected foals soon after birth. Clinical signs associated with NMD may include localized signs (dysphagia) or generalized paresis. Rhabdomyolysis in foals may be precipitated by stress such as sepsis or excessive periparturient hypoxia. Affected foals are reluctant to move, paretic, and occasionally dysphagic.[27] Pelvic limb muscles are often palpably firm. Elevated serum creatinine kinase and electrolyte disturbances of hyponatremia and hyperkalemia may be observed.

It should be determined whether drugs or anesthetics were administered to the dam before or at the time of delivery, as many agents cross the placenta and exert depressive and other adverse effects on the fetus. Phenylbutazone administered to normal pregnant mares crosses the placenta and results in substantial concentrations of phenylbutazone and its active metabolite oxyphenbutazone in the foal. Although clinical signs of phenylbutazone toxicity are not noted in the foals postnatally,[28] adverse effects are possible, particularly if other problems are present. Neonatal depression induced by drugs is particularly important following cesarean section deliveries. Maternally administered anesthetics and analgesics can suppress respiration and heart rate in the newborn. In horses, both xylazine and detomidine cause maternal and fetal bradycardia and reduced cardiac output.[29,30] These effects will cause a reduction in placental perfusion and fetal oxygenation. If the newborn shows depression associated with maternal administration of these drugs, an α_2-adrenergic antagonist, such as yohimbine, can be given. Adverse reactions to adrenergic antagonists in adult horses have been reported, some of which were fatal.[31]

Weakly basic drugs, when given to the mare, tend to concentrate in the fetus. Diazepam is an example of such a drug that crosses the placenta rapidly and accumulates in the fetal circulation resulting in lethargy, hypotonia, and hypothermia in the neonate following delivery. Flumazenil has been used to reverse the sedative effects of benzodiazepines. Maternal systemic illness of various types may also result in a weak newborn.

Many neonatal disorders are associated with severe electrolyte and metabolic derangements that may clinically manifest as weakness, including hypoglycemia, acidosis, hyponatremia, hypernatremia, or hyperkalemia. Such abnormalities may occur before or at the time of birth, and laboratory assessment of the weak newborn is essential for accurate diagnosis. Young foals with hypocalcemia can present with stiff gait, muscular tremor, tachycardia, sweating, muscular tremor, and recumbency.[32] Profound weakness associated with metabolic acidosis is commonly observed in foals with diarrhea. Correction of the acidosis by rehydration or intravenous administration of bicarbonate usually produces rapid improvement.

A number of congenital bacterial, fungal, and viral infections that cause abortions and stillbirths may also result in the birth of a live, weak neonate. Clinical manifestations of fetal infections depend on the age of the fetus and virulence and trophism of the infecting agent.

Generally, weakness secondary to uroperitoneum, renal, and liver failure, postnatally acquired infections, and neonatal isoerythrolysis are not expected to appear during the first 24 hours of age. Rather, foals with neonatal isoerythrolysis are usually presented between 24 and 72 hours of age, foals with uroperitoneum at 2 to 5 days or older, and neonates with postnatally acquired infections most commonly at 2 to 5 days of age or older.

Paraplegia and tetraplegia are commonly associated with spinal cord compression. Compression of the spinal cord in neonates most commonly results from vertebral body malformations, osteomyelitis, or fractures. Occipitoatlantoaxial malformations (OAAMs) involve the occipital condyles of the skull and the first two cervical vertebrae.[33] Vertebral body malformations occur sporadically, with genetic, nutritional, and/or environmental factors being implicated.[34] Osteomyelitis and vertebral body abscess may be a sequel to bacteremia following neonatal sepsis or pneumonia. *Rhodococcus equi* vertebral osteomyelitis with or without associated pulmonary infection has been reported in foals.[35] Leukocytosis and hyperfibrinogenemia are commonly observed in neonates with vertebral body abscesses. In most instances, vertebral abscesses do not infiltrate the pachymeninges, so the cerebrospinal fluid (CSF) is normal or has a mild elevation of protein and or a mild pleocytosis.

A complete neurologic examination is an important component of the work-up of the weak neonate. In particular, it should be noted if the weakness is accompanied by signs of somnolence or diffuse cerebral disease. Limb reflexes should be tested to establish whether components of the spinal reflex pathways are involved in the disease process (sensory nerve, lower motor neuron, neuromuscular junction, muscle). For example, foals with severe spinal cord hemorrhage may have relatively normal mentation, but spinal reflexes may be greatly diminished and profound weakness may be present. Animals with other types of spinal cord disease (e.g., trauma, vertebral malformations) may also show weakness and ataxia yet appear clinically to have normal cerebral function.

VetBooks.ir

Virtually any severe systemic disease such as generalized infection can cause both profound somnolence and weakness in a neonate without the presence of actual brain pathology. Primary neurologic disease in neonates is rare. Commonly, neurologic dysfunction is associated with multisystemic disease. A thorough comprehensive physical examination and work-up is required to define a problem list and formulate an appropriate management plan. A complete blood count, blood cultures, and assessment of immunoglobulin status provide an indication of the likelihood of sepsis. Hypoxia and metabolic acidosis are ruled out by assessing arterial blood gas status, and electrolyte disturbances and hypoglycemia are evaluated by measuring serum electrolytes and blood glucose concentration. Collection of cerebrospinal fluid to assess the central nervous system is usually performed when disease in other organ systems that may account for the altered mental state has been ruled out and no improvement in the patient's condition is observed following correction of electrolyte, blood gas, and metabolic derangements.

Sepsis

David P. Byrne • Chris Sanchez

Introduction

Sepsis is the major cause of morbidity and mortality in the equine neonate.[36,37] The response to microbial invasion of the bloodstream involves the systemic inflammatory response syndrome (SIRS), and it is this nonspecific inflammatory response, rather than the infectious organism, that is responsible for the classical signs of sepsis. Deterioration can occur rapidly, even in the face of aggressive treatment.

A variety of terms have been used to describe the host response to infection and associated processes and syndromes. A set of definitions was published by the American College of Chest Physicians and Society of Critical Care Medicine in 1992.[38] Briefly, SIRS refers to a systemic response, regardless of the inciting cause, that results in at least two of the following four clinical features: fever; tachycardia; tachypnea or hyperventilation; or leukocytosis, leukopenia, or a relative increase of circulating immature neutrophils. When SIRS occurs in response to a suspected or confirmed infectious process, the process is termed *sepsis*. Specific definitions for SIRS in equine neonates of various ages have been published that modify the original definitions to include venous lactate and glucose concentrations.[39] More recently, in humans, it has been suggested that sepsis should be suspected when there is a combination of hypotension, tachypnea, and altered mental status.[40] Interestingly, hyperlactatemia did not improve the accuracy of the model in this set of definitions. This is not without controversy, with some arguing that SIRS remains more sensitive in detecting systemic sepsis in humans.[41,42]

Infection with gram-negative bacteria occurs commonly in neonatal foals.[37,43–45] The pathophysiology of septic shock in gram-negative sepsis involves bacterial endotoxin and the subsequent release of proinflammatory and antiinflammatory cytokines.[46,47] Septic foals can have decreased gene expression of tumor necrosis factor (TNF)-α and TNF-β and increased expression of IL-8 relative to healthy foals[48] or increased gene expression of IL-4 and TLR4[49] among other abnormalities.

Predisposing Factors

Factors that may predispose to infection are numerous and include maternal illness, increases or decreases in gestational length, partial or complete failure of passive transfer, poor environmental conditions, and inadequate or improper umbilical care. Maternal factors have been reported to play a central role in 24% of bacteremic foals.[50] These include dystocia,[51] premature placental separation, placentitis, and various other forms of maternal illness such as colic and respiratory disease. Many of these factors coexist, but some occur primarily, such as placentitis, while others are secondary, such as premature placental separation. In utero infection of the fetus typically occurs due to an ascending infection of the fetal membranes and often results in premature delivery.[52] Because chronic placentitis often results in accelerated or precocious fetal maturation, a resultant premature foal born to such a mare likely has a greater chance of being septic but a higher probability of survival than a foal born at a similar gestational age to a mare without placentitis or other chronic stimulation.

Failure of transfer of passive immunity (FTPI) predisposes to an increased risk of postnatal infection. A number of studies have documented a close relationship between the foal serum IgG concentration, incidence of disease, and survival.[53–57] Colostrum administration via nasogastric tube was associated with disease in one report,[51] which supports the notion that route and timing of transfer are likely relevant, along with the potential for bacterial challenge. Farm management is important, including general hygiene, stocking density, exposure to disease, nutrition, and prepartum vaccination and deworming programs. Foals with partial failure of passive transfer were not at any greater risk of disease than those with adequate transfer on a well-managed Standardbred farm.[58]

Common postnatal routes of infection include umbilical remnants, gastrointestinal tract, and the respiratory tract. The umbilicus was traditionally regarded as the most important site for pathogen entry, but there has been heightened recognition of the role of the gastrointestinal tract as an important portal for bacteria.[59] The absorption of macromolecules in the proximal small intestine occurs through specialized cells via pinocytosis, with little discrimination between maternal immunoglobulin and other macromolecules. Absorption peaks shortly after birth and declines to less than 1% by 20 hours.[60] Unlike other species, the absorption of immunoglobulins does not appear to be Fc-receptor mediated in the foal. The foal will selectively absorb IgG and IgM over IgA.[61] In neonatal pigs and lambs, deprivation of milk or colostrum can extend intestinal permeability to immunoglobulins by up to 5 days.[62] In contrast, intestinal permeability to immunoglobulins cannot be delayed through withholding of macromolecules to newborn foals.[63] It is not known if closure can be hastened by the feeding of macromolecules immediately after birth in foals. The other main postnatal factors beyond FTPI include gestational age and environmental conditions. Foals with exceptionally short or long gestational lengths may be at a heightened risk for development of sepsis.[64] Poor environmental conditions can result in an increased bacterial load to the gastrointestinal tract, especially during the initial periods of udder seeking.[59]

Causative Organisms

A summary of reported bacterial isolates is presented in Table 17.1. *Escherichia coli* is the predominant organism isolated from septic foals in recent studies, irrespective of location or methodology.[44,50,57,65–72] The next most common isolate varies with era and geographic location. In the late 1990s a group from the University of Pennsylvania reported an important role of gram-positive bacteria (*Enterococcus*, *Streptococcus*, *Staphylococcus* spp.), whereas the nonenteric gram-negative organism, *Actinobacillus* spp., accounted for approximately 30% of all isolates at Ohio State University in the late 1990s.[44,50] When evaluating trends over time (1982 to 1989, 1990 to 1999, 2000 to 2007) *E. coli* remained the predominant isolate

Admission only: Yes, samples restricted to those obtained within 24 hours of a foal's admission to the hospital; *Blood cultures only? Yes*, samples restricted to culture of blood only; *No*, samples included blood or infected tissue collected at necropsy; *Number of foals*, number of foals from which bacteria were cultured; *NS*, not stated.

[a]Survivors calculated from total septic foal population.

VetBooks.ir

in a Florida population of sick foals; *Actinobacillus* spp. were more common in the 1980s relative to the 1990s and 2000s, *Salmonella* spp. were isolated less frequently in the 2000s relative to other decades, and enteric gram-negative organisms were less frequently isolated in the 2000s relative to the 1980s.[45] In a similar study from California, gram-positive species became more important over time, mostly due to a decrease in *E. coli* and an increase in *Enterococcus* species.[72] Other groups have demonstrated the importance of gram-positive infections.[57,70,73,74]

Systemic fungal infections are uncommon in neonatal foals, with *Candida albicans*, a dimorphic fungus, the most frequently reported.[75,76] *Candida* infections have been associated with lengthy hospitalization and invasive monitoring techniques or immunodeficiency. Prolonged antimicrobial therapy and administration of parental nutrition have been suggested as risk factors for the development of candidiasis. Infection should be suspected when there is a fever that is unresponsive to antimicrobial therapy. Most foals with systemic infection will also develop thrush (white plaques on the lingual surface) either concurrently or before showing clinical signs of systemic infection.

Physical Examination Findings

Physical examination of the mare and placenta is an important adjunct to the foal's physical examination. Any indication of placental or maternal abnormality should raise suspicion for neonatal illness. Initial clinical signs of sepsis in foals can be vague and highly variable. Frequently reported signs include decreased or absent milk intake, diarrhea, and lethargy, which may progress to recumbency. Examination should always include assessment of the mare's udder for fill; depressed foals will often stand with their head underneath the mare but fail to suck, leading to dried milk on their foreheads (Fig. 17.2). Clinical signs of dehydration occur as time progresses due to lack of intake. Tachycardia and tachypnea are common but not always present. Oral, conjunctival, and vulvar mucous membranes can become hyperemic, injected, and/or petechiated. Petechiae may be noted along the internal pinnae of the ears, and hyperemia can be noted along the coronary bands. Capillary refill time may be rapid in hyperemic foals or substantially delayed in those that have become hypovolemic. Other signs of hypovolemia include decreased borborygmi, poor peripheral pulses, cool extremities, and decreased or absent urine output. It should be noted that the absence of signs of hypoperfusion does not rule out sepsis.[77] Rectal temperature may be normal or mildly increased, or low if there has been progression to shock. Sepsis should not be ruled out on the basis of a normal or low rectal temperature. If untreated, these early signs can progress to septic shock and, often, death.

FIG. 17.2 A septic somnolent foal standing under a mare that is spontaneously lactating.

Septic foals can also have localizing signs associated with specific foci of infection. Diarrhea is common, and can be the first clinical sign noted. Other localizing signs include uveitis, seizures, joint effusion, lameness, physeal swelling, respiratory disease or distress, subcutaneous abscesses, patent urachus, and omphalitis.

Clinicopathologic Findings

Consideration of clinical signs and historical information is often sufficient for a provisional diagnosis of sepsis, but laboratory data will increase the index of suspicion. The most common hematologic finding in acute sepsis is leukopenia, characterized by neutropenia with shifting toward immature forms and toxicity (Doehle bodies, toxic granulation, and vacuolization). Septic foals, younger than 1 week of age, have lower total white blood cell (WBC) counts, neutrophils, and lymphocytes, as well as a higher number of band neutrophils and monocytes than healthy age-matched controls.[78] Premature or dysmature foals will commonly have a decreased neutrophil count in the absence of sepsis, but without a degenerative left shift or evidence of toxicity, unless prematurity is complicated by sepsis. Age is an important factor in considering hematologic findings. In older foals (8 to 14 days) with confirmed sepsis, the total WBC count, neutrophil count, and number of band neutrophils were higher than in age-matched controls.[78] A high fibrinogen or serum amyloid A concentration at or shortly after birth should raise the suspicion of in utero infection.[66]

Blood glucose concentrations are commonly abnormal in septic foals. Hypoglycemia (<100 mg/dL; <5.6 mmol/L) is common initially, especially in foals younger than 24 hours of age.[66] Hypoglycemia is primarily related to decreased intake, but endotoxemia can also contribute to hypoglycemia. Hyperglycemia commonly occurs in response to dextrose infusion in septic foals. Other biochemical abnormalities common in septic foals include azotemia and hyperbilirubinemia.[37] Acidemia and hyperlactatemia are also common.[79] Arterial hypoxemia and hypercapnia can occur in sepsis independent of pulmonary disease but are not consistent findings and are influenced by recumbency. Triglyceride concentrations are higher in foals with positive bacterial cultures,[80] and albumin concentrations are higher in septic and hypoperfused foals,[77,81] likely related to circulatory volume status.

The coagulation and fibrinolytic systems of the septic newborn are often abnormal, with clinically relevant decreases in antithrombin III and elevations in prothrombin time, activated partial thromboplastin time, fibrin degradation products, and D-dimer concentrations.[78,82] Some patients may develop active hemorrhage and/or thrombosis. This can include thrombosis of the aorta, iliac, femoral, or brachial arteries. Nonsurviving foals often have postmortem evidence of fibrin deposits in the lungs and other organs.[83]

Endocrine adaptations to illness, including sepsis, occur in neonatal foals. Plasma AVP concentrations are higher in septic foals on admission than in healthy and sick nonseptic foals.[84] Increased concentrations of adrenocorticotropic hormone (ACTH) and cortisol have been documented in both septic and nonseptic hospitalized neonates.[85–91] Some septic foals are capable of a stress response, while critical illness–related corticosteroid insufficiency occurs in others. Consequently,

VetBooks.ir

nonsurvival has been associated with both higher and lower cortisol concentrations and a high ACTH-to-cortisol ratio.[86–90] Evaluation of basal total cortisol, ACTH, and the cortisol response to ACTH stimulation can provide information regarding HPA axis status in septic foals.[88] Other endogenous steroids, including aldosterone, dehydroepiandrosterone sulfate, allopregnenolone, and 17α-OH-progesterone, have been shown to predict sepsis in neonatal foals, although commercial assays may not be widely available.[77] Similarly, sepsis is associated with alterations in the somatotropic axis, although considerable overlap between groups makes the interpretation of these alterations difficult in individual foals.[92] Septic foals often have dysregulation of calcium and phosphorous homeostasis, with lower concentrations of calcium and vitamin D and higher concentrations of phosphorous and parathyroid hormone.[93]

Establishing a Definitive Diagnosis

Blood culture is the gold standard for diagnosis of systemic bacterial infection. Identification of a causative organism allows for directed antimicrobial therapy, as well as monitoring for patterns of antimicrobial resistance. Samples for culture should be collected into a sterile syringe without anticoagulant from a large vein (usually jugular, cephalic, or saphenous) after surgical preparation. The sample should be placed into appropriate blood culture media using volumes consistent with manufacturer recommendations. For those foals receiving antimicrobial therapy before sample collection, an appropriate medium with resins may improve microbial recovery.[94] Collection from a venous catheter is acceptable, provided it is done directly from the catheter at the time of placement without compromise of aseptic technique. Healthy foals may have temporary bacteremia as detected by blood culture up to 12 hours of age.[95] However, false positives are unlikely in ill foals.

There are limitations to blood culture, including delayed results and reduced sensitivity. Many foals with histologic evidence of sepsis at necropsy have negative antemortem blood culture results. This can occur because of prior antimicrobial therapy or low circulating bacterial numbers. In one study, only 40% of *E. coli* infections were successfully identified by antemortem blood culture relative to recovery at necropsy.[69] These factors led to the development of scoring systems to predict sepsis.[96,97] The modified "sepsis score" is calculated using historical findings, physical findings, and laboratory data. The initial sensitivity and specificity of the score were reported at 92.8% and 85.9%, respectively,[96] but more recent data indicated regional variability with lower sensitivity and/or specificity.[50,65,74,98,99] Due to the heavy weighting of historical information and related problems, moderate to severely premature foals often have a positive sepsis score without positive blood culture. Many of the maternal problems resulting in prematurity can also lead to systemic sepsis. Consequently, this crossover is predictable. When the original or modified equine neonatal SIRS criteria were added to the modified sepsis score, the diagnostic accuracy of the scores was low.[74] The problem with clinical application of these scoring systems is their relatively low specificity and negative predictive value. While a "positive" score is supportive of sepsis, a "negative" score should not be used as a basis of withholding antibiotic therapy from an at-risk animal.

Therapy

Antimicrobial Therapy

Antibiotics are the mainstay of therapy for septic foals. Initially a broad-spectrum bactericidal approach is recommended with selection influenced by costs, availability, and local knowledge of common isolates. Recommended dosages for commonly used antimicrobials are listed in Table 17.2. Reported antimicrobial susceptibility patterns of microorganisms isolated from equine neonates are presented in Table 17.3. Antimicrobial therapy should begin immediately when sepsis is suspected and should not be delayed pending blood culture results, as culture and sensitivity data typically require 3 to 4 days. Therapy can be altered if required when these data become available. A minimum therapeutic course of 2 weeks is recommended for bacteremic foals without localizing clinical signs. If localizing signs, such as pneumonia or septic arthritis, are present, a minimum course of 4 weeks is recommended.[64]

A commonly recommended initial therapeutic approach involves combining an aminoglycoside, typically amikacin or gentamicin, with penicillin or ampicillin. Alternatively, ceftiofur can be used alone, or in combination with an aminoglycoside. The use of amikacin or gentamicin should be tempered in light of the foal's cardiovascular and renal status. If a foal is severely hypovolemic and azotemic, a safer initial choice would likely involve a third-generation cephalosporin. If amikacin or gentamicin is used, therapeutic drug monitoring is recommended to ensure appropriate individual dosing. If not available, then an alternative recommendation includes serial creatinine monitoring every 2 to 3 days and/or serial

TABLE 17.2

Recommended Antimicrobial Dosages

Agent	Preparation	Route	Frequency (h)	Dosage (/kg)	References
Amikacin	Sulfate	IV, IM	24	21-25 mg	401,402
Gentamicin	Sulfate	IV, IM	36	12-15 mg	403
Ampicillin	Sodium	IV, IM	6	25 mg	
Ampicillin	Trihydrate	IM	12	25 mg	
Penicillin G	Potassium	IV	6	22,000-40,000 IU	
Penicillin G	Procaine	IM	12-24	22,000 IU	
Cefotaxime	Sodium	IV	6	40 mg	100,404
Ceftiofur	Sodium	IV, IM	12	5 mg	405
Ceftiofur	Crystalline free acid	SC	72	6.6 mg	406
Cefpodoxime	Proxetil	PO	6-12	10 mg	106
Cefquinome	Sulfate	IV, IM	12	1 mg	107
Trimethoprim/ sulfamethoxazole		PO	12	30 mg	
Oxytetracycline	Hydrochloride	IV	12-24	5-10 mg	

These represent recommendations only. Label indications and national or international rules regarding off-label usage of antimicrobials remain the responsibility of the provider.

Antimicrobial susceptibility is expressed as a percentage of all isolates for which susceptibility to a given antimicrobial were reported.
EGN, Enteric gram-negative isolates; *GN*, gram-negative isolates; *GP*, gram-positive isolates; *NEGN*, nonenteric gram-negative isolates.
See Table 17.1 for key to study details.

urinalyses, including sediment examination. Cefotaxime is a good choice for foals with gram-negative meningitis[100] or those with poorly responsive pneumonia. Oxytetracycline has been recommended in foals with suspected or confirmed septic osteitis or osteomyelitis.[101]

Due to emerging resistance, trimethoprim/sulfa combinations should not be used in septic foals without documented sensitivity and then only as a long-term option following initial parenteral therapy. In contrast to older foals and adult horses, several aminobenzyl penicillins (amoxicillin and ampicillin) and first-generation cephalosporins (cefadroxyl and cephradine) have good bioavailability in young foals but a limited spectrum of activity.[102–105] Cefpodoxime proxetil, a third-generation cephalosporin available for oral administration, was effective against 90% of *Klebsiella* spp., *Pasteurella* spp., and β-hemolytic streptococci, and an increase in the frequency of administration would likely increase the effectiveness against *E. coli*.[106] Cefquinome is a fourth-generation cephalosporin licensed for neonatal sepsis in Europe, with good activity against *Streptococcus* spp., *Staphylococcus* spp., *Actinobacillus equi*, and the *Enterobacteriaceae*.[107,108] Fluoroquinolones, such as enrofloxacin, have an excellent spectrum of activity against gram-negative and some gram-positive bacteria but have been associated with arthropathy in foals.[109,110] Therefore use of these agents should be reserved for those cases where there is suspected resistance to other antimicrobial agents and informed owner consent.

Source control, where possible, should be instigated in any cases with identifiable local infection. This may include synovial structure lavage, abscess drainage, omphalitis resection, and removal of infected catheters.

Antifungal Therapy

Medical treatment options for systemic candidiasis include fluconazole, itraconazole, miconazole, and amphotericin B.[76,111] Fungal sensitivity profiles may help direct therapy if available. Pharmacokinetics of these drugs have not been established in foals. Amphotericin B (conventional form, not liposomal/lipid complex form) has been administered at a range of 0.1 to 0.5 mg/kg IV SID, starting therapy at the lower dose and increasing by 0.1 mg/kg increments per day.[76] Because this drug can cause potentially life-threatening nephrotoxicity, serum creatinine, urine production, and urinalysis should be monitored closely. Fluconazole has previously been administered at 4 to 10 mg/kg PO SID. This agent is cheaper and easier to administer and has far fewer side effects. Miconazole has also been used at a dose of 1 mg/kg IV q8h.[76] Voriconazole has also been used to treat pulmonary aspergillosis.[112]

Antiendotoxin Therapy

Many septic foals have detectable plasma endotoxin concentrations.[78] Concerns exist regarding the potential for antibiotics to exacerbate the release of endotoxin through death of circulating gram-negative bacteria. In vitro work has shown that β-lactam antimicrobials appear more likely than aminoglycosides (alone or in combination with ampicillin) to induce endotoxemia and TNF-α activity during treatment of *E. coli* sepsis. Agents commonly used for the treatment of endotoxemia include flunixin meglumine, pentoxifylline, and polymyxin B sulfate.[113,114] Recommendations are extrapolated with caution from work in vitro and in adult horses. Polymyxin B has been shown to improve certain clinical and clinicopathologic findings in experimental endotoxemia in foals,[115] but no survival benefit has been observed in septic humans using hemoperfusion with polymyxin B bound and immobilized to polystyrene fibers.[116] Flunixin and polymyxin B are potentially nephrotoxic, and flunixin has the potential for gastric ulceration. Pentoxifylline has also been shown to reduce mortality without adverse effects in septic neonates[117] but not adults.[118]

Cardiovascular Support

Cardiovascular support is critical in foals with hypovolemia, septic shock, or hypotension. When a foal presents in septic shock, initial fluid resuscitation choices commonly include a combination of crystalloid and colloid (such as hydroxyethyl starch) preparations. Meta-analyses in human medicine have shown that artificial colloid therapy is associated with coagulopathies and kidney injury in the critically ill.[119,120] Studies in healthy ponies and foals have not identified clinically significant effects, although this should be evaluated in critically ill foals.[121–123] Arterial or venous lactate concentration, systemic blood pressure, cardiac output, and central venous pressure can provide additional information regarding volume status and estimation of tissue perfusion.[124] Once normovolemia is restored, neonates typically require approximately 80 to 100 mL/kg/day (5 L/day for a 50-kg foal) in order to maintain adequate hydration. Clinicopathologic variables to monitor in septic foals include arterial or venous blood gases, electrolytes (especially sodium and potassium), and glucose. Physical parameters of importance include careful examination for the development of edema (conjunctiva, prepuce, ventrum, distal limbs, etc.), urine output and specific gravity, vital signs, and temperature of the distal limbs. Derangements in any of the monitored parameters should be addressed as they arise. One should be particularly mindful of sodium load in the neonate, as requirements and sodium tolerance can differ widely between foals, and specific care should always be taken to avoid fluid overload.[2] In human medicine, point-of-care ultrasound (US) has been used to evaluate "fluid tolerance" (i.e., whether additional IV fluid is likely to lead to fluid overload).[125,126] Respiratory variation in caudal vena cava collapsibility, as a component of fluid tolerance assessment, has been evaluated in healthy foals.[127]

If, with appropriate fluid resuscitation, hypotension and signs of poor perfusion persist, consideration should be given to the administration of vasopressors and inotropes, the use of which is covered earlier in this chapter. Previously recommended early–goal directed therapy protocols have been comprehensively shown to be no better than current usual care in the treatment of sepsis in humans.[128–130]

Antiacid Therapy

Although uncommon, sick foals can develop gastric ulcers in the glandular region of the stomach. The ulcers can preferentially occur in the cardiac gland region and may reflect reduced blood flow to the organ during hypovolemia. The use of prophylactic antiacid therapy is controversial and highly dependent on clinician preference. Gastric pH in critically ill foals can differ greatly from that seen in healthy foals.[131,132] Severely ill, predominantly recumbent patients frequently have alkaline pH profiles, and sick foals capable of acid production respond more variably to IV ranitidine administration than their normal cohorts.[132] Thus, glandular ulcer disease in sick neonates is likely not a strictly acid-related problem and factors such as alterations in mucosal blood flow may contribute. In addition, gastric alkalinization can contribute to bacterial translocation.[133] The use of antiulcer medications (ranitidine, omeprazole) was associated with an increased risk of diarrhea in a large multicenter retrospective study.[134] In that report, antiulcer medications did not appear to protect against ulcer development in a small number of foals in which ulcers were detected. Should one choose to use them, options for acid suppression include ranitidine, omeprazole, and pantoprazole.[131,132,135–137] Sucralfate remains a possible alternative for ulcer prophylaxis, especially in foals receiving nonsteroidal antiinflammatory drugs, without altering intragastric pH.

Additional Therapy

In light of the critical illness–related corticosteroid insufficiency identified in some septic foals, low-dose corticosteroid therapy

VetBooks.ir

has been suggested for a subset of the septic foal population. But given the wide variability seen in the septic foal population, more data are needed before such therapy is recommended. The combination of hydrocortisone, vitamin C, and thiamine has recently been suggested to have dramatically improved survival in a small group of septic human patients, although the data are limited and not widely accepted.[138] Treatment of coagulopathies may include plasma transfusions as a source of procoagulant and anticoagulant factors, or low-molecular-weight heparin, although the effect of the latter on patient outcomes is currently unknown in neonates. Its use was not associated with adverse outcomes in a small number of septic foals, at a higher dose (100 IU/kg dalteparin SC) than that used in adults.[139]

Focal Infection and Potential Sequelae

The lungs are a common location of focal infection in the septic foal, with a reported incidence of pneumonia ranging from 28% to 50%.[50,140] Many bacterial pneumonias are acquired in utero through aspiration of contaminated amniotic fluid. Respiratory rate and effort, thoracic auscultation, and rectal temperature can often alert the clinician to the possibility of pneumonia in a given animal. Respiratory function is best assessed in septic foals via arterial blood gas analysis.[124] Thoracic radiography and ultrasonography can provide an estimation of disease severity and distribution. In addition to hematogenously acquired pneumonia, septic foals can be at risk for aspiration of either meconium or milk, depending on their presentation. Directed antimicrobial therapy and maintenance of an acceptable arterial oxygen tension with intranasal oxygen insufflation are the most commonly administered forms of therapy. In those foals with severe hypercapnia in addition to hypoxemia, mechanical ventilation may be necessary.

Diarrhea and/or enteritis are common in septic foals, with reported incidence between 16% and 38%.[50,64,140,141] Conversely, approximately 50% of neonates with a primary complaint of diarrhea are bacteremic.[142,143] Therefore sepsis should be suspected in any diarrheic neonatal foal. Foals with *Actinobacillus* sp. bacteremia were six times more likely to have diarrhea than those with other isolates[50]; in another, gram-negative enteric bacteremia was positively associated with diarrhea.[45] With or without enteritis, septic foals can also display signs of ileus and/or colic. Most of these problems resolve with symptomatic treatment and systemic improvement. Ultrasound can be useful in differentiating enterocolitis from other forms of colic. Analgesic therapy in colicky foals is somewhat limited, and flunixin meglumine should be used cautiously due to the potential for gastric ulceration. Butorphanol can be used intramuscularly to control gut pain in foals with colitis without increasing the risk of ulceration and nephrotoxicity. Interestingly, diarrhea has been positively correlated with survival to discharge in one report of bacteremic foals.[45]

Omphalitis refers to infection of umbilical structures. Umbilical remnant infections are considered to be a common source of continued bacterial shedding. Ultrasonographic evaluation of these structures is critical, as external signs (pain, heat, and swelling) are frequently absent. Treatment options include long-term antibiotic therapy or surgical resection. The reported incidence in septic foals has ranged from 9% to 21%.[45,141] Many septic foals will develop a patent urachus without involvement of other structures. This problem will often resolve with continued antibiotic therapy, with or without topical therapy. Uroperitoneum in septic foals could result from ischemia and subsequent necrosis of the bladder and/or urachus. Most of these foals will not have classical serum electrolyte findings due to intravenous fluid therapy and limited milk intake. Routine ultrasonographic assessment of the umbilical structures is recommended in all hospitalized neonates in whom sepsis is either confirmed or suspected.

Meningitis is a rare but extremely serious complication. Major clinical signs include seizures and severe somnolence, although this is somewhat difficult to assess in a severely compromised foal. Other signs can include head tilt, strabismus, nystagmus, and extensor rigidity, depending on the areas of involvement. CSF normally provides a definitive diagnosis, with a pleocytosis (normally neutrophilic) being the typical abnormality. Prognosis is poor to grave, but if therapy is attempted, third-generation cephalosporins (such as cefotaxime) have been recommended.[100] The major differential diagnosis for neurologic signs in a septic neonate is neonatal encephalopathy (NE). Typically foals with NE present within 24 to 48 hours following birth, whereas the age of foals with meningitis is more variable. One report noted that none of 11 bacteremic foals with meningitis survived to discharge from the hospital.[45]

The most common ocular complication in the septic foal is corneal ulceration, noted in up to 12% of bacteremic foals.[45] Ulceration can occur due to entropion in a dehydrated foal or, more commonly, trauma. Because foals do not always show clinical signs of corneal ulceration, a daily ophthalmic examination, including fluorescein staining, should be performed in all hospitalized foals. Uveitis can also occur as an ocular extension of systemic disease and is associated with positive bacterial blood cultures and survival.[144]

Disorders of coagulation can occur in septic foals, manifested clinically by either hemorrhage or thrombosis. Probably the most common abnormality is jugular venous thrombosis at the site of an indwelling venous catheter. Other areas of thrombosis include the brachial artery, digital artery, metatarsal and metacarpal arteries, diffuse vascular thromboses throughout the distal limb, the aortic termination, the lungs, and the colon.[78,145–148]

Prognosis/Outcomes

Survival rates have increased from the 25% reported in the early 1980s.[66] More recent retrospective studies have reported short-term survival rates ranging from 45% to 55%.[50,65,141,149] Others have reported survival rates as low as 32% and as high as 70% to 72%.[67,78,140,150] Given the overall advances in neonatal care, it is not surprising that year of admission was positively correlated with survival in a University of Florida report (with an overall survival of 60%) from 1982 to 2007.[45]

Several factors have been associated with survival in retrospective studies. Barton and colleagues[78] reported that foals infected with gram-negative organisms were more likely to die than those with gram-positive infections, although this is not universally true.[57] In another study, the duration of illness before admission was inversely related to survival, while the ability to stand on admission was positively correlated with survival.[141] Foals were more likely to survive if they had a sepsis score <11, a negative blood culture at admission, blood glucose greater than or equal to 60 mg/dL (>3.3 mmol/L), body temperature greater than or equal to 100° F (37.8° C), TCO_2 greater than 15 mmol/L, or a low or normal fibrinogen in a study from the University of Georgia.[65] In a Florida study, age at admission, septic arthritis, band neutrophil count, and serum creatinine concentration were negatively associated with survival, whereas year of admission, diarrhea, rectal temperature, neutrophil count, and arterial blood pH were positively associated with survival to discharge in bacteremic foals.[45] In an Ohio study, foals with multiple blood isolates had longer periods of hospitalization but not decreased survival.[50] Arterial lactate concentration, either at admission or 18 to 36 hours after admission, was a good predictor of survival in a further study.[79] In a large, prospective, multicenter study, increased lactate concentrations were associated with increased odds of death in septic foals.[70] This relationship remained true when examining lactate concentrations over time during hospitalization, with

VetBooks.ir

septic foals having higher concentrations than sick, nonseptic foals.[151] Interestingly, lactate concentrations were slower to fall in septic foals, despite volume resuscitation, suggesting other sources of lactate production, or altered clearance. This is consistent with current understanding of lactate production in sepsis in humans.[152,153] While lactate concentrations in populations of nonsurvivors have been shown to be increased at all time points in comparison with survivors, considerable overlap between the groups makes prognostication difficult based on lactate concentrations alone.[154]

A foal survival score has been developed in a multicenter study using a seven-point scale and a combination of historical, physical examination, and clinicopathologic variables.[155] While this scoring system had a sensitivity and specificity for mortality of 96% and 71%, respectively, further external validation is required. Despite the multitude of scoring systems developed to predict survival, clinician gestalt has been shown to be more accurate in predicting survival than a multivariable model in a large population of ill foals.[156]

Few studies have addressed the long-term survival and performance of septic foals. In one report of bacteremic Thoroughbred foals, there was no significant difference in percentage of starters, percentage of winners, or number of race starts, relative to a control group of maternal siblings. But bacteremic foals had a lower number of wins, total earnings, and Standard Starts Index rating, relative to control maternal siblings.[45] This is similar to that reported for overall neonatal intensive care unit (NICU) survivors, where the percentage of starters was lower than the control population, but performance over a 2-year period was not different in those animals able to make at least two starts.[150] Also, NICU treatment was found not to significantly affect sales performance.[157]

Preventative Strategies

Clearly, given the wide range of potentially devastating problems associated with sepsis, prevention will always outweigh treatment, but no one program will ever totally eliminate the risk of sepsis. Not surprisingly, methods of prevention coincide with the documented risk factors and routes of infection previously discussed. The following suggestions comprise a basic guide one can offer to clients. While many of the presented options make sense, none have been proven to reduce the incidence of sepsis. Thus the decision to implement some or all of these practices will depend on the individual farm scenario.

Maintain a Clean Environment

While this is one of the most basic concepts in all of medicine, its importance cannot be overemphasized. With specific reference to the foaling situation, foaling stalls should be thoroughly cleaned and disinfected between mares. For each inhabitant, the stall should be cleaned at least daily, if not twice daily, and plentiful clean, dry, fresh bedding provided for the mare and foal.

Reduce the Potential Bacterial Load Introduced During Udder Seeking

Ideally, the mare's hindquarters, perineum, and udder should be thoroughly cleaned with soap and water before the introduction of the foal.[59] The key feature to this step, which is often overlooked, is that the mare must also be dried. This should be done just outside the stall, rather than in the stall to prevent contamination of the environment. This step requires a great deal of commitment on the part of the farm, as it is labor intensive.

Ensure Gastrointestinal Intake of Colostrum

The volume, quality, and timing of colostrum administration are all likely important, rather than just the quality. The ideal scenario involves feeding 6 to 8 oz (180 to 240 mL) of good-quality colostrum as soon as the foal develops a good, strong suckle reflex. One of the main concerns with this recommendation is the risk of milk aspiration when untrained individuals are trying to bottle feed newborn, potentially weak foals.

Confirm Adequate Transfer of Passive Immunity

Traditionally, transfer of passive immunity to the foal has been considered to be the most important factor in disease prevention. While other factors clearly play a role, adequate immunoglobulin transfer should still be assessed and managed, if necessary. A complete discussion on treatment of FTPI is included elsewhere in this text. It should be noted that plasma transfusion in septic foals is not as effective at increasing serum IgG concentrations as in healthy or sick, nonseptic foals.[158]

Ensure Appropriate Umbilical Care

This recommendation is followed by most horse owners, from the backyard client to the large breeding operation. No published studies in foals have critically evaluated the different preparations used for routine umbilical care. In human neonates, surprisingly few randomized, double-blinded clinical trials have broached this issue. In a review of published studies, 4% chlorhexidine was a popular choice and consistently reduced the risk of umbilical and periumbilical infections.[159] This concentration of chlorhexidine is also commonly used for foals and thus appears to be a better alternative to previously used povidone-iodine solutions. Use of iodine solutions results in brown discoloration of the external umbilicus and surrounding hair, and therefore have an advantage of allowing managers and clinicians to confirm that a disinfectant is being applied.

Monitor Foals Closely and Treat Suspect Foals Quickly

When identified early, sepsis can often be treated effectively on the farm with few complications. Thus when prevention fails, early intervention is critical. Any foal with a fever, diarrhea, lethargy, or inappetence should be thoroughly evaluated and treated appropriately.

Septic Arthritis and Osteomyelitis

Rachael L. Smith

Neonatal foals are particularly susceptible to septic arthritis, osteitis, and osteomyelitis.[160] The incidence of this form of sepsis was estimated at 1% of all foals in the 1970s[161] but has likely reduced in recent decades as a result of improved management practices. This manifestation of sepsis represents significant loss to the industry, with reported survival rates to discharge from veterinary facilities between 42% and 81%, but with only 30% of those with septic arthritis and 48% of those with septic osteomyelitis achieving long-term athletic soundness.[162–166] Prognosis is influenced by the number of joints affected, number of bones involved, age of the foal, and presence of other medical problems.[101,162,167]

A classification scheme for septic arthritis and osteomyelitis has been developed on the basis of radiologic and pathologic findings.[168] The "S-type" describes bacterial infection of the synovial membrane of one or more joints with no radiographic changes, but there is joint effusion and possible periarticular soft tissue swelling. This form is typically seen in the first 2 weeks of life, and the most commonly affected joints include the carpus, stifle, and hock. The "E-type," or epiphyseal, classification describes infection of the joint and osteomyelitis of adjacent subchondral bone. It is usually seen at 3 to 4 weeks of age, and common sites are femoral condyles, distal radius, distal tibia, or patella. "P-type," or physeal-type, classification

is used for cases of osteomyelitis of the physis on the metaphyseal side of the growth plate. This form occurs in foals 1 to 12 weeks of age and occurs most commonly in the distal radius or tibia, as well as the distal metacarpi/tarsi. The "T-type," or tarsal, classification describes osteomyelitis of the cuboidal bones of the tarsus or carpus.

Etiology and Pathophysiology

Joint and bone infections of neonates most commonly result from persistent or transient hematogenous dissemination of bacteria from distant sites of infection.[168,169] Gastrointestinal, respiratory and umbilical infection, and failure of passive transfer are common predisposing causes. Less commonly, infection can occur after direct trauma or penetrating wounds and extension of an infection from adjacent infected soft tissues. Common bacterial isolates include *Enterobacteriaceae (Escherichia coli)*, *Salmonella*, *Actinobacillus equuli*, *Klebsiella* spp., *Streptococcus*, and *Rhodococcus equi*.[170] Bacterial colonization of joints resulting from bacteremia is facilitated by the vascular pattern of neonates. Rapidly growing bones and joints require increased blood flow, derived from a main arteriole providing blood supply to the synovial membrane and epiphysis, and the nutrient artery supplying the metaphysis. In neonatal foals, transphyseal vessels connect epiphyseal and metaphyseal blood supplies. Bacterial deposition in the synovium and subchondral bone occur as epiphyseal vessels branch toward the articular surface and form hairpin bends ending in wide venous sinusoids—regions of lower blood flow, oxygen tension, and pressure. The synovial membrane lacks a basement membrane; therefore bacteria that are deposited in the subsynovial capillaries are able to readily migrate into the joint. Physeal infection is more likely to occur after closure of the transphyseal vessels, around 7 to 10 days of age, because of localization of the infection in metaphyseal vessel loops.[168,171] Colonization of bacteria in the articular, metaphyseal, and synovial vessels can lead to thrombosis and subsequent ischemic necrosis.[172] This can initiate a severe inflammatory response in associated tissues, producing classical clinical signs of joint effusion, heat, lameness, and pain on palpation of the periarticular tissues. Normal synovial fluid production and drainage is also impaired, leading to compromised articular cartilage metabolism. An influx of degradatory inflammatory mediators, white blood cells, serum proteins, and proteolytic enzymes leads to further disruption of chondrocyte metabolism and degradation of the cartilage.

The magnitude of the inflammatory response is determined by the virulence of the causative organisms, the size of the inoculum, and host resistance. The described sequelae resulting from infection highlight the importance of early diagnosis and treatment to achieve successful resolution before permanent degradative changes occur in the joint and periarticular tissue.

Diagnosis

Any lameness, joint effusion, or periarticular swelling in a neonatal foal should be considered significant and investigated regardless of history. Often, reporting is delayed as owners commonly suspect mare-induced trauma to the foal, or they may describe the foal as moving "stiffly" or "slowly" rather than being overtly lame. Large joints such as the stifle, hock, carpus, and fetlocks are more commonly affected.[163,166,172,173] Pain in the foot or swelling of the coronary band could also be due to septic arthritis or osteitis/osteomyelitis.[82,134] Other causes of lameness and swelling associated with joints include cellulitis, hemarthrosis, fracture, trauma, and subsolar/solar bruising of the foot (Box 17.1).

The most consistent and early clinical sign of joint sepsis is effusion. Periarticular swelling, heat, pain on palpation of the bone or joint, and restricted passive movement of the joint are commonly reported. Less consistent clinical signs include lameness, an elevated rectal temperature, and hematologic changes consistent with infection. Lameness may escape identification if foals are systemically ill, weak, or recumbent. Lameness can take 8 to 24 hours to develop after bacteria have colonized the joints.[174] If there is swelling detected in one joint, thorough palpation of all other joints is recommended. Regardless of history and complete diagnostic findings, it is prudent to treat any joint swelling or lameness in a neonatal foal as septic until proven otherwise.

BOX 17.1

Lameness in Foals

Septic arthritis/osteitis/osteomyelitis
Fracture
Common sites: PIII, physis of P1, proximal sesamoid bones, olecranon
Hemarthrosis
Cellulitis
Flexural deformity
Rupture of the common digital extensor tendons
Rupture of the gastrocnemius muscle
Subsolar/solar bruising of the foot
Laminitis
Peripheral nerve injury

Hematologic changes can be inconsistent early in the disease course, but typically by 72 hours post inoculation there is leukocytosis and hyperfibrinogenemia. These findings lack both sensitivity and specificity. Fibrinogen levels greater than 900 mg/dL (>9 g/L) can be a useful indicator for epiphyseal or physeal osteomyelitis, but again this is neither sensitive nor specific.[175] Ultrasonography can be useful in detecting bone irregularities; defining and classifying joint effusion; as well as detecting associated problems such as pneumonia, omphalitis, or omphalophlebitis.

In order to reach a definitive diagnosis of septic orthopedic disease, additional diagnostic tests are required. These include diagnostic imaging and synovial fluid analysis following arthrocentesis, including cytology, Gram stain, and bacterial culture. To facilitate these procedures, adequate restraint of the foal is required. For neonatal foals, diazepam (0.1 mg/kg body weight IV) provides around 10 to 15 minutes of sedation to perform minimally invasive procedures. Before synoviocentesis, the skin should be clipped and aseptically prepared at the site of needle placement. Chlorhexidine or povidone-iodine scrubs are commonly used with isopropyl alcohol. Practitioners should not be overly vigorous in preparation of the skin and should avoid use of abrasive swabs as the skin of foals is particularly susceptible to trauma. It is likely that repeated scrubbing will be needed during the course of treatment, so preservation of the epithelial integrity is important. Lavage of the prepared area following the procedure with saline, drying the skin, and application of a topical antibiotic or antiseptic emollient cream is recommended before covering the site. Intraarticular administration of antibiotic into the joint following synoviocentesis is recommended, even if sepsis is not yet confirmed on cytology.

Any region of fluid distention of the joint, identified by bulging or balloting of the joint capsule, is appropriate for sampling, provided there is awareness of local anatomy. Ultrasonography is recommended to identify pockets of synovial fluid. In joints such as the stifle, carpus, and hock where multiple joint compartments are in close proximity, the potential for communication should always be considered. For this reason, arthrocentesis from each compartment should be performed and the synovial fluid from each analyzed to determine the

exact joint involvement. A 20- to 21-gauge needle can be used to aseptically collect synovial fluid. Fluid should be collected for cytologic examination into an EDTA tube and a sterile serum tube for culture. Alternatively, synovial fluid can be injected into a blood culture medium to increase the chance of a positive culture. Confirmation of synovial sepsis from synovial fluid evaluation and testing is not always straightforward.[176]

Normal synovial fluid is of a light yellow to straw color, is transparent (should be able to see newspaper print through the tube and fluid), and has good viscosity. Signs consistent with sepsis include increased turbidity, darkening in color (dark yellow to orange), and reduced viscosity. In severe cases, flocculent debris may be identified. The total protein (TP) of normal joint fluid is typically less than 20 g/L. Septic fluid usually has a TP greater than 40 g/L, but values greater than 20 g/L should be regarded as suspicious if other findings are supportive of synovial sepsis. The total nucleated cell count (TNCC) and differential nucleated cell count are considered the most useful evaluation of synovial fluid when diagnosing sepsis. Typically cell counts that are considered diagnostic of septic arthritis are greater than 30×10^9 cells/L, but infection should be suspected with values between 10×10^9 cells/L and 30×10^9 cells/L, particularly if the percentage of neutrophils is high.[171,176] Sequestration of WBCs into fibrin clots within the joint can result in lower-than-expected cell counts. Normal synovial fluid has less than 10% neutrophils. A cytologic differential greater than 80% neutrophils is highly suggestive of sepsis.[177] Synovial fluid lactate, glucose, and pH have been evaluated to improve the accuracy of diagnosis, and it appears synovial lactate may be useful; however, reference ranges are yet to be established.[162]

Sympathetic synovitis results from increased blood flow to a region, most commonly due to adjacent infected bone. The TNCC and TP of synovial fluid in sympathetic effusions are often elevated, but the percentage of neutrophils remains less than 80%.[168] Despite a low sensitivity for identification of bacteria, a Gram stain of synovial fluid should be performed. If bacteria are present, the results can guide antimicrobial selection while culture results are pending. Given the difficulty in culturing bacteria from joint fluid, a Gram stain result can sometimes be the only available option.[172] Synovial fluid should be submitted for aerobic and anaerobic culture. Positive cultures are obtained in 55% to 85.7% of synovial fluid samples submitted.[162,165,178,179] This range likely reflects the different inclusion criteria and culture techniques used in the referenced studies.

A positive culture more accurately guides antimicrobial selection, but it is associated with a poorer prognosis.[179] Synovial biopsy for culture does not increase the chance of a positive culture compared with synovial fluid alone.[178] A blood culture should also be performed, especially in the neonatal foal. If septic physitis or osteomyelitis is present, culture of débrided and necrotic bone is indicated at the time of surgery.

Ultrasonography can aid in quantifying synovial distention, identifying the presence of intrasynovial masses, thickening of the joint capsule and synovial membrane, and identifying irregularities of the subchondral bone and abnormalities of the physis. The contralateral limb is used for comparison when there are findings of questionable significance. Figs. 17.3 and 17.4 show both longitudinal and cross-sectional ultrasonographic images of the diverticulum of the lateral femorotibial joint, respectively, in a foal with septic arthritis. Radiographs of the affected and contralateral limb should be taken because concurrent infection of the physis and subchondral bone is common due to the vascular network of neonatal foal joints and extension of infection.[172,180] Bone infection has been reported in 38% to 80% of foals with septic arthritis.[67,101,163,166,168,172] In the initial stages of septic arthritis, radiographic changes may be absent or demonstrate mild soft tissue displacement as a result of joint distention. As progression occurs, joint space narrowing may occur, associated with articular cartilage destruction, periosteal reaction, and subchondral bone osteolysis. Radiographic changes of bone sepsis are not evident until 7 to 10 days after the onset of infection.[169] Baseline and serial radiographs over time can help to determine the progress of the disease and response to treatment.[172]

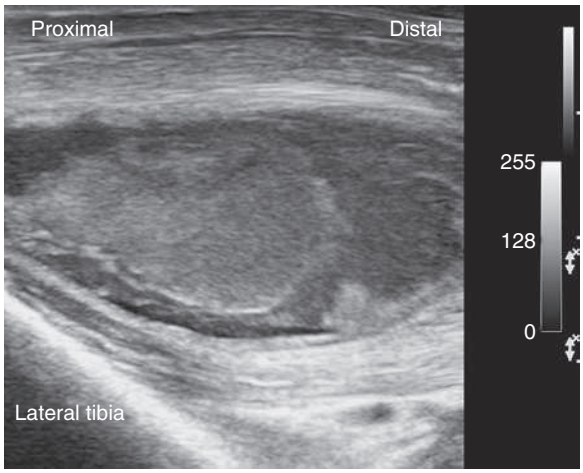

FIG. 17.3 A large mass of echogenic material consistent with fibrin. The distal aspect of the diverticulum of the lateral femorotibial joint is surrounded by hyperechoic synovial fluid.

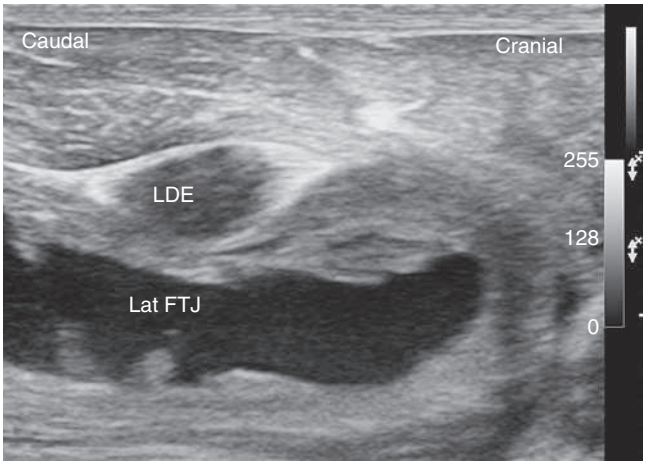

FIG. 17.4 The lateral femorotibial joint (Lat FTJ) compartment in cross-section positioned between the lateral tibia and tendon of the long digital extensor (LDE) tendon. The synovial fluid has increased echogenicity; the synovial lining and joint capsule is thickened with proliferative intrasynovial masses.

If radiographic examination is inconclusive or earlier identification of bone involvement is desired in cases where there is a high clinical suspicion of bone infection, advance imaging modalities should be recommended. Both computed tomography (CT) and magnetic resonance imaging (MRI) offer improved sensitivity for detection of bone and soft tissue pathology, respectively. These modalities are particularly valuable in the proximal limb or axial skeleton where overlying soft tissue and incomplete ossification of subchondral bone can limit radiographic evaluation of joint surfaces and physes.[170] CT provides increased sensitivity and detail with improved detection and characterization of periarticular lesions and osteomyelitis, but it is subject to availability and often requires general anesthesia. MRI offers superior imaging of periarticular soft tissue and cartilage, but the expense of the modality, limited availability, need for general anesthesia, and time for image

VetBooks.ir

acquisition limit the use of the modality for the diagnosis of septic orthopedic disease.[169]

It is imperative to clinically and diagnostically evaluate all other body systems in neonates with septic orthopedic disease to determine the presence of comorbidities, especially concurrent infections that have likely led to hematogenous dissemination to joints, bone, and physes. Failure to identify, diagnose, and treat comorbidities in neonatal foals will negatively influence prognosis when treating septic osteitis, physitis, or synovitis. In addition, serial body system and joint examinations are indicated on a daily basis to monitor response to therapy and identify development of additional sites of infection in joints or physes.[170]

Treatment

The early diagnosis of disease and initiation of aggressive therapy are paramount to successful outcomes. The cornerstones of therapy include resolution of distant underlying sources of infection, if present; systemic and local antimicrobial therapy; and drainage and lavage of the infected joint or joints. The choice of treatment regime will depend on facilities, economics, value of the foal, number and location of joints involved, any underlying disease process, presence of concurrent osteomyelitis, and identification of a causative organism.

Systemic Antibiotic Therapy

The selection of systemic antibiotics was discussed previously. Given the similarity between bacteria localized to joints of bone and those isolated from blood, the same initial protocols are warranted and should include broad-spectrum coverage, pending culture results. Despite a strong focus on local antibiotic delivery techniques for treatment of synovial or bone infection, the use of systemic antimicrobials is not negated and remains imperative for successful outcomes. This is likely due to primary and distant sources of infection and the development of multiple sites of joint infection due to hematogenous dissemination. Recently, a retrospective study of foals with septic arthritis reported that of the 85.7% of synovial fluid samples cultured that yielded growth, 62.4% were gram-negative organisms and 37.5% were gram-positive organisms.[162] Antimicrobial sensitivities for the isolates in this study suggest that aminoglycosides (gentamicin and amikacin) and cephalosporins (third generations or later) would be reasonable options for empirical treatment for septic arthritis in foals if gram-negative organisms are presumed to be the cause. Gram-positive organism susceptibilities were more varied with 81% tested susceptible to trimethoprim-sulfamethoxazole and 67% to ceftiofur. Most isolates were susceptible to fluoroquinolones, but the detrimental effects on developing cartilage and tendon cells preclude routine use in foals.[181,182]

Doxycycline (10 mg/kg PO bid) or oxytetracycline (5 to 10 mg/kg IV q12h) have been used successfully to treat septic arthritis and osteomyelitis.[164,183] Oxytetracycline has a relatively good spectrum of activity and good penetration into bone and synovial fluid. If osteomyelitis is present, continued treatment with systemic antimicrobials for up to 2 months is recommended. Serial monitoring of synovial fluid analysis is useful to determine the trend in response to therapy, but normalization should not determine when antimicrobials are discontinued due to the risk of recrudescence of infection if treatment is ceased too early.

Local Antibiotic Therapy

The local administration of antimicrobials allows delivery of higher concentrations to the tissues of interest. Intraarticular administration of antibiotics results in significantly higher synovial fluid levels than systemic routes. The technique is preferred when tourniquet application and regional perfusion are difficult, such as the proximal limb or axial skeleton. In addition, higher and more reliable antimicrobial concentrations are achieved in synovial fluid following intraarticular administration compared with regional perfusion techniques. Aminoglycosides, such as gentamicin (500 mg) and amikacin (125 to 250 mg), are commonly used (SID for 3 to 5 days) because of their effectiveness against many gram-negative pathogens. Ceftiofur sodium (125 to 500 mg) is also commonly used as an intraarticular therapy.

Regional limb perfusion techniques include intravenous (IVRP) and intraosseous (IORP) routes of antibiotic delivery, coupled with a tourniquet applied proximal to the affected joint or bone. IVRP or IORP can be performed concurrently with a joint lavage. A combination of sedation and local anesthesia or a short intravenous general anesthetic is usually required for these procedures, but these can be performed stall-side and should only take 30 to 40 minutes. The application of the tourniquet and injection of the infusate can be painful; therefore sedation and analgesia are required. Sedation can be achieved safely using diazepam (0.1 to 0.2 mg/kg IV) in combination with butorphanol (0.1 mg/kg IV). If general anesthesia is required, the regime just described serves as a good premedication, after which ketamine (2 to 2.2 mg/kg IV) can be used for induction. If additional time is required, the ketamine can be repeated. If the foal has minimal cardiovascular compromise, α_2 agonists, such as xylazine (0.5 to 1 mg/kg IV) or romifidine, in combination with butorphanol, also provide good sedation and analgesia; again, general anesthesia can be achieved through a follow-up bolus of ketamine.

The antibiotic is administered into a pressurized vascular environment, which aids in diffusion of the antibiotic from the vascular system into the interstitial tissues distal to the tourniquet. This allows high concentrations of antibiotics to be achieved in the poorly perfused and infected or ischemic tissues and exudate. Regional perfusion techniques typically achieve 5 to 50 times the MIC required to inhibit common pathogens in synovial fluid.[172,184,185] The techniques are preferred over simple intrasynovial administration, if osteomyelitis is present.

Administration of local anesthetic via the intravenous catheter or intramedullary screw before infusion of the antibiotic-saline combination is helpful in improving tolerance of the procedure, if general anesthesia is not used. The total dose of lidocaine used in the regional perfusion technique should be in the range of 1.3 to 5 mg/kg. Therefore for a 50-kg foal, the amount used should be between 3.25 and 12.5 mL of 2% lidocaine, with the lower end of the range used in very young foals because of a lack of pharmacokinetic data.

Following sedation or induction of general anesthesia, an Esmarch bandage (or equivalent 5- to 12-cm-wide elastic or rubber bandage) or a pressurized tourniquet cuff can be applied proximal to the affected region. It should only be left on for 30 minutes following infusion of the antibiotic and a maximum of 60 minutes total tourniquet application time. For IVRP a 22-gauge butterfly needle, Teflon catheter, or polyurethane over-the-needle catheter is advanced into a superficial vein below the tourniquet. A small amount of cyanoacrylate glue can be used to fix the catheter to the skin to prevent removal, kinking, or movement. Commonly used veins include the saphenous, cephalic, or palmar/plantar vessels. The perfusate (local anesthetic followed by antibiotic and saline) can be injected over 1 to 5 minutes.[186] Following injection, the catheter is removed and gauze swabs are placed over the site with several wraps of tape to provide pressure. This can be removed following the removal of the tourniquet after the appropriate time. The procedure is typically repeated at 24- to 48-hour intervals for three to five treatments, depending on the response to therapy.

The intraosseous route requires a custom-made cannulated cortical screw with a welded Luer-Lok adapter or an

VetBooks.ir

intraosseous infusion needle (Cook Critical Care, Bloomington, Ind.). A hole is drilled through the cortex of the metacarpus or metatarsus for placement of the screw, after which time perfusate can be injected. Because of the small size of foals and the specific equipment required, intraosseous perfusion is used in limited situations or equine hospitals. In addition, increased complications are recognized with the intraosseous technique.[186]

The aminoglycosides amikacin and gentamicin are commonly used since most joint infections are caused by gram-negative bacteria. Penicillin, cefazolin, and ceftiofur have also been used safely in local therapy, but only in response to culture and sensitivity testing. The size of foal and the area to be infused below the tourniquet should be considered when deciding on total volume, but volumes are typically between 30 and 60 mL, with 0.9% saline used to dilute the antibiotic. If local anesthetic is used, that volume is considered as part of the total perfusate. The daily systemic dose of aminoglycoside should be reduced by the amount used in the perfusion, and the total dose used in the perfusion should not exceed the total systemic dose. The procedure should be performed at the same time of day that the systemic dose is administered. Commonly recommended doses for foals are 250 to 500 mg of amikacin, 400 to 600 mg of gentamicin, and 500 mg of ceftiofur.[164,169]

Complications of IVRP or IORP include soft tissue swelling at the infusion site, thrombophlebitis, difficulty in injecting during IORP, and tissue sloughing. Most of these can be avoided with careful aseptic technique, by avoiding catheter repositioning and minimizing the number of procedures.[186]

Antimicrobial-containing substances, including collagen or beads made of bone cement such as polymethylmethacrylate (PMMA) or Plaster of Paris (POP), can also be implanted at the site of local bone infection. Their use within joints is not recommended due to the need for removal (PMMA) and rapid dissolution or inflammation incited (PMMA/collagen sponges). These beads are readily prepared aseptically for immediate use and, when using PMMA with a heat-stabile antibiotic such as aminoglycosides, can be gas or steam sterilized for later use. The beads provide an antibiotic depot when implanted adjacent to infected bone; however, the necessity for surgical removal following resolution of infection is one of the limitations of their use. The beads can be prepared by adding 10% to 20% antibiotic (2 to 4 g) to the bone cement powder (20 g), then mixing with the liquid (monomer) until the mixture can be molded into beads or cylinders. The larger surface area allows for increased antibiotic elution.[170]

Intrathecal catheters and constant rate infusion pumps can also be used for local delivery of antibiotics to infected synovial cavities in foals. High antimicrobial concentrations in synovial fluid lead to high concentrations in adjacent bone and physes.[187] Catheters can be passed into synovial cavities via arthroscopic guidance or placed directly. Included items are an intrasynovial catheter, flow control tubing, and an elastomeric pump (Mila International, Florence, KY.). The pump allows continuous rate delivery of the selected antibiotic solution. The flow of the pump and concentration of the solution is determined by the amount of antibiotic to be delivered over a timed period.[170] Maintenance of the catheter and the pump through frequent and careful monitoring is required prevent complications, such as dislodging, blockage, or restricted delivery rates.

Drainage and Lavage of the Septic Joint

Joint drainage, lavage, and débridement are important components in the management of synovial sepsis. The aim of lavage is to reduce the number of organisms in the synovial fluid, remove debris and inflammatory products, and reduce the level of pain associated with inflammation and joint distention. Techniques include needle lavage (ingress-egress, through and through), arthroscopic lavage and débridement, or arthrotomy. Needle lavage has the most beneficial effect if performed within 24 to 48 hours after the onset of infection, or, more importantly, before accumulation of fibrin. Ultrasound can aid in determining the location for needle placement and the amount of intrasynovial fibrin. A large amount of fibrin or intrasynovial masses will compromise lavage as a result of needle plugging. It is also unlikely that fibrin will be removed by needle lavage. Aggregates of microorganisms can be sequestered in fibrin and escape the effects of antibiotics, resulting in persistence of clinical signs or recrudescence of infection once therapy has been discontinued.

For needle lavage, the skin should be clipped and aseptically prepared, and the foal sedated or anesthetized as described previously. Synovial fluid should be collected for confirmation of sepsis or for serial cytologic monitoring to assess response to treatment. If general anesthesia is not used, the joint can be distended with local anesthetic after a single needle placement. The ingress-egress lavage technique involves repeated distention of the joint with sterile saline, followed by aspiration using a single portal. The technique is indicated in joints that have difficult access or where additional needles have become plugged or displaced from the joint. Through-and-through lavage is more commonly used. After distention of the joint with sterile saline or local anesthetic, additional superficial pouches of the joint become visible, aiding in placement of further needles. Needle size is based on clinician preference, but usually 18- to 14-gauge needles are used. Practitioners placing additional needles must try to keep the joint distended to avoid iatrogenic damage to the cartilage. Precise landmarks for needle placement are not necessary, but a sound knowledge of the local anatomy and visualization of the three-dimensional structure of the joint will help to maintain correct placement of the needles during the lavage. Between 1 and 2 L of physiologic saline or lactated Ringer solution are typically used to complete the lavage. The bags can be pressurized and attached to the ingress needle, allowing the clinician to place additional needles and subtly adjust needle position to facilitate flow. The risk of using a pressure bag system is rapid delivery of saline outside the joint if the ingress needle position changes slightly. Joint lavage becomes futile once subcutaneous saline restricts the distention potential of the joint pouches. In joints with moderate periarticular soft tissue structures or swelling, the author prefers to use 20- to 30-mL syringes to lavage the joint. Any increase in resistance to injection is easily appreciated, and correction of needle placement can occur before fluid is delivered outside the joint (Fig. 17.5). The use of different ingress needles is recommended to increase turbulence and facilitate removal of joint debris, irrespective of whether syringes

FIG. 17.5 Lavage of a septic joint using a syringe and separate egress needle.

VetBooks.ir

or pressurized bags are used. This also prevents the egress needles from plugging with fibrin. On completion of the lavage, as much fluid as possible should be expressed before removing all needles except one, which can then be used to administer intraarticular antibiotic.

The number and frequency of needle lavages are determined by the response to treatment. If the clinical signs progress in the face of 3 to 5 days of systemic and local antibiotic therapy and needle lavage, then reevaluation of the foal including US and radiography is indicated. Signs of treatment failure include persistent lameness or pyrexia, periarticular swelling, persistence or worsening of joint effusion, additional joint involvement, or failure to decrease synovial cell counts or differential. It is important to identify if there has been subchondral bone lysis. Treatment failure may prompt an antibiotic change and/or more aggressive joint lavage via arthroscopy or arthrotomy, if arthroscopy is not available. Arthroscopy offers many advantages over needle lavage and arthrotomy and is the preferred choice for chronic or refractory cases of synovial infection, or those where there is evidence of fibrin or subchondral defects within the joint. The technique permits superior visualization of most aspects of the joint, including the articular cartilage, bone, joint capsule, and synovial membrane. Targeted lavage and débridement can be achieved for removal of fibrin and debris, synovial resection, and débridement of necrotic cartilage or subchondral bone. Arthroscopic and arthrotomy approaches and intraarticular anatomy of commonly affected joints are reviewed comprehensively elsewhere. Arthrotomy is generally reserved for chronic or refractory cases that have been poorly responsive to other forms of lavage and débridement. It is imperative that a sterile absorbent bandage is maintained for drainage of synovial fluid to reduce the risk of ascending infection.

Generally, the duration of local antimicrobial administration (intraarticular, regional perfusions or continuous delivery systems) is determined by clinical and synovial cytologic improvements, including resolution of joint swelling, lameness, and a neutrophil percentage below 80%. Systemic antimicrobial administration is usually continued for a minimum of 2 weeks beyond the resolution of clinical signs.[170]

Septic Osteomyelitis

Septic osteomyelitis occurs as a primary disease entity or concurrently with septic synovitis, with infections commonly occurring at the epiphysis of long bones, metaphyseal side of growth plates, costochondral junctions, and articular facets of vertebral bodies. Radiographic evidence of osteomyelitis includes regions of focal loss of bone density, osteolysis, or sequestrum formation. Necrotic bone can act as a nidus for continued bacterial growth. The treatment of osteomyelitis includes systemic and local antibiotics and possible débridement.[164,188] Necrotic subchondral bone can be débrided using arthroscopy, and infected physeal bone can be débrided under radiographic or fluoroscopic guidance. Débridement of necrotic bone is not indicated in extensive lesions where mechanical joint stability may be jeopardized or where the surgical access and débridement would create significant surgical complications.[164,188] Evidence suggests that surgical curettage may not offer significant advantages over prolonged systemic and local antibiotic therapy alone.[164,183,189] In addition to the regional perfusion techniques described previously, there is occasional indication for implantation following débridement of antibiotic impregnated polymethylmethacrylate, calcium sulfate, or collagen sponges. These substances elute antibiotic at the site of bone infection.[171]

IV tetracycline (5 to 10 mg/kg IV q12h) or oral doxycycline (10 mg/kg bid PO), along with local treatment with amikacin (IVRP or IA 250 to 500 mg), is indicated if culture and sensitivity results suggest susceptibility, or if culture results are unavailable. Surgical débridement is indicated if there is radiographic evidence of sequestrum formation, chronicity of the disease in the face of medical therapy, or progression of the osseous infection.

In cases of osteomyelitis, serial monitoring of fibrinogen or SAA may aid in determining the response to therapy. A positive response results in decreasing SAA levels over 48 to 72 hours, and this commonly precedes improvement in lameness.

Management and Adjunctive Therapy

Nonsteroidal antiinflammatory drugs (NSAIDs) are indicated in the management of septic orthopedic disease resulting from antiinflammatory, analgesic, and antipyretic effects. Commonly used NSAIDs include flunixin meglumine, ketoprofen, phenylbutazone, and, less commonly, ibuprofen. Dosages cannot be directly extrapolated from adults because healthy foals have a greater volume of drug distribution and prolonged clearance.[190] For flunixin and ketoprofen, this results in a dose rate that is 1.5 times that of the adult dose and extension of the dosing interval to q24h. The drugs should be used judiciously in compromised or critically ill foals because of the potential adverse effects such as gastrointestinal (GI) ulceration, nephrotoxicity, and platelet dysfunction. Oral meloxicam at a dose rate of 0.6 mg/kg q12h achieves plasma concentrations that are likely therapeutic without evidence of drug accumulation in plasma. Foals appear to be more resistant to the adverse effects of meloxicam than adult horses, and drug clearance was more rapid in foals.[190] If additional analgesia is required, butorphanol (0.05 to 0.1 mg/kg IV or IM) or transdermal fentanyl patches (100 µg/h patch) can be used safely in foals. The clearance and systemic uptake of butorphanol are faster in foals, suggesting that higher doses may be required. A dose rate of 0.1 mg/kg of butorphanol-provided analgesia for 150 minutes in 4- and 8-week-old pony foals.[191]

The affected limb should be bandaged during treatment to cover needle/arthroscopy portals, provide compression and support to the limb, limit swelling and reduce pain, and absorb exudate if an arthrotomy has been performed. Application of bandages with adequate padding in the secondary layer is recommended in the distal limb because of the combination of thin skin, bony protuberances, and minimal subcutaneous soft tissues. Adhesive dressings can be used over joints where a bandage cannot be maintained.

Restoration of joint health and range of movement is important following infection. Gentle forced flexion and extension of the joint while non–weight bearing will help maintain joint function and movement. The foal should be stall confined and weight-bearing exercise avoided for 3 to 4 weeks following the resolution of infection and clinical signs. The stall should have a deep bedding of clean straw to reduce the risk of pressure necrosis during recumbency. The stall should be cleaned two to three times a day to reduce the risk of the foal lying in feces or urine-soaked bedding. Handlers and clinicians should use strict personal hygiene when treating foals. Controlled hand walking of the mare on a daily basis for 1 to 2 weeks should be initiated before free turnout.

The decision to discontinue antibiotic therapy is based on clinical judgment and resolution of clinical, hematologic, radiographic, and cytologic abnormalities. Generally, local antibiotic therapy and lavage are continued until normalization of the synovial fluid and cytology, and systemic antibiotic therapy is continued for 2 to 3 weeks beyond the resolution of clinical signs.

Prognosis

The prognosis of foals with septic arthritis/osteomyelitis is dependent on a number of factors, but short-term survival is

considered good to excellent with studies reporting 71% to 81% survival to discharge.[101,163,166] The prognosis for future athletic performance is less favorable, with 30% to 48% of foals affected with septic arthritis/osteomyelitis going on to race.[101,166,167] Factors affecting prognosis include prolonged duration (>24 hours) of signs before the initiation of treatment, concurrent systemic disease or comorbidities, the number of joints infected, the location of infected joints, the presence of concurrent osteomyelitis, and the type and diversity of bacteria involved. The financial constraints for treatment, facilities, and technical skill available for treatment and the expected long-term use of the foal can also affect outcomes.[164,166,167,171,172] These factors and the high cost and long duration of treatment should be considered when counseling owners. Foals that are treated expediently with appropriate systemic and local antibiotic therapy and without concurrent disease may have a more favorable prognosis for survival and athleticism than previously indicated.[162,170]

Noninfectious Causes of Lameness

Rachael L. Smith

Fractures occur relatively commonly in young foals and are an important differential diagnosis for foals that are lame (see Box 17.1). They are most often due to traumatic insult or an isolated event. Fractures are differentiated from septic arthritis or osteomyelitis through history and physical findings; relevant laboratory data, including hematology and synovial fluid analysis; and, most importantly, diagnostic imaging. Several factors may predispose foals to fracture, including prolonged stall confinement leading to osteoporosis and weakened soft tissue support structures, trauma from the dam or other horses, or management systems that allow overexercise.[192] Common sites of fracture in the distal limb include the distal phalanx, physeal fractures of the first phalanx, and proximal sesamoid bones. Physeal fractures of other bones are also common due to the relative weakness of this structure and are described by the Salter-Harris classification system. Olecranon fractures are the most common fracture of the upper limb. Premature or dysmature foals are prone to crushing injuries of the cuboidal bones of the carpus or tarsus.

In foals, rupture of the common digital extensor tendon may be present at birth or develop within a few days of life. Rupture occurs within the carpal synovial sheath and produces swelling over the dorsolateral surface of the carpus at the level of the middle carpal and carpometacarpal joints. Palpation of the fibers reveals tearing of the tendon and can be confirmed with ultrasonography. Splinting of the limb is required in foals that continually buckle forward at the fetlock. Box confinement for the first 3 to 4 weeks usually results in healing. Surgery is not required, and the tendon ends usually reappose over 6 months with minimal swelling and a good long-term prognosis.

Rupture of the gastrocnemius muscle at the level of its fossa in the femur can also occur during parturition, especially if assisted, or if the stifle is forced into extension during delivery while the hock is flexed. Hyperflexion of the hock occurs, and diagnosis of this is confirmed with concurrent flexion of the hock and extension of the stifle (Fig. 17.6). Ultrasound evaluation usually shows hemorrhage within the muscle belly and edema at the fossa of the femur. Treatment is complete stall rest if the foal can bear weight, but if the hock is severely flexed, a full limb case should be applied. The prognosis for long-term soundness is guarded.[26]

Congenital contractural deformities of joints can be bilateral or unilateral and present at birth. They are usually the result of external environmental factors during gestation, bone or joint malformation, or other physiologic causes such as intrauterine malpositioning. They are described with reference to the affected joint and can occur in the carpus, fetlock, pastern, coffin joint, or tarsus. Diagnosis of contractural deformities is relatively straightforward based on the inability to straighten affected joints and difficulty in standing and movement at birth as a result.[172] This predisposes to failure of passive transfer of immunoglobulin by impeding the ability to adequately nurse. The degree of contracture varies from mild to severe and may be associated with scoliosis and/or torticollis.[193] Conservative therapy consisting of bandaging or splinting the limbs to induce tendon laxity may be helpful. Care must be taken to provide adequate padding under the splint and to reset the splint every day. Oxytetracycline (2 g slow IV) in combination with splinting induces relaxation of the musculotendinous unit, and although results can be remarkable, they are not always reliable[172]; repeat treatments are often required.

FIG. 17.6 Rupture of the gastrocnemius muscle.

Twins, premature foals, foals that are small for gestational age, and foals with in utero–acquired infection are likely to have incomplete ossification of cuboidal bones at birth. Foals with substantially reduced ossification may damage bone with limb loading. Limited exercise may be prudent until ossification begins to increase radiographically, which can be within 7 days. Hypothyroidism has been identified in foals with angular limb deformities, contracted tendons, and tarsal bone collapse.

Young foals can suffer physitis when there is excess load caused by overexercise or weight on the newly forming bone, or as a result of normal loading on abnormal conformation. The physis of the distal metacarpus/tarsus or proximal phalanx is most commonly affected. Clinical signs can vary and be subtle, such as a stiff gait, shortened cranial phase of stride, trembling when standing, or buckling forward at the carpus or fetlock. Pain in the physis can lead to contracture of fetlock tendons. Treatment is aimed at reducing pain with anti-inflammatory therapy and reducing exercise level or correcting underlying angular limb deformities.[172]

Other causes of lameness and swelling associated with joints include cellulitis, hemarthrosis, subsolar/solar bruising of the foot, and hoof wall cracks causing laminae pain.

Seizures

Guy D. Lester

Recognition

Foals have a lower seizure threshold than adult horses.[194] Seizures are generated by abnormal electrical activity within the cerebral cortex. Depending on the location and extent of the abnormal activity, the seizures may be partial or generalized. Generalized seizure activity is characterized by recumbency, widespread involuntary muscle activity, paddling of the limbs, and extensor rigidity. Partial seizure activity may be more difficult to identify and could be limited to mild movements of the face and jaw, or stretching of the limbs.[25]

Rapid eye movement (REM) sleep can be easily confused with seizure activity. Normal activity is particularly prominent in premature or dysmature foals. Signs can include motor activity, including rhythmic paddling of the limbs, neck extension, chomping of the lips, rapid eye movements, and vocalization.[195] Episodes can last several minutes and be distinguished from seizure activity by attempting to arouse the animal. A foal in REM sleep should be easily aroused to full consciousness.

A foal that is simply resisting restraint in lateral recumbency may also appear to be seizuring, and violent paddling of the limbs and occasionally opisthotonos are noted. If confusion exists as to the cause of the activity, the animal should be encouraged to stand and its behavior reevaluated.

Once seizure activity is identified, a complete history should be obtained, including a detailed description of the delivery process, and complete physical and neurologic examinations should be performed. Any signs of trauma, infection, or congenital malformations should be noted. Evaluation of hematologic data and IgG status, combined with historic and physical examination parameters, result in an assessment of the likelihood of sepsis. Blood glucose and serum electrolyte concentrations should be determined promptly. A biochemistry panel, blood gas analysis, bacterial cultures of blood and other body fluids, and possibly CSF analysis complete the database in most cases.

CT or MRI scans are advanced diagnostic procedures for evaluating the anatomic causes of seizures. Premortem diagnosis of agenesis of the corpus callosum and associated malformations was made using CT scanning in a foal that had an abnormally shaped head and seizures refractory to anticonvulsant therapy.[196] Identification of the specific abnormalities early in the clinical course allowed the owners to make more of an informed decision regarding the treatment of the foal and the clinicians to acquire valuable information regarding the prognosis of a specific malformation in the horse.

Seizures in foals have numerous causes (Box 17.2). The most common cause of seizure activity in foals is described by the syndrome known as *neonatal encephalopathy* (NE).

BOX 17.2

Seizure Disorders in the Neonatal Foal

Neonatal encephalopathy
Bacterial meningitis
Viral encephalitis
Benign juvenile epilepsy
Lavender foal syndrome
Kernicterus
Hepatic failure
Congenital brain disease
Hydrocephalus, hydranencephaly
Head trauma
Hypoglycemia
Electrolyte disorders
Hypocalcemia, hyponatremia, hypernatremia
Tetanus
Toxicities
Ivermectin, moxidectin
Glycogen storage disease IV
Hyperammonemia of Morgan foals

Neonatal Encephalopathy

David Wong

NE is one of the most common neurologic diseases affecting neonatal foals with a reported incidence of 1% to 2% of all equine births.[197] Other synonyms for NE reflect proposed etiologies of the disease, such as hypoxic-ischemic encephalopathy (HIE), perinatal asphyxia syndrome (PAS), and neonatal maladjustment syndrome; alternatively, more descriptive names reflecting the clinical manifestations of NE, such as barker, wanderer, or dummy foal, also have been used.[6] It is important to note that foals with NE may have a hypoxic-ischemic event contributing to the disease process, but it is not uncommon for foals with NE to have no evidence of hypoxia-ischemia and an apparently normal birth. Therefore other associated pathophysiologic mechanisms, such as excessive neurotransmitters, inflammation, and/or abnormal postpartum hormonal concentrations, also might contribute to the development of abnormal neurologic function.[198–201] In this text, the broader term of NE is used rather than HIE or PAS. Despite the frequency with which veterinarians encounter NE, there are no direct studies in regard to the pathophysiology of NE in foals, thus the reader must acknowledge this limitation as the knowledge of this condition has been extrapolated from infants and other animal models.

Pathophysiology

The exact biochemical and pathophysiologic mechanism(s) that result in NE are unknown, but at a rudimentary level, reduction in cerebral blood flow and oxygen to tissues during the antepartum (maternal hypotension, severe hypoxia, infection, placental insufficiency); peripartum (cord occlusion, premature placental separation, dystocia); or postnatal (neonatal shock, respiratory or cardiac arrest) period is believed to be a central theme in many affected patients.[201] After a reversible hypoxic-ischemic brain insult, neuronal injury and/or death occurs in two phases: an acute, primary neuronal cell death followed by a delayed phase of cell death. The primary or acute phase of injury results from reduced cerebral blood flow, which consequently decreases both oxygen and glucose delivery to the brain, thus resulting in a switch to anaerobic respiration and concomitant decrease in phosphocreatine and adenosine triphosphate (ATP) and increased lactic acid production.[202,203] The decreased availability of ATP causes failure to maintain cellular integrity and homeostasis, in part due to decreased energy available to maintain both low intracellular calcium concentrations and the normal activity of cell membrane Na^+/K^+ pumps.[204] Not only does excessive influx of sodium into the cell cause concomitant movement of water into neurons, resulting in cell swelling and edema formation, but it also results in depolarization of neurons, which precipitates the release of the excitatory neurotransmitter, glutamate.[205] Glutamate also accumulates in the extracellular space because of failure of energy-dependent glutamate uptake back into neurons.[205,206] Glutamate then activates receptors within the central nervous system (CNS), resulting in sodium entry through ionotropic receptors, passive influx of chloride and water, additional influx

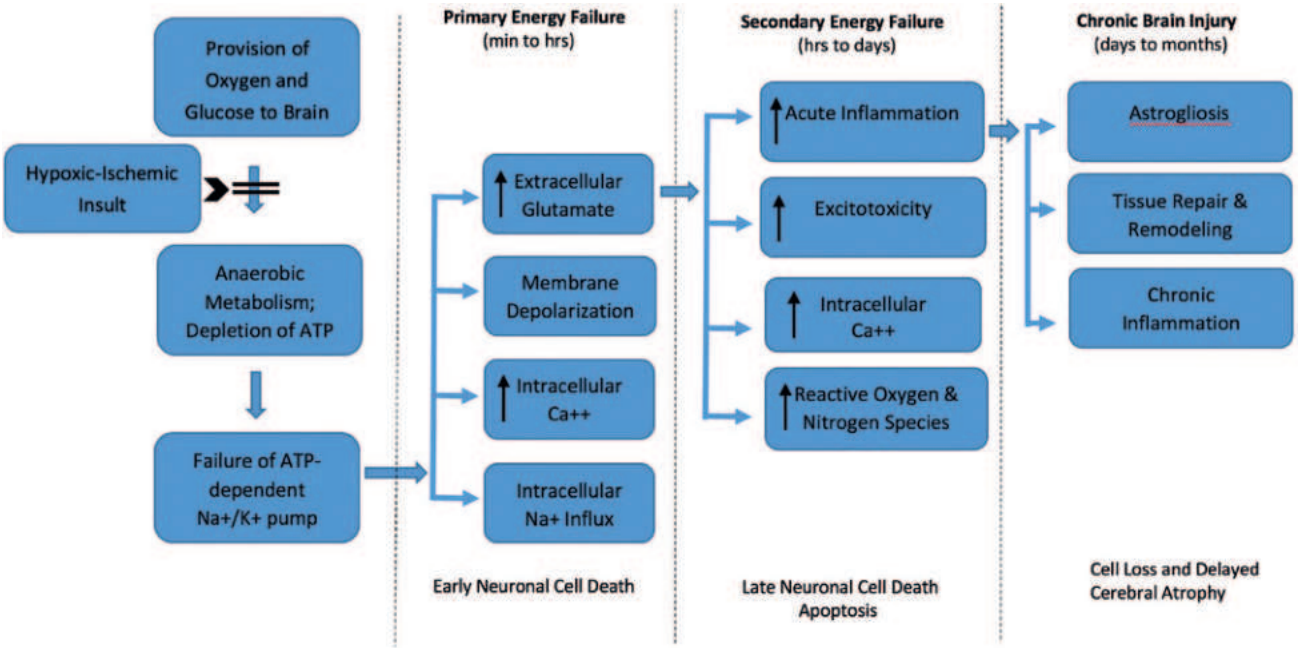

FIG. 17.7 Proposed pathophysiologic mechanisms associated with neonatal encephalopathy. Hypoxic-ischemic insult results in deprivation of oxygen and glucose to the central nervous system and cells shift to anaerobic metabolism. Reduction in adenosine triphosphate causes failure of energy-dependent cell membrane ion channels resulting in acute intracellular influx of calcium and sodium, along with cell membrane depolarization and accumulation of extracellular glutamate. This series of events can lead to cell swelling and cell death (primary energy failure). If initial insult is prolonged or severe, cascade of events can lead to excitotoxicity and increased production of inflammatory molecules and reactive oxygen species/reactive nitrogen species resulting in further cell death and apoptosis (secondary energy failure). Chronic brain injury, characterized by astrogliosis, chronic inflammation, and tissue repair and remodeling can occur over days to months and further contribute to loss of brain cells and cerebral atrophy. *(Adapted from Li B, Concepcion K, Meng X, et al: Brain-immune interactions in perinatal hypoxic-ischemic brain injury. Prog Neurobiol 159:50–68, 2017.)*

of calcium, cell swelling, and potential cell lysis.[204,206] Depending on the severity of the initial insult to the brain, the acute phase of primary energy failure can result in impaired cellular integrity, disruption of the cytoskeleton and cell membrane, and ultimately cellular necrosis. Upon cell rupture, cellular contents are released, which results in additional inflammation. Microglia subsequently migrate into the area of necrosis and release further inflammatory mediators that can damage the CNS. If the insult is less severe, cells may recover or undergo apoptosis.[206] Once blood flow is restored, a brief recovery or latent period occurs in which normal cerebral metabolism is reestablished.[206]

Conceptually, neuronal cell death as a result of a hypoxic-ischemic event and energy failure is a plausible mechanism of CNS injury and certainly contributes to the pathophysiologic mechanisms of NE (Fig. 17.7). However, studies suggest that this mechanism alone is too simplistic and continued neuronal damage occurs after the initial hypoxic-ischemic insult.[205,207] The second phase of neuronal death, sometimes referred to as *delayed neuronal cell death* or *secondary energy failure*, occurs 6 to 48 hours after the initial injury and is believed to be associated with one or more of the following mechanisms: excitotoxicity, accumulation of intracellular calcium and resultant activation of numerous enzymes and pathways, reperfusion injury (oxidative stress), cytotoxic actions of activated microglia, inflammation, and apoptosis.[6,199,201,203,204]

Linked with hypoxia-ischemia are other damaging processes, such as the accumulation of extracellular glutamate and production of reactive oxygen species (ROS) and inflammatory mediators. Glutamate is the predominant excitatory amino acid neurotransmitter in the brain and initiates biochemical changes through its interaction with specific receptors.[6,199,206] The ionotropic receptors, so named because they are linked to ion channels, include the N-methyl-D-aspartate (NMDA) receptor, which is linked to calcium channels, and the α–amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and kainite (KA) receptors, which are linked to sodium channels.[6,199,206] In the healthy individual, glutamate is released from presynaptic nerve terminals when signaled by neuronal depolarization.[208] Glutamate is rapidly removed from the synaptic cleft by glutamate transporters in astroglia and converted to glutamine, which is then transported back into nerve terminals for reuse.[208] Hypoxia or ischemia, as well as decreased glucose delivery to the brain, impairs normal function of astroglial glutamate transporters in the synaptic cleft, resulting in accumulation of extracellular glutamate and ensuing opening of ion channels operated by glutamate receptors.[199,208] In turn, increased glutamate concentrations result in excessive calcium influx into neurons, which consequently triggers activation of lipases, proteases, and endonucleases.[201] This excitotoxicity, in which excessive activation of glutamatergic neurotransmission occurs, can result in cell apoptosis and necrosis.[199,208]

The neonatal brain is particularly vulnerable to oxidative injury owing to its high concentrations of unsaturated fatty acids, high rate of oxygen consumption, and low concentration of antioxidants.[199,209] As a result of hypoxia-ischemia and/or increased intracellular calcium in neurons, a number of enzymatic pathways produce ROS through several enzyme systems including NADPH oxidase (NOX), glutathione peroxidase, cyclooxygenase, xanthine dehydrogenase, monoamine oxidase, myeloperoxidase, and nitric oxide synthase (NOS).[201,209,210] Some evidence suggests that NOS and NOX, along with an oxygen-deprived mitochondrial electron transport system, comprise the major sources of ROS in the brain during a hypoxic-ischemic event.[209] In addition, after a hypoxic-ischemic event, immune cells (infiltrating neutrophils, resident microglia) within the brain are stimulated and generate proinflammatory mediators and oxygen free radicals, such as superoxide anion ($\bullet O_2^-$), hydrogen

peroxide (H_2O_2), hypochlorous acid (HOCl), and hydroxyl radicals (•OH).[6,209] Furthermore, NOS, specifically neuronal NOS (nNOS), which is localized with NMDA receptors and activated by calcium influx through the NMDA receptor, can produce nitric oxide (•NO) and reactive nitrogen species (RNS); RNS can subsequently react with superoxide anion to form the powerful oxidant, peroxynitrite ($ONOO^-$).[208,211,212] Cumulatively, ROS and RNS can cause significant damage to biological proteins (membrane protein degradation), lipids (lipid oxidation), and nucleic acids (DNA degeneration).[209]

The inflammatory and immunologic response to a hypoxic-ischemic insult also contributes to the pathogenesis of cerebral injury.[201] In the neonatal brain, an immediate innate immune response occurs within minutes of hypoxic-ischemic injury with stressed or dead neurons resulting in diffuse activation of neuroglial cells.[203] Activated astrocytes, microglia, and endothelial cells then release proinflammatory cytokines, such as tumor necrosis factor–α (TNF-α), interleukin (IL)-1, IL-6, and IL-8.[201,203] In addition, release of matrix metalloproteinases (MMPs) and proinflammatory chemokines and cytokines facilitates recruitment and activation of peripheral immune cells.[203] Subsequently, activated peripheral inflammatory cells release neurotoxic agents, such as proinflammatory cytokines, NO, ROS, and myeloperoxidase, which further contribute to neuronal death, cytotoxic edema, and brain injury.[203,213] Cytokines may injure white matter by inhibiting differentiation of developing oligodendrocytes, causing myelin degeneration and inducing oligodendroglial apoptosis, which further exacerbates neuronal injury.[210,213] Despite the detrimental effects of the inflammatory response, however, it also serves a beneficial role by facilitating functional recovery of the CNS by eliminating cellular debris and tissue recovery. Thus in response to hypoxic-ischemic injury, the inflammatory response attempts to remove cellular debris and promote healing of the tissues but paradoxically results in cellular injury.[6]

Evidence of hypoxic-ischemic injury is not always identified historically or microscopically in foals with NE, and long-term neurologic deficits commonly reported in people with NE, such as cerebral palsy, visual and auditory disorders, and epilepsy, are not typically observed in foals.[201] Thus alternative causes of NE have been explored. One such pathophysiologic mechanism that might play a role in a subset of foals with NE is the presence of altered concentrations of neurosteroids, which can cross the blood-brain barrier and have neuromodulatory effects resulting in clinical signs of NE in foals shortly after birth.[214] In utero, the fetus maintains a quiet, suppressed, and relatively inactive state under the influence of neurosteroids, as compared with the precocious newborn foal that must be active and ambulatory shortly after birth.[215] Some foals with NE have persistently increased concentrations of neurosteroids, such as plasma progestagens,[200,216] and in one study, several plasma progestagens (progesterone, epitestosterone, androstenedione) were significantly increased in foals with NE when compared with foals with other disorders.[214] Experimentally, intravenous infusion of allopregnenolone in a healthy newborn foal resulted in sedation and decreased responsiveness, with higher dosages of allopregnenolone resulting in dramatic neurobehavioral effects including recumbency, stupor, and unresponsiveness to the mare, environment, sound, and tactile stimulation.[214] These clinical signs persisted during the CRI of allopregnenolone but waned over 15 minutes after cessation of the infusion followed by normal behavior 30 minutes post infusion.[214] Allopregnenolone is believed to mediate its effects in the CNS via the $GABA_A$ receptor, and although this study only involved one foal, consideration must be granted to the possibility that persistence of fetal progestagens by the newborn foal can affect the CNS and cause signs compatible with NE in a subset of foals.[77,217] Moreover, the rapid recovery from clinical signs of NE in some foals, especially in light of no obvious residual neurologic deficits, might be associated with a decline of pregnene-mediated sedative effects.[214]

Expanding on the theory that neurosteroids may impact the level of consciousness in newborn foals, one theory suggests that signaling of the transition from an in utero unconscious state to extrauterine consciousness may involve labor-induced physical compression (squeezing) and this compression might be associated with changes in neurosteroid concentrations.[218,219] Studies investigated the use of a rope restraint device (Fig. 17.8) in neonatal foals in efforts to demonstrate that application of physical pressure via rope restraints activates the HPA axis, affects neurosteroid concentrations, and causes quiescence that is essential to the transition from fetus to newborn by preventing malposition during parturition.[218,219] In one study involving eight healthy neonatal foals, a soft linen rope was secured around each foal's neck and under the shoulder and then looped around the thorax and abdomen using half-hitch knots positioned directly on the dorsal thoracolumbar area.[219] The handler gently pulled on the rope from behind the foal, which produced a generalized squeezing of the foal while a second individual assisted the foal to lay down; tension on the rope was maintained for 15 to 20 minutes.[218,219] During the restraint, foals assumed lateral recumbency with relaxed, somnolent behavior along with a significant decrease in heart and respiratory rate and rectal temperature. Furthermore, electroencephalography (EEG) recordings revealed patterns consistent with slow wave sleep and plasma ACTH, β-endorphin, dehydroepiandrosterone sulfate, and androstenedione concentrations significantly increased during restraint, compared with pre-restraint values.[219] A follow-up survey involved equine clinicians that collected observational data from foals with NE that were treated with standard medical therapy with or without the inclusion of the rope restraint/squeeze method.[218] The survey inquired about medical treatments and a response to medical treatment only (nonsqueezed group) versus the squeeze procedure with or

FIG. 17.8 Foal fitted with a soft linen rope restraint device. Squeeze effect generated by a person who stands behind the foal and gently pulls on the rope; an assistant helps the foal to lie down. Completion of the rope squeeze after 15 to 20 minutes.

VetBooks.ir

without medical therapy (squeezed group). There were 51 respondents to the survey providing information on 195 foals with NE (108 nonsqueezed; 87 squeezed). In this survey, foals that received the squeeze procedure with or without medical therapy had significantly faster recovery rates, were 3.7 times more likely to recover faster, and were 15 times more likely to recover in less than 1 hour than foals that were not squeezed.[218] The authors concluded that foals that were squeezed for 20 minutes had significantly faster and higher recovery rates than foals that did not receive the procedure. There were several limitations to this study, but the authors proposed that the pressure from the birth canal that the fetus is exposed to during stage 2 of labor might influence the balance of neurosteroids and play a role in the neonatal transition from neuroinhibition to neuroactivation.[218,220,221] Thus simulation of stage 2 labor with the rope restraint may reset the balance of these neurosteroids and expedite recovery from NE and facilitate normal behavior in the neonatal foal.

Yet another alternate theory by which foals may develop NE outside the framework of a hypoxic-ischemic insult involves the inflammatory response in the neonatal brain associated with chorioamnionitis (placentitis), maternal and fetal inflammation, and resultant injury to the fetal/neonatal brain.[199,222,223] In health, the chorioallantois has properties of an immunologically privileged site in order to protect the allogenic fetus from rejection by the mother. When an infectious agent invades the placental membranes, both a maternal and fetal inflammatory response, characterized by release of proinflammatory and inhibitory cytokines and chemokines, can occur. The initial response to intrauterine infection involves leukocytes derived from the maternal circulation (maternal inflammatory response).[223] Subsequently, intrauterine inflammation also involves leukocytes derived from the fetal vessels and systemic activation of the fetal innate immune system (fetal inflammatory response syndrome, FIRS).[223] Both maternal and fetal inflammatory responses are typified by production of inflammatory mediators (IL-1, IL-6, TNF-α) and activation of neutrophils and other components of the innate immune system.[222,223] Although not fully understood, the FIRS may induce cerebral white matter injury, intraventricular hemorrhage, and/or periventricular leukomalacia, manifesting clinically as neurologic deficits. Proposed mechanisms by which this occurs includes cerebral hypoperfusion and ischemia, activation of the coagulation cascade resulting in capillary thrombosis, and necrosis of white matter and/or increased permeability of the blood-brain barrier, which potentially allows direct passage of microbes and cytokines into the CNS.[222,223] Other body systems that may be impacted by FIRS include the hematopoietic system, thymus, adrenal glands, skin, kidneys, heart, and lung.[222] Equine studies directly linking placentitis, FIRS, and brain injury are lacking, but placentitis is a noted risk factor for the development of NE in foals and a study investigating placentitis in mares demonstrated significantly more expression of mRNA for IL-6 and IL-8 from the cervical star region in mares with experimentally induced *Streptococcus equi* ssp. *zooepidemicus* placentitis when compared with healthy pregnant mares.[6,224] Thus it is plausible, but unsubstantiated, that placentitis and FIRS may play some part in the pathophysiologic development of NE in foals.

Risk Factors and Clinical Signs

Recognized risk factors for NE in infants include maternal systemic hypotension, maternal cardiac arrest, clotting of placental arteries, placental abruption, uterine rupture, and inflammation.[203] In comparison, risk factors in horses associated with NE include dystocia, induced parturition, Cesarean section, placentitis, premature placental separation, severe illness, post-term pregnancy (fescue toxicity), and maternal hypotension (endotoxemia, hemorrhage, anemia, severe respiratory disease).[225–228] Other factors, such as meconium aspiration, twin foals, fetal infection, congenital malformations, and umbilical cord accidents, may also be risk factors for the development of NE.[225–228] In a retrospective study involving 79 neonatal foals with a primary diagnosis of NE, the presence of placental abnormalities (55% of foals), gestational problems (21%), premature placental separation (34%), and dystocia (30%) were reported.[197] Conversely, foals with NE may have no reported problems during gestation or parturition.

In regard to clinical signs, affected foals can be born demonstrating abnormal behavior or, alternatively, demonstrating clinical signs of NE 12 to 48 hours after birth. This temporal observation of delayed clinical signs may reflect the biphasic acute and delayed injury to the CNS discussed in the proposed pathophysiology. Clinical signs are quite variable and range in severity to include alterations of consciousness (stupor, somnolence, difficult to arouse, coma); weakness (hypotonia); inability to suckle; lack of affinity for the dam; inability to find the udder; inappropriate nursing behavior; localized or generalized seizures; tongue protrusion or weak tongue tone; star gazing; loss of recognition of the environment; abnormal vocalization; dysphagia; central blindness; irregular respiratory pattern (apnea, abnormally slow respiratory rate); and proprioceptive deficits.[6,25,229,230] In a retrospective study involving 94 foals, the most frequent reported clinical signs included abnormal udder seeking (59%), abnormal suckle (55%), inability to stand (42%), abnormal gastrointestinal motility (37%), abnormal consciousness (34%), and seizure activity (22%).[230] In another retrospective report, dysphagia was observed in 16 neonatal foals, and of these 16 foals, 6 foals (38%) had a clinical diagnosis of NE; 15/16 foals were discharged from the hospital (median 6.3 days; range 0 to 22 days), with 14/15 nursing from the mare with no evidence of dysphagia.[231] Clinical signs reflective of other body systems that can be impacted by hypoxic-ischemic injury, such as the renal, gastrointestinal, cardiac, and pulmonary system, also can be present. Moreover, clinical signs of other concurrent diseases that occur with NE, such as sepsis, pneumonia, prematurity/dysmaturity, patent urachus/omphalitis, limb deformity, colic, and uroperitoneum, may also be observed.[230]

Diagnosis

Currently, establishing a diagnosis of NE in foals remains at a rudimentary level and is confounded by concurrent diseases frequently encountered with NE, such as sepsis, hypoglycemia, prematurity, and congenital anomalies. In infants, diagnosis of NE is based on historical information, neurologic examination, and ancillary diagnostic tests such as brain imaging studies and EEG.[232,233] At present, MRI, including diffusion-weighted MRI, is the method of choice for imaging infants with HIE and has provided insight in regard to timing, location, and severity of brain injury.[232] The characteristic paradigm of brain injury in infants with HIE includes predominant injury to the gray matter structures, such as the basal ganglia and thalamus, related to acute profound asphyxia; watershed injury, which affects border zones of the brain between major arteries that lose blood flow and oxygen supply when blood perfusion is decreased, of the parasagittal white matter with possible extension to the cortex can also be observed and is related to partial prolonged asphyxia.[202,234–237] Other brain lesions include hemorrhage, focal to multifocal white matter injury, and global brain injury in more severe cases.[235]

Although MRI description of the healthy neonatal foal brain has been reported, there are minimal reports available in regard to MRI changes observed in foals with NE.[238] In one report involving a 10-hour-old foal with a putative diagnosis of NE based on presenting clinical signs of absent suckling behavior

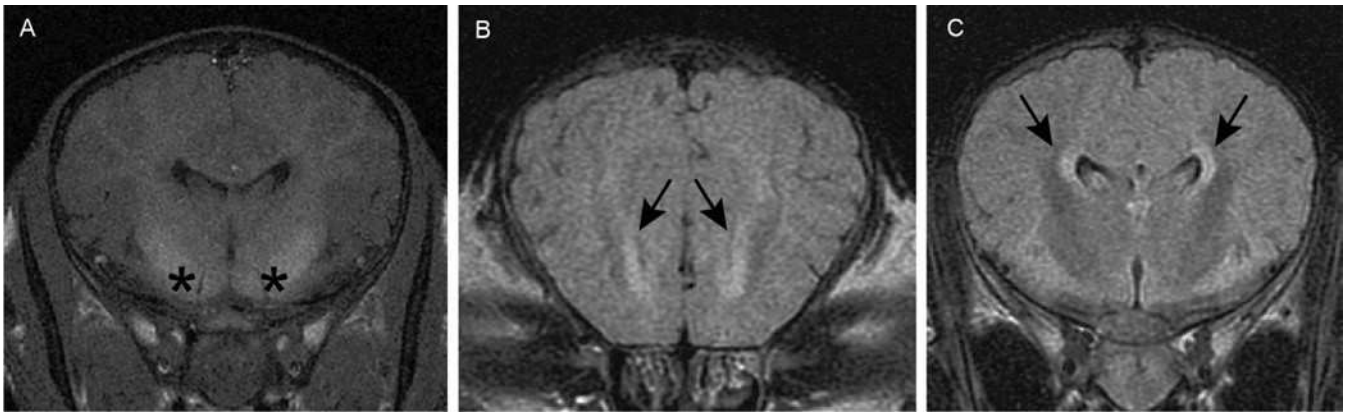

FIG. 17.9 Magnetic resonance imaging scans of the brain of a 5-day-old Thoroughbred filly with symmetric abnormalities in the cerebrum. **A,** T-1 transverse image through the cerebral hemispheres immediately rostral to the pituitary. *Asterisks* indicate regions of hyperintensity of basal nuclei. **B,** T2-weighted (T2W) fluid-attenuated inversion recovery (FLAIR) transverse image through rostral limit of lateral ventricles. *Arrows* indicate areas of hyperintensity associated with rostral poles of the ventricles. **C,** T2W FLAIR image through cerebral hemispheres immediately rostral to pituitary (same level as image A). *Arrows* indicate regions of hyperintensity adjacent to lateral ventricles. *(From Wong DM, Jeffery N, Hepworth-Warren KL: Magnetic resonance imaging of presumptive neonatal encephalopathy in a foal. Equine Vet Educ 29:534-538, 2017).*

and disassociation from the mare, an MRI of the brain was performed because of worsening clinical signs of NE (i.e., seizures).[239] MRI revealed symmetric, poorly delineated areas of high signal intensity (compared with gray matter regions elsewhere) involving the basal nuclei (accumbens, putamen, claustrum); ventral thalamic nuclei; and rostral aspect of the ventral midbrain (in the region of the substantia nigra) on T1-weighted (T1-W) images (Fig. 17.9).[239] Hyperintensity associated with the margins of the lateral ventricles were noted on T2-weighted (T2-W) and T2-W fluid-attenuated inversion recovery (FLAIR) images.[239] The lesions noted in this foal were similar to those described in infants with HIE.[234,235] Whether or not MRI and its associated risks of general anesthesia and added client expense is a feasible diagnostic test in foals with NE remains to be determined, but imaging studies might help elucidate the pathophysiology of NE in foals and guide prognostication.

The use of cranial US has also been used in infants to help identify neonates with HIE, as well as other disorders, such as cranial hemorrhage, congenital structural abnormalities of the cerebrum, and other causes of fetal brain injury.[232] Abnormalities associated with HIE in infants that were identified with cranial US included changes in ventricular size, periventricular echogenicity, increased echogenicity in the thalami, extra-axial fluid collection, and intracranial hemorrhage.[232] Although cranial US was able to identify all infants with a poor outcome, MRI was better at detecting changes associated with HIE.[240] One study in foals has examined and described ultrasonographic measurements of a variety of variables viewed from the atlanto-occipital (AO) space in healthy neonatal foals and foals with NE.[241] In that study, an 8-MHz microconvex transducer was used to image the AO space using a depth of 6 to 8 cm. Specifically, the transducer was placed immediately cranial to the wings of the atlas to obtain a transverse image and then rotated 90 degrees to obtain a longitudinal image.[241] Measurements of the height of the spinal cord, depth of dorsal subarachnoid space (mid-AO space), maximal depth of the dorsal subarachnoid space (cranial-AO space), and dorsoventral diameter of the ventral spinal artery were collected from longitudinal images (Fig. 17.10).[241] On transverse images, measurements of the height, width, and cross-sectional area of the spinal cord and spinal canal were taken along with the depth of the dorsal subarachnoid space. In addition, ratios of the spinal canal to spinal cord height measurements, spinal canal to cord width measurements, and spinal canal to cord cross-sectional area measurements were calculated from transverse images. When comparing healthy foals with foals with NE, the dorsoventral diameter of the ventral spinal artery (longitudinal images) and absolute measurements of the spinal cord height, width, and cross-sectional area (transverse images) were all significantly smaller in foals with NE.[241] Moreover, ratios of spinal canal to spinal cord width and cross-sectional area were significantly larger in foals with NE when compared with healthy foals. One possible explanation for the reduced spinal cord dimensions in foals with NE is related to elevated intracranial pressure; however, the clinical application, utility, and reliability of ultrasonographic examination of the AO region in foals suspected to have NE is unknown and requires further study.[241]

EEG is the graphic recording of the rhythmic bioelectrical activity that arises predominantly from the cerebral cortex and has been used in people and, to a lesser extent, horses as a screening procedure in patients with intracranial neurologic disorders.[242] There is a lack of a single accepted classification system in regard to EEG interpretation in infants evaluated for NE, so a good degree of variation in terms of EEG definitions and grading schemes are published within the literature.[243,244] Commonly reported abnormal EEG findings in infants with NE include frequent spikes, positive temporal sharp waves, polyphasic sharp waves, mild voltage depression, persistent discontinuity, burst suppression, and modified burst suppression pattern.[243,244] In one study involving a 1-day-old filly, later confirmed to have histopathologic abnormalities compatible with NE, EEG recordings revealed diffuse high-voltage slow waves and focal discrete paroxysmal discharge activity, as well as multifocal paroxysmal activity. The practical application of EEG in equine medicine remains limited because of the restricted availability of equipment and trained personnel to perform and interpret the EEG.[242]

Finally, a variety of blood parameters also have been examined in foals with NE. In one study, 32% of foals with NE had increased serum creatinine concentration and 61% of affected foals had increased activity of serum creatine kinase.[197] Another retrospective study investigating spurious hypercreatinemia noted that of 28 foals with spurious hypercreatinemia (mean creatinine concentration 13.6 mg/dL), 20 foals (71%) had a clinical diagnosis of NE.[245] However, elevations in serum creatinine and creatine kinase can be associated with a number of other disease processes in neonatal foals. A more recent equine study measured plasma concentrations of ubiquitin C-terminal hydrolase 1, a biomarker for brain injury, and noted significantly higher values in foals with NE (mean 6.57 ng/mL; range 2.35 to 11.90 ng/mL) when compared with

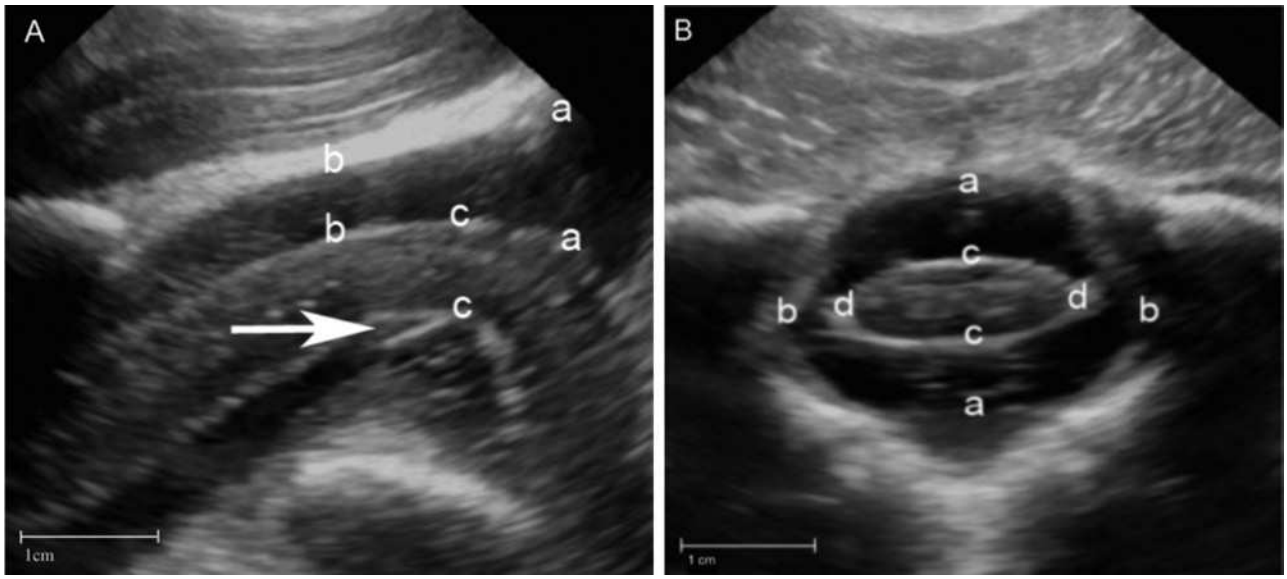

FIG. 17.10 Ultrasonographic images of the atlanto-occipital region in a 1-day-old Thoroughbred foal with neonatal encephalopathy. **A,** Longitudinal ultrasound image (cranial to right of image). Measurements of the maximal depth of the dorsal subarachnoid space (cranial atlanto-occipital space) (*a* to *a*), dorsal subarachnoid space (mid atlanto-occipital space) (*b* to *b*), height of the spinal cord (*c* to *c*), and dorsoventral diameter of the ventral spinal artery (*arrow*). **B,** Transverse ultrasound image (right side of foal to right of image). Measurements of the spinal canal height (*a* to *a*) and width (*b* to *b*), spinal cord height (*c* to *c*), and width (*d* to *d*), and dorsal subarachnoid space (dorsal *a* to dorsal *c*). *(From Mackenzie CJ, Haggett EF, Pinchbeck GL, et al. Ultrasonographic assessment of the atlanto-occipital space in healthy Thoroughbred foals and Thoroughbred foals with neonatal maladjustment syndrome. Vet J 223:55-59, 2017.).*

healthy foals (median 2.53 ng/mL; range 1.4 to 4.01 ng/mL). Currently, measurement of this biomarker is not readily available for clinical use.[246]

At present, practicality dictates that NE in foals be based primarily on clinical impression, founded on historical information, neurologic examination, compatible clinical signs, and exclusion of other disease processes. In foals, NE may occur as a primary problem or may be coupled with failure of passive transfer of maternal antibodies, sepsis, musculoskeletal abnormalities, prematurity/dysmaturity, and other congenital disorders. Thus the clinician should perform diagnostics, such as a complete blood count, serum biochemistry profile, arterial blood gas analysis, blood culture, urinalysis, and assessment of passive transfer of maternal antibodies, to establish a complete assessment of the foal.[6]

Treatment

In equine medicine, the core component of treatment of NE is appropriate supportive and nursing care. This entails maintenance of adequate blood pressure and hydration, meeting caloric needs, facilitation of gas exchange, prevention of skin sloughing and ulceration by keeping the foal clean and dry, and prevention or treatment of infection. There are varied opinions on appropriate intravenous maintenance fluid rates for neonatal foals, but one approach is the Holliday-Segar method[2] (see previously and Chapter 44); the clinician must also consider renal function in calculating IV fluid rates as the kidneys can sustain injury from hypoxic-ischemic insult. Maintenance of adequate blood pressure and perfusion is also important for supporting cerebral (and other organ) perfusion and avoiding further ischemic injury.[247,248] Identifying any underlying cause(s) of hypotension, coupled with cautious use of IV fluid therapy and vasopressors or inotropes, might be necessary. Likewise, slow and judicious introduction of enteral milk feedings should be implemented as the gastrointestinal tract can be impaired from hypoxia-ischemia. Foals should be evaluated for gastric reflux before feeding. A conservative rate of 5% of the foal's body weight of mare's milk divided over a 24-hour period (i.e., 50 kg × 0.05 = 2.5 L mare's milk delivered every 2 hours over a 24-hour period = 100 mL every 2 hours) is a reasonable starting point, while monitoring for any clinical signs of indigestion (gastric reflux, colic). Milk supplementation should be increased gradually to a total of 20% to 25% of the foal's body weight per day over the next several days if the foal's gastrointestinal tract is functioning normally. Alternatively, or in addition to milk feedings, IV glucose supplementation can be used to provide another source of calories. A rate of 5 mg/kg/min of glucose has been suggested as an initial IV glucose CRI flow rate based on placental blood flow in late gestation (6.8 mg/kg/min).[9] This equates to an hourly flow rate of 3 mL/kg (150 mL/hr for a 50-kg foal) of a 10% glucose solution. Blood glucose concentration must be monitored and fluid rate adjusted routinely to avoid hyperglycemia or hypoglycemia. Moreover, as energy depletion plays a role in the development of NE, coupled with the fact that neonates have minimal energy reserves, it is important to maintain the blood glucose concentration within the reference range.[247,248] If enteral feedings cannot be initiated in the first 24 to 48 hours, consideration of partial (PPN) or total parental nutrition (TPN) should be given. An arterial blood gas sample should be performed to gauge pulmonary function and supplemental intranasal oxygen provided if necessary. Furthermore, foals should be maintained in sternal recumbency where possible to facilitate adequate ventilation of both left and right lung lobes. If hypoventilation and hypercapnia are observed, doxapram (0.02 to 0.05 mg/kg/hr) can be administered as a CRI as a respiratory stimulant.[249] Although doxapram was found to be more effective at lowering $PaCO_2$ in foals with NE, caffeine can be administered per os (loading dose 7.5 to 12 mg/kg, followed by daily dose 2.5 to 5 mg/kg) if a CRI is not feasible. Provision of soft bedding with clean dry blankets will help prevent skin trauma and ulceration. Assessment of passive transfer of maternal antibodies should be evaluated as many NE foals fail to ingest enough colostrum and IV administration of equine plasma can be necessary. The rope restraint squeeze method can also be used in efforts to alter neurosteroid concentrations, and administration of broad-spectrum antimicrobials is indicated to treat or prevent sepsis.[219] Evaluation and treatment of other body systems, particularly the gastrointestinal and renal system,

VetBooks.ir

which are predisposed to hypoxic-ischemic insult, should be considered.

Many foals with NE will respond to the aforementioned treatment suggestions within 3 to 5 days and have a complete recovery. However, a few specific therapies should also be considered with more complicated cases of NE. Moreover, numerous medications have been suggested, mainly used in infants with NE, that target specific pathophysiologic mechanisms that may be involved with the development of NE. Importantly, seizures should be treated immediately if observed, as ongoing seizure activity increases cerebral oxygen consumption and can further contribute to neuronal damage. Intravenous diazepam (0.1 to 0.2 mg/kg) typically controls seizures in the neonatal foal and can be given intermittently if the incidence of seizures is infrequent. An alternative benzodiazepine that can be used for seizures is midazolam given as a single dose (0.04 to 0.1 mg/kg IV) or a CRI (0.02 to 0.06 mg/kg/h IV) to control intractable seizures.[250] If seizure activity persists, phenobarbital (2 to 10 mg/kg IV over 15 minutes, then 5 mg/kg PO q12h) may be necessary. Side effects of phenobarbital, such as mild sedation, ataxia, and hypothermia, can be observed. Intravenous anesthesia with propofol can be required for several hours to manage intractable cases of status epilepticus.[25] Pharmacokinetics of levetiracetam, a novel antiepileptic drug used in people and dogs, has recently been investigated in healthy neonatal foals, but exact therapeutic ranges for this drug have not been established in horses.[251] On the basis of this study, levetiracetam administered at a dose of 32 mg/kg by mouth twice daily was predicted to maintain plasma concentrations above target concentrations for other species. Published use of levetiracetam in foals with NE is not available but might have potential for seizure control in future cases, although adjustment of dose and frequency of administration may be required in the clinical setting.[251] Hyperbaric oxygen therapy has been suggested as a potential therapy for NE with proposed benefits including reduced apoptosis, promotion of neuronal stem cell proliferation, enhancement of oxygen radical scavengers, increased oxygen delivery to the brain, and increased activity of superoxide dismutase.[6,210,252] Hyperbaric oxygen therapy has been used in a limited number of infants and foals with NE and has been purported to have beneficial effects.[253–255]

Medications that combat edema and oxidative damage have been used in foals with NE but have not undergone clinical trials or received scientific scrutiny; thus their effectiveness has been debated. Nonetheless, some clinicians have used mannitol (0.5 to 2.0 g/kg as a 20% solution over 20 minutes, IV q12-24h) or furosemide (1 mg/kg IV q12-24h) in efforts to reduce cerebral edema. Dimethyl sulfoxide (0.5 to 1 g/kg IV as a 10% solution given over 30 minutes, q12-24h) has also been used to treat cerebral edema and for its purported free radical scavenging abilities. Other putative therapeutics acting as free radical scavengers or antioxidants administered to foals with NE include thiamine (5 to 10 mg/kg IV or SC q24h), vitamin E (20/kg IU/kg, SC, or PO q24h), and vitamin C (100 mg/kg/day, IV). Allopurinol is a medication that inhibits xanthine oxidase, the enzyme responsible for production of superoxide radicals during reperfusion injury[201,209]; a dosage of 6 mg/kg PO once was used in a foal in conjunction with other treatments.[209a]

Accumulation of glutamate and excitotoxicity is another component of the pathophysiology of NE, and medications that help reduce the impact of excess glutamate have been investigated. Magnesium sulfate ($MgSO_4$) prevents calcium entry into the cell by noncompetitive voltage-dependent inhibition of NMDA receptors.[201] This in turn blocks the release of glutamate and antagonizes the influx of calcium.[201,209] In addition, $MgSO_4$ reduces secondary inflammation-induced injury via cell membrane stabilization and inhibition of free radical formation.[201] Rodent models have demonstrated that $MgSO_4$ can be strongly protective against hypoxic-ischemic injury if given before or shortly after a hypoxic-ischemic insult.[208] A dose of 0.05 g/kg/h of $MgSO_4$ for the first hour, followed by 0.025 g/kg/h IV as a CRI has been suggested as a treatment for NE in foals.[256]
