Because of the lack of epidemiologic data regarding potential natural reservoir hosts, as well as the lack of information pertaining to the biological processes of *L. intracellularis*, management changes should not be made on endemic farms. Moreover, maintaining good pest control and preventing nonequine domestic and wild animals from obtaining access to feed and feeding areas may potentially minimize the risk of disease spread.

Prevention strategies have been best described in pigs with in-feed antimicrobials and a commercially available *L. intracellularis* vaccine.[65-67] Detectable humoral and cellular responses can be measured in foals administered an avirulent live *L. intracellularis* vaccine.[68,69] The *L. intracellularis* vaccine has been shown to be safe and its administration well tolerated by the foals. A field efficacy trial performed on EPE-endemic farms in central Kentucky in 2008 showed that vaccinated foals maintained higher daily weight gains and higher total protein concentrations than did a nonvaccinated, naturally seroconverted group.[70] Under experimental conditions, weanling foals vaccinated intrarectally with an avirulent live vaccine against *L. intracellularis* were protected against clinical and subclinical EPE after challenge exposure with a virulent *L. intracellularis* isolate of equine origin.[71] This was determined by lack of clinical disease, absence of hypoproteinemia and ultrasonographic abnormalities compatible with EPE, and a significant reduction in *L. intracellularis* fecal shedding in vaccinated foals in comparison with nonvaccinated foals. Moreover, average daily weight gains from the vaccinated foals over the entire study period were similar to those of the control foals and significantly higher than those of the nonvaccinated foals, which highlights the benefit of the vaccine in the prevention of subclinical disease. The extralabel use of the *L. intracellularis* vaccine should be considered on EPE-naive and endemic farms in an attempt to reduce or prevent EPE. Timing of vaccine administration should again be synchronized with historical disease occurrence. Moreover, routine monitoring for clinical signs and hypoproteinemia/hypoalbuminemia is still recommended even when vaccine prophylaxis is used.

Rhodococcus equi *Enteritis*

R. equi most frequently causes a severe pyogranulomatous pneumonia in foals 2 to 3 months of age. Extrapulmonary disorders have been associated with *R. equi* infection in foals, and the presence of these disorders is associated with an increase in mortality. Extrapulmonary disorders of the gastrointestinal system may occur in as much as 50% of cases. Diarrhea is reported to occur in up to 33% of *R. equi* cases. In one study of 150 affected foals, enterocolitis and typhlitis were reported in 31, intraabdominal abscesses in 25, abdominal lymphadenitis in 25, and septic peritonitis 11.[72]

PATHOPHYSIOLOGY. Intestinal infection with *R. equi* can occur through either fecal-oral transmission or swallowing of infected sputum. The organism invades and reproduces within the macrophages, causing a pyogranulomatous disease. In a survey of normal foals on two different farms, *R. equi* was shed in the feces of 16 of 17 and 19 of 26 foals, respectively.[73] Only 2 foals developed clinical signs of intestinal disease, and the shedding of bacteria in the feces increased threefold to fourfold

VetBooks.ir

during those times. Such foals, as well as adults, are probably the source of repeated contamination on endemic farms. The organism's ability to cause disease is based on the presence of virulence factors, particularly virulence-associated protein A (VapA), which has been most commonly associated with disease in pneumonic foals.

CLINICAL AND LABORATORY FINDINGS. Foals diagnosed with *R. equi* enteritis typically manifest the signs of pneumonia first, although foals in which the enteric form is the major pathologic process have been reported.[74] With the enteric form of the disease, diarrhea, weight loss, and colic are present. Many affected foals are febrile, anorexic, and depressed. Typical clinicopathologic findings include leukocytosis with neutrophilia and severe hyperfibrinogenemia. Ultrasonography of the abdomen may reveal pyogranulomatous abscesses in the lymph nodes.

A diagnosis of *R. equi* enteritis can be presumed in pneumonic foals showing signs of gastrointestinal disease for which cultures of transtracheal wash fluid yield positive results for *R. equi*. *R. equi* can also be cultured from the feces, small intestinal luminal contents, or, occasionally, the peritoneal fluid of affected animals. A PCR based on the *vapA* gene has been developed and can be used as an adjunct diagnostic tool in these cases.[75]

PATHOLOGIC FINDINGS. The most common small intestinal lesion is multifocal ulcerative enteritis in the area of the Peyer patches of the ileum. Other parts of the small intestine may be affected, with lesions present throughout the entire small intestine.[75] These lesions frequently extend into the cecum and colon as well. A suppurative exudate is also present, along with pyogranulomatous inflammation of the mesenteric lymph nodes. Co-infection with *L. intracellularis* has also been reported to occur.[76]

TREATMENT. Treatment of *R. equi* enteritis is similar to treatment of *R. equi* pneumonia. Erythromycin estolate (25 mg/kg PO q6-8h) or erythromycin phosphate (37.5 mg/kg PO q12h) combined with rifampin (5 to 7.5 mg/kg PO q12h) has been the traditional treatment for these foals, and it is still effective but requires a longer duration of treatment and is difficult for owners to administer because of the frequency of the treatments. Alternative treatments include azithromycin (10 mg/kg PO q24h for 5 days, followed by q48h) and clarithromycin (7.5 mg/kg PO q12h), with or without rifampin. To prevent relapses, it is very important to continue treatment until the hematologic abnormalities and radiographic or ultrasonographic examinations have returned to normal.

COMPLICATIONS. Complications associated with *R. equi* enteritis include septic peritonitis and the development of intestinal adhesions. These may lead to death of affected animals or chronic abdominal problems in those that survive. Therapy is often prolonged in these cases, and owners should be warned that foals with extrapulmonary disorders associated with *R. equi* pneumonia have a more guarded prognosis.[72]

Enteric Pythiosis

Pythium spp. are protistal organisms that belong to a group of phycomycotic organisms that also includes *Conidiobolus* and *Basidiobolus* spp. They are a frequent cause of severely pruritic cutaneous granulomas in horses along the Gulf Coast and southern United States. Much less frequently, the disease can cause granulomatous lesions in the small intestine.

PATHOPHYSIOLOGY. *Pythium* spp. are presumed to be transmitted via contact with contaminated water. Once ingested, the organisms are thought to penetrate the intestinal mucosa through an existing lesion because necrotic tissue is considered chemotactic.[77] *Pythium* spp. may be able to penetrate healthy tissue, however, because some cases in dogs have been reported to have mesenteric lymph node involvement without any mucosal lesions.[78]

CLINICAL AND LABORATORY FINDINGS. Four reports of equine enteric pythiosis can be found in the literature.[79-82] In all cases, masses occurred in the middle to distal sections of the jejunum. One horse died suddenly, one was euthanized during surgery, and two were successfully treated with a jejunal resection. Organic iodide therapy was instituted in one horse postoperatively for 30 days. In three cases, clinical signs of intestinal disease had been present for several months before diagnosis. Chronic colic, weight loss, inappetence, and ill thrift have all been reported and could be related to the intestinal lesion. None of the reported animals had skin lesions. Hematologic evaluation was nondiagnostic in the three cases in which it was performed.

On gross examination, lesions appear caseous with discrete yellow foci ("kunkers"), and the intestinal wall is thickened because of a pyogranulomatous inflammation. On microscopic examination, a diffuse, mixed inflammatory infiltrate, along with granulation tissue, is found in the submucosa, tunica muscularis, and mesenteric attachments. Culture of the organism from these lesions is difficult; however, an indirect immunoperoxidase technique to stain for *Pythium*-positive hyphae is available in some laboratories.[81] Serologic testing for *Pythium* in canine and equine cases is available; however, it has been validated only for cutaneous disease in horses.

TREATMENT. Treatment of phycomycetes is often difficult. They are not true fungi; therefore they are resistant to many antifungal drugs. Systemic amphotericin B is only rarely effective in treating the cutaneous disorder. Organic iodides are inexpensive and safe when administered orally, but the mechanism of action as antimicrobial drugs is not understood, and the efficacy of this compound to treat this disease has not been proven. A vaccine can be formulated against the organism, and this has been shown to shrink the lesions in horses with cutaneous disease. Its efficacy against enteric disease is unknown at this time. In addition, premortem or presurgical diagnosis of the disease is extremely difficult, and so surgical resection with biopsy are the most effective treatment.

Inflammatory Bowel Disease

Several intestinal disorders characterized by inflammatory cell infiltration have been placed under the umbrella of IBD, including granulomatous enteritis, multisystemic eosinophilic epitheliotropic enterocolitis, eosinophilic enterocolitis, lymphocytic-plasmacytic enteritis, and basophilic enterocolitis.[83-89] IBD in humans is typically characterized by a neutrophilic inflammation, but neutrophils are only the effector cell in a highly complex disease process.[90] The syndromes described for equine inflammatory intestinal disorders therefore appear to differ from those of human IBD; because of the different types of cellular infiltrates found in affected horses, these disorders presumably reflect different pathophysiologic mechanisms. Thus use of the term *inflammatory bowel disease* is not intended to imply either a similarity to the condition described in human beings or similarity among the various syndromes described in horses.

CLINICAL AND LABORATORY FINDINGS. Horses with IBD typically have progressive weight loss despite a good appetite and have intermittent abdominal discomfort. If the disease predominates in the small intestine, diarrhea may not be a feature. In some cases, associated dermatitis is present.[91] Affected horses often present with peripheral edema secondary to hypoproteinemia from enteric protein losses. Ultrasonographic examination may reveal thickened walls of the small intestine (>5 mm in diameter).

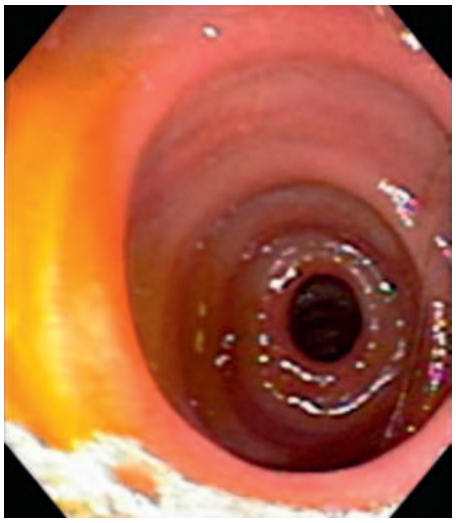

FIG. 32.63 Endoscopic view of the duodenum in a horse with lymphocytic-plasmacytic enteritis. Note the heterogeneous appearance of the duodenal mucosa.

Clinicopathologic abnormalities may include anemia, hypoalbuminemia, hypoproteinemia, and malabsorption of glucose and D-xylose. The results of a glucose tolerance test were abnormal in 70% of cases in one report.[92] Hypoalbuminemia in the absence of proteinuria or severe liver dysfunction is consistent with protein-losing enteropathy. Some horses may have a relative gammopathy. Serum electrolyte concentrations and total CO_2 levels are usually normal. Subclinical disseminated intravascular coagulation with thrombocytopenia and increased fibrinogen degradation products have been identified in horses with chronic enteritis.[86,93] Serum antibodies to gluten have been detected in horses with IBD, as well as in those on a gluten-rich diet.[94] This suggests a potential pathogenic role of gluten in at least some cases of equine IBD, and dietary changes may play an important role in treatment.

In most affected horses, cellular infiltration can be found to varying degrees throughout the intestinal tract. Therefore rectal mucosal biopsy may be useful for identifying cases of IBD in horses.[95] If the proximal duodenum is involved, endoscopic biopsies can be used for diagnosis (Fig. 32.63). A definitive diagnosis often requires biopsy of the small intestine, large intestine, or both. With appropriate instruments, this can be done through laparoscopy, although an exploration via a ventral midline approach enables a more thorough evaluation of the abdomen.

Histopathologic evaluation of biopsy specimens can be used to differentiate among the various IBDs reported in horses, according to the respective criteria.[87] A diagnosis of granulomatous enteritis is made when aggregates of macrophages and epithelioid cells are found in the mucosa, submucosa, or both, along with villous atrophy. In lymphocytic-plasmacytic enterocolitis, lymphocytes and plasmacytes are present in the lamina propria, and villous atrophy usually occurs. For multisystemic eosinophilic epitheliotropic disease, eosinophils, lymphocytes, and macrophages are found in the mucosa and submucosa. In rare cases, basophils have also been reported.

IBD syndrome, termed *idiopathic focal eosinophilic enteritis* (IFEE), involves focal areas of eosinophilic inflammatory infiltrates within the small intestine.[89,96-100] Affected horses typically are examined not because of chronic weight loss or diarrhea, but rather because of acute colic. Hypoproteinemia and malabsorption are not characteristic. The lesions are intramural masses or circumferential mural bands. Eosinophils with or without lymphocytes are seen infiltrating all layers of the intestine, with varying degrees of fibrosis.[100] Further characterization of the inflammatory lesions indicate that IFEE probably represents a focally exacerbated inflammatory reaction in horses with diffuse eosinophilic enteritis.[99] No underlying cause of the disease has been found, although food allergy, parasitism, and *Pythium* spp. have all been suggested.[100] The incidence, or at least the diagnosis, of this disease appears to be increasing.

TREATMENT AND PROGNOSIS. Because the specific diseases included in the general category of IBD are quite different, a generalized treatment recommendation cannot be made, although corticosteroids are considered the mainstay of medical management. In one study, a lack of response to initial steroid therapy (prednisolone) was associated with a poorer prognosis for long-term survival, as was a lower peak xylose concentration.[101] The horses in this study were also treated with coadministration of anthelmintic drugs (fenbendazole) and reported a 3-year survival rate of 65%. The high survival rate may also be a result of case selection and case definition. Reported cases of eosinophilic, lymphocytic, and basophilic enteritis have classically failed to respond to treatment. If treatment is attempted, immunosuppressive doses of dexamethasone, up to 0.2 mg/kg IM or IV once daily, are recommended. Successful remission of granulomatous enteritis was reported in one patient that was treated with dexamethasone.[102] Cases of IFEE should be differentiated from other types of IBD with regard to treatment and prognosis. These cases frequently respond to surgical decompression without resection if circumferential mural bands are the only lesion present.[100] In cases of intramural masses, surgical resection of the lesions usually resolves the problem.[98] Other treatments attempted include anthelmintic drugs with larvicidal activity, hydroxyurea, metronidazole, clioquinol (iodochlorhydroxyquin), and sulfasalazine.[103]

Neoplasia

Primary and secondary neoplasia involving the alimentary tract of horses is relatively uncommon, but several cases have been reported.[104] Typical signs associated with, but not diagnostic for, small intestinal neoplasia include colic and weight loss. In most horses with focal intestinal neoplasia, the problem becomes apparent only when lumen obstruction develops. Lymphosarcoma can be disseminated throughout a large portion of intestine, eventually resulting in a malabsorption and weight loss syndrome. Alimentary lymphoma is the most common intestinal neoplasia, and the small intestine is the most commonly affected intestinal segment.[105] Lymphosarcoma affects horses of all ages, although many of those with the alimentary form are older. The diagnosis of enteric lymphosarcoma is occasionally based on cytologic examination of fluid obtained by abdominocentesis, although multiple samples may be required before a positive sample is obtained.[106] In other cases, intestinal biopsy is necessary to diagnose the neoplastic disorder. Ultrasonography may reveal thickening and decreased echogenicity of the small or large intestinal wall or of both.[107] The prognosis is best if the tumor is discrete and can be removed surgically. A combination chemotherapy protocol of cytarabine (170 mg/m^2 IM), cyclophosphamide (142 mg/m^2 IV), and prednisolone (86 mg/m^2 PO q48h) has been reported to be effective in the treatment of mixed-cell thoracic lymphoma.[108] In other cases, corticosteroid therapy may induce clinical remission for several months, although it is not curative.

Other neoplasms affecting the small intestine are unusual; they typically arise from the wall of the bowel and include adenocarcinoma,[109] leiomyosarcoma,[110] and neurofibroma.[111] These tumors often result in intestinal obstruction and signs of abdominal discomfort. Discrete tumors may be surgically removed.

Paraneoplastic syndromes may be the first sign of neoplastic processes in a horse. Pemphigus, hypoglycemia, hypercalcemia, erythrocytosis, and neuropathies have all been associated with tumors in horses.[112] Paraneoplastic processes may also lead to

intestinal tract dysfunction in horses with extraintestinal tumors. Amyloid deposition secondary to multiple myeloma in a horse has been described.[113]

Small Intestinal Fibrosis

Small intestinal fibrosis is a rare syndrome that causes weight loss, chronic colic, and progressive debility in horses and ponies. Clusters of affected animals have been reported in Colorado[114,115] and Missouri.[116] The pathophysiologic origin of the fibrosis is not known, although ingestion of toxins (*Convolvulus arvensis* or common bindweed), inhibitors of 11β-hydroxysteroid dehydrogenase, and compounds with mineralocorticoid activity has been suggested.

Rectal palpation typically reveals thickening of the small intestinal wall, which may be confirmed by ultrasonography.[115] Gross examination may reveal that the overall length of the intestine is shortened by as much as 50%.[114,115] The histologic lesions include arteriosclerosis, capillary endothelial hypertrophy, extensive fibrosis of the submucosa, and hypertrophy of the muscularis mucosae and tunica muscularis.[114] The prognosis with the disease is determined by the length of the intestine that is involved. Surgical resection may be attempted.

Lymphangiectasia and Chyloabdomen

There are few reports of lymphangiectasia and chyloabdomen in the literature. Lymphangiectasia is dilation of the lymphatic channels of the small or large intestine (Fig. 32.64), usually caused by an abscess[117] or neoplasia. There are reports of chyloabdomen resulting from congenital lymphatic defects in a neonatal foal, intraabdominal abscesses in a foal, and abdominal adhesions in a miniature horse.[117-119] Typically, thickening of the intestinal wall and leakage of chyle into the peritoneal cavity result from obstruction or rupture of the lymphatic channels. Signs include abdominal discomfort, diarrhea, and chronic weight loss. Diagnosis is made on the basis of abdominal fluid analysis and ultrasonography. Chylous abdominal fluid appears milky and may contain a high percentage of lymphocytes. Ultrasonograms may reveal segments of thickened small intestine. Diagnosis is confirmed at surgery or postmortem examination, and treatment, if possible, is usually surgical, although in the author's experience, medical resolution of the effusion has been achieved.

Surgical Disorders of the Small Intestine

John F. Marshall • Anthony T. Blikslager

Simple Obstruction

Simple intestinal obstruction is a physical obstruction of the lumen without obstruction of mesenteric vascular flow (i.e., nonstrangulating obstruction). The most common causes are intraluminal masses composed of feed material (e.g., ileal impaction) and accumulation of parasites (e.g., ascarid impactions). Other instances in which the bowel is obstructed without associated compromise of blood supply include extraluminal compression by a mass or band of tissue in horses with intraabdominal adhesions and IFEE lesions. The large volume of fluid entering the small intestinal lumen on a daily basis[1,2] causes the obstructed intestine to become distended. Therefore although the mesenteric blood supply is not directly involved in simple obstructions, progressive and marked distention can result in decreased mural blood flow[3,4] and eventual necrosis of tissues.[5]

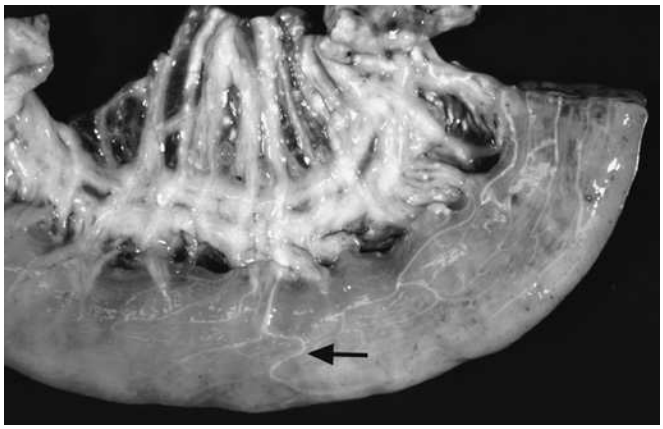

FIG. 32.64 Section of small intestine from a foal with chyloabdomen and a *Rhodococcus equi* abdominal abscess *(arrow)*. Mesenteric lymphatic channels are distended with white chyle, as are serosal lymphatic channels. *(Courtesy Dr. M.J. Murray.)*

ASCARID IMPACTIONS. Impactions caused by *Parascaris equorum* typically occur in weanling foals (median age, 5 months; range, 4 to 24 months) that have been on a poor deworming program and that are administered an anthelmintic when they have a heavy parasite burden.[6] Products that cause sudden ascarid paralysis or death, including piperazine, organophosphates, and pyrantel pamoate, have been incriminated.[7] However, any effective broad-spectrum anthelmintic, such as the avermectins, probably has the same effect. Clinical signs include variable onset of colic after administration of an anthelmintic (usually within 1 to 5 days) and signs compatible with small intestinal obstruction, including nasogastric reflux.[6] The onset of the disease varies according to the degree of obstruction.[7] Diagnosis may be tentatively based on the history in a foal that appears unthrifty, has been recently dewormed, and has signs referable to small intestinal obstruction. The presence of dead ascarids in nasogastric reflux raises the index of suspicion of this particular form of obstruction.[6] Abdominal radiographs or ultrasonography may indicate the presence of multiple loops of distended small intestine, but neither imaging study is needed if clinical signs indicate the need for immediate surgery. Surgical treatment typically involves an enterotomy made over the intraluminal impaction and removal of ascarids.

Although simple intestinal obstruction tends to carry a favorable prognosis for survival, ascarid impaction is a notable exception. The mortality rate in these cases is high (up to 92% in one study) as a result of severe intestinal compromise, peritonitis, and development of adhesions. The severe intestinal compromise is almost entirely attributable to the duration of impaction, which, for unknown reasons, is not as readily recognized in foals as it is in adults. Reasons for this could include failure of the owner or farm manager to recognize colic in foals or failure on the part of the owner or veterinarian to recognize the implications of colic in foals. Although foals readily display signs of colic, other medical causes of colic such as gastric ulcer disease or enteritis might be more significant in the differential diagnosis than for adults. Second, the size of a foal may make episodes of colic appear more manageable than in adults, in which colic-induced trauma, especially to the head, may force the issue of referral and surgery at an earlier stage. This is speculative, but early intervention in foals with ascarid impaction would probably result in dramatic reductions in the reported mortality rate.[6] Improved survival rates have, in fact, been reported: For example one case series indicated that 12 (80%) of 15 horses studied survived to discharge, and 6 (60%) of 10 for which follow-up data were available survived for at least 1 year.[8] This improvement was related to changing the surgical technique to manually evacuating ascarids into the cecum rather than performing an enterotomy or resection and anastomosis.[8] However, many cases have multifocal and marked impaction by ascarids that are large and difficult to manipulate. The need for an enterotomy or resection probably relates to the initial severity of disease, and not all cases may be amenable to manual evacuation into the cecum.

VetBooks.ir

ILEAL IMPACTION. Ileal impactions occur most commonly in adult horses in the southeastern United States. Although feeding of coastal Bermuda hay has been implicated in the regional distribution of this disease, it has been difficult to separate geographic location from regional hay sources as risk factors.[9] However, a study from the southeastern United States showed that the feeding of coastal Bermuda hay and failure to deworm with an anthelmintic with efficacy against tapeworms are significant risk factors for ileal impaction.[10] Furthermore, in a study performed in the United Kingdom, horses with evidence of tapeworm infection were at risk for developing ileal impaction.[11]

Typical signs in an adult horse with small intestinal obstruction include onset of moderate to severe colic and loops of distended small intestine rectally palpable as the condition progresses. Because the ileum is the most distal aspect of the small intestinal tract, nasogastric reflux may take a considerable time to develop and is found in only approximately 50% of horses requiring surgical correction of ileal impaction.[12,13] The diagnosis is usually made at surgery, although an impacted ileum may be palpated rectally.[14] However, multiple loops of distended small intestine frequently make the impaction difficult to palpate. Nonetheless, clinicians working in the southeastern United States who evaluate horses with cases of mild or moderate colic that have a history of eating coastal Bermuda hay, and in which distended loops of small intestine can be detected adjacent to the cecum, should strongly suspect ileal impaction.

Ileal impactions may resolve with medical treatment. In particular, horses with clinical signs compatible with obstruction of the small intestine and normal abdominal fluid should be treated medically unless pain is unmanageable or subsequent abdominal fluid samples indicate intestinal compromise. In cases in which surgery becomes necessary, fluids (2 to 3 L) can be directly infused into the mass, which allows the surgeon to break down the impaction. However, extensive small intestine distention and intraoperative manipulation of the ileum frequently leads to postoperative ileus (POI).[15] Therefore some surgeons now elect to perform an enterotomy and to flush the contents from the intestinal lumen with minimal manipulation. Although early studies indicated a guarded prognosis,[13] a more recent study indicated that the prognosis is excellent for both medically and surgically managed ileal impactions.[16]

ILEAL HYPERTROPHY. Ileal hypertrophy is a disorder in which the muscular layers (both circular and longitudinal) of the ileum enlarge for unknown reasons. Parasitism has been implicated, particularly parasites that tend to localize to the ileum (such as tapeworms),[17] but this has never been proven. In some cases the jejunum may also be hypertrophied, either alone or in combination with the ileum.[18] It is clear from these findings that initial functional obstruction initiates this syndrome, causing the musculature of the intestine to hypertrophy in order to push intestinal contents aborally, but there is no evidence as to the mechanisms of this disease. Clinical signs include chronic intermittent colic as the ileum hypertrophies and gradually occludes the lumen. In one study, partial anorexia and chronic weight loss (1 to 6 months) were documented in 45% of affected horses.[19] The diagnosis is usually made at surgery, although in some cases the hypertrophied ileum may be palpated rectally or visible on ultrasonographic evaluation of the abdomen.[19] Treatment involves an ileocecal or jejunocecal anastomosis to bypass the hypertrophied ileum. Without surgical bypass, intermittent colic persists, and the thickened ileum may ultimately rupture. According to one report of 11 horses with hypertrophy of the ileum, only 1 horse survived, which indicates a poor prognosis. The most common reason for euthanasia was spontaneous ileal rupture.[18]

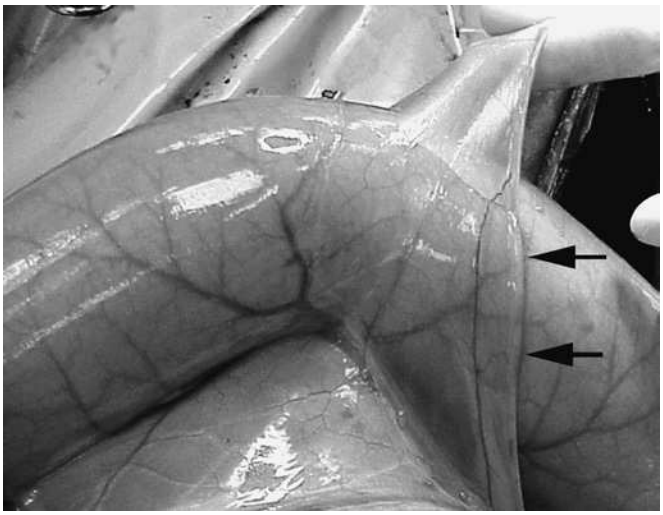

FIG. 32.65 Jejunal mesodiverticular band. This anomaly was an incidental finding during exploration of the horse's abdomen. Intestine may become entrapped within the mesenteric pocket formed by the attachment of the ventral to the dorsal mesentery *(arrows)*.

MECKEL DIVERTICULUM. A Meckel diverticulum is an embryonic remnant that may become impacted. The diverticulum arises from the vitelloumbilical duct, which fails to atrophy completely and becomes a blind pouch projecting from the antimesenteric border of the ileum.[20,21] An associated mesodiverticular band occasionally extends from the diverticulum to the umbilical remnant and serve as a point around which small intestine may become strangulated. Mesodiverticular bands may also originate from the embryonic ventral mesentery and attach to the antimesenteric surface of the bowel, thereby forming a potential space within which intestine may become entrapped (Fig. 32.65).[22] Clinical signs range from chronic colic for an impacted Meckel diverticulum to acute severe colic if a mesodiverticular band strangulates intestine. The diagnosis is made at surgery, and treatment entails resection of the diverticulum and any associated bands.[23]

IDIOPATHIC FOCAL EOSINOPHILIC ENTERITIS. IFEE is a relatively recently described condition of the small intestine of horses. Since 2000, the condition has been reported in the United Kingdom and the United States, and although its diagnosis appears to be increasingly common, no causative agent or other etiology has been described.[24,25,26] The clinical presentation of horses with this condition is consistent with that of nonstrangulating small intestinal obstruction, and horses younger than 5 years of age are at increased risk.[26] IFEE is diagnosed during exploratory celiotomy when palpably thickened serosal plaques or circumferential constricting bands are identified in the jejunum. Multiple plaques or bands may be present throughout the jejunum. Early reports of surgical resection of the affected intestine revealed a fair prognosis; in one, 7 of 10 surgically treated horses survived to discharge.[24] In cases in which abnormal portions of small intestine has been resected, the diagnosis can be confirmed by histologic examination, which reveals severe transmural eosinophilic enteritis. However, pathologic and histologic examinations have not identified the cause of these lesions, and helminths have not been associated with them.[24] Although surgical treatment of this condition (resection and anastomosis) is frequently required, the majority of cases are treated by manual evacuation of impacted feed material into the cecum and parenteral administration of corticosteroids. An epidemiologic study of IFEE in the northwest of England revealed a seasonal pattern of the disease: The risk was highest between July and November.[26]

Strangulating Obstruction

Strangulating obstruction of the intestine is characterized by simultaneous occlusion of the intestinal lumen and its blood supply. Although strangulation of the intestinal lumen results in clinical signs similar to those of simple obstruction, occlusion of the blood supply results in a more rapid deterioration of the intestinal mucosa and subsequent onset of endotoxemia. Therefore clinical signs (including pain, heart rate, mucous membrane color, and capillary refill time) are typically more severe, and the prognosis is less favorable.

A great deal of work has been done to characterize mucosal injury that occurs during strangulation[27,28] and reperfusion.[29] In general, the lesion that develops during strangulation is severe: the small portion of bowel left viable is vulnerable to further injury during reperfusion.[30] The severity of the ischemic lesion is partly attributable to the fact that in most cases, initial occlusion of veins and partial occlusion of arterial blood supply during strangulation induces a hemorrhagic lesion. This results in extensive congestion and mucosal degeneration (Fig. 32.66).[27] Bowel peripheral to the strangulating lesion may also become injured as a result of distention.[31] In addition, distended small intestine that remains viable after surgical correction of strangulation may be subject to postoperative reperfusion injury through the generation of reactive oxygen metabolites.[32] Although attempts at reducing mucosal injury in a horse with antioxidants have met with some success,[33] their clinical use is limited.

The prognosis for survival in horses with SISO is generally poorer than those of most other types of colic. In a number of studies, rates of short-term survival of horses with SISO were between 55% and 84%. A large single-center study that included 147 horses with small intestinal disease demonstrated that short-term survival rate was significantly lower among horses with SISO (54.8%) than among those with a simple obstruction (79.6%).[34] In contrast, however, a review of 74 horses revealed no significant difference in short-term survival rate between horses with SISO (84%) and those with a simple obstruction (91%).[35] The importance of early referral and diligent assessment of intestinal viability was highlighted by a case series of 35 horses with strangulating small intestinal lesions that were managed without resection and anastomosis; the reported rate of survival to discharge was 100%.[36] It is important to discuss with owners the potential postoperative complications and long-term survival rates. Studies in which horses were monitored after discharge from the hospital have revealed significantly lower survival rates after 12 months, ranging from 47% to 68%.[37-39]

Episodes of colic are the most frequently reported complication after discharge[38,40] and are significantly more common in horses with small intestinal obstruction than in those with large colon disease.[38] A significant reason for repeated episodes of colic and reduced long-term survival in patients that have had small intestinal surgery is intraabdominal adhesions (Fig. 32.67). For example, in one study, 22% of horses undergoing small intestinal surgery required further surgery or were euthanized because of adhesions, and only 25% of horses that had a clinical problem with adhesions survived.[41] A more recent study of 99 horses requiring repeat celiotomy demonstrated that intraabdominal adhesions were the most common pathologic finding.[42] In that study, however, horses with small intestinal lesions were not more likely to develop adhesions than were those with large colon lesions, and horses with adhesions were no less likely to survive than those without.[42]

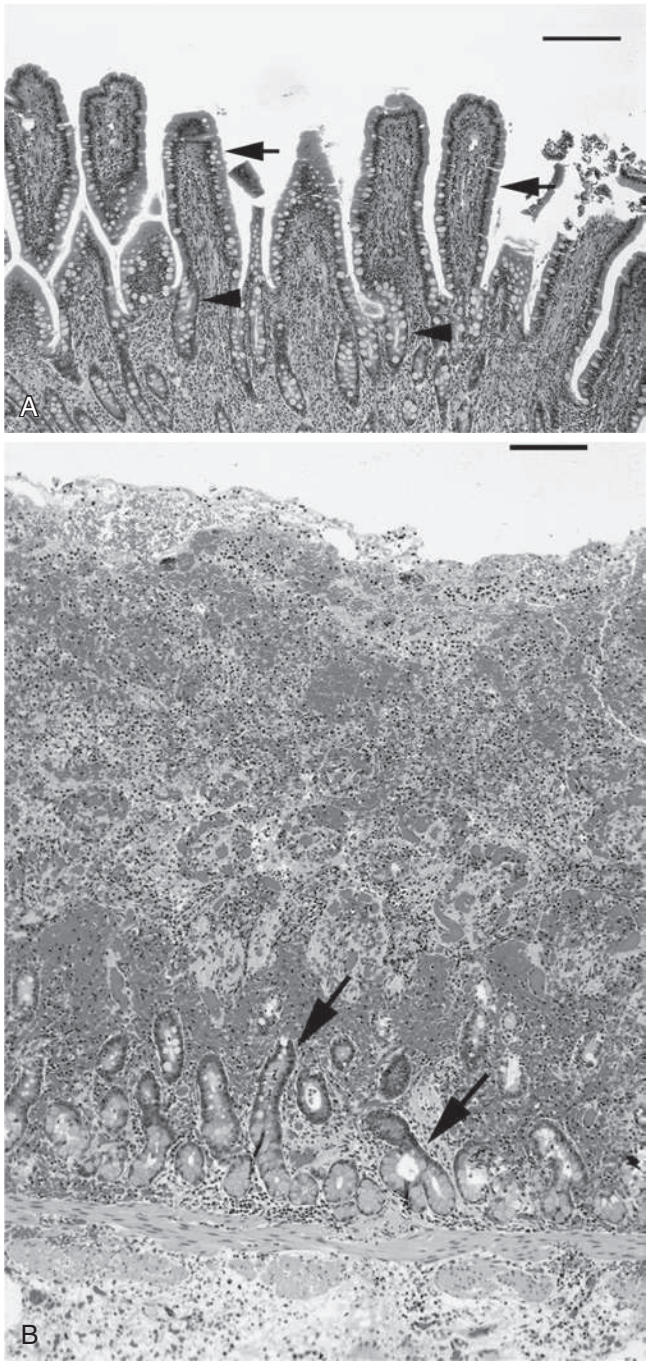

FIG. 32.66 Histologic appearance of normal and strangulated jejunal mucosa. **A,** Normal equine jejunal mucosa, with extensive villi *(arrows)* and mucosal crypts *(arrowheads)*. **B,** Hemorrhagic strangulating lesion of the jejunum, with complete loss of villi and extensive hemorrhage. Note the presence of crypts *(arrows)*, which remain relatively undamaged. (Scale: 1 cm = 100 μm.)

EPIPLOIC FORAMEN ENTRAPMENT. The epiploic foramen is a potential opening (because the walls of the foramen are usually in contact) to the omental bursa located within the right cranial quadrant of the abdomen. It is bounded dorsally by the caudate process of the liver and caudal vena cava and ventrally by the pancreas, the hepatoduodenal ligament, and the portal vein.[43,44] Clinical signs include acute onset of severe colic, and examination findings are compatible with small intestinal obstruction. Although the condition was reportedly more prevalent in older horses, studies have not revealed an age predilection.[45] However, a seasonal pattern for this disease has been detected. Specifically, more horses appear to suffer from epiploic foramen entrapment during the fall and winter months, which may reflect management practices.[46] An additional factor associated with epiploic foramen entrapment is

VetBooks.ir

FIG. 32.67 Intraabdominal adhesion in a foal. Note the presence of a mature fibrous adhesion between two segments of jejunum *(arrows)* that resulted in kinking and partial obstruction of the affected intestine.

FIG. 32.68 Strangulating lipoma of the ileum. A lipoma, together with its mesenteric stalk *(arrows)*, has become intertwined with a loop of the ileum, which resulted in a hemorrhagic strangulating obstruction.

crib-biting. One possible reason for this association is the development of negative intrathoracic pressure during cribbing, which might then result in cranial movement of intestine into the vicinity of the epiploic foramen. The association between crib-biting and epiploic foramen entrapment has been shown in separate studies performed in the United Kingdom and the United States.[47]

The diagnosis is definitively made at surgery, although ultrasonographic findings of distended loops of edematous small intestine adjacent to the right middle body wall are suggestive of epiploic foramen entrapment.[43] Entrapped small intestine may enter the foramen from the visceral surface of the liver toward the right body wall or in the opposite direction. In most cases, however, the intestine enters the foramen in a left-to-right direction.[43,47] Small intestine entrapment may be limited to a portion of the intestinal wall (parietal hernia).[49] In addition, the large colon may become entrapped within the epiploic foramen.[50] In the treatment of epiploic foramen entrapment, the epiploic foramen must not be enlarged either by blunt force or with a sharp instrument because the vena cava or portal vein may be ruptured and fatal hemorrhage may occur. In addition, excessive force used to extract entrapped bowel during surgery may also result in rupture of a mesenteric branch of the cranial mesenteric artery. In some cases of epiploic foramen entrapment, intraabdominal hemorrhage found before surgery may result from compromise of the mesenteric blood supply rather than the major blood vessels that border the epiploic foramen. The prognosis has substantially improved since the 1990s, with short-term survival rates (discharge from the hospital) ranging from 74% to 95% in the most recent studies.[43,51,52]

STRANGULATION BY MESENTERIC PEDUNCULATED LIPOMA. Lipomas form between the leaves of the mesentery as horses age, and mesenteric stalks develop as the weight of the lipoma tugs on the mesentery. The stalk of the lipoma and a loop of small intestine or small colon may become intertwined and lead to strangulation (Fig. 32.68). Strangulating lipomas should be suspected in mature horses (>10 years old) with acute colic referable to the small intestine.[53] In addition, geldings and ponies appear to be at risk for developing strangulating lipomas,[54] possibly because of differences in fat metabolism. One study documented a case of strangulating lipoma in a much younger patient, which indicates that although the aging process is associated with development of lipomas, this diagnosis cannot be ruled out preoperatively on the basis of age alone.[55,56] The diagnosis is usually made at surgery.

Treatment involves surgical resection of the lipoma and strangulated bowel, although strangulated intestine is, on occasion, viable. Studies indicate that approximately 60% to 78% of horses are discharged from the hospital after surgical treatment.[53,57,58]

SMALL INTESTINAL VOLVULUS. A volvulus is the twisting of a segment of small intestine more than 180 degrees along the axis of the mesentery. Small intestinal volvulus is theoretically initiated by a change in local peristalsis, but the mechanisms of this disease are unclear.[59] It is reportedly one of the most commonly diagnosed causes of small intestinal obstruction in foals.[60] It has been theorized that young foals may be at risk for small intestinal volvulus because of changing feed habits as they adapt to a forage-based adult diet. However, a report of 115 cases of small intestinal volvulus found that 74% of the affected animals were aged 3 years or older.[61] Onset of acute, severe colic, a distended abdomen, and radiographic or ultrasonographic evidence of multiple loops of distended small intestine in a young foal are suggestive of small intestinal volvulus. However, volvulus cannot be differentiated preoperatively from other causes of small intestinal obstruction.

In adult horses, volvulus frequently occurs in association with another disease process, during which small intestinal obstruction results in distention and subsequent rotation of the small intestine around the root of the mesentery (e.g., in horses that have strangulation caused initially by a pedunculated lipoma). Although any segment of the small intestine may be involved, the distal jejunum and ileum are most frequently affected, probably because the mesentery is longer in the more distal portion of the bowel. The diagnosis is made on palpation of a twist at the origin of the cranial mesenteric artery during surgical exploration. Treatment includes resection of devitalized bowel, which may not be an option because of the extent of small intestinal involvement. For example, if complete volvulus of the small intestinal tract occurs, the only option would be to untwist the intestine and hope that the bowel was sufficiently viable to survive the disease process. This would in turn depend on the duration of disease and the extent of intestinal ischemia

VetBooks.ir

(i.e., how tightly the intestine twisted as the volvulus developed). Prognosis is based on the extent of small intestine involved and its appearance after surgical correction of the lesion.[62] For example, the degree of sepsis may be related to the surface area of devitalized tissue. In addition, the length of the time it takes to complete the surgery can become problematic, particularly in patients with sepsis, in which it is difficult to maintain adequate arterial blood pressure. Nonetheless, survival in patients with extensive small intestinal resection may not be related to the absolute length of intestine resected.[63] The prognosis for short-term survival is good; one study suggested that 80% of horses are discharged after surgery.[34]

INGUINAL HERNIA. Inguinal hernias are more common in Standardbred and Tennessee Walking horses, which tend to have congenitally large inguinal canals. Inguinal hernias may also occur in neonatal foals, but they differ from hernias in mature horses in that they are typically nonstrangulating. Typical historical findings in mature horses with inguinal hernias include acute onset of colic in a stallion that has recently been used for breeding. A cardinal sign of inguinal herniation is coolness and enlargement of one testicle.[64,65] This is attributable to occlusion of the testicular blood supply in most cases rather than strangulated intestine within the scrotum itself. Inguinal hernias can also be detected on rectal palpation, and ultrasonography of the testicle is very helpful in determining the diagnosis, particularly of testicular torsion. The nature of the hernia (direct versus indirect) is determined by the integrity of the parietal vaginal tunic. In horses in which the bowel remains within the parietal vaginal tunic, the hernia is said to be indirect because the bowel remains within the peritoneal cavity. Direct hernias are those in which the bowel ruptures through the parietal vaginal tunic and occupies a subcutaneous location, followed by strangulation. Direct hernias most commonly occur in foals and should be suspected when a congenital inguinal hernia is associated with colic, swelling that extends from the inguinal region of the prepuce, and intestine that may be palpated subcutaneously.[66,67] Although most congenital indirect inguinal hernias resolve with repeated manual reduction or application of a diaper, or both, surgical intervention is recommended in foals with congenital direct hernias in order to reduce the hernia, as well as repair the parietal vaginal tunic.

In stallions with indirect inguinal hernias, the hernia is typically surgically reduced via combined inguinal and midline ventral abdominal incisions to allow visual inspection of the small intestine and, if necessary, resection and anastomosis. However, in many cases taken to surgery the short segment of herniated intestine improves markedly in appearance once it has been manually or surgically reduced, and in some cases the affected intestine can be left unresected. In these cases, subsequent laparoscopic closure of the internal vaginal ring is recommended to prevent recurrence and simultaneously retain the associated testicle.[68] In cases of nonreducible hernias, the affected testicle is congested because of vascular compromise within the spermatic cord, and although it may remain viable, it is recommended that it be resected and the external inguinal ring closed. If the testicle is retained, the inguinal canal should be partially closed at surgery to prevent recurrence, but the risk that this procedure will reduce spermatic cord vasculature is another problem. The prognosis in adult horses is good; 76% of horses in one study were alive 6 months after discharge.[65] Horses that have been unilaterally castrated during surgical treatment of inguinal hernias may be used for breeding. In these horses, the remaining testicle has increased sperm production, although an increased number of sperm abnormalities will be noticed after surgery because of edema and increased temperature of the scrotum.

STRANGULATING UMBILICAL HERNIAS. Whereas umbilical hernias are common in foals, strangulation of herniated bowel is rare. In one study, 6 (4%) of 147 horses with umbilical hernias had incarcerated intestine.[69] The hernia sac is warm, swollen, firm, and painful in association with signs of colic. The affected segment of bowel is usually the small intestine, but herniation of the cecum or large colon has also been reported.[70] In rare cases, a hernia involves only part of the intestinal wall and is referred to as *Richter hernia*. In foals that have Richter hernia, an enterocutaneous fistula may develop. In one study, all 13 foals with strangulating umbilical hernias survived to discharge, although at least 3 died because of long-term complications.[70]

DIAPHRAGMATIC HERNIAS. Herniation of intestine through a rent in the diaphragm is uncommon in horses, accounting for 0.3% of all cases of colic in a large multicenter study.[34] Any segment of bowel may be involved, although the small intestine is most frequently herniated.[71] Diaphragmatic rents may be congenital or acquired, but acquired hernias are more common. Congenital rents may result from incomplete fusion of any of the embryonic components of the diaphragm: pleuroperitoneal membranes, transverse septum, and esophageal mesentery. In addition, abdominal compression of the foal at parturition may result in a congenital hernia. Acquired hernias are presumed to result from trauma to the chest or a sudden increase in intraabdominal pressure, as might occur during parturition, distention of the abdomen, a sudden fall, or strenuous exercise.[72] In one study, of 40 horses diagnosed with diaphragmatic hernia, 19 (48%) had a history of recent trauma.[72] Hernias have been found in several locations, although large congenital hernias are typically present at the most ventral aspect of the diaphragm, and most acquired hernias are located at the junction of the muscular and tendinous portions of the diaphragm. In addition, a peritoneal-pericardial hernia has been documented in at least one horse.[73]

The clinical signs are usually associated with intestinal obstruction rather than respiratory embarrassment. However, careful auscultation may reveal an area of decreased lung sounds in association with obstructed intestine and increased fluid within the chest cavity. Such signs may prompt thoracic radiography or ultrasonography, both of which can be used to make a diagnosis. In one review, of 40 horses reported in the literature with diaphragmatic hernia, 7 (18%) had dyspnea.[72] Auscultation may also reveal thoracic intestinal sounds, but it is typically not possible to differentiate these from sounds referred from the abdomen. In another report, two of three horses with small intestinal strangulation by diaphragmatic hernia had respiratory acidemia, attributable to decreased ventilation.[74] Because of the difficulties in correcting diaphragmatic hernias and the associated complicating factors such as pneumothorax, these cases are generally considered to have a poorer prognosis than are other causes of colic. Reports of 31 and 44 cases demonstrated that 46% and 27%, respectively, of affected horses undergoing surgical treatment survived to discharge, and the overall success rates were only 23% and 16%, respectively.[75,76]

INTUSSUSCEPTIONS. An intussusception involves a segment of bowel (intussusceptum) that invaginates into an adjacent aboral segment of bowel (intussuscipiens). The reason for such invagination is not clear, but it may involve a lesion at the leading edge of the intussusception, including small masses, foreign bodies, or parasites. In particular, tapeworms *(Anoplocephala perfoliata)* have been implicated.[77] Ileocecal intussusceptions are the most common intestinal intussusceptions in horses and typically affect young animals. For example, in one evaluation of 26 cases of ileocecal intussusception, the median age of the horses was 1 year.[78] Acute ileocecal intussusceptions are those in which the duration of colic is less than 24 hours, and they involve variable lengths of intestine that ranged in one study from 6 cm to 457 cm long. In acute cases the involved

VetBooks.ir

segment of ileum typically has a compromised blood supply. Chronic ileocecal intussusceptions typically involve short segments of ileum (up to 10 cm long), and the ileal blood supply is frequently intact.

Abdominocentesis results are variable because strangulated bowel is contained within the adjacent bowel. There is often evidence of obstruction of the small intestine, including nasogastric reflux and multiple distended loops of small intestine on rectal palpation. Horses with chronic ileocecal intussusceptions have mild, intermittent colic, often without evidence of small intestinal obstruction. A mass may be palpated in the region of the cecal base in approximately 50% of cases. Transabdominal ultrasonography may be helpful in discerning the nature of the mass. The intussusception has a characteristic target appearance on cross-section.[79]

Other segments of the small intestine, including the jejunum, may also be intussuscepted. In one study on 11 jejunojejunal intussusceptions, the length of bowel involved ranged from 0.4 to 9.1 m.[80] Attempts at reducing intussusceptions at surgery are usually futile because of intramural swelling of affected bowel. Jejunojejunal intussusceptions should be resected. For acute ileocecal intussusceptions, the small intestine should be transected as far distally as possible and a jejunocecal anastomosis created. In cases of particularly long intussusceptions (lengths up to 10 m has been reported), an intracecal resection may be attempted. For horses with chronic ileocecal intussusceptions, a jejunocecal bypass without small intestinal transection should be performed.

In one study of the survival of horses with ileocecal intussusceptions, all 7 horses with chronic intussusceptions survived long term (>4 months), whereas only 5 (42%) of 12 horses with acute intussusceptions survived long term.[78] In a separate study of survival in horses with jejunojejunal intussusceptions, 6 (54%) of 11 horses were discharged from the hospital after surgery, and 4 (36%) of 11 horses survived long term (>16 months).[80]

OTHER SMALL INTESTINAL STRANGULATIONS. Entrapment of the small intestine may occur through rents in the mesentery or in internal ligaments such as the gastrosplenic ligament,[81] the broad ligament, and the proximal aspect of the cecocolic ligament.[82] Entrapments may also occur through trauma-induced body wall hernias. For all of these conditions it is often necessary to enlarge the rent or hernia to allow reduction of entrapped small intestine. In the case of body wall hernias, the defect should be closed with suture or patched with mesh. Entrapment of small intestine within mesenteric rents can be particularly problematic because they can be difficult to reduce and the rents are often difficult to close. Mesenteric rents have been associated with an unfavorable prognosis, possibly because large lengths of intestine may become strangulated and because the mesenteric vasculature is frequently compromised to the extent that intraabdominal hemorrhage has been noted in some cases.[83] However, a case series involving 38 Thoroughbred broodmares with small intestinal mesenteric rents reported short-term survival rates of 76% overall and 88% among horses that recovered from anesthesia.[84] The inability to close the rent at surgery was associated with increased likelihood of colic after hospital discharge but did not affect overall survival. This study probably highlights the benefits of prompt referral before significant lengths of intestine are strangulated and the importance of making every effort to close the rent at surgery.

Nonstrangulating Infarction

Nonstrangulating infarction occurs secondary to cranial mesenteric arteritis caused by migration of *S. vulgaris*[85] and has become rare during surgery since the advent of broad-spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases. These findings suggest that vasospasm plays an important role in this disease.[85] Clinical signs are highly variable, depending on the extent to which arterial flow is reduced and the segment of intestine affected. Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved. There are no clinical variables that can be used to reliably predict or differentiate this disease from strangulating obstruction. In some cases massive infarction results in acute, severe colic. In other cases intermittent colic develops as smaller emboli are released into the colonic blood supply. An abnormal mass and fremitus are occasionally detected on palpation of the root of the cranial mesenteric artery on rectal palpation. This disease should be considered part of the differential diagnosis in horses with a history of inadequate anthelmintic treatment and the presence of intermittent colic that is difficult to localize. Although fecal parasite egg counts should be performed, they are neither indicative of the degree nor specific for the type of parasitic infestation.

In addition to routine treatment of colic, dehydration, and endotoxemia, medical treatment may include aspirin (20 mg/kg q24h) to decrease the risk of thrombosis. Definitive diagnosis requires surgical exploration. Surgical treatment depends on the distribution of infarction. Unfortunately, these cases are difficult to treat because of the patchy distribution of the lesions and the possibility that lesions extend beyond the limits of surgical resection. In addition, further infarction may occur after surgery. The prognosis is fair for horses with intermittent mild episodes of colic that may be amenable to medical therapy, but horses that require surgical intervention have a poor prognosis.[85]

Medical Disorders of the Large Intestine

Samuel L. Jones

Acute Diarrhea

Diarrhea in horses can be defined as the passage of fecal material that has increased water content. It can vary from soft, formed stools with a mild to moderate increase in water content to projectile fecal passages that contain little solid matter. The passage of excessive water in the feces reflects disruption of the normal balance of fluid and electrolyte secretion and absorption in the intestinal tract. In adult horses, diarrhea results almost exclusively from disorders of the large intestine, although it may be a feature of some disorders of the descending small colon. Diarrhea can result in significant losses of water, electrolytes, and plasma protein and is often accompanied by local and systemic inflammatory responses.

Diarrhea disorders in adult horses can be divided into those characterized by inflammation of the cecum and large intestine (typhlitis, colitis) and those in which there typically is no inflammatory response. Inflammatory disorders include those characterized by an acute inflammatory response (salmonellosis, Potomac horse fever [PHF], clostridiosis, and equine coronavirus, described later), disorders associated with endoparasitism (small and large strongyle larval migration or encystation), disorders arising from toxicity (cantharidin toxicity, described later, and NSAID toxicity), and disorders included under the umbrella term *inflammatory bowel disease* (IBD). Disorders that can manifest with diarrhea but are not characterized by colonic inflammation include those in which intestinal hydrostatic pressure is increased (congestive heart failure, cirrhotic liver disease), those in which intraluminal osmolarity is increased, and poorly defined disorders in which fluid secretion may be stimulated by the enteric nervous system.

VetBooks.ir

Colitis is active inflammation within the colon that is usually associated with myriad local and systemic pathophysiologic events. Diarrhea is an important problem in horses with colitis, but sepsis resulting in impaired cardiopulmonary function, coagulopathies, and other sequelae of activation of inflammatory mediator cascades can be life-threatening. Other complications that occur in patients with colitis and sepsis, regardless of cause, include hematogenous organ colonization by bacteria, immune suppression and susceptibility to superinfection with bacteria or fungi, cecum or colon infarction, jugular vein thrombosis, and laminitis.

A variety of inflammatory cells and mediators affect the equine colon. In acute colitis the neutrophil is the effector cell, and the cascade of activation of inflammatory mediators associated with acute colitis is designed to bring neutrophils to where chemical signals indicative of bacterial infection have been detected. Signs of sepsis frequently accompany, or even precede, diarrhea in horses. Severe tissue inflammation can cause ulceration of the mucosal epithelium, which results in chronic malabsorption and protein-losing enteropathy. Malabsorption of volatile fatty acids (VFAs) and metabolic alterations that result from excessive production and release of inflammatory mediators can lead to an energy deficit and catabolism of body tissues.

Specific diseases affecting the equine large colon (e.g., salmonellosis, PHF, clostridial and equine coronavirus colitis, and cantharidin toxicity) may have different activators of local and systemic inflammatory responses, and they can produce unique toxins that further contribute to tissue injury. Regardless of the cause, the clinical problems of affected horses are often similar, and the clinician must consider treatments that modify inflammatory changes and replace losses of fluid, electrolytes, and plasma protein. In many cases, the cause of the diarrhea is not determined. Descriptions of important causes of diarrhea in horses are as follows.

Salmonellosis

Salmonella bacteria possess an array of virulence factors that confer attributes of mucosal adhesion and invasion, produce enterotoxins that stimulate intestinal fluid secretion, activate local inflammation (including recruitment of inflammatory cells and the release of their mediators), cause local cytotoxic effects, and initiate systemic responses attributable to LPS and other microbial molecules.

EPIDEMIOLOGY. Numerous *Salmonella* serotypes have been associated with equine colitis, and overall more than 2500 serotypes of *Salmonella* have been described. *Salmonella enterica* serovar Typhimurium is the most frequently isolated serotype in horses; dozens of other serotypes are isolated sporadically. Many clusters of cases of equine salmonellosis in which specific *Salmonella* serovars predominate have been described. Nosocomial infections associated with *S. enterica* serovars Krefeld,[1-3] Typhimurium,[2] Anatum,[4] Infantis,[5] and Newport[6] have been reported. Pertinent features of these bacteria are the ability to withstand a wide range of environmental conditions, the ability to rapidly invade and spread within the host (and thus be shed into the environment through the feces), and the range of severity of illness that results from infection.

Other key elements that influence whether clusters of cases will occur if an *S. enterica* serovar is present in the environment are availability and population density of susceptible hosts and the size of the infective dose of the pathogen. For these reasons, veterinary hospitals, breeding farms, and other facilities that may have a high density of horses are most vulnerable to the development of *Salmonella* outbreaks. In several studies at veterinary teaching hospitals, horses that were at greatest risk for developing salmonellosis or shedding *Salmonella* in their feces were those treated with antimicrobial drugs or admitted for treatment of colic.[7-9] Such horses are the majority of patients in any equine referral hospital and account for a significant biosecurity concern in equine hospitals and potentially in the home stables of shedding patients after discharge if susceptible animals have contact with discharged horses that are shedding.[10] Breeding farms are susceptible to *Salmonella* outbreaks (or other enteric infections) because of the concentration of large numbers of immunologically immature newborn animals. In either case the particular *Salmonella* organism involved in disease outbreaks may not have to be especially virulent because the inherent susceptibility of the host provides the microbe the opportunity to colonize and invade the host. Also of importance is the ability of the organism (inherent or acquired) to persist in the environment, lying in wait for both susceptible hosts and environmental conditions that favor its propagation and dissemination.

Serovars or strains of *Salmonella* that have newly acquired virulence plasmids can rapidly become established and spread among farms, sales areas, veterinary clinics, and veterinary teaching hospitals. Often the origin of these "new" bacteria is undetermined, but in some cases the organism can be traced to contaminated feed,[11] a specific shedder or index case introduced into the environment,[6] or domestic, feral, or wild animals.

Salmonella organisms are ubiquitous in the environment, and the prevalence of fecal shedding varies by the group of horses sampled and the method of detection. Prevalence of fecal shedding, based on fecal culture, in asymptomatic horses admitted to teaching hospitals varied from 1% to 5%.[12,13] In a nationwide survey of prevalence of *Salmonella* in fecal samples from horses on farms and ranches, *Salmonella* bacteria were cultured from fewer than 1% of horses.[14] The incidence of *Salmonella* shedding in feces has been reported to be 17% among horses admitted to a teaching hospital for lameness examination and 35% to 60% or higher in hospitalized horses with gastrointestinal disease.[9,15] In these reports PCR was determined to be specific for *Salmonella* DNA, but the test cannot differentiate between shedding of live bacteria and that of DNA from dead organisms.

Horses are not considered to be carriers per se of *Salmonella* because no host-adapted *Salmonella* spp. have been identified in horses. *Salmonella abortus equi* has disappeared in the United States. Horses that shed *Salmonella* spp. in the feces usually do so transiently for several days to weeks; infrequently, horses shed *Salmonella* bacteria for several months.

In acutely affected horses, large numbers of highly infective *Salmonella* organisms can be shed in the diarrheic feces. Susceptible animals such as young foals, hospitalized horses receiving antimicrobial drugs, and horses under stress can become ill after becoming infected by the bacteria in numbers far lower (1% to 0.1%) than the number necessary to infect immunocompetent normal horses. Thus particular care should be taken in the management of horses and foals with diarrhea in environments in which there are other animals at risk (e.g., hospitals, breeding farms, show stables, racetracks). Asymptomatic shedders generally pass relatively small numbers of *Salmonella* organisms in the feces and do not appear to pose an important threat to healthy horses not being treated with antibiotics,[10] but asymptomatic shedders have been responsible for outbreaks of salmonellosis in hospitals and on breeding farms.

CLINICAL FINDINGS. Salmonellosis typically is characterized by an acute colitis that results in profuse diarrhea and occasionally abdominal pain. Many horses with salmonellosis have signs of sepsis and potentially cardiovascular shock, vascular leak syndrome, and coagulopathies. Horses are usually febrile, tachycardic, moderately to severely obtunded, and dehydrated. With other clinical syndromes of *Salmonella* infection, diarrhea is not a feature. These syndromes include fever and leukopenia, colic, and proximal enteritis with gastric reflux.

VetBooks.ir

DIAGNOSIS. Salmonellosis is most commonly confirmed through bacteriologic culture or quantitative PCR detection of *Salmonella* bacteria. Other diagnostic tests such as lateral flow immunoassay and DNA hybridization are becoming commercially available and may become useful for rapid detection of *Salmonella* bacteria.[16] Multiple fecal cultures or quantitative PCR, or both, for *Salmonella* spp. should be performed on all horses with diarrhea, particularly if they have signs of systemic inflammation (fever, neutropenia or leukopenia, tachycardia, or tachypnea). It is recommended that at least three to five fecal samples collected 12 to 24 hours apart be submitted to increase the sensitivity of culture.[17] Samples with little solid matter often yield negative culture results, even when horses are infected with *Salmonella*. Formed fecal samples from infected horses are more likely to produce a positive culture result. A 5- to 10-g amount of feces should be submitted for culture in selective media such as tetrathionate broth or selenite broth and brilliant green agar or XLD agar. Culture of a rectal mucosa biopsy sample may be a useful adjunctive test for diagnosing salmonellosis. PCR is a sensitive screening tool for detection of fecal *Salmonella* DNA and is important for environmental monitoring and biocontrol measures in hospitals. Quantitative PCR is very sensitive and specific in comparison with conventional culture and has a high positive predictive value for individual patients that have clinical signs consistent with salmonellosis.[18]

TREATMENT AND PREVENTION. In most cases of salmonellosis, aggressive treatment facilitates resolution of the severe diarrhea and associated metabolic disorders within 7 to 10 days of the onset of illness. Intravenous administration of polyionic fluids is necessary to replace fluid and electrolyte losses and to augment preload in horses with poor venous return (see the Fluid Therapy for Horses with Gastrointestinal Diseases section in this chapter and also Chapter 44 for more comprehensive information about fluid therapy for diarrhea). Plasma may be needed to replace lost plasma proteins and increase plasma colloidal pressure. Alternative colloidal fluids, such as hetastarch, may be useful and more cost-effective than plasma in horses with vascular leak syndrome and hypoproteinemia. Flunixin meglumine is often used to treat inflammation in horses with signs of sepsis. Flunixin and other NSAIDs should be used with caution and at the lowest dose possible to prevent worsening of colonic mucosal damage or inhibition of mucosal repair.

Other antiinflammatory strategies may be used to treat sepsis associated with salmonellosis. Total or partial parenteral nutritional support is often indicated to provide adequate calories and amino acids during the most debilitating period of the illness. Antimicrobials are not universally administered to horses with suspected or known salmonellosis, but antimicrobial administration may decrease the spread of *Salmonella* bacteria to other organs and may have some direct effect on *Salmonella* bacteria in the colon. Traditionally, use of antimicrobial drugs such as chloramphenicol, trimethoprim-sulfonamide, gentamicin, and cephalosporins has not appeared to accelerate resolution of signs of colitis. Fluoroquinolones, such as enrofloxacin, although potentially arthropathic in young horses, may be more effective because of high lipid solubility and bactericidal activity against *Salmonella* bacteria. The prevalence of infection with and shedding of multidrug-resistant *Salmonella* strains appears to be increasing in high-risk facilities such as equine veterinary hospitals, which potentially affects treatment success and zoonotic transmission.[6,19]

Horses that have severe diarrhea and sepsis for 10 days or longer are unlikely to survive, even with intensive therapy, because many have extensive ulceration of colonic mucosa and chronic, severe inflammation within the wall of the colon. Ulceration may be exacerbated by administration of NSAIDs.

FIG. 32.69 Colonic infarction in a horse with salmonellosis. Tenesmus and rectal prolapse were early clinical signs of colonic infarction. *(Courtesy Dr. M.J. Murray.)*

Complications such as catheter-associated thrombophlebitis, colonic infarction (Fig. 32.69), colonization of other organs by *Salmonella* spp. or other enteric bacteria, and laminitis can occur.

Measures designed to prevent the spread of *Salmonella* in an environment with potentially susceptible hosts need not be excessively laborious or expensive. The goal is to minimize the size of the infective dose of an enteric pathogen to which a susceptible host may be exposed. Thorough cleaning of areas where fecal contamination is likely and prevention of mechanical distribution of contaminated material are the most important measures. Extensive use of disinfectants may not be necessary if cleaning measures are adequate. Cleaning must include removal of organic debris, which can be accomplished with several products designed for that task. Areas that require particular attention are stalls, including water buckets or automatic watering systems, drains, and cracks in the floors and wall; stall implements; surgical areas, including drains; and nasogastric tubes and pumps.

If a diarrheic horse is not hospitalized, it should be isolated to the greatest degree possible, and biosecurity measures should be instituted to prevent transmission and to detect and monitor any potential outbreak.[6] Bedding material should be removed frequently to minimize accumulation of potential enteropathogens. Personnel entering the stall should be restricted to the professional staff, and they should wear gloves, disposable coveralls, and disposable plastic boots. Footbaths with disinfectant are effective only if they are kept clean and fresh because they quickly accumulate organic material that interferes with the action of the disinfectant. Vacated stalls should be thoroughly cleaned, allowed to dry, and disinfected, and culture or PCR testing of selected sites in the stall (floor, drain, waterer) must yield negative results for *Salmonella*. Biosecurity protocol compliance is crucial for preventing an outbreak.

Potomac Horse Fever

PHF is an infectious enterocolonic disorder caused by *N. risticii* (formerly *Ehrlichia risticii*).[20-22] The organism is an obligate intracellular parasite, infecting peripheral monocytes and macrophages, colonic and small intestinal epithelial cells, and colon mast cells.[23] The pathophysiology of the disease is incompletely understood, although many horses infected with *N. risticii* have clinical signs and complications similar to those in horses with salmonellosis. Two to 4 days after experimental inoculation with *N. risticii*, horses had a mild, transient fever.[24] By 10 to 14 days after experimental infection, horses had become febrile, had a poor appetite, and exhibited mild to severe gastrointestinal signs ranging from mild colic and soft stool to profuse diarrhea.

In clinical cases of PHF, there are signs of sepsis, including fever, leukopenia, congested mucous membranes, and

VetBooks.ir

hypercoagulability. The early fever observed in experimental cases is usually not detected by owners, and when clinical signs are seen, it is presumed that the affected horse was infected 10 to 14 days previously. Hypoproteinemia is a frequent finding in horses with clinical cases of PHF, which reflects loss of serum protein through inflamed intestinal mucosa. Of interest is, however, that the magnitude of intestinal inflammation is typically much less than with salmonellosis, and yet the magnitude of hypoproteinemia (total protein concentration < 3 g/dL) can be as severe.

Laminitis is a frequent sequela and may occur in 30% in horses with PHF. *N. risticii* has also been associated with abortion in mares, although this is an unusual occurrence.[25] In some horses that show significant seroconversion to *N. risticii*, laminitis is the only clinical sign.

MODE OF TRANSMISSION. Although originally described as a disease of horses living near the Potomac River in Maryland and Virginia, horses with serologic evidence of exposure to *N. risticii* have been reported in most U.S. states. Because early research on PHF demonstrated that infection was readily transmitted through blood,[24] it was presumed that the natural mode of transmission involved an insect or arthropod vector. However, several studies have failed to demonstrate any such vectors.[26,27]

The association between an affected horse and proximity to a river (within 5 miles) remains strong. Investigators have found a possible link between this association and how the disease may be transmitted. *N. risticii* and *Neorickettsia helminthoeca* were found to share a high degree of DNA homology.[28] *N. helminthoeca* is transmitted to mammals by a trematode that parasitizes fish and aquatic snails.[28] This discovery prompted investigators to search for evidence that *N. risticii* might reside in trematodes and their hosts found in riverine inhabitants. *N. risticii* DNA was detected in operculate and pulmonate snails (*Juga* spp. and *Planorbella* spp., respectively) collected from stream water in northern California, where PHF is enzootic.[29,30]

Moreover, *N. risticii* was detected in trematode stages found in the secretions of freshwater snails and in aquatic insects.[31,32] The sequences of these genes were virtually identical to those of the genes of an equine *N. risticii* strain isolated from horses located on a property near the snail collection site. Further work demonstrated *N. risticii* DNA in two trematodes, *Acanthatrium* spp. and *Lecithodendrium* spp., found in bats and swallows, which suggests that these animals may serve as reservoirs and that trematodes are a vector for the organism.[33] Oral transmission of *N. risticii* with infected cell cultures has been produced experimentally,[34] which indicates that ingestion of *N. risticii*, rather than blood transmission, is the route of natural infection. Oral transmission and clinical signs of PHF were demonstrated in horses fed *N. risticii*–infected aquatic insects (caddisflies), which suggests that ingestion of infected aquatic insects may be the natural route of infection.[35,36] Ingestion of water containing infected trematode stages released from aquatic snails may also be a route of infection.

DIAGNOSIS. Accurate confirmation of PHF can be difficult because clinical signs of disease are nonspecific and available diagnostic tests are not entirely reliable. The conventional recommendation is that paired acute and convalescent blood samples be submitted for indirect fluorescent antibody or ELISA testing for antibodies to *N. risticii*. However, serologic evaluation to confirm the disease is not as straightforward as in many other infectious diseases. A fourfold increase in titer between acute and convalescent sera is considered to confirm infection with *N. risticii*, but failure to seroconvert does not rule out infection. Because the onset of clinical signs can be delayed as long as 14 days after infection, horses may seroconvert by the time an acute sample is obtained.[34] The magnitude of titer is not always correlated with active infection, inasmuch as many horses in endemic areas have high titers but no disease. Vaccination also can affect the titer. There is significant interlaboratory variability in results of indirect fluorescent antibody tests, and false-positive results occur frequently.[37] Therefore it has been suggested that indirect fluorescent antibody testing for antibodies to *N. risticii* not be performed in areas that are not endemic for *N. risticii*.[37]

The current standard for diagnosis of PHF used by most clinicians is quantitative PCR testing of whole blood samples to detect *N. risticii* DNA in leukocytes.[38] PCR testing appears to be sensitive and specific in horses with compatible clinical signs.

TREATMENT AND PREVENTION. Treatment with oxytetracycline (7 to 11 mg/kg IV twice daily for 4 days) effectively eliminates *N. risticii* from horses in experimental infections. Fever should resolve within 48 hours of beginning treatment with oxytetracycline, and diarrhea typically resolves within 24 to 72 hours of beginning treatment. In one horse the author treated, clinical signs persisted until the dose of oxytetracycline was increased to 15 mg/kg twice daily. Orally administered doxycycline (10 mg/kg q12-24h) may be effective, although horses with severe gastrointestinal signs may not absorb doxycycline efficiently. Doxycycline must not be given intravenously because it will cause a horse to collapse. Some horses have had clinical relapses 2 to 3 weeks after initial resolution of clinical signs that were responsive to tetracycline. Horses do not remain chronic carriers of *N. risticii*.

In most cases of PHF, intravenous administration of polyionic fluids is necessary to replace fluid and electrolyte losses and to augment preload in horses with poor venous return. Plasma may be required to replace lost plasma proteins. Other colloidal fluids may also be used in patients with hypoproteinemia or sepsis. Because horses improve rather quickly once treatment with oxytetracycline has begun, parenteral nutritional support is usually unnecessary.

Vaccination has appeared to diminish the incidence and severity of disease, but PHF may still develop in vaccinated animals. Experimental results with vaccine were mixed, and the duration of immunoprophylaxis was very limited.[39] Disease severity has appeared to be less in vaccinated animals, although in the summer of 1994 many vaccinated horses developed severe cases of PHF. All of these horses were located in the area where PHF was originally described, and a new strain of *N. risticii* was identified.[40] PCR analysis has revealed multiple strains of *N. risticii*, which may account for the unreliability of the vaccine.[41] Horses in endemic areas should be vaccinated in the early spring and early to mid-summer on an annual basis.

Clostridial Diarrhea

Enteric clostridiosis was reported as a clinical problem in the 1970s, and clostridial bacteria were implicated as the causative agents of colitis X.[42] Difficulty in substantiating clostridial bacteria as the cause of enterocolitis in horses led to a deemphasis of this pathogen as a potential cause of diarrhea in adult horses. In the 1990s, with improved laboratory techniques for identification of clostridial toxins, clostridial bacteria were confirmed to be common causative agents of colitis in foals and adult horses.

The two most important clostridial species affecting the equine intestinal tract are *C. difficile* and *C. perfringens*. Most reported cases in adult horses have involved *C. difficile*, although in one report the prevalences of *C. difficile* toxin A and *C. perfringens* enterotoxin in fecal samples from horses with diarrhea were similar, and in some horses toxins from both clostridial species were identified.[43]

PATHOGENESIS. *C. difficile* is a Gram-positive sporulated obligate anaerobe responsible for most cases of antibiotic-associated diarrhea in many species, including horses, and for

a substantial proportion of nosocomial infections in humans and horses.[44,45] *C. difficile* produces two important toxins, named A and B. Most isolates of *C. difficile* produce both toxins, but some isolates produce only one of these. Toxin A can elicit both fluid secretion and a pronounced inflammatory response in the bowel. Toxin A has intestinal secretory and cytotoxic effects,[46,47] increases intestinal permeability,[48] and can activate epithelial cells, neutrophils, mast cells, monocytes, and macrophages to release a multitude of proinflammatory cytokines and vasoactive mediators.[49-51] Two interesting features of toxin A are its induction of the neurotransmitter substance P in both the intestine and dorsal root ganglia and its apparent dependence on substance P for full expression of its pathologic effects in the intestine of rodents.[52] Thus the effects of toxin A appear to be mediated both through direct effects on intestinal cells and through the enteric nervous system.

Toxin B exhibits enterotoxigenic (secretory) activity and has also been shown to have potent cytotoxic effects on human colonic epithelium.[53] Toxin B has little relevance to the pathogenicity of *C. difficile* in animal models, however, and the roles of toxins A and B in the pathogenesis of equine clostridial enterocolitis are not known.

Strains of *C. perfringens* are classified on the basis of the toxins that are produced; at least a dozen have been identified to date.[54] *C. perfringens* type A and type C have been recovered from equine specimens,[55] and several *C. perfringens* toxins have been identified in equine specimens.[56,57] *C. perfringens* type A is the most frequently isolated type, and its enterotoxin is released on sporulation of *C. perfringens* within the intestine. Other exotoxins of *C. perfringens* have phospholipase activity (alpha-toxin), necrotizing cytotoxic effects (beta-, epsilon-, and iota-toxins), and hemolytic effects (theta-toxin).

CLINICAL FEATURES. Clostridial enterocolitis affects foals and adult horses. In some reports, toxigenic *C. perfringens* organisms were isolated from more than 50% of foals with diarrhea.[57,58] The clinical presentation in foals with *C. perfringens* is predominantly hemorrhagic diarrhea with sepsis. *C. perfringens* can cause septicemia and is often cultured from the blood of foals with hemorrhagic diarrhea. In some foals, classic necrotizing enterocolitis is manifested by gas- or fluid-distended intestines and thickened intestinal mucosa. These changes can be appreciated radiographically and ultrasonographically, and intramural gas produced by clostridial bacteria may be detected with ultrasonography as hyperechoic areas within the bowel wall. *C. difficile* infection is also a cause of acute enterocolitis in foals.[59]

Adult horses with clostridial enterocolitis frequently have diarrhea, but abdominal discomfort or fever may be the primary presenting problem. There are no clinical features that consistently distinguish clostridiosis from salmonellosis, and a spectrum of clinical signs exists, from moderate illness to severe toxemic colitis. Most horses with clostridial enterocolitis develop diarrhea, but in some cases enteritis manifested by ileus and gas distention of the small intestine may be the primary problem. Although both *C. perfringens* and *C. difficile* and their toxins have been detected in a significant number of adult horses with colitis, *C. difficile* appears to be more common.[60-62] In fact, *C. difficile* appears to be the most common cause of antibiotic-associated diarrhea and is a very significant cause of nosocomial diarrhea in horses.[45,63] The most common antibiotics associated with *C. difficile* colitis in horses are erythromycin, trimethoprim/sulfonamides, β-lactam antimicrobials, clindamycin, rifampicin, and gentamicin. Strain differences among isolates of *C. difficile* cultured from the diarrheic feces of horses in intensive care units are associated with toxigenicity, severity of disease, and metronidazole resistance.[45,64] *C. difficile* has been implicated in DPJ,[65] but a cause-and-effect association has not been proven.

Similar to salmonellosis, clostridial enterocolitis can develop into a widespread problem affecting several animals in a hospital or equine facility.[66] Risk factors for developing nosocomial clostridial enterocolitis are similar to those for nosocomial salmonellosis: antimicrobial administration, concurrent gastrointestinal disease, and age susceptibility (foals). In addition, *Clostridium* spp. are well suited to persist in the environment because of the production of spores that are resistant to environmental extremes and many disinfectants.

DIAGNOSIS. Diagnosis of clostridial enterocolitis requires identification of toxigenic clostridia from intestinal contents or tissue. Several direct and indirect methods are used to detect toxigenic clostridia; these methods include culture, identification of toxins, and identification of toxin genes. Culture of *C. difficile* or *C. perfringens* requires anaerobic conditions, and the ability to culture these organisms from ingesta or fecal specimens rapidly diminishes with increased time from collection to arrival at a laboratory. It is recommended that samples be transported, chilled (not frozen) on ice, immediately or by overnight delivery for best recovery of clostridial organisms. Tissue specimens submitted for culture, toxin identification, or toxin gene identification should be handled similarly. Because nonpathogenic clostridia are common,[62,67] isolates should be tested for toxin production either by PCR or with bioassay before a definitive diagnosis is made in horses with clinical signs consistent with clostridial enterocolitis. Commercially available tests for clostridial toxins include an ELISA for *C. difficile* toxin A/B, a latex-agglutination test for *C. perfringens* enterotoxin, and an ELISA for *C. perfringens* enterotoxin. *C. difficile* A/B toxin tests have the advantages of being rapid, sensitive, and specific. Tests for *C. perfringens* enterotoxin are not as reliable for definitive diagnosis in most species. Also available is quantitative PCR for *C. difficile* toxin A/B genes and several *C. perfringens* toxin genes that can be applied directly to intestinal content or fecal samples without prior culture and isolation of the bacteria.[68]

TREATMENT. Supportive care may be required, as with other cases of acute diarrhea in horses. Treatment with metronidazole (15 to 20 mg/kg PO q6-8h) appears to be effective in eliminating enteric clostridial infection in most cases. In one veterinary teaching hospital, isolates of *C. difficile* were resistant to metronidazole,[69] and vancomycin was used with reported success. Large-scale resistance to metronidazole has not been reported elsewhere, and it should be the first choice in the treatment of suspected clostridial enterocolitis. *Saccharomyces boulardii* is a nonpathogenic yeast used in the treatment of *C. difficile* diarrhea and colitis in humans. The yeast releases a protease that specifically degrades *C. difficile* toxins A and B, and this has been shown to be protective in experimental *C. difficile* colitis in rats and to prevent damage to human colonic epithelium by *C. difficile* toxins A and B in vitro.[70] Although *S. boulardii* (25 g PO q12h) has been shown to colonize the intestinal tract in horses,[71] its efficacy in preventing or treating enterocolitis in horses is not clear. *S. boulardii* decreased the severity and duration of enterocolitis in one small study[72] but not in a larger study of antibiotic-associated diarrhea in horses.[71] Di-tri-octahedral smectite has been shown to bind clostridial toxins[73] and may be useful for treating clostridiosis in horses. Di-tri-octahedral smectite is available as a powder or paste and should be administered according to the manufacturer's instructions for 3 to 5 days.

Equine Coronavirus Enterocolitis

Equine coronavirus is an enteric pathogen that causes fever, lethargy, colic, and diarrhea primarily in adult horses.[74] Infections have been reported in horses housed in boarding, racing, and show stables and on breeding farms. Rates of morbidity in outbreaks range

from 10% to 83%.[75-78] Infections last a week or less and are usually self-limiting unless accompanied by potentially fatal complications such as sepsis or hypoammonemia. Equine coronavirus is shed in feces for several days; shedding may persist as long as 24 days.[77]

PATHOGENESIS. Equine coronavirus is a primary pathogen in adult horses and appears to be involved in co-infections with other enteric pathogens in foals, at least in one study in the United States.[79]

Equine coronavirus infection in adult horses causes an acute necrotizing, neutrophilic inflammation that has been well documented in the small intestine.[80] Disease in the large intestine was not significant in a limited study,[80] but it presumably also occurs in the large intestine, at least in horses with diarrhea. Epithelial cell necrosis and intestinal inflammation result in damage to the mucosal barrier, and subsequent sepsis probably results from absorption of microbial molecules. Equine coronavirus can be recovered from the respiratory tract in infected adult horses, but it is not clear whether clinically relevant respiratory disease accompanies enteric infections.[81,82] Fatal hyperammonemia has been reported in some cases of equine coronavirus–infected horses,[77,78,80] probably as a result of changes in the mucosal barrier and intestinal microbiome.

CLINICAL FEATURES. The most common clinical signs in adult horses with equine coronavirus infection are fever, lethargy, and anorexia.[77] Encephalopathy characterized by circling, ataxia, head pressing, nystagmus, seizures, or a combination of these is a less common clinic feature and appears to be associated with hyperammonemia in at least some cases.[77] Clinicopathologic findings include neutropenia and band neutrophilia (especially early in the course of disease), hyperfibrinogenemia, elevated serum amyloid A concentration, electrolyte and acid-base changes typical of acute enterocolitis, elevated concentration of unconjugated bilirubin, transiently elevated liver enzyme activities, and prerenal azotemia.[74] Hyperammonemia may be present in encephalopathic patients.[77,78]

DIAGNOSIS. Diagnosis is currently based on quantitative PCR testing of feces while the animal is alive or intestinal tissues or contents after its death. Fecal quantitative PCR is quite sensitive.[77,78] Shedding of equine coronavirus begins after 3 or 4 days, at least in experimentally infected horses,[83] so quantitative PCR test results may be falsely negative very early in the course of disease. Fecal shedding can persist from 3 to 24 days, and so infected horses may test positive after clinical signs resolve.

TREATMENT. Most cases are self-limiting and necessitate no specific treatment. Intravenous isotonic fluid administration with appropriate electrolyte supplementation may be required in some cases if diarrhea is persistent and severe. NSAID therapy may be indicated if fever and lethargy persist longer than a day or two. Analgesic drugs are indicated if colic is a problem. Complications such as sepsis and hyperammonemia may occur and necessitate intensive treatment and management as described elsewhere.

Cantharidin (Blister Beetle) Toxicity

PATHOGENESIS. Cantharidin is the toxic principal found in beetles of the genus *Epicauta*, commonly known as blister beetles.[84-86] Ingestion of the beetles in contaminated alfalfa hay results in absorption of cantharidin through the gastrointestinal tract. Blister beetles feed on the flowers of alfalfa and are incorporated into baled alfalfa hay if the hay is cut and processed simultaneously.[84-86] Large swarms of beetles may be found in relatively small portions of hay. The lethal dose of cantharidin is less than 1 mg/kg, but the concentration of cantharidin varies from species to species of blister beetles.[84,85] Therefore ingestion of as many as 100 to as few as 6 to 8 beetles may be lethal. Often more than one horse is affected. The fatality rate may be 50% or greater.[84,87]

Cantharidin is a potent irritant, causing cell damage and necrosis on contact.[84,86,87] The mucosa of the gastrointestinal tract is most commonly affected in horses because they ingest the toxin. Ulceration throughout the alimentary tract has been observed in natural and experimental cantharidin toxicity. Diarrhea probably results from the severe ulceration and inflammation of the large intestine, causing increased secretion of water, electrolytes, and protein. Large volumes of fluid and protein are lost in the gastrointestinal tract, which leads to hemoconcentration and profound hypoalbuminemia in some cases.[84,85,87] Cystitis, nephrosis, and myocarditis occur in natural and experimentally produced cases of cantharidin toxicity.[84,86,87] Cystitis and nephrosis result from the high concentration of cantharidin in the urine. The cause of the myocarditis and myocardial necrosis is unknown, but they may also be direct effects of the toxin on the myocardium. Plasma CK activity is often elevated, and this elevation has been postulated to arise from the damaged myocardium.[84,85] Affected horses have a characteristically stiff gait, but histopathologic evidence of skeletal muscle injury that explains the elevated plasma CK activity has not been observed.[85] Hypocalcemia and hypomagnesemia are characteristic features of cantharidin toxicity in horses that have not been explained.[84,85,87] Hypocalcemia may result from hypoalbuminemia, but the ionized calcium concentration is often decreased, along with the total calcium concentration, which indicates that hypoalbuminemia is not responsible for the hypocalcemia.[85]

CLINICAL FEATURES. Cantharidin toxicity can cause a range of clinical signs, from mild depression and abdominal discomfort to fulminant signs of toxemia and rapid death, depending on the ingested dose of toxin.[84,85,87] Most commonly, clinical signs include depression, sweating, irritability, abdominal pain, elevated heart and respiratory rates, fever, polyuria, polydipsia, and profuse diarrhea.[84,85,87] Blood is rarely seen in the feces. Affected horses frequently posture to urinate; indeed, stranguria and pollakiuria are characteristic of cantharidin toxicity.[84] Signs of hypocalcemia include synchronous diaphragmatic flutter and tremors. Gait may be stiff and stilted. Neurologic signs include head pressing, swaying, and disorientation.[87] Signs of systemic inflammation from sepsis may occur in severe cases. Some affected horses develop severe depression and toxemia and may die within hours after ingestion of cantharidin without developing diarrhea.[84,87] Hematologic abnormalities are similar to those of other causes of acute diarrhea, reflecting dehydration and sepsis. Hypocalcemia (both ionized and total calcium concentrations) and hypomagnesemia are characteristic biochemical features of cantharidin toxicity and may be profound. Azotemia with a urine specific gravity in the hyposthenuric range is common.[84,85,87] Microscopic hematuria and mild proteinuria may be evident.

DIAGNOSIS. Tentative diagnosis is based on clinical signs and the finding of blister beetles in the hay. Determining the species of the insects may be necessary to estimate the amount of cantharidin ingested. All species of *Epicauta* contain cantharidin, but some have small amounts. Definitive diagnosis requires the measurement of the cantharidin concentration in gastric or intestinal contents and urine.[84,88]

TREATMENT. Fluid therapy and maintenance of electrolyte balance are important, as in all cases of acute diarrhea. Particular attention should be paid to the degree of hypocalcemia and renal function as a fluid therapy plan is developed. Specific therapy is limited. Administration of absorbent powders via

VetBooks.ir

VetBooks.ir

nasogastric tube is important early to prevent further systemic absorption of cantharidin and local toxicity. Mineral oil administration may also help reduce absorption of the toxin. Pain control may be needed for colic or urinary pain. NSAID therapy should be used judiciously to avoid further injury to the intestinal mucosa and renal toxicity. Alternative analgesics, such as butorphanol or a lidocaine controlled-rate infusion, may be better choices.

Antimicrobial-Associated Diarrhea

The onset of acute diarrhea in horses has been associated with the use of several antimicrobial drugs. Lincomycin administered orally and tetracycline administered parenterally have been demonstrated to induce severe diarrhea in horses.[89,90] The oral administration of trimethoprim-sulfonamide, kanamycin, erythromycin, metronidazole, and penicillin and parenteral administration of ceftiofur and gentamicin have been implicated in onset of diarrhea, including fatal colitis, in horses. In one report there was no association between trimethoprim-sulfonamide and diarrhea.[91] However, in other reports, prior administration of antimicrobial drugs was positively associated with onset of colitis and negatively associated with prognosis for survival in horses with colitis.[92]

Antimicrobial-associated diarrhea is presumed to be secondary to disruption of normal colonic microflora and the proliferation of an enteropathogen, such as *Salmonella* spp., *C. perfringens*, and *C. difficile*. Of these, *C. difficile* is the most common cause of antimicrobial-associated diarrhea in horses.[45] Of interest, it was reported that mares whose foals were treated with erythromycin for *R. equi* infection developed severe, acute colitis, from which *C. difficile* and its toxins were isolated.[93] Erythromycin was detected in the mares' feces, and exposure to the erythromycin was presumed to have occurred when the mares licked erythromycin from the foals' faces.

Other Causes of Acute Diarrhea

NSAID toxicity has been associated with diarrhea secondary to damage to the colonic mucosa. Grain (carbohydrate) overload may cause overproduction of lactate in the colon, which leads to acute diarrhea. A combination of hyperosmolarity of the luminal contents and damage to the colonic mucosa account for the pathophysiologic process grain overload. The clinical signs are similar to those of other acute diarrheal diseases in horses and depend on the severity of the overload. Hyperlactemia, metabolic acidosis, and sepsis are key features of grain overload, and laminitis is a common sequela. Acute diarrhea in adult horses has also been associated with conditions such as lymphosarcoma enterocolitis and other IBDs, intestinal lymphosarcoma, peritonitis, heavy metal intoxication, anaphylaxis, and stress.

Clinical Assessments of Patients With Acute Diarrhea

The diagnostic evaluations performed on a horse with acute diarrhea are intended to provide the clinician with information to accurately assess the horse's condition and thus direct therapy toward specific requirements. The first part of the evaluation is a thorough physical examination, with particular attention to the horse's hydration status (skin turgor, gum moisture, capillary refill time), evidence of sepsis (fever or hypothermia, hyperemic mucous membranes, prolonged capillary refill time), cardiovascular system (heart rate and rhythm, character of peripheral pulse, capillary refill time), and signs of laminitis (lameness, digital pulse, palpable temperature of hoof walls). Many horses with colitis are moderately to severely dehydrated, with either purplish or brick-red mucous membranes. Purple mucous membrane color reflects venous congestion and poor venous return, whereas brick-red mucous membrane color reflects venous congestion and poor venous return plus arteriole and venule shunting and poor tissue oxygen exchange.

Blood pressure should be monitored; direct measurements via an arterial catheter are the most accurate, but indirect pressure measurements obtained with the use of a Doppler transducer placed over the coccygeal artery are satisfactory. Hypotension and hypertension occur in horses with colitis, and the blood pressure status of a patient often is unpredictable. Blood pressure can be monitored as frequently as labor allows and should be monitored hourly if vasoactive pharmaceutical agents are used.

Laboratory tests that should be performed include CBC and measurements of plasma protein and total solids. Total hemoglobin and PCV are used to assess hydration status. Total protein concentration is used to assess hydration status and degree of protein loss through inflamed intestinal mucosa and, in more chronic cases, through protein catabolism. Clinical hydration, PCV, and total protein concentration are compared to determine the extent of protein loss, and daily evaluations can be used to determine the rate of protein loss. Colloid oncotic pressure measurements are also useful, particularly if colloidal fluids other than plasma are given.

Total WBC count, WBC differential, and WBC structure are examined to assess severity of sepsis; plasma fibrinogen is examined to assess the severity of inflammation. Typically, the total WBC and neutrophil counts decrease initially. This is attributable primarily to bacterial endotoxins and the host's mediators of systemic inflammation, and it occurs in most cases of acute colitis, not just in those caused by *Salmonella* spp. The structure of the WBCs reflects the severity of the inflammatory response. "Toxic" changes such as basophilia, granulation, vacuolation of the cytoplasm, and scalloped borders of the cell membrane or adherence of neutrophils to RBCs do not reflect injury to the neutrophils by toxins but reflect the cells' responses to stimulation by proinflammatory agents (TNF-alpha, IL-1) and the production of inflammatory mediators by the neutrophils that are toxic to bacteria. The degree of these changes in circulating neutrophils can be used to assess the severity of disease and also to assess the progress the horse is making. Often the initial sign that the horse is improving is a decrease in the "toxic" appearance of the neutrophils and a regenerative neutrophil response. A horse that continues to have severe neutropenia with a degenerating left shift or neutrophils, with cytoplasmic vacuolation, granulation, and basophilia, for more than 10 days has severe colitis that is unlikely to resolve.

Serum chemistry tests that should be performed include measurements of electrolytes (sodium, chloride, potassium, and calcium), BUN and creatinine, and blood lactate concentration, as well as assessment of acid-base status (blood pH and bicarbonate, or total CO_2). Many horses with diarrhea are hyponatremic, hypochloremic, and hypokalemic. With decreased feed intake, hypocalcemia occurs. A high–anion gap metabolic acidosis with hyperlactemia may be noted, particularly in horses with sepsis. The severity of these electrolyte disturbances should be monitored, in many cases daily, to allow for appropriate therapy. Parameters of renal function (BUN and creatinine) are frequently increased in horses with diarrhea for several reasons. Prerenal azotemia resulting from dehydration and decreased filtration across the glomerulus accounts for some of the increase in these parameters. Hyponatremia and hypochloremia can cause a decrease in glomerular filtration and an increase in BUN and creatinine levels that are secondary to tubuloglomerular feedback. Many horses that are adequately hydrated and yet moderately hyponatremic (serum sodium 120 to 128 mEq/L) remain azotemic until sodium levels increase above 130 mEq/L. In addition, many horses with toxemic colitis have damage to renal parenchyma, presumably the result of the effects of inflammatory mediators and alterations in renal blood flow.

The acid-base status can be evaluated by estimating serum bicarbonate on the basis of the total CO_2 or directly from a

VetBooks.ir

venous or arterial blood gas analysis. A venous blood gas sample helps in assessing perfusion and oxygen extraction. An increased venous oxygen partial pressure (>60 mm Hg) is indicative of poor capillary perfusion and oxygen delivery to the tissues. Affected horses usually have brick-red mucous membranes.

Principles of Therapy for Acute Diarrhea

Because the pathophysiologic process of equine colitis is complex, treatment is often multifaceted. Many of these treatments provide well-documented benefit, whereas with others the efficacy is based only on empirical judgment. Outcome is determined not only by the severity of the primary disease causing colitis but also by complications that may arise from the disease.

In cases of acute colitis, fluid administration remains the treatment of primary importance. Most patients require intravenous administration in the early stages. The fluids used must replace fluid, sodium, chloride, and potassium losses. In many cases, large volumes are required for several days. (More specific guidelines for fluid therapy in colitis patients are covered in the Fluid Therapy for Horses with Gastrointestinal Diseases section and in Chapter 44.)

Most horses with colitis become hypoproteinemic as a result of protein leakage through the inflamed colon and catabolism of albumin secondary to negative energy balance. Hypoproteinemia frequently leads to edema formation in several areas of the body, including the intestinal tract, and can compromise the clinician's ability to keep the patient properly hydrated through fluid administration. Intravenous plasma therapy (6 to 10 L) is often beneficial as a colloidal fluid and as a protein replacement fluid. Other colloidal fluids may be more cost-effective for increasing colloidal oncotic pressures in hypoproteinemic horses but do not have the additional properties of plasma that may be beneficial. Plasma contains other proteins besides albumin and therefore can be of benefit beyond improvement of plasma oncotic pressure. Fibronectin is essential to the normal function of the monocyte-macrophage system in the processing of a variety of antigens. Other plasma proteins such as elastase and proteinase inhibitors, complement inhibitors, AT-III, and other inhibitors of hypercoagulability may be beneficial to patients with colitis.

The nutritional requirements of patients with colitis need to be considered, particularly in a case that may be protracted. Horses with colitis are typically anorexic, and the disruption of normal physiologic processes in the inflamed cecum and colon limits the effectiveness of these organs to digest and absorb nutrients. In addition, several mediators of inflammation and septicemia alter protein and calorie metabolism, which results in a catabolic state. Therefore even if an affected horse eats, it is likely to be in a severe caloric deficit for some time. Normally an average horse requires approximately 15 MCal/day. An septic horse may require 25 MCal/day. In a catabolic patient, muscle and fat tissue are mobilized and used in lieu of ingested nutrients. The plasma protein pool, including albumin and immunoglobulins, also is catabolized. In many cases of colitis, the decrease in plasma protein may be as much a result of catabolism as of leakage through the inflamed colon. A variety of products can be used for enteral feeding (see Chapter 50).

Colitis is an inflammatory disease, and limiting inflammation is desirable when treating patients, particularly those with severe disease. Moreover, horses with acute colitis, regardless of the cause, have signs compatible with systemic inflammation associated with sepsis. Flunixin (0.25 to 0.5 mg/kg IV q6-8h) is the most commonly used antiinflammatory therapy in horses with colitis. However, the use of flunixin should be judicious and must be carefully monitored to avoid unwanted side effects on the gut mucosa and kidneys. Other antiinflammatory therapies, such as COX-2 selective firocoxib or lidocaine administered by controlled-rate infusion, may also be beneficial with less detriment to the gastrointestinal mucosa.

Sepsis is a common clinical feature in horses with acute colitis. Most of the clinical signs of sepsis are probably attributable to the effects of endotoxin. Therefore specific therapy for endotoxemia may be warranted.

The use of antimicrobial drugs in the treatment of colitis is controversial. In cases of colitis caused by *N. risticii*, the efficacy of tetracycline (6.6 to 11 mg/kg IV once or twice daily) is documented.[94,95] In other cases of colitis, including *Salmonella* colitis, in which specific antimicrobial sensitivities to the *Salmonella* spp. have been established, the efficacy of antimicrobial administration is not as well documented. Many clinicians believe that the use of an antimicrobial for which the *Salmonella* spp. have demonstrated sensitivity, such as chloramphenicol, enrofloxacin, gentamicin, amikacin, or a third-generation cephalosporin, does not significantly alter the course of the disease or hasten the elimination of the organism from the body. However, there is no published evidence either supporting or disputing the efficacy of antimicrobial treatment for salmonellosis, and the use of antibiotic therapy remains a judgment of the clinician. In patients with sepsis, the use of broad-spectrum antibiotics is justified to prevent bacteremia or organ colonization by *Salmonella* spp. or other enteric organisms. Antibiotics such as chloramphenicol and enrofloxacin that are lipid permeable or are concentrated in cells are a benefit because *Salmonella* reside, proliferate, and persist intracellularly in macrophages and other cells.

Medications that minimize or abolish colonic fluid secretion are of tremendous benefit in the treatment of equine colitis. Medications such as kaolin, bismuth subsalicylate, and activated charcoal are frequently used in cases of colitis in adult horses, but their efficacy as antisecretory agents in this context is unknown. These medications are more effective in foals with diarrhea, than in affected adult horses, probably as a result of an effect on the small intestine rather than the colon. Absorbent powders such as activated charcoal or di-tri-octahedral smectite (Bio-Sponge) may be useful for absorbing bacterial toxins, particularly in horses with clostridiosis.

Chronic Diarrhea

Chronic diarrhea is one of the most frustrating disorders encountered by equine practitioners, with regard to both determining the cause and therapeutically managing the diarrhea.[96] Chronic diarrhea may be defined as persistent diarrhea of at least a month's duration. Although there are many causes of chronic diarrhea, these cases can generally be divided into two groups: diarrhea resulting from a chronic inflammatory condition and diarrhea resulting from a disruption in normal physiologic processes. Inflammatory conditions cause histologic changes in the colon mucosa, including pleocytosis (neutrophils, eosinophils, and lymphocytes), mucosal congestion, and mucosal erosion and ulceration. Submucosal edema, capillary congestion, and lymphatic congestion may be present. With physiologic disorders, there are no morphologic changes in the colon, and diarrhea is presumed to result from abnormal VFA synthesis or absorption. A small percentage of horses with chronic diarrhea have a primary disorder of a system other than the intestinal tract, such as congestive heart failure or hepatic disease. A thorough physical examination and evaluation of a minimum database (CBC, serum chemistry profile, urinalysis) should help establish whether a disorder is nonenteric.

CAUSES. Inflammatory disorders that can cause chronic diarrhea include disorders caused by infectious agents such as chronic salmonellosis; chronic parasitism with *S. vulgaris*, *Strongylus edentatus*, and larval cyathostomiasis; abdominal abscessation; and, in weanling foals, equine proliferative enteritis caused by *L. intracellularis*, gastrointestinal *R. equi* infection, and rotavirus infection.

Noninfectious inflammatory causes include cellular infiltrative disorders such as granulomatous enteritis and lymphosarcoma,

VetBooks.ir

as well as sand enteropathy. Sand causes diarrhea through continued irritation of the mucosal lining of the colon. In weanling foals, gastric ulceration and gastric emptying disorders have been associated with chronic diarrhea that resolved when H_2 antagonist therapy was started. NSAIDs can cause chronic diarrhea, which is accompanied by varying degrees of pathologic change in the large intestine.

Noninflammatory chronic diarrhea of colonic origin is thought to be a result of abnormal fermentation of cellulose by the resident bacteria in the large intestine. In vitro fermentation of feces from normal horses and horses with chronic diarrhea revealed that feces from the diarrheic horses produced more gas, acetate, and propionate than did feces from normal horses.[97] Whether this reflects fermentative activity within the colon is not known, but an abnormal increase in acetate could lead to fluid retention within the colonic lumen because acetate inhibits colonic absorption of sodium and water.

DIAGNOSIS. The diagnostic approach to cases of chronic diarrhea should be based on an attempt to differentiate inflammatory from physiologic causes. The evaluation can be extensive and expensive, and the owner should be prepared for the cause of the diarrhea to remain undetermined. Horses with chronic diarrhea may be adequately hydrated if water consumption has matched water losses; however, many such horses are brought to the veterinarian in a condition of mild to moderate dehydration. Moderate weight loss also has often occurred. On physical examination, signs of toxemia (injected mucous membranes, congested or hyperemic mucous membranes) should be noted.

A CBC should be evaluated for signs of chronic inflammation. Such changes include a decrease in the RBC count and PCV as a result of decreased erythrogenesis secondary to sequestration of iron by bone marrow macrophages (anemia of chronic inflammation). The WBC count may be normal or moderately increased. The fibrinogen levels can be normal or increased. Changes in WBC count and fibrinogen levels are influenced by the degree of inflammation and whether the inflammatory response is localized. Therefore a normal CBC does not rule out an inflammatory cause of the chronic diarrhea.

Peritoneal fluid analysis may reveal an increase in protein or WBCs, which is indicative of an inflammatory process within the peritoneal cavity. Often, however, colon inflammation is not reflected by alterations in the peritoneal fluid.

Serum chemistry values vary in horses with chronic diarrhea. Many affected horses have evidence of hyponatremia, hypokalemia, hypochloremia, azotemia, and metabolic acidemia. Other horses, particularly those with less severe chronic diarrhea, may have no serum chemistry abnormalities.

With a chronic inflammatory disorder of the colon, the total serum protein concentration is usually decreased because of protein leakage from the capillaries and disruption of the colonic mucosal integrity. This is usually reflected by hypoalbuminemia. In some cases, hyperglobulinemia occurs, and total serum protein concentration may be normal.

Increases in hepatic-associated enzymes, including sorbitol dehydrogenase, GGT, and aspartate aminotransferase, and serum bile acids indicate that hepatic disease is present. Hepatic changes and dysfunction such as inflammation, fibrosis or fatty infiltration, or biliary inflammation can be associated with diarrhea.

Feces should be examined for parasite ova; cultured for *Salmonella* spp., *C. difficile*, and *C. perfringens;* and tested for clostridial toxins. Weanlings should be tested for *L. intracellularis* and *R. equi*. In cases of acute diarrhea, it has been recommended that five consecutive fecal samples be cultured for *Salmonella* spp., but in cases of chronic diarrhea, many more are often necessary. As many as 15 fecal cultures may be needed to get a positive *Salmonella* spp. culture. In addition, a rectal mucosal biopsy sample should be cultured. In weanlings, the feces should be examined for rotavirus by transmission electron microscopy or ELISA. Although it is an unusual cause of diarrhea in weanlings, rotavirus should be considered when several foals on the same farm have chronic diarrhea.

An oral glucose absorption test can be done to determine whether there is small intestinal malabsorption, which would indicate a widespread small and large intestinal disorder if both diarrhea and glucose malabsorption are present.

A rectal mucosal biopsy may provide evidence of a widespread inflammatory disorder, such as one of the IBDs.[98] Biopsy specimens should be evaluated by a pathologist experienced in examining equine tissue specimens, and some caution should be used to avoid overinterpretation of the presence of few lymphocytes, plasma cells, and eosinophils.

Frequently the results of the previously mentioned diagnostic procedures do not determine the cause of the chronic diarrhea. In such cases, exploratory laparotomy may be warranted. This is particularly true if episodes of abdominal discomfort accompany the chronic diarrhea. In addition to exploration of the abdomen for the presence of masses or abscesses, the colon and cecum should be thoroughly examined. Biopsy samples from several sites of the colon, cecum, and mesenteric lymph nodes should be submitted for histopathologic study and culture for *Salmonella* spp.

TREATMENT. Treatment of horses with chronic diarrhea is often empirical because either a cause has not been determined or the cause is not amenable to treatment. With inflammatory causes such as lymphosarcoma and granulomatous enteritis, the disease is usually untreatable. Some cases of eosinophilic colitis have been treated successfully with corticosteroids.

Chronic parasitism may be resolved with appropriate anthelmintic therapy, although damage to the mucosa may have become too extensive to allow normal absorption to occur. Administration of larvicidal doses of fenbendazole (15 mg/kg PO daily for 5 days) is usually effective in horses with nonresistant small strongyle infections. Treatment with ivermectin (0.2 mg/kg PO) or moxidectin (0.4 mg/kg PO) may be indicated when benzimidazole resistance is encountered. Concurrent administration of prednisolone (1 mg/kg PO once daily for 5 to 7 days) may minimize inflammation secondary to dying migrating larvae within the vasculature and mucosa of the colon.

Chronic salmonellosis does not lend itself to specific treatment because antimicrobial therapy generally does not resolve *Salmonella* infection in horses.

Administration of products containing bismuth subsalicylate is effective in some cases of chronic diarrhea. The action of bismuth subsalicylate is mediated through inhibition of prostaglandin synthesis and possibly by other undefined mechanisms. In full-size horses, a large volume, 1 to 4 L/day, must be administered to be effective.

Iodochlorhydroxyquin administered orally is effective in managing some cases of chronic diarrhea caused by maldigestion of cellulose by colonic microorganisms.[99] The actual mechanism of action of iodochlorhydroxyquin in resolving the diarrhea is not known. The drug was originally administered to horses with chronic diarrhea because an increase in fecal trichomonads was observed. However, this observation probably reflected the fact that trichomonads were washed out of the cecum and colon rather their being the cause of the diarrhea. Iodochlorhydroxyquin has minimal effect on colonic protozoal populations. It is not uniformly effective, and in many cases its effectiveness is only transient. Stools may initially become formed, but the diarrhea often recurs within several days. An initial dose of 20 mg/kg/day is recommended. If diarrhea recurs, decreasing the dose to 10 mg/kg/day is sometimes effective. If the medication is effective, it must be continued because if it is discontinued, the diarrhea resumes.

VetBooks.ir

Changes in diet occasionally are helpful in horses with noninflammatory chronic diarrhea. A complete pelleted feed may positively affect the constituent VFAs produced in the colon and thus facilitate water absorption. Alternatively, trying different types of roughage may result in selecting one that creates a more favorable metabolic environment in the large intestine.

The removal of sand from the colon by nonsurgical means is difficult, and in one report the administration of psyllium to remove experimentally introduced sand was not effective.[100] Other treatments used with anecdotal, but undocumented, success include fecal transfaunations, probiotics, cultured yogurt, and brewer's yeast.

Surgical Disorders of the Large Intestine

Anthony T. Blikslager • John F. Marshall

Simple Obstruction

Simple obstructions of the large intestine tend to have a more gradual onset than those of the small intestine and, in the case of large colon impactions, are frequently amenable to medical therapy.[1] Cecal impactions present much more of a dilemma because of the greater propensity of the cecum to rupture[2] and the relative difficulty of surgically manipulating it.[3]

Cecal Impaction Cecal impaction may develop as a primary condition or may arise as a complication in horses with another disease state, particularly those that have been hospitalized and undergone surgery.[4,5] Reasons for development of cecal impaction in hospitalized horses are unclear, although motility disturbances arising from postoperative pain may play a role. Primary cecal impactions typically manifest as firm ingesta-filled impactions, whereas impactions that occur as an apparent secondary impaction tend to manifest as gross distention of the cecum with fluid ingesta. The latter has been termed *cecal dysfunction* and may be initiated by abnormalities in cecal motility. Evidence in favor of this supposition includes the fact that the right ventral portion of the colon is typically empty in horses with cecal dysfunction, which suggests a lack of aborad movement of digesta through the cecocolic orifice. However, clinical differentiation of cecal impaction and cecal dysfunction may be very difficult.[6] Horses with primary dry ingesta–filled cecal impactions tend to have a gradual onset of abdominal pain over a number of days. Such impactions have a propensity to rupture before the development of severe abdominal pain or systemic deterioration and therefore must be closely monitored.[5] In many horses with secondary cecal impactions, such as an impaction that arises in a horse hospitalized for surgery, it is very difficult to detect onset of colic because there is an expectation for horses to show some degree of depression after surgery and because many affected horses are already receiving analgesics such as NSAIDs or opiates. One potential method of detecting these cases is to closely monitor fecal output in the postoperative period.[7] Normal horses should produce six to eight piles of manure per day, whereas abnormal horses may produce no evidence of defection or a marked reduction in fecal production (less than three piles of manure per day). The latter should be carefully evaluated for both pain and intraabdominal evidence of an impaction and treated accordingly.

The diagnosis of cecal impaction is based on rectal palpation of a firm, impacted cecum or a grossly distended fluid-filled cecum. According to one study, such findings were detected in 89% of horses with cecal impaction that underwent rectal palpation of the abdomen.[6] However, there are cases in which only the cupula is impacted, and these are reportedly not palpable rectally.[8] Treatment for horses with dry ingesta–filled cecal impactions may include initial medical therapy, including aggressive administration of intravenous fluids, judicious use of analgesics, and administration of oral laxatives (e.g., 2 to 4 L of mineral oil per 500 kg).[9] Other oral laxatives have also been recommended, including magnesium sulfate (1 g/kg in 4 L of water PO up to twice daily for up to 3 days) and psyllium (1 kg q6-8h).

However, if the cecum is grossly distended or if medical therapy has had no effect within a reasonable period of time, surgical evacuation of the cecum via a typhlotomy is indicated. In one comparison of treatment of cecal impaction medically or by surgical intervention, horses that had surgery had a significantly improved prognosis for survival.[5] As far as surgery, it has been difficult to determine whether a cecal bypass should be performed. In some cases, if the cecum is not bypassed, cecal impaction recurs. This may be because the cecum becomes dysfunctional as a result of the impaction or because cecal dysfunction was the initial reason of impaction.[10] However, in another study in which horses that had had typhlotomy alone were compared with those that had had both typhlotomy and a cecal bypass via jejunocolostomy, there was no significant difference in outcome.[5] Nonetheless, this aspect of surgical treatment remains controversial.[11,12]

With regard to the prognosis, a study of 150 horses with cecal impaction showed that horses treated medically had a short-term survival rate of 61%, which was significantly lower than that of horses treated surgically (82%). One year later, 57% of horses treated medically were still alive, whereas 70% horses treated with typhlotomy were still alive, as 73% of those treated with typhlotomy and jejunocolostomy.[5] As previously mentioned, there was no significant difference in prognosis with the two surgical approaches. However, clinicians should be aware that there may be regional differences in the types of cecal impactions and prognoses. For example, in a study from the United Kingdom, cecal bypass was preferred because of the authors' experience with recurrence of cecal impaction.[12]

Large Colon Impaction Impactions of the large colon with ingesta occur at sites of anatomic reductions in luminal diameter, particularly the pelvic flexure and the right dorsal portion of the colon.[13] Although a number of reported risk factors have been reported, most have not been proven. However, a sudden restriction in exercise in association with musculoskeletal injury appears to be frequently associated with onset of impaction. In addition, one study of 120 horses with large colon impaction showed that 41% of cases were diagnosed in the winter,[14] possibly in relation to reduced water intake or changes in diet. Equine feeding regimens may be very important in the development of large colon impactions. For example, twice-daily feeding of concentrate are associated with secretion of large volumes of fluid into the small intestine, which results in transient hypovolemia (15% loss of plasma volume).[15] This leads to activation of the renin-angiotensin-aldosterone system; aldosterone stimulates absorption of fluid from the large colon, which may may dehydrate colonic contents.[15,16] Large concentrate meals may also decrease small intestinal transit time, which results in increased presentation of soluble carbohydrate to the cecum and large colon. Large amounts of fluid enter the colon occur as concentrates are readily fermented in the large intestine, which would also be expected to activate the renin-angiotensin-aldosterone system. This in turn also triggers net fluid absorption from the large colon. The effects of these large fluid fluxes on development of large intestinal disorders remains to be fully characterized, but undoubtedly they play some role in the syndrome of colic. From a practical standpoint, intestinal fluid fluxes may be reduced with frequent small feedings in horses requiring concentrate to maintain condition.[15]

Clinical signs of large colon impaction include slow onset of mild colic that is typically well controlled with administration of

VetBooks.ir

analgesics but becomes increasingly more severe and refractory if the impaction does not resolve.[14] The diagnosis is based on rectal palpation of a firm mass in the large colon. However, the extent of the impaction may be underestimated by rectal palpation alone because much of the colon is out of reach. Adjacent colon may be distended if the impaction has resulted in complete obstruction. Initially, medical treatment should be attempted. Intermittent abdominal pain is controlled with administration of analgesics (flunixin meglumine, 0.25 mg/kg IV q6h to 1.1 mg/kg IV q12h; butorphanol, 0.05 mg/kg IV as needed; or xylazine, 0.3 to 0.5 mg/kg IV as needed). Detomidine (4 to 10 mg IV as needed) can be administered but with great caution because this agent readily masks severe pain. If there are concerns about use of nonselective COX inhibitors, including flunixin meglumine, COX-2 inhibitors such as firocoxib can be used. Considerations related to nonselective COX inhibitors relate to concerns about gastrointestinal mucosal integrity, or other organ systems such as the kidneys. In these instances, a COX-2 inhibitor may be indicated for control of pain. These drugs include meloxicam, which is not labeled for horses in the United States and only modestly targets COX-2, or the highly selective COX-2 inhibitor firocoxib, which is available in the United. States. Firocoxib must be administered in an off-label loading dose (0.3 mg/ kg), followed by the labeled dose (0.1 mg/kg, IV, q24h).[17]

In addition to analgesics, an oral laxative should be administered via nasogastric tube. Although mineral oil (2 L/500 kg to 4 L/500 kg PO) is commonly used as a laxative, hydration of the colonic contents can be better achieved by magnesium sulfate (1 g/kg in 4 L of water PO) or sodium sulfate (1g/kg in 3 L of water PO) by stomach tube.[18] Sodium sulfate has been shown to result in greater colonic content hydration than does magnesium sulfate, but it also results in significant thirst and hypocalcemia; therefore magnesium sulfate is preferred.[18] Access to feed should not be permitted, but water should be freely available. For impactions that persist, aggressive oral or intravenous fluid therapy, or both, should be instituted. One study demonstrated the increased efficacy of a continuously administered oral rehydration solution in softening feces in comparison with intravenous fluids, which are probably best suited to restoring the systemic extracellular fluid compartment.[19] If the impaction remains unresolved, if the pain becomes uncontrollable, or if extensive gas distention of the colon occurs, surgery is indicated. At surgery the contents of the colon are evacuated via a pelvic flexure enterotomy. The prognosis is good for horses in which impactions resolve medically (95% long-term survival in one study) and fair for horses that require surgical intervention (58% long-term survival in the same study).[1]

Enteroliths

Enteroliths are mineralized masses typically composed of ammonium magnesium phosphate (struvite).[20] One study has suggested that an increase in magnesium in the diet may predispose to the formation of enteroliths.[21] Enteroliths almost always form around a nucleus such as a silicon dioxide stone, a nail (Fig. 32.70), or a piece of rope that has been ingested and are most commonly found in the right dorsal and transverse portions of the colon. Although enterolithiasis has a wide geographic distribution, the incidence in California is high. In one California-based study, horses with enterolithiasis represented 28% of the surgical colic population. In addition, Arabian, Morgan, and American Saddlebred horses and donkeys are at risk of this disease.[22] A prospective, unmatched case-control study performed in California indicated that horses fed a diet composed predominantly of alfalfa hay are at risk for development of enterolithiasis, and allowing horses to graze on pasture was protective against this disease.[23]

Initially, clinical signs include intermittent abdominal pain in mature horses (almost always older than 4 years of age),[24] with few abnormalities on rectal examination. As enteroliths become larger, they may occlude the lumen of the colon and cause acute pain and large colon distention that necessitate surgical exploration. In some cases an enterolith is forced into the small colon, where it causes acute small colon obstruction. Enteroliths may be diagnosed on abdominal radiographs or at surgery. On rare occasions, an enterolith may be palpated rectally, particularly if it is present in the distal small colon.

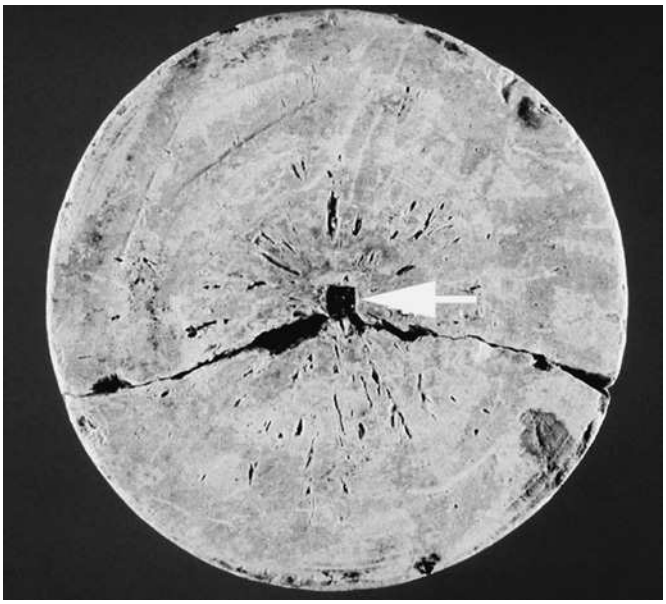

FIG. 32.70 Cut section of an enterolith. Note the presence of a nail head *(arrow)* that served as a nucleus for the formation of a struvite enterolith. *(Courtesy Dr. David G. Bristol.)*

In general, surgery is required for these cases, although there are reports of enteroliths being retrieved rectally. In fact, in one study, 14% of horses that presented for treatment of enterolithiasis had a history of passing an enterolith in the feces.[22] However, enteroliths are typically located in the right dorsal portion of the colon, transverse colon, or small colon. At surgery the enterolith is gently pushed toward a pelvic flexure enterotomy, but removal frequently requires a separate enterotomy of the right dorsal portion of the colon to prevent rupture of the colon. After removal of an enterolith, further exploration must be conducted to determine whether other enteroliths are present. Solitary enteroliths are usually round, whereas multiple enteroliths have flat sides. The prognosis is good (the rate of 1-year survival among 900 horses that underwent surgery in one study was 92%) unless the colon is ruptured during removal of an enterolith.[22] Colon rupture occurred in 15% of the 900 cases.[22]

Sand Impactions of the Large Colon

Sand impaction of the large colon is common in horses with access to sandy soils, particularly horses whose feed is placed on the ground. Sand accumulates in the large colon, particularly the right dorsal portion of the colon and pelvic flexure, but may be present in multiple locations.[25,26] In addition, sand may trigger diarrhea, presumably as a result of irritation of the colonic mucosa.[27] In horses with sand impactions, clinical signs are similar to those of horses with large colon impactions. In addition, sand may be found in the feces, and auscultation of the ventral abdomen may reveal sounds of sand moving within the large colon.[28] Radiography of the cranioventral portion of the abdomen may be useful for the detection of sand within the large colon and can serve to monitor resolution of sand accumulation.[29] In

particular, one study showed that horses with a greater area of sand accumulation, multiple sand accumulations, and more gas on radiographs were significantly more likely to require surgery.[30] The diagnosis is definitively made at surgery but may be tentatively based on clinical signs compatible with a large colon impaction, together with evidence of sand in the feces. To determine the presence of sand, several fecal balls are placed in a rectal palpation sleeve or other container, which is subsequently filled with water. Sand, if present, will accumulate at the bottom of the container.

Initially, medical therapy should consist of a laxative such as mineral oil, magnesium sulfate, or psyllium in combination with enteral or intravenous fluid therapy; this is usually successful in the management of uncomplicated sand enteropathy.[29] Administration of psyllium hydrophilic mucilloid in water by stomach tube may facilitate passage of sand, although an experimental study failed to show a benefit of this treatment.[31] If colic becomes intractable, surgical evacuation of the large colon should be performed. Care must be taken to prevent tearing of the colon as a result of the weight of sand during exteriorization.[32] The prognosis is good; for instance, in one study, more than 94% of horses survived to discharge, regardless of whether they were treated medically or surgically.[30]

Nonstrangulating Obstruction of the Colon

Several configurations of displacements, including nephrosplenic entrapment of the colon, obstruct the colonic lumen but do not compromise the colonic blood supply. Therefore these are technically simple obstructions. However, the lumen may not be completely obstructed, and some degree of venous congestion is common.[34] In some cases, nonstrangulating obstructions are difficult to differentiate from large colonic volvulus because a volvulus of less than 270 degrees does not result in strangulation of blood supply but can cause considerable abdominal pain and gas distention of the abdomen. In this regard, nonstrangulating obstructions represent early stages of strangulating obstructions. Clinical signs include mild to moderate colic with evidence of large colon distention on rectal palpation of the abdomen. The diagnosis is confirmed at surgery.[35] However, there is evidence that horses with suspected displacements can be successfully treated with a medical regimen, including fluids, analgesics, and exercise.[33] However, if pain is recurrent, particularly if it is of increasing intensity and frequency, or if there is evidence of intestinal compromise (particularly progressive changes in abdominal fluid and cardiovascular parameters indicating systemic deterioration), the horse should undergo surgery immediately. The prognosis for nonstrangulating obstructions of the large colon is good; more than 80% of horses in one report survived to hospital discharge.[36]

Right Dorsal Displacement of the Large Colon

With right dorsal displacement of the colon, the colon is displaced to the right of the cecum. Findings on rectal palpation typically include colonic bands coursing horizontally across the abdomen, with evidence of colon lateral to the cecum. In the most common configuration of right dorsal displacement, the large colon wraps around the cecum (pivoting counterclockwise around the cecum, in a view from above the horse), with the pelvic flexure lying in the left dorsal quadrant. Alternatively, the colon may wrap around the cecum in the opposite direction, with the pelvic flexure lying in the right dorsal quadrant.[37] One study suggested that although the prognosis for recovery after surgical correction of right dorsal displacement is good, this condition is associated with an increased risk of colic episodes in the postoperative period.[38] The reason for this has not been elucidated but may reflect an etiologic difference between right dorsal displacement and other simple obstructions of the large colon.

Nephrosplenic Entrapment (Left Dorsal Displacement) of the Large Colon

On the left side of the equine abdomen, colon displacements most commonly involve entrapment of the colon over the nephrosplenic ligament, although left dorsal displacements may be detected before the colon is fully entrapped. Clinical signs include gradual onset of mild to moderate colic as the entrapped colon fills with gas. Rectal palpation reveals gas distention of the ventral portion of the colon and displacement of the spleen toward the center of the abdomen. Careful palpation by following colonic bands up to the left dorsal quadrant often reveals the presence of colon between the left kidney and the spleen. Diagnosis may be based on rectal palpation of the colon traversing the nephrosplenic ligament. Alternatively, a tentative diagnosis can be reached with abdominal ultrasonography.[39] The spleen can be visualized on the left side of the abdomen, but the dorsal spleen and left kidney are obscured by gas-distended bowel, the dimensions of which may extend cranially from the paralumbar fossa. As with other examination techniques, ultrasonography is not uniformly reliable and occasionally yields false-positive results and false-negative results. A definitive diagnosis may necessitate surgery.

Treatment has traditionally been surgical intervention, during which the colon is gently rocked free of the nephrosplenic space. However, good success rates have been reported for nonsurgical intervention such as either light exercise (trotting) or physical manipulation (rolling) to return the colon to a normal location.[40,41] In addition, phenylephrine (3 to 6 µg/kg/min over 15 minutes) may be administered before exercise or rolling to decrease the size of the spleen.[42] In affected horses exhibiting mild pain and normal abdominocentesis findings, light trotting exercise for a period of 30 to 45 minutes may help correct the displacement.[40,43] Alternatively, the horse is anesthetized and placed in right lateral recumbency in preparation for rolling. The horse is rotated up to dorsal recumbency, rocked back and forth for 5 to 10 minutes, and then rolled down into left lateral recumbency.[44] One study showed that rolling is more effective than other medical treatments, including administration of phenylephrine and exercise.[45] Regardless of nonsurgical technique adopted, the resolution of displacement should be monitored by repeat rectal palpation of the nephrosplenic space and by ultrasonography to determine whether the entrapment has been relieved. If the entrapment remains, or there is any deterioration in clinical signs, the horse should undergo surgery.

Regardless of technique, the prognosis is good. Several studies have demonstrated survival rates exceeding 90%.[40,46] Recurrence of left dorsal displacement has been described and may affect up to 23% of horses.[47] To prevent recurrence, laparoscopic closure of the nephrosplenic space may be performed after correction of the displacement.[47-49]

Atresia Coli

Atresia of any segment of the colon is a rare congenital abnormality in horses (Fig. 32.71).[50] The heritability and causes of the condition are unknown. One potential mechanism for development of the lesion is intestinal ischemia during fetal life, which secondarily results in necrosis of a segment of intestine. Clinical signs include a failure to pass meconium and colic within the first 12 to 24 hours of life. Secondary abdominal distention results from complete intestinal obstruction, and abdominal radiographs may reveal gas distention of the colon. The diagnosis is made at surgery. Any portion of the colon may be absent, but the distal segment of the large colon or the proximal small colon is usually most severely affected. If sufficient tissue is present, anastomosis to the proximal blind end of the colon may be attempted. The prognosis depends on which segment of the colon is absent but is usually poor because of an absence of distal portion of the colon.

VetBooks.ir

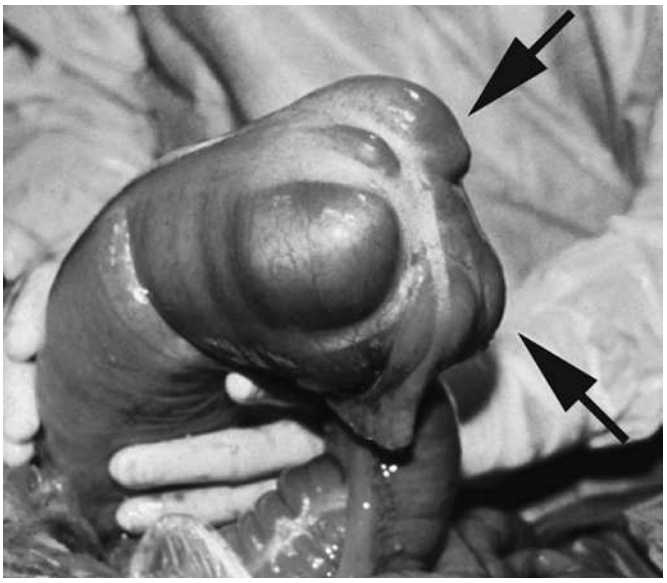

FIG. 32.71 Operative view atresia coli in a foal. Complete atresia of the pelvic flexure has resulted in a blind-ended ventral portion of the colon *(arrows)*, which in turn resulted in gas distention of the colon. The ventral portion of the colon was subsequently anastomosed to the dorsal portion of the colon in this case.

Strangulating Obstruction

Although simple obstruction of the large colon carries a very favorable prognosis, strangulating obstruction of the large colon is associated with high fatality rates in most centers.[51] However, this is likely to be dependent on the duration of disease: In at least one referral center, early referral was associated with a marked increase in survival.[52] Two forms of strangulating obstruction are recognized: hemorrhagic strangulating obstruction, in which the arterial blood flow remains patent while veins are collapsed, and ischemic strangulating obstruction, in which both the arteries and veins are collapsed. The differentiating factor between the two is probably how tightly twisted the volvulus is. It has been suggested that ingesta-filled intestine is more likely to develop a hemorrhagic lesion during the development of volvulus because the intestinal contents prevent the intestine from twisting tightly.[53]

■ ***Large Colonic Volvulus*** Clinical signs of large colonic volvulus include rapid onset of severe, unrelenting abdominal pain.[54] Although postparturient broodmares appear to be at risk, this association has not been conclusively determined. However, one study demonstrated that Thoroughbred horses are at significant risk for volvulus.[51] Once the large colon is strangulated (>270-degree volvulus), gas distention is marked, leading to gross distention of the abdomen, respiratory compromise as the distended bowel presses against the diaphragm, and visceral pooling of blood as the caudal vena cava is compressed. This condition is frequently refractory to even the most potent of analgesics. Affected horses may prefer to lie in dorsal recumbency, presumably to take weight off the strangulated colon. An abbreviated physical examination is warranted in these cases because the time elapsed from the onset of strangulation to surgical correction is critical.[52] In experimental conditions, the colon is irreversibly damaged with 3 to 4 hours of 360-degree volvulus of the entire colon.[55]

Despite severe pain and hypovolemia, the heart rate may be paradoxically slow, possibly in relation to increased vagal tone. A fast heart rate can be associated with a poor prognosis.[56] More accurate prognostic information can be obtained from plasma lactate. A plasma lactate concentration of 6.0 mmol/L or higher is 84% sensitive and 83% specific for predicting death.[57] In another study, preoperative PCV of more than 46% was associated with a significantly increased risk of death.[52] Results of abdominocentesis are often not indicative of the degree of colon compromise,[58] and in many cases abdominocentesis is not advisable because of extreme colonic distention. Rectal palpation reveals severe gas distention of the large colon, which often restricts access of palpation to the abdomen beyond the pelvic brim. In most cases, colonic bands can be palpated, which indicate that the ventral portion of the colon is uppermost and crossing the abdomen horizontally. The diagnosis may be tentatively based on signalment, severity of pain, and degree of distention.

At surgery the volvulus is typically located at the mesenteric attachment of the colon to the dorsal body wall, and the most common direction of the twist is dorsomedial with the right ventral portion of the colon as a reference point. However, the colon may twist in the opposite direction, twist more than 360 degrees (up to 720 degrees has been reported), or twist at the level of the diaphragmatic and sternal flexures. In all cases, the colon should be decompressed as much as possible, and in many cases, evacuation of colon contents via a pelvic flexure enterotomy helps correct the volvulus. However, in horses in which colonic volvulus is diagnosed in the early stages, the volvulus can be corrected within the abdomen without evacuation of the colon.[52]

After correction of the volvulus, the colon should be assessed for irreversible injury. This determination is frequently based on mucosal color and bleeding (if an enterotomy has been performed), palpation of a pulse in the colonic arteries, serosal color, and appearance of muscular motility. However, determination of viability on the basis of these parameters is unreliable. Currently, one of the most reliable techniques for determining viability is histologic evaluation of frozen sections of colonic mucosa. Biopsy samples may be obtained at the pelvic flexure because it has been determined that mucosal changes are uniform throughout strangulated colon.[59] A prediction of viability can be based on the degree of luminal and crypt epithelial loss and the interstitium-to-crypt ratio (calculated from measurements of the crypt width and the width of interstitial space between crypts). In one study, morphologic changes consisting of an interstitium-to-crypt ratio of less than 3 and a 60% or less loss of glandular epithelium were predictive of survival with a sensitivity and specificity of 95% and 92%, respectively, in a population of 52 horses.[60]

In addition, it has been suggested that accuracy of viability determination can be increased by combining histologic evaluation with surface oximetry or laser Doppler determination of blood flow.[61] Unfortunately, frozen histologic sections are not available at most referral centers on an emergency basis. A retrospective study of formalin-fixed biopsy specimens of pelvic flexure from 28 horses found that morphologic scoring was not accurately predictive of short-term survival.[62] In another study, investigators assessed intraoperative colonic intraluminal pressure as a more practical potential indicator of outcome in horses with large colonic volvulus but found this measurement inaccurate for making this determination.[63] In a more recent study of formalin-fixed biopsy samples of pelvic flexure from a population of horses recovered from surgery for large colonic volvulus, a combination of both interstitium-to-crypt ratio and mucosal hemorrhage score was accurately predictive of survival.[51]

If the colon is judged to be irreversibly damaged, the feasibility of a large colon resection can be considered. Although 95% of the colon can be resected (that part of the colon distal to the level of the cecocolic fold), damage from the volvulus usually exceeds what can be resected. In these cases surgeons may advise euthanasia or may elect to resect as much damaged bowel as possible; however, resection of the colon has not been found to improve survival.[51]

Postoperative complications include hypovolemic and endotoxemic shock, extensive loss of circulating protein, disseminated intravascular coagulation, and laminitis. In addition, large colonic volvulus has a propensity to recur. The prognosis for survival to hospital discharge for cases of large colonic volvulus has been reported as between 58% and 88%.[52,64-67] Studies in which long-term follow-up has been completed have demonstrated that survival rates decline to between 34% and 66% after 2 years.[63,64] Although one study documented a recurrence rate of less than 5%,[58] some authors believe recurrence may be as high as 50%. Methods of preventing recurrence can be considered in patients considered at risk for recurrence.[68,69]

Intussusception The most common intussusception of the large intestine is cecocolic intussusception, although in comparison with all forms of colic, it is a relatively rare condition of horses, accounting for 11 (1.3%) of 842 horses taken to surgery because of colic at one hospital.[70] The condition tends to occur in young horses (2 to 3 years of age) and may be associated with intestinal parasites, particularly tapeworms[71] and a heavy larval cyathostome burden.[72]

Clinical signs include acute onset of colic that varies in severity according to the degree of intussusception. Initially, the cecal tip inverts, creating a cecocecal intussusception, which does not obstruct flow of ingesta. As the intussusception progresses, the cecum inverts into the right ventral portion of the colon (cecocolic intussusception), which obstructs flow of ingesta and often causes severe colic. In one report on cecocecal and cecocolic intussusception, 26 of 30 horses presented with signs of acute colic.[71] However, the condition may also manifest as a chronic disease.[71] The cause of abdominal pain is often difficult to differentiate in these cases, although it is sometimes possible to detect a mass on the right side of the abdomen and the concurrent absence of a palpable cecum. Treatment involves manual surgical reduction by retracting the intussusceptum directly or via an enterotomy in the right ventral portion of the colon, with or without a partial typhlotomy.[71] The prognosis is usually regarded as poor because of severe compromise to the cecum and the risk of cecal rupture or severe contamination during surgery. However, a report of 18 horses without peritonitis that recovered from surgery showed that 15 survived long term.[71]

Colocolic intussusceptions are rare but have reportedly affected the pelvic flexure and the left portion of the colon.[73-76] The condition is reportedly more common in young horses, but some older horses are affected. Clinical findings may include a palpable mass on the left side of the abdomen. Ultrasonography may also be useful. Treatment requires manual reduction of the intussusception at surgery, or resection of affected bowel.

Disorders of the Descending (Small) Colon

Nimet Browne • Vanessa L. Cook

Colic resulting from a problem with the small colon is comparatively rare: It has been identified in only 4.2% of cases of surgical colic but represents up to 18% of horses admitted to referral centers with gastrointestinal disease.[1-3] However, American Miniature horses seem to be at increased risk for obstruction of the small colon[2]; small colon lesions account for 60% of cases of surgical colic in that breed.[4] Arabian horses and ponies also appear to be predisposed to small colon disease.[2,5,6] Of interest is that horses older than 15 years of age also seem to be at an increased risk for small colon conditions,[2] especially strangulating lipoma, injury from foaling, and submucosal hematoma.[6] Mares may also be at increased risk for small colon lesions, possibly because of hormonal fluctuations affecting gastrointestinal motility,[2] because of the small colon's predisposition to injury during foaling, or because of the small colon could become entrapped by an ovary.

One of the biggest challenges with small colon lesions is that the associated clinical signs and rate of physiologic deterioration are less severe than those of a more orad obstruction, which often results in later referral.[2,6] Early clinical signs include lethargy and inappetance, whereas progression of disease typically results in abdominal pain, diarrhea, decreased fecal production, and abdominal distention. Gastric reflux occurs in 30% of cases with small colon strangulation.[7] A complete examination of abdominal distention with rectal examination and abdominocentesis provides useful information in determining the diagnosis and indicating surgical intervention.[6,8,9] However, because the small colon lies caudally in the abdomen, transabdominal ultrasonography may be less useful than it is for lesions in other sections of the intestinal tract. Transrectal ultrasonography, performed with care, may be a more sensitive method of detecting a compromised small colon and may aid in earlier diagnosis.[4]

Conditions affecting the small colon can be categorized as congenital diseases, simple obstructions, vascular lesions, neoplasia, or strangulating lesions.

Congenital Diseases

ATRESIA COLI AND AGANGLIONOSIS. Atresia coli is much rarer in foals than in calves; the reported incidence is 0.44%.[10] There are several theories on the pathogenesis of this disease, but an ischemic vascular accident that results in atrophy of the affected segment is the most widely accepted one.[11,12] One study showed that fibroblastic growth factor 10 and its receptor are important in colonic development in mice; the lack or deficiency in growth factors could play a role in colonic atresia in foals.[13,14] There are four types of atresia.[15] Type 3, blind-end atresia, with no connection of the atretic segments, is the type most commonly found in foals.[10,14] Atresia coli may be confused with overo lethal white syndrome, in which affected foals have myenteric aganglionosis of the distal intestinal tract as the result of a mutation in the endothelin receptor type B gene.[16,17] In atresia coli, however, the intestinal tract is patent but nonfunctional. Loss of neurons in the myenteric plexus of the small colon can also be found in equine dysautonomia (grass sickness), although it is usually less severely affected than the ileum.[18]

Newborn foals with atresia coli usually appear normal but develop progressive abdominal distention and colic within 24 hours of birth. Atresia can be differentiated from other causes of colic in foals by the complete absence of feces with no meconium staining on digital rectal examination or even after an enema.[11] It may be possible to confirm a blind-ending rectum or distal small colon by digital palpation or passage of a soft catheter or endoscope. However, the defect is usually too proximal to visualize this way, and the friable colonic mucosa can be perforated easily; therefore this method is not recommended for diagnosis, but the use of *N*-butylscopolammonium can aid in diagnosis when colonoscopy is performed.[19] Plain radiographs do not usually identify the atresia but can help differentiate it from a meconium impaction. Retrograde contrast radiography, as described later in this section for meconium impaction, may give a more definitive answer.[20] A large volume of barium sulfate, up to 20 mL/kg, may be needed if the atresia is proximal to the transverse colon. If atresia is present, the path of the contrast agent is seen to end abruptly at the atretic segment.

The only chance for survival in cases of atresia is early exploratory celiotomy to assess the affected segment and determine whether surgical correction is possible. In calves with atresia, the prognosis is vastly improved if the diagnosis is made early and the animal is alert and is stabilized medically before surgery.[21,22] However, in foals, despite attempts at surgical resection of the atretic segment and anastomosis, the prognosis

is grave; a 100% mortality rate has been reported in several studies.[10,14]

Simple Obstructions

SIMPLE IMPACTION. Small colon impaction is the most common abnormality of the small colon in adult horses, affecting 1.9% to 2.5% of all horses seen for colic at referral institutes.[3,9,23] Several studies report a strong association between small colon impaction and diarrhea. The most recent study documented that horses with diarrhea are 10 times more likely to develop a small colon impaction than are horses with a large colon impaction.[8,24] In other studies, diarrhea developed during hospitalization in 70% of all horses with small colon impaction, and 43% of those treated surgically yielded cultures positive for *Salmonella* spp.[23] These studies suggest that impaction of the small colon may be a sequela to colonic inflammation or colitis, such as *Salmonella* infection; therefore some hospitals use isolation protocols for all horses with a small colon impaction. Diarrhea, fever, leukopenia, and rectal mucosal edema are findings with small colon impactions and colitis; it is not known whether the underlying mucosal inflammation led to the impaction or whether the inflammation caused primarily by the small colon impaction predisposes horses to colitis.[2,8,9] A dramatic increase in the incidence of small colon impaction has been documented in the fall and winter, possibly because of decreased water intake or close housing that increases the incidence of infectious colitis, but a definitive reason is unknown. Of interest is that this seasonal incidence was not significant in the most recent study, possibly because of the milder winters in the southern United States.[8]

Diagnosis of a small colon impaction is most easily made by rectal palpation, with an accuracy of 79 to 87%.[8,23] A solid tube of ingesta with loss of the normal sacculations is found, but other rectal examination findings include gas distention of the large intestine and cecum and loose manure.[6,8,23] Great care should be taken in performing a rectal examination because the rectal mucosa may be edematous, and many horses will strain. [3] One of the best parameters for determining when surgical treatment of these cases is required is the presence of abdominal distention; affected patients are five times more likely to require surgical correction than are horses without abdominal distention.[8] In addition, increases in abdominal pain and alterations in abdominal fluid that are consistent with deterioration of the bowel are also indications for surgery.[2,6,8,23] Transabdominal trocharization in the right paralumbar fossa can be an effective and safe method of relieving gas accumulating orad to the impaction. This can be performed to relieve abdominal distention and improve the chance of success with medical therapy without the need to proceed directly to surgery.

Medical therapy should consist of intravenous fluid therapy to correct electrolyte abnormalities, in combination with enteral fluid therapy with a balanced electrolyte solution, and analgesics as necessary.[9,23] Because enteral fluids can iniate the gastrocolic reflex and gastric distention can stimulate contraction of the colon, typically 4 to 6 L of warm water with 1 oz of sodium chloride alternating with 1 oz of potassium chloride can be administered via nasogastric tube every 2 hours.[25,26] The administration of oral laxatives such as mineral oil, dioctyl sodium sulfosuccinate, or magnesium sulfate can be used to soften the impaction. The time it takes for the impaction to resolve with medical treatment is often longer than for large colon impactions; mean time to resolution is more than 2 days.[8] Affected horses that develop signs of systemic inflammation, such as fever, leukopenia, tachycardia, or tachypnea, may require treatment with antibiotics or antiendotoxin therapies.[9] Enemas may be administered in a standing horse to break down very aborad impactions but should be done so with extreme caution to avoid mucosal injury. Adequate sedation, epidural anesthesia, and the administration of *N*-butylscopolammonium bromide may decrease the risk of injury.[1,3,9,27]

Surgical correction of the impaction through exploratory celiotomy is usually performed with administration of a high enema and extraluminal massage by the surgeon. The impacted small colon is extremely friable, and the surgeon should be careful when manipulating the bowel in order to avoid serosal tears. Application of sterile carboxymethylcellulose to the serosal surface may help lubricate the intestine and reduce the trauma of manipulation. In severe cases, infusion of the impacted contents with isotonic fluids or an enterotomy in the small colon may be necessary to facilitate evacuation of the impaction.[3] An additional concern is the risk of reimpaction of the small colon as ingesta from the large colon move aborally after surgery. Therefore if there are ingesta in the large colon at the time of surgery, a pelvic flexure enterotomy is also recommended so as to empty the large colon and reduce the risk of recurrence.[23] Surgical correction of the impaction can be time-consuming; to reduce anesthesia time, the items needed for high enema administration, such as a stomach tube with a rounded atraumatic end, a stomach pump, and buckets of warm water, should be assembled in the operating room before induction.

The prognoses with medical and surgical treatment appear to be similar in most studies.[8,23] Of interest is, however, that overall prognosis appears to have improved since the 1980s, increasing from approximately 75% in cases from 1986 to 1996 [23] to approximately 95% in cases from 1999 to 2004.[8] Therefore overall, the prognosis for small colon impaction is excellent, even if surgical intervention is necessary. However, because of the underlying inflammatory cause of this condition, length of hospitalization tends to be longer and associated costs higher than those incurred with a simple large colon impaction.[8]

FECALITHS, ENTEROLITHS, AND FOREIGN BODIES. Simple obstruction of the small colon also involves inspissated feces (fecaliths), enteroliths, foreign bodies, or, less frequently, concretions of plant material (phytobezoars) or masses of matted hair (trichobezoars).

Fecaliths are improperly formed fecal balls, ranging in size from 4 to 6 cm, that are a result of poor diet, inefficient mastication, or reduced water intake.[28,29] They are a common cause of colic in young or old (>15 years) miniature horses; an occurrence rate of 63% was documented in a study of surgical colic in miniature horses.[4,29-31] Fecaliths that become lodged in the small colon usually cause complete intestinal obstruction and necessitate surgical removal, as described later. When colic is managed in a miniature horse, regardless of the cause, the serum triglyceride concentration should be monitored to allow early detection and treatment of hyperlipemia.[32]

Enteroliths are, as described previously, composed mainly of magnesium ammonium phosphate deposited in concentric layers around a nidus such as a small rock.[33] The incidence is very high in certain regions, such as California, where enterolithiasis accounts for 15.1% of all cases of colic seen at the University of California, Davis,[34] in comparison with less than 2% of colic cases at Texas A&M University.[35] Enteroliths can lodge in the large colon, transverse colon, or small colon. According to some studies, the transverse colon may be the most common site of obstruction; however, larger trials indicate that the small colon is most commonly involved, with an incidence of 22%.[34,36-38] Horses with enteroliths were found to have certain changes in the composition of their colonic contents, in comparison with other surgical colic cases, which may predispose them to enterolith formation. These differences include a more alkaline pH, more colonic fluid, and higher mineral concentrations.[38] Certain management practices, including a high proportion of alfalfa in feed and less access to pasture, may also predispose a horse to enterolith formation.[35,38]

Clinical signs of enterolithiasis are similar to those seen with other nonstrangulating obstructions of the large or small

colon. Many horses with enterolithiasis have a history of intermittent colic, but once the stone becomes lodged within the small colon, it can either be passed in the feces or become wedged.[34] Most enteroliths that obstruct the small colon lodge in the proximal third, presumably because of the change in lumen diameter between the transverse colon and descending colon.[38] Horses with an enterolith in the small colon are more likely to be tachycardic and leukopenic than are horses with an enterolith in the ascending colon.[38] Sensitivity of radiography for the diagnosis of enterolithiasis ranges from 41.6% to 62.5% for enteroliths located in the small colon and from 75% to 91.67% for enteroliths located in the transverse colon. Digital radiography has been shown to be more sensitive than computed radiography, which in turn is more sensitive than analog radiography. Enteroliths in the large colon are easier to identify than those located in the small colon, and increased gas distention negatively affects the sensitivity of radiographic images of enteroliths.[39-41]

Medical management aimed at reducing colonic pH has been suggested to try to prevent recurrence after surgery. However, when an enterolith lodges in the small colon, it usually causes complete obstruction and acute colic that necessitate surgical intervention, as described later. Rupture of the gastrointestinal tract is particularly common if the enterolith is lodged in the small colon and surgery is delayed.[34]

Ingestion of foreign material such as rope, twine, rubber fencing, cloth, or tires can also cause obstruction of the small colon.[31,42] This is usually a problem in younger horses, possibly because they are more inquisitive and will eat nonfood items found in their environment. It is possible for the foreign body to cause signs of small intestinal obstruction first, followed by a period of quiescence while it passes through the large colon before it finally causes complete obstruction of the small colon and causes acute onset of severe colic and abdominal distention.[1,42] The fibers become covered in crystalline material during their transit through the intestinal tract, and the resulting irregular sharp projections cause pressure necrosis and mucosal ulceration,[6] which can be seen during exploratory celiotomy orad to the site where the foreign body has finally become lodged. These sharp projections make it virtually impossible to manipulate the foreign body orally or aborally within the lumen and thus make removal more complicated.

The majority of these obstructions necessitate exploratory laparotomy and an enterotomy to allow the obstruction to be removed.[29,34,42] Regardless of the cause of the obstruction, the overlying intestine is friable and can rupture easily either during induction of anesthesia or during surgical manipulation.[31,34,42] If possible, the mass should be gently manipulated more proximal or distal to the original site at which it lodged, so that the enterotomy can be performed in uninjured areas of the intestine.[6] However, foreign bodies in particular may be difficult to manipulate, and the enterotomy may have to be performed directly over the top of the obstruction. The site selected for the enterotomy should be isolated from the abdomen with sterile towels before the enterotomy incision is made. The incision should be made longitudinally through the antimesenteric taenia in order to preserve luminal diameter, reduce hemorrhage, and maximize speed and ease of the procedure.[43,44] The enterotomy can be closed in one layer with an inverting suture pattern.[44] Small areas of necrosis caused by transmural pressure from the obstruction can be managed by oversewing the affected segment.

Problems arise when intraluminal obstructions occur at the proximal portion of the descending colon, where the lumen narrows between the transverse and descending colon. Here, manipulation of the obstruction aborally into a section of small colon that can be exteriorized may be impossible. In such cases, an antimesenteric teniotomy, through the seromuscular layer alone, can be performed. This allows the obstruction to be advanced aborally into a section that can be exteriorized, while the intact mucosa prevents abdominal contamination.[45] The enterotomy and seromuscular incision are then closed as described earlier. An alternative approach is to administer a high enema to repulse the obstruction in an orad direction into the ascending colon, where it can be removed via a pelvic flexure enterotomy. Approximately 50% of horses with enteroliths in the descending colon have additional stones in the ascending colon; thus complete examination of the large intestine, especially the right dorsal and transverse portions of the colon, is recommended after the removal of a stone through a small colon enterotomy.[34,38] The overall prognosis for horses with enteroliths of the descending colon is excellent. In one study, the short-term survival rate among horses that survived surgery was 94%.[38] Common postoperative complications include fever, anorexia, and diarrhea, which do not seem to worsen the prognosis but may prolong hospitalization. Recurrence has been identified in up to 7% of horses.[34]

MECONIUM RETENTION. Meconium is composed of substances that are present in the intestinal tract at birth, such as glandular secretions, sloughed cells, and swallowed amniotic fluid, and is therefore sterile. Healthy foals pass meconium, which is a thick, tarry substance, within 48 hours; the presence of soft, yellowish stool is an indicator that meconium passage is complete.[30,46,47] Several studies indicate a higher incidence of meconium retention in colts than in fillies, presumably because the pelvis is longer and narrower in males.[30,47] Any factors that reduce intestinal motility (such as failure to ingest colostrum) and dysmaturity can result in difficulty passing meconium, which is described as *meconium retention.* Clinical signs include tail flagging, straining, and reduced suckling, which can progress to more severe signs of colic over time, such as rolling and abdominal distention. These signs are similar to those seen with ruptured bladder, and the two conditions can occur together; therefore a complete examination of an affected foal is important.

It may be possible to palpate meconium retained at the pelvic inlet by careful digital rectal examination. If the meconium is retained more proximally, it may be identified on a plain lateral radiograph. Presence of the obstruction may be confirmed by retrograde contrast radiography, which provides excellent sensitivity and specificity for evaluation of the transverse and descending colon.[20] Retrograde contrast radiographs may provide additional information when plain radiographs are inconclusive. A Foley catheter (28- to 30-French) is placed into the rectum, and up to 20 mL/kg (approximately 1 L) of 30% barium sulfate is carefully allowed to flow in by gravity until it squirts around the catheter or discomfort is observed.[20] Lateral and, of more importance, ventrodorsal radiographs are then obtained. If a meconium impaction is present, the path of the contrast agent stops before it reaches the transverse colon. Ultrasound examination can reveal gas distention of the large intestine and, in some cases, the meconium itself can be identified as a row of fecal balls in the small colon. The echogenicity of the meconium varies, but a typical "speckled" appearance has been described.[48-50]

Supportive medical management of all affected foals should be performed first, including correction of fluid and electrolyte imbalances, provision of nutritional support, and correction of failure of passive transfer if indicated.[51] Judicious use of analgesics such as flunixin meglumine or butorphanol and oral fluids may aid resolution of the impaction. The most effective treatment is administration of an enema. The enema can be a commercial phosphate enema or simply soap and water administered through a Foley catheter by means of gravity flow, as described previously. In cases that are refractory to simple enemas, an acetylcysteine enema may be effective.

VetBooks.ir

VetBooks.ir

Acetylcysteine is a mucolytic, which acts by breaking disulfide bonds to make meconium less viscous. These enemas are available commercially (E-Z Pass Foal Enema Kit; Animal Reproduction Systems, Chino, Calif.) or can be formulated by adding 20 g of baking soda to 200 mL of water and then adding 8 g of acetylcysteine powder to make a 4% solution.[47] The solution is infused slowly through a Foley catheter, which is then clamped to allow the solution to be retained for up to 45 minutes to allow maximum activity of the acetylcysteine. The meconium retention was resolved successfully in all acetylcysteine-treated foals in one study, although 5% of foals required three enemas before resolution was obtained, and three foals in the study developed a bladder rupture.[47]

One report indicated that in approximately one third of foals with meconium retention, exploratory celiotomy is needed for resolution.[30] However, this study was carried out before the increased use of acetylcysteine retention enemas, and the current rate of surgical intervention is probably much lower. Because adhesions can develop in up to 33% of foals undergoing gastrointestinal surgery, long-term prognosis may be improved by reducing the number of foals undergoing exploratory celiotomy.[30,47,52]

OTHER CAUSES OF SIMPLE OBSTRUCTION. Because of the proximity of the descending colon to the urogenital tract, it is possible for the descending colon to be obstructed by intraabdominal structures such as an ovary or retained testicle. Although such conditions occur infrequently, the most common is for the small colon to become entwined around an ovary.[6] The intestine can be freed and is not usually compromised, but the ovary itself is usually nonviable and must be resected.[53] A similar problem has been reported from the spermatic cord of a retained teratoma that occluded the small colon.[54]

Neoplasia

With the exception of lipomas, neoplastic processes of the small colon are quite rare. In a study characterizing intestinal neoplasia in horses, lymphoma and adenocarcinoma were the most frequent neoplastic lesions located in the small colon.[55] Development of leiomyomas has been attributed to small colon intussusceptions, but they are also as incidental findings.[56]

Vascular Lesions

INTRAMURAL HEMATOMA. Intramural or submucosal hematomas are rare, although some cases may not be diagnosed if they do not cause complete obstruction and if they resolve without intervention.[57,58] Blood hemorrhages between the mucosa and muscularis layers, which expand to occlude the lumen and cause complete obstruction. If left untreated, hematomas can lead to ischemic necrosis of the bowel wall and thus to septic peritonitis, endotoxemia, circulatory shock, and possible death.[57,58] The length affected has been reported to range from 24 to 65 cm. The cause is unknown, although blunt abdominal trauma has been associated with the condition in humans.[59] In one equine case series, iatrogenic rectal trauma was implicated as the cause. [58] There is an increased incidence among older horses; those affected had an average age of 11 years in one study.[6] Clinical signs include varying degrees of abdominal pain, as well as signs of vascular compromise from blood loss.[6,58] The presence of dark or clotted blood on rectal palpation may aid diagnosis, and in some cases, a mass within the small colon may be identified.[57,58]

Exploratory celiotomy with complete resection of the affected segment and end-to-end anastomosis (as described later) is necessary. Because of the length of the affected segment, it may be difficult to exteriorize and resect all damaged intestine. However, if the entire affected segment can be removed, the prognosis is good; one study demonstrated a 75% survival rate.[57]

MESOCOLIC TEARS AND RECTAL PROLAPSE. Tears in the mesentery of the small colon can occur as a complication of parturition, especially in multiparous mares,[60,61] and result in segmental ischemic necrosis of the small colon. Trauma and straining during parturition can result in tearing of the mesocolon and devitalization of the associated descending colon, which may progress to an intussusception of the small colon, which manifests as a type III or IV rectal prolapse. In a type III rectal prolapse, the rectal ampulla prolapses, as with a type II prolapse, but in addition, a portion of the small colon intussuscepts into the rectum. In type IV rectal prolapse, part of the small colon and the rectum intussuscepts through the anus.[60,62] Gentle palpation around the prolapse can help determine the type of prolapse. Although a rectal prolapse is readily identifiable, devitalization of the small colon caused by tears of the mesocolon results in a more insidious onset of clinical signs, including depression and lack of feces.[60,61]

The mesocolic tear is frequently located caudally; as a result, the affected area is inaccessible through a midline celiotomy. Therefore it may be more prudent to first perform standing flank laparoscopy to determine the location and extent of the lesion.[63] This allows assessment of the lesion to determine whether resection and anastomosis of the affected segment via celiotomy are feasible or whether a permanent colostomy is required.[64,65] The prognosis is often poor because of the extent of the tear or delay in surgical intervention.[60,61,65]

Strangulating Obstructions

STRANGULATING LIPOMA. Pedunculated lipomas can cause a strangulating or nonstrangulating obstruction of the small colon, but this occurs much less frequently than in the small intestine. In a large retrospective study, lipomas were found to involve the descending colon in approximately 10% of cases.[2,7,66] The overall incidence of lipomas affecting any portion of the gastrointestinal tract is increased among older geldings and in Saddlebred and Arabian horses.[66,67] It is therefore likely that lipomas specifically affecting the descending colon have a similar distribution. Fig. 32.72 illustrates a pedunculated lipoma that had strangulated a short section of the small colon.

FIG. 32.72 A short section of small colon that had been strangulated by a pedunculated lipoma.

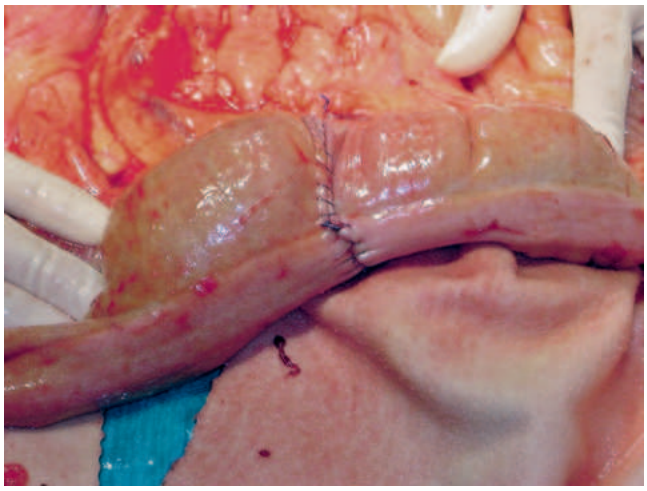

FIG. 32.73 The same case as in Fig. 32.72 after resection of the ischemic segment and end-to-end anastomosis.

Clinical signs typical of a strangulating obstruction include a significantly elevated heart rate, abnormal abdominocentesis findings, and distendtion of the large colon on rectal examination.[6] Horses may only show mild to moderate signs of abdominal pain, in contrast to strangulating lesions in other parts of the gastrointestinal tract.[7] Rectal examination may yield unspecific findings, but a constriction of the lumen of the small colon caused by the lipoma may be palpated and feels like a blind end or narrowing of the lumen.[7]

Surgery is necessary to free the constricting lipoma, followed by resection and anastomosis if the intestine is nonviable (Fig. 32.73). Strangulating lipomas of the small colon are the most common reason for resection and anastomosis.[7] The prognosis is worse if resection is required, with a 50% survival rate in one study, in comparison with 100% survival for nonstrangulating lipomas.[6] However, a multicenter study documented a substantially better survival rate after resection and anastomosis of the small colon; the majority of patients were horses with a strangulating lipoma.[7] In that study, 84% of cases were discharged after hospitalization for a median of 8.5 days. The end-to-end anastomosis is usually sutured in two layers, with a simple continuous pattern in the mucosa followed by closure of the serosa with an inverting suture pattern interrupted at 180 degrees. It is possible that failure of the anastomosis occurs more commonly in the small colon than the small intestine, but numbers are too low to definitively confirm this.[7] Diarrhea, fever, and delayed passage of feces are common postoperative complications, but long-term survival is good; of horses discharged in the aforementioned study, 93% were alive at 6 months.[7]

OTHER CAUSES OF STRANGULATING OBSTRUCTION. Several other causes of strangulating obstruction can occur, but each condition is relatively rare. These include volvulus of the small colon[1] and strangulation through internal hernias such as a vaginal tear[2] or tears in the gastrosplenic ligament.[68] Intussusception can occur without rectal prolapse, and in some cases, the intussusceptum may protrude from the anus. Diagnosis can be made if a finger can be inserted between the protruding bowel and anal sphincter.[56,65,69,70]

Prognosis A good survival rate was found in two large reviews of small colon disorders: 71% and 91% of patients were discharged from the hospital.[2,6] The main reason for euthanasia at the time of surgery was an inability to completely exteriorize the affected segment to allow adequate resection and anastomosis.[6] Previous reports have suggested that resection and anastomosis in the small colon may carry a poor prognosis because of a relatively poor blood supply, higher bacterial counts, the presence of solid fecal material, and increased collagenase activity in comparison with the small intestine.[1] However, among patients that survive surgery, short-term survival after surgery for a small colon lesion is excellent a rate of 100% survival was reported in one study.[71] In addition, horses that required resection and anastomosis did not have a worse prognosis for survival[2] and were less likely to develop the complications associated with small intestinal resection, such as postoperative ileus (POI).[71]

Disorders of the Peritoneum in Horses

Tiffany L. Hall

Peritonitis in Horses

Anatomy and Physiology

The peritoneum consists of a single layer of mesothelial squamous cells covering the peritoneal cavity and abdominal organs. These cells rest on a thin basal lamina attached to a layer of loose connective tissue, which allows a variable degree of motion. The peritoneum is coated with a thin serous film that serves to minimize friction and facilitate free movement between abdominal viscera. In males the peritoneum forms a closed sac, whereas in females it communicates with the external environment via the fallopian tubes.

The peritoneum is divided into the visceral peritoneum and the parietal peritoneum. The visceral peritoneum, which encloses the intraperitoneal organs and forms the omentum and mesenteries, is supplied by the splanchnic vasculature and is innervated by the visceral autonomic nervous system. The parietal peritoneum lines the abdominal walls, pelvis, and diaphragm and receives its blood supply via branches of the lower intercostal, lumbar, and iliac arteries, which drain via veins into the caudal vena cava. Irritation of the parietal peritoneum gives rise to afferent stimuli that are perceived as somatic pain, which is transmitted by the intercostal and phrenic nerves and may manifest as splinting of the abdomen and a reluctance to move. In contrast, there are no pain receptors in the visceral peritoneum.

Peritoneal fluid is constantly being produced and absorbed through the passive diffusion of fluid and solutes across the semipermeable peritoneum. Transperitoneal fluid movement is increased during peritoneal inflammation and may cause a rapid, massive transudation of fluid into the peritoneal cavity that can lead to hypotension and shock.[1]

The peritoneal lymphatic channels, particularly the diaphragmatic lymphatic channels, play a major role in the removal of fluid and solutes from the peritoneal cavity, emptying primarily into the thoracic duct and providing the first line of defense against peritoneal contamination. Cellular defenses are provided by peritoneal macrophages, mast cells, mesothelial cells, and activated peritoneal T cells. Peritoneal macrophages have antimicrobial activity as a result of their complement receptors, phagocytic ability, cellular recruitment, and T-cell–mediated immune responses. Peritoneal mesothelial cells are an abundant source of plasminogen activator, which is responsible for normal fibrinolytic activity on peritoneal surfaces.[1]

Pathogenesis Peritonitis is inflammation of the peritoneum that results from a number of infectious and noninfectious causes. It is classified as primary or secondary, acute or chronic, and localized or diffuse. Common causes of peritonitis in horses are listed in Box 32.2. Primary peritonitis is uncommon in adult horses but may be diagnosed in foals with sepsis or young horses infected with *Streptococcus equi*. More commonly,

peritonitis is secondary to translocation of bacteria from the gastrointestinal tract, occurs after urogenital trauma, or results from other inflammatory conditions. A subset of infectious peritonitis with a unique presentation and associated with *Actinobacillus equuli* has been described and is discussed at the end of this section.

Retrospective studies concluded that a cause of peritonitis is often not identified (as was the case in 50 of 65 horses and in 19 of 55 horses).[2,3] In both groups, cases of confirmed gastrointestinal rupture were excluded from analysis, and horses that had undergone abdominal surgery were excluded from one study. The conditions most commonly associated with peritonitis in these studies included recent abdominal surgery (18 of 55), postpartum complications (22 of 120), suspected cyathostomiasis (4 of 65), infiltrative bowel diseases (3 of 65), and internal abscesses (3 of 65).[2,3]

The local response of the peritoneum to insult is similar regardless of the cause. Initially, peritoneal mast cells and macrophages release histamine and serotonin, which results in vasodilation and increased vascular permeability with transudation of fibrinogen-rich plasma into the peritoneal cavity. The release of TNF-alpha and IL-1 stimulates neutrophil chemotaxis and degranulation, and the inflammatory response is promoted by the release of platelet-activating factor, prostaglandins, and leukotrienes. Damage to mesothelial cells results in release of tissue thromboplastin and decreased levels of plasminogen activator, which are conducive to fibrin formation and deposition.[4] Fibrin functions to confine bacteria and seal the peritoneal defect; however, if the immune system fails to clear the bacteria and foreign debris, the inflammation continues, and fibrin production results in abscess and adhesion formation.

Clinical Features

Clinical signs of peritonitis vary and depend on the cause and duration of the peritonitis. Localized infections often have limited systemic symptoms, whereas diffuse peritonitis can elicit generalized signs of endotoxemia and sepsis. Horses with peracute peritonitis caused by intestinal rupture show signs of acute, severe sepsis and cardiovascular collapse with tachycardia, tachypnea, sweating, varying degrees of abdominal discomfort, and death within hours.

According to two retrospective studies, the most common presenting clinical signs for peritonitis include colic, depression/lethargy, tachycardia, tachypnea, pyrexia, and altered mucous membrane character.[2,3] Much of the clinical presentation in acute colic reflects the degree of systemic inflammation and hypovolemia caused by third spacing. Colic symptoms may be related to inflammation of the parietal peritoneum and are characterized by guarding or splinting of the abdomen and a reluctance to move or defecate.[5] Sympathetic stimulation, hemoconcentration, or serosal surface trauma may decrease gastrointestinal motility, leading to ileus, which may result in gastric fluid accumulation and small intestine distention, thereby intensifying the abdominal pain. In addition, gastrointestinal impactions commonly develop as fluid is reabsorbed from the cecum and large colon in an attempt to replace intravascular fluid deficits resulting from extravasation of fluid into the peritoneal cavity. Chronic peritonitis generally manifests with more insidious signs, including lethargy, inappetance, and weight loss.

Rectal examination may identify either roughened peritoneal surfaces or an abnormally empty abdomen in cases of intestinal rupture. The bowel may become distended in association with the presence of adhesions or ileus. Abdominal masses, abscesses, or enlarged mesenteric lymph nodes are occasionally palpable; however, in many cases, no abnormalities are identified on rectal palpation. Animals with a recent history of foaling or castration should undergo urogenital examination to rule out vaginal, cervical, and uterine tears in mares or infected castration sites in males.

Diagnosis

ULTRASONOGRAPHY. Ancillary diagnostic testing such as transabdominal and transrectal ultrasonography aid in diagnosis of peritonitis and identification of the source. The clinical utility of ultrasonography greatly depends on the quality of equipment and the experience of the practitioner; identification of abnormalities in cases of peritonitis ranges from 50% to 90%.[2,3] The most common finding on transabdominal ultrasonography is an increase in volume or altered echogenicity of peritoneal fluid. Other findings can include intraabdominal abscesses, lymphadenopathy, or dilation of the small intestine with or without increased intestinal wall thickness. Fibrinous strands or fibrin adhesions may also be identified by ultrasonography (Fig. 32.74) and a site for abdominocentesis selected. Perirectal masses may be observed on transrectal ultrasonography, particularly in cases associated with vaginal tears.

VetBooks.ir

HEMATOLOGY AND BIOCHEMISTRY. Alterations in laboratory values vary widely, depending on the cause and duration of peritonitis. Hematologic abnormalities seen in acute, severe peritonitis include elevated PCV secondary to transudation of fluid into the peritoneal cavity and severe neutropenia in association with endotoxemia and systemic inflammation. Initially, plasma protein levels increase, which reflects the degree of hypovolemia; in chronic cases, however, hypoproteinemia may be present. Peripheral cell counts can exhibit leukopenia or leukocytosis, and a left shift with more than 5% immature neutrophils is observed in approximately 40% of patients.[3] Hyperfibrinogenemia is a common finding; fibrogen levels ranged from 490 to 1120 mg/dL in a review of 65 cases.[2] Peritonitis of longer duration and internal abscesses may manifest with a normal or increased systemic neutrophil count, monocytosis, and elevated plasma protein levels, fibrinogen levels, or a combination of these.[6] In addition, peripheral and peritoneal levels of serum amyloid A may be greatly increased in cases of peritonitis.

Alterations in serum chemistry and blood gas values reflect the patient's cardiovascular status at the time of presentation, in association with the degree of systemic inflammation. Prerenal azotemia, hypokalemia, hyponatremia, and hypochloremia may be present, as may acidosis and an increase in unmeasured anions, such as lactate, as the patient's condition declines. Other changes in serum chemistry values could indicate an underlying condition in a specific organ system.

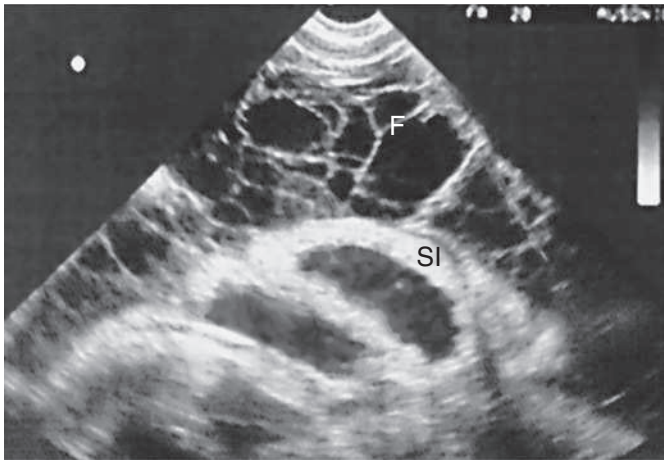

FIG. 32.74 Abdominal ultrasound image in an adult horse with chronic peritonitis, showing web of fibrin *(F)* surrounding anechoic fluid. The small intestinal wall *(SI)* is thickened. *(Courtesy Dr. David Schmitz, Texas A&M University.)*

ABDOMINOCENTESIS. Peritoneal fluid analysis confirms the diagnosis of peritonitis, although the cause may remain unknown. Expected values for peritoneal fluid in normal horses, as well as in horses that have undergone abdominal exploratory surgery and castration and in postpartum mares, are listed in Table 32.9.[7-10] The cytologic appearance of the leukocytes and mesothelial cells should be normal, although activated mesothelial cells with vacuolation are not an unusual observation in normal horses.

Evaluation of fluid character and quantity can aid in developing and prioritizing a differential list. Turbid, cloudy fluid indicates an increased cell count. Serosanguineous fluid indicates an increase in erythrocytes or free hemoglobin that may be caused by intestinal degeneration with transmural erythrocyte leakage, splenic puncture during abdominocentesis, abdominal viscera laceration, or skin contamination. Green fluid results from enterocentesis or intestinal rupture, and brown fluid is associated with late-stage tissue necrosis. The quantity of fluid varies among horses and can be increased in acute, diffuse peritonitis, or fluid may be absent in low-grade and localized peritonitis. The presence of large quantities of dilute, colorless fluid should alert the clinician to the possibility of ascites or uroperitoneum.

Cytologic examination of the peritoneal fluid should include Wright-Giemsa and Gram stains. Peritoneal fluid cell structure is an important diagnostic aid and can be evaluated wth the Wright-Giemsa stain. Neutrophils are evaluated for degenerative changes such as nuclear swelling and cytoplasmic vacuolation, which indicates activation associated with the presence of bacterial toxins. Identification of exfoliative cells from neoplasms, such as melanoma, is rare but diagnostic and aids in directing therapy and prognosis.[11] The Gram stain is used to identify bacteria and guide initial antimicrobial therapy until culture and sensitivity results become available.

Peritoneal fluid parameters consistent with peritonitis vary widely, depending on the disease process. Cytologic findings consistent with peritonitis include increases in total nucleated cell counts and protein with the predominance of degenerative neutrophils and intracellular bacteria. Nucleated cell counts ranged from 5800 to 350,000 cells/μL, and protein levels were as high as 8 g/dL, in one study,[2] but nucleated cell counts as high as 800,000 cells/μL have been reported in horses with peritonitis. Cytologic evidence of extracellular bacteria can result from skin contamination and should be interpreted in relation to the clinical signs and remainder of the fluid analysis.

TABLE 32.9

Peritoneal Fluid Analysis in Normal Horses and After Conditions That Alter Peritoneal Fluid Values[7-10]

Parameter	Normal	After Celiotomy	After Castration	After Foaling	Dystocia
Fluid character	Clear, straw-colored	Clear, straw-colored	Clear to cloudy	Clear, straw-colored	Serosanguineous
Total nucleated cell counts (#/μL)	<5000	200,000 (postoperative day 4)	30,000 (postoperative day 5)	<5000	40,500 (postnatal day 1)
Cell structure	24 to 60% nondegenerate neutrophils	Nondegenerate neutrophils	85% neutrophils	Increased nondegenerate neutrophils	NR
Total protein	<2.0 g/dL	6 g/dL (postoperative day 6 post)	NR	<2.0 g/dL	4 g/dL (postnatal day 1)
Cytologic values	Mesothelial cells may be activated	NR	NR	NR	NR

NR, Not reported.

VetBooks.ir

Distinguishing between early, mild septic peritonitis and nonseptic peritoneal inflammation with clinical findings and routine fluid analysis alone may be difficult; however, peritoneal fluid pH and glucose concentrations have been found to be significantly lower in horses with septic peritonitis than in those with nonseptic peritonitis and in healthy horses. In a prospective study in 46 horses, serum-to-peritoneal fluid glucose concentration differences greater than 50 mg/dL were diagnostic for septic peritonitis. Peritoneal fluid pH less than 7.3, glucose concentration below 30 mg/dL, and fibrinogen concentration above 200 mg/dL were highly indicative of septic peritonitis.[12] A more recent study showed that peritoneal concentrations of L- and D-lactate were highest in horses with peritonitis, in comparison to other causes of colic; however, determination of the bacterial origin of D-lactate is not possible in the clinical setting.[13] In addition to these findings, other markers of inflammation and coagulopathy are altered in cases of septic peritonitis; alterations include significant elevations in peritoneal transforming growth factor β_3 in comparison with other causes of colic and significantly higher peritoneal D-dimer concentrations than in healthy horses or those with obstructive colic.[14,15]

BACTERIAL CULTURE AND SENSITIVITY. Microbiological culture and sensitivity testing are recommended to help identify bacterial agents and direct antimicrobial therapy. Serial cultures of the peritoneal fluid may be necessary to identify emerging or resistant bacterial strains. Optimal isolation of bacteria from peritoneal fluid requires the use of an enriching broth, blood culture medium, an antimicrobial removal device, or a combination of these.

Bacteria were cultured in cytologic study in 48 (71.6%) of 67 horses with peritonitis and identified in 28 (77.8%) of 36 cases of peritonitis. *E. coli*, *Staphylococcus epidermidis*, and *S. aureus* were the most common bacteria isolated from peritoneal fluid samples.[3,5] Anaerobes are frequently cultured from peritoneal fluid of equine peritonitis cases, *Bacteroides fragilis* being the most commonly identified.[16] Failure to identify or culture bacteria from peritoneal fluid does not rule out septic peritonitis.

Treatment

Many horses with peritonitis require early, aggressive therapy to address hypovolemia and dehydration, correct metabolic and electrolyte abnormalities, and reduce the effects of endotoxemia. The goals of therapy are to (1) stabilize the patient, (2) treat the inciting cause of peritonitis, (3) manage pain and inflammation, and (4) minimize complications.

FLUID THERAPY. Horses with peritonitis present with varying degrees of hypovolemia, dehydration, or both; thus fluid resuscitation with balanced, polyionic crystalloids should be the first step in treatment. Hypertonic solutions may be indicated in horses presenting with signs of hypovolemic shock, which may develop secondary to massive fluid shifts into the peritoneal cavity as a result of severe, acute inflammation. Because third spacing of albumin can lead to hypoproteinemia, administration of colloid solutions may be beneficial. Hetastarches (6%) are effective in fluid resuscitation and increase colloid oncotic pressure at doses of 8 to 10 mL/kg; however, caution should be used in patients with azotemia or underlying renal insufficiency because administration of those solutions is associated with acute kidney injury in humans.[17] Large volumes of hyperimmune plasma may be used to raise plasma protein levels, whereas low doses (4.4 mL/kg) may aide in alleviating signs of endotoxemia.[18]

Acid-base disorders, as well as shifts in calcium, potassium, sodium, and chloride concentrations, may be observed in cases of peritonitis. Monitoring of acid-base status and electrolyte concentrations is recommended during the course of therapy with intravenous or oral supplementation as needed. See the Fluid Therapy for Horses with Gastrointestinal Diseases section for a more in-depth discussion of fluid resuscitation and selection.

TABLE 32.10

Antimicrobial Therapy for Peritonitis in Adults

Drug	Dosage	Route	Schedule
Potassium penicillin	22,000 to 25,000 IU/kg	IV	q6h
Ceftiofur sodium	2.2 to 4.4 mg/kg	IV/IM	q12h
Gentamicin	7 to 10 mg/kg	IV	q24h
Enrofloxacin	7.5 to 10 mg/kg	IV	q24h
	10 mg/kg	PO	q24h
Metronidazole	20 to 25 mg/kg	PR	q6-8h
Doxycycline	10 to 20 mg/kg	PO	q12-24h
Minocycline	4 mg/kg	PO	q12h
Trimethoprim-sulfonamide	30 mg/kg	PO	q12h
Chloramphenicol	50 mg/kg	PO	q6h
Rifampin	5 to 10 mg/kg	PO	q12h

IM, Intramuscular; *IV*, intravenous; *PO*, oral; *PR*, rectal.

ANTIMICROBIAL THERAPY. Antimicrobial therapy should be initiated in all cases of peritonitis, even when the inciting cause cannot be immediately identified. The site of infection, pathophysiologic features, pathogens probably involved, and concurrent patient conditions should be taken into consideration when an antimicrobial regimen is selected (Table 32.10). Lipophilic antibiotics (fluoroquinolones, potentiated sulfonamides) reach higher concentrations within the peritoneal cavity and in abscesses than do hydrophilic antibiotics (aminoglycosides, β-lactams); however, in the acute stages of the disease, inflammation of the peritoneal surfaces often causes hydrophilic antibiotics to reach therapeutic levels.[18] Moreover, intravenous administration is recommended as drug concentrations achieved are more reliable than those achieved with oral administration in horses suffering from dehydration or ileus.

A broad-spectrum antimicrobial regimen is recommended until culture and sensitivity results are available. Administration of a combination of a β-lactam and an aminoglycoside is appropriate; however, enrofloxacin may be substituted for gentamicin because of its increased lipophilicity or activity against *Staphylococcus*, or in cases of renal compromise. Metronidazole is often added on the basis of the frequency of *B. fragilis* isolated in horses with peritonitis. Oral antibiotic administration may be initiated after patients are stabilized and should be based on culture and sensitivity results.

Antimicrobial selection in foals is based on age and likely causes of peritonitis. Neonatal foals with peritonitis should be maintained on broad-spectrum intravenous antibiotics, as for septicemia, including a combination of a β-lactam (ampicillin, 20 mg/kg IV qid, or ceftiofur, sodium 5 mg/kg IV bid) and an aminoglycoside (amikacin, 20 to 25 mg/kg IV q24h). Older foals and weanlings have a higher incidence of *R. equi* and *S. equi* infection; thus antimicrobial regimens in these patients include either penicillin (procaine penicillin G, 20,000 IU/kg IM bid) or a macrolide/rifampin combination in the absence of other inciting causes.[19,20]

The duration of antimicrobial therapy is dependent on the inciting cause and the patient's response to treatment. Most peritonitis cases necessitate a minimum antimicrobial course of 7 to 10 days, and cases with intraabdominal abscesses may necessitate a 6- to 8-week course of antimicrobials. In cases of idiopathic peritonitis, antibiotics should be continued for

VetBooks.ir

several days after clinical signs resolve and peritoneal fluid counts return to normal. Other methods for monitoring progress and determining termination of therapy include serial ultrasound evaluation, CBCs, and measurement of fibrinogen levels in cases of internal abscesses.

ANTIINFLAMMATORY THERAPY. All horses with peritonitis have varying degrees of local and systemic inflammation, and some may present with endotoxemia or endotoxic shock. Administration of medications with antiinflammatory properties, as well as those that bind and inactivate endotoxin, may be beneficial.

NSAIDs should be administered in all cases of peritonitis for both analgesic effects and ability to reduce the production of inflammatory mediators through COX inhibition. Flunixin meglumine is most often used for its antiinflammatory properties and may be administered at higher doses (1.1 mg/kg IV or PO bid) in horses showing signs of discomfort or at lower doses (0.25 mg/kg IV or PO q6-8h) to minimize side effects. Other NSAIDs such as phenylbutazone (2.2 mg/kg IV or PO bid) or COX-2 selective firocoxib (0.1 mg/kg IV or PO q24h), may be used in place of flunixin meglumine.

Lidocaine has become widely used as an antiinflammatory agent. Research demonstrated that horses administered LPS intraperitoneally and treated with lidocaine (1.3 mg/kg IV bolus followed by constant-rate infusion 0.05 mg/kg/min) had significantly lower clinical scores of endotoxemia and lower concentrations of plasma and peritoneal TNF-α than did those receiving saline.[21]

Therapy targeted at binding and inactivating endotoxin includes the administration of hyperimmune plasma, endoserum, and polymyxin B. Polymyxin B (3000 to 6000 IU/kg IV bid) has been demonstrated to effectively bind circulating endotoxin; however, its use carries a risk of nephrotoxicity and is cautioned in cases with azotemia or preexisting renal insufficiency. The pathophysiologic features of and therapy for endotoxemia are discussed in depth in the Endotoxemia and Sepsis section.

ANTHELMINTICS. Peritonitis may develop in association with intestinal cyathostomiasis or verminous arteritis secondary to *S. vulgaris* migration; therefore anthelmintic administration is recommended when peritonitis is strongly suspected or in horses with a poor deworming history. Traditionally, fenbendazole (15 mg/kg PO for 5 days) or ivermectin (0.2 mg/kg PO) has been recommended after a horse with peritonitis is stabilized; however, resistance to both drugs has been reported. Alternative deworming protocols may include administration of moxidectin (0.4 mg/kg PO) or oxibendazole (10 mg/kg PO for 3 days).

SURGICAL MANAGEMENT. Surgical intervention in peritonitis may be indicated to identify and correct the underlying cause, particularly when leakage or compromise of the intestinal or urogenital tracts is suspected. Ultrasonography occasionally reveals intraabdominal abscesses that could be drained via catheter or marsupialization. Peritoneal lavage and drainage should also be considered on the basis of peritoneal fluid analysis and are recommended when total nucleated cell counts exceed 100,000 cells/μL. The benefits of lavage and drainage include (1) reduction of bacterial numbers and concentrations of inflammatory mediators, (2) removal of foreign debris from the peritoneal/serosal surfaces, and (3) dilution of adhesion-promoting substances. Horses treated with peritoneal lavage must be monitored for dehydration, protein loss, and electrolyte imbalances. Complications associated with peritoneal drains include visceral puncture during insertion, ascending infection, subcutaneous leakage and edema, and herniation of intestine or omentum through the drain.[22]

Several techniques for peritoneal lavage and drainage have been described elsewhere, including the placement of ventral midline catheters in a standing horse, the use of active intraabdominal systems, and open peritoneal drainage.[18,23,24] Standing intraabdominal catheters, such as Foley, mushroom, or thoracic catheters, may be briefly placed aseptically under ultrasonographic guidance by insertion through the skin, subcutaneous tissues, and external muscle layers at ventral midline, then secured in place with a purse-string suture and several half-hitch knots. Catheters are either allowed passive drainage and connected to a Heimlich valve or are connected to an active-drain system, to prevent ascending contamination.

Balanced, polyionic solutions with a neutral pH are used to irrigate the abdomen. Antibiotics, antiseptics (povidone-iodine), and heparin have been suggested as additives to the lavage solution; however, no controlled studies have been performed to demonstrate any benefit. Severe inflammation of the peritoneal surfaces has been reported after the use of 3% or higher povidone-iodine lavage solutions. To perform peritoneal lavage, 10 to 20 L of solution is allowed to enter the abdomen via gravity flow through the ventral catheter. The catheter is then clamped and the patient is walked for 10 to 20 minutes to encourage distribution of the lavage fluid, after which the clamp is removed and the fluid is drained. This is repeated once or twice daily for 3 to 5 days or until fluid analysis findings normalize.

A retrospective evaluation of 67 horses receiving active intraabdominal drainage after celiotomy revealed a high incidence of minor complications (49%), including obstruction of the drainage system, leakage of fluid around the system, and subcutaneous fluid accumulation. Moreover, the incidence of incisional infection in this group was higher (32%) than in the control group (23.5%); however, this was attributed to the severity of the primary condition for which the patients had undergone surgery.[24]

Although open peritoneal drainage is preferred in humans and is reported to be successful in management of dogs and cats with peritonitis, this method has not been promoted in horses. In an experimental study, horses with induced peritonitis that received open drainage therapy with a plastic mesh sutured at the ventral abdominal wall had a significantly increased inflammatory reaction at the linea alba in comparison with those that were closed routinely. Moreover, all horses in the open drainage group developed incisional infections after removal of the mesh.[23]

ADHESION PREVENTION. Development of intraabdominal adhesions has a significant effect on long-term outcomes for horses with septic peritonitis. Systemic administration of antimicrobials, dimethyl sulfoxide, and flunixin meglumine has been promoted because it reduces adhesion formation by decreasing peritoneal inflammation.[25] In addition, the systemic administration of heparin (20 to 40 IU/kg SC q8h) has been advocated for up to 72 hours in horses at risk of adhesion development or coagulopathy.[25] Heparin acts to decrease fibrin formation through its inhibition of thrombin.

Various intraperitoneal therapies have been evaluated in horses for the prevention of adhesions. Abdominal lavage, both intraoperatively and postoperatively, has demonstrated benefit in reducing the incidence of adhesion formation in horses undergoing exploratory celiotomy and those with peritonitis.[22,24] Introduction of heparin directly into the peritoneum during abdominal lavage may be beneficial; doses of 20,000 IU are recommended[26]; however, studies of the effects of concurrent systemic and local administration on systemic coagulation have not been reported in horses. Intraperitoneal administration of recombinant tissue plasminogen activator and 0.4% sodium hyaluronate has been shown to decrease adhesion formation; however, these are currently cost prohibitive in clinical cases.[25] The use of 1% sodium carboxymethylcellulose (2 L throughout the abdomen and applied to intestinal surfaces intraoperatively)

has the most dramatic effect on adhesion formation, significantly decreasing the incidence of adhesions and the risk of death in experimental horses in comparison with untreated horses.[27,28]

Prognosis Prognosis depends on the cause, severity, duration, and complications associated with peritonitis. Among horses with peritonitis, the prognosis is poorest for those suffering from gastrointestinal perforation or rupture and best for those with peritonitis associated with *A. equuli*. In two retrospective studies, rates of short-term survival were 86% (56 of 65) and 78% (43 of 55); however, both of these studies excluded horses with a diagnosis of gastrointestinal rupture.[2,3] Another retrospective evaluation of 67 cases, including those with gastrointestinal rupture, demonstrated a higher mortality rate (40%).[5] In that study, serum creatinine levels, anion gap, and pH at the time of presentation were significantly different between survivors and nonsurvivors; however, more recent research has not confirmed these findings. Celiotomy was found to have a negative effect on survival, with an odds ratio of 9.87 for nonsurvival in horses undergoing exploratory within 2 weeks of diagnosis or as a part of the treatment for peritonitis.[3]

Complications are not uncommon, occurring in 40% (22 of 55) of cases, and can have a negative effect on long-term survival.[2,3] Reported complications include thrombophlebitis, ileus, diarrhea, drain site complications, intraabdominal adhesions, and laminitis. Monitoring and prophylactic therapy for these conditions may help reduce their adverse effect on outcome. With early diagnosis, correction of the inciting cause, aggressive medical therapy, and peritoneal lavage, the prognosis can be fair to good in acute cases of septic peritonitis in horses.

Actinobacillus Peritonitis

A subset of cases of peritonitis attributed to *A. equuli* infection has been reported among horses in Australia, New Zealand, and North America. Infection is generally thought to be secondary to translocation of the bacteria from the gastrointestinal tract or associated with *Strongylus* migration; however, the exact origin is unknown.[29-31] Affected horses present with symptoms of mild to moderate colic (60%), tachycardia (94%), tachypnea (90%), decreased to no borborygmi (88%), and elevated rectal temperature (77%). A chronic form of the disease with a history of progressive weight loss is also reported. A poor deworming history was noted in 9 of 18 horses tested in which elevated numbers of strongyle ova were found on fecal examination.[29,30]

As with other causes of peritonitis, hemoconcentration, an absolute left shift, and hyperfibrinogenemia are common. In addition, peritoneal fluid cell counts are markedly increased—100,000 cells/μL in 88% of samples (46,000 to 810,000/μL)—and protein levels are elevated in 98%. In contrast to other cases of peritonitis, cytologic findings are characterized by a predominance of nondegenerate neutrophils, and pleomorphic Gram-negative rods are identified in 53% of slides. A pure growth of *A. equuli* was obtained in 72% of cases.[30] These cases responded rapidly to antibiotic administration (100% short-term survival), and most isolates were sensitive to penicillin; however, it is recommended that therapy include penicillin/gentamicin or oral therapy with trimethoprim-sulfonamide until sensitivity results are available. Therapy should be continued for 7 days beyond return of peritoneal fluid analysis to normal values.

Peritonitis associated with *A. equuli* is characterized by mild to moderate signs of colic, lethargy, elevated heart and respiratory rates, and marked elevations in peritoneal fluid protein and cell counts. It does not progress to endotoxemia or shock, and it is characterized by a rapid response to antimicrobial therapy, which distinguishes peritonitis associated with *A. equuli* from other causes of peritonitis.

Hemoperitoneum

Hemoperitoneum is defined as the abnormal accumulation of blood within the abdominal cavity. In several retrospective case series, researchers have evaluated the causes, clinical presentations, and outcomes associated with the diagnosis of hemoperitoneum.[32-34] The various conditions diagnosed in horses with hemoperitoneum are summarized in Box 32.3. Clinical signs and prognosis depend on the cause and severity of the hemorrhage; however, most affected horses present with symptoms referable to abdominal discomfort/colic (78% to 79%) and hemorrhagic shock (60% to 85%), including tachycardia, tachypnea, pale mucous membranes, depression, weakness, and cool extremities.[33,34]

Antemortem diagnosis of hemoperitoneum is based on the identification of hemorrhagic effusion within the abdominal cavity by either ultrasonography or abdominocentesis. Characteristic swirling of echogenic fluid is noted on ultrasonography in cases of intracavitary hemorrhage, and a specific origin of hemorrhage may be identified on ultrasonography in 25% to 44% of cases.[33,34] Peritoneal fluid analysis confirms hemorrhage with findings of PCVs greater than 5%, elevated protein levels, and gross appearance. Hematologic and biochemistry values are often unremarkable; however, alterations in acid-base status, blood gas analysis, and plasma lactate concentrations reflect the severity of hemorrhagic shock.

Therapy for hemoperitoneum includes emergency stabilization of hemorrhagic shock, promotion of clot retention, and addressing the primary cause. Treatment of hemorrhagic shock includes conservative volume resuscitation with intravenous crystalloids, colloids, and blood transfusion (see the Fluid Therapy for Hemorrhagic Shock section in Chapter 44). Additional medications to support perfusion (inotropes, vasopressors) may also be indicated. Antifibrinolytics (aminocaproic acid at 3.5 mg/kg IV, conjugated estrogens at 25 to

50 mg/500 kg) are often administered to prevent breakdown of clots and help suppress continued hemorrhage.[35] Exploratory laparotomy may have both diagnostic and therapeutic indications because the source of bleeding may be identified and corrected.[34] Abdominal drainage and lavage is often not performed in these cases, unless severe abdominal distention precludes autotransfusion. To guard against development of septic peritonitis, antimicrobial administration is indicated if bacterial contamination is probably present.

The prognosis for horses presenting with hemoperitoneum is guarded; overall survival rates range from 39% to 74% and depend greatly on the severity of hemorrhage, ability to control hemorrhage, and underlying cause.[32-34] Nonsurvival is associated with respiratory rates higher than 30 bpm, diagnosis of neoplasia (odds ratio, 35.08), mesenteric vessel injury (odds ratio, 243.5), and uterine artery rupture (odds ratio, 13.72).[33] Idiopathic hemoperitoneum is associated with the best long-term survival outcomes.[34]

Gastrointestinal Ileus

Chris Sanchez • Guy D. Lester • Samuel L. Jones

A number of factors are responsible for movement of feed through the gastrointestinal tract, and disturbance in any of these can result in ineffective transit and signs of abdominal pain. Gastrointestinal motility involves an extremely complex interaction among the enteric nervous system, intestinal wall, and luminal contents. Other factors that potentially influence the transit of digesta include gravity, the volume and viscosity of intestinal contents, and pressure gradients created by simultaneous contraction and relaxation of adjacent bowel segments. The inhibition of propulsive bowel activity is usually referred to as *ileus*.

Several equine diseases and syndromes that probably involve altered gastrointestinal motility include POI, cecal emptying defect, gastroduodenal ulcer disease, simple bowel distention, intraluminal and extraluminal obstructions, peritonitis, and IBDs. Ineffective intestinal motility can also be a feature of several neonatal disorders, including prematurity, systemic sepsis, and neonatal encephalopathy, and can be found in postparturient mares. Certain parasitic infections, electrolyte derangements, and endotoxemia can modify intestinal transit in horses of all ages. Intestinal motility is also disturbed by general anesthesia and sedation, especially with the α_2 receptor agonists.

Physiology of Intestinal Motility

The control of intestinal motility is complex and involves a combination of central innervation, autonomic innervation, and the enteric nervous system. Intestinal contractions are controlled primarily by the enteric nervous system and do not require extrinsic neural input. The inherent rhythmicity of electrical activity in the intestine is controlled by the interstitial cells of Cajal. These are highly specialized cells that are electrically coupled to the smooth muscle syncytium via gap junctions.[1] They are responsible not only for generation of slow waves (cyclical electrical activity) but also for coordination of pacemaker activity and propagation of slow waves along the intestine. Interstitial cells of Cajal appear to be critically involved in a range of motility disorders in human beings, including gastroparesis, pseudoobstruction, and chronic constipation.[1] In horses, a reduction in the density of interstitial cells of Cajal has been demonstrated with equine grass sickness and other large intestinal diseases.[2,3] The inherent "excitability" of smooth muscle cells in response to stimuli varies among regions of the gastrointestinal tract and among species. This variability in cell excitability is dependent on the magnitude of the membrane potential, which in turn is regulated by the number and subtype of potassium channels.[4]

The enteric nervous system plays an important role in control and coordination of intestinal contraction. Contractile events are influenced by central and autonomic innervation, but external neural input is not required for contraction. The parasympathetic supply to the gastrointestinal tract is via the vagus and pelvic nerves, and the sympathetic supply is through postganglionic fibers of the cranial and caudal mesenteric plexuses. A complex network of interneurons within each plexus integrates and amplifies neural input, and the intensity and frequency of resultant smooth muscle contractions are proportional to sympathetic and parasympathetic input. Additional binding sites for a number of other endogenous chemicals, including dopamine, motilin, and serotonin, can be found within the enteric nervous system and on smooth muscle cells.[5] Of importance is that mechanisms to slow progressive intestinal motility are also critical in order to retain feed for adequate digestion and absorption of nutrients. The terms *jejunal* and *ileal brake* have been used to describe the slowing of transit caused by mediators such as peptide YY, noradrenergic nerves, and opioid, serotonergic, and chemosensitive afferent neurons.[6]

Acetylcholine is the dominant excitatory neurotransmitter in the gastrointestinal tract and exerts its action through muscarinic type 2 (M_2) and and type 3 (M_3) receptors. Sympathetic fibers innervating the gastrointestinal tract are adrenergic, postganglionic fibers with cell bodies located in the prevertebral ganglia. Activation of α_2-adrenergic receptors on cholinergic neurons within enteric ganglia inhibits the release of acetylcholine and therefore reduces intestinal contraction. The β_1, β_2, and β-atypical receptors directly inhibit the activity of intestinal smooth muscle.[7] Inhibitory nonadrenergic, noncholinergic neurotransmitters include adenosine triphosphate (ATP), vasoactive intestinal peptide, and nitric oxide.[8,9] These neurotransmitters are critical for mediating descending inhibition during peristalsis and receptive relaxation. Substance P is a nonadrenergic, noncholinergic neurotransmitter that may be involved in contraction of the small intestine and large colon.[10-12] The rate and force of intestinal contractions along the small intestine and large colon of horses are key determinants of intestinal motility. Of even greater importance to the net propulsion of digesta are the cyclical patterns of contractile activity. These patterns are known as the small intestinal and colonic *migrating motility complexes* (MMC).[13] The colonic MMC usually originates in the right ventral portion of the colon and variably traverses the ascending and descending portions of the colon. Many of these complexes are temporally related to a specialized motility event of the ileum known as the *migrating action potential complex*.

Mediators of Gastrointestinal Ileus and Major Disease Categories

Inflammation within the intestinal muscularis layers and inhibitory neural events are important initiators of intestinal ileus.[14,15] Intestinal inflammation is important in primary inflammatory intestinal diseases in horses, such as DPJ and colitis, but it is also induced after simple intestinal handling during laparotomy. Experimental data from other species suggest that handling of the small or large intestine at the time of surgery induces an intense inflammatory response within the muscularis layers and a reduction in the intensity of smooth muscle contraction.[15-17] Furthermore, the inflamed intestine fails to contract normally in response to putative prokinetic agents. Additional studies have determined that this inflammatory response was not restricted to segments that were manipulated at the time of surgery but also involved other regions throughout the gastrointestinal tract.[14] Intestinal handling in experimental animals causes local overproduction of nitric oxide because of the upregulation of inducible nitric oxide synthase by resident macrophages.[18] Nitric oxide is a key inhibitory neurotransmitter of the nonadrenergic, noncholinergic system.[9] Consequently, nitric oxide synthase inhibition could be an important target for prevention of ileus.

VetBooks.ir

The inhibition of motility associated with peritoneal inflammation may also be mediated through neural reflexes. The afferent segment is composed partly of capsaicin-sensitive visceral afferent C-fibers that terminate in the dorsal horn of the spinal cord, where they can activate inhibitory sympathetic fibers or, alternatively, synapse directly on the sympathetic ganglia. Consequently, the efferent limb of the neural pathway of the reflex expresses increased sympathetic outflow, mediated primarily through stimulation of α_2-adrenoreceptors, with subsequent inhibition of acetylcholine release. This provides the rationale for α_2 blockade in the treatment of ileus. Intraluminal infusion of capsaicin before abdominal surgery ameliorated the severity of POI in experimental rats.[19] This finding highlights the importance of visceral afferent fibers in the development of POI.

Ileus can also occur with intestinal obstruction or displacement. Mild to moderate distention of the bowel, such as that occurring in the early stages of an intraluminal obstruction, evokes an increase in local contractile activity.[20,21] Excessive distention results in inhibition of motility within the distended segment of bowel. Intestinal stasis is not always detrimental and, in certain conditions, may be protective.

Endotoxemia is a feature of many diseases of the equine gastrointestinal tract, and endotoxins can independently exert a negative effect on intestinal motility and transit.[22] Various mediators are probably involved, but activation of α_2-adrenoreceptors and production of prostanoids appear to be important, as the inhibitory effects of experimental endotoxin infusion are ameliorated by pretreatment with yohimbine or NSAIDs (phenylbutazone or flunixin), respectively.[23,24] Endotoxin infusion induced an inflammatory response in the intestine of rats that mimicked that induced by handling during laparotomy.[25]

Cecal Emptying Defect (Cecal Impaction)

An important and specific motility problem involving the cecum occurs sporadically in adult horses and foals.[26-30] The pathophysiologic origin of cecal emptying defect is not known. This syndrome may best mimic POI in humans, which is generally considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extraabdominal surgical procedures. General anesthesia is a potent inhibitor of gastrointestinal motility in horses, but the effects are short-lived and reversible within hours of anesthetic withdrawal.[31] The return of normal motility in horses after experimental ileus was most delayed in the cecum, which suggests that this may be a common site of ileus in horses.[32]

Retrospective data regarding cecal impactions suggest that two subtypes exist, and retrospective studies highlight those differences. In a United Kingdom report of 20 horses undergoing surgery because of cecal impaction, the condition appeared after orthopedic (10 of the 20) or colic (5 of the 20) surgery in the majority of horses.[33] Short-term survival in that report was 65%, and all but 3 horses underwent cecal bypass. Alternatively, in a Texas report of 114 horses with cecal impaction, approximately half were treated medically and half surgically.[34] Of the horses allowed to recover from surgery, 95% survived to discharge, and typhlotomy alone was performed in 34 of 37 horses. Eighty-one percent of horses treated medically survived to discharge.[34] These reports appear to describe the two types of cecal impactions well, and the secondary (also called *type II*) impactions appeared to be associated with cecal emptying defect, and are therefore often categorized as a form of POI. In horses, postoperative cecal impaction was evident at a mean of 3.6 and 7.5 days after orthopedic and colic surgery, respectively.[33] The earliest detectable signs include lethargy and a reduction in appetite, fecal output, or both. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifest by signs of mild to moderate colic. If the condition is recognized late or untreated, the cecum may rupture, resulting in fatal peritonitis.

Postoperative Ileus

The most frequently reported form of ileus occurs after laparotomy and is termed *simple* or *uncomplicated postoperative ileus.* The condition in which intestinal motility is disturbed for longer periods after surgery, typically for more than 72 hours, is called *complicated* or *paralytic ileus.*[35] POI in horses is most commonly associated with surgery of the small intestine, particularly after resection and anastomosis. As stated previously, intestinal inflammation, particularly in the muscularis layers, is probably a key factor associated with the development of POI. The true incidence of POI in horses undergoing laparotomy for gastrointestinal disease is difficult to determine because of variation in definition, surgical skill, and anesthetic technique. POI was reported as a complication in only 10% of horses that underwent laparotomy for a small intestinal lesion at one referral practice[36] but in 27% in another.[37] In the latter study, horses with DPJ were included, but 30% of horses developed POI after small intestinal resection. In a multicenter study, 47 (19%) of 251 horses undergoing laparotomy for acute colic, including those with small and large intestinal disease, developed POI.[38] As stated previously, the retrospectively collected POI data are extremely hard to interpret, and many mechanical obstructions and surgical complications can mimic POI[39]; thus authors are encouraged to adopt uniform definitions of POI and make every attempt possible to distinguish POI from intestinal obstruction.[40]

POI can have a significant negative effect on short-term postoperative survival.[41-43] Motility dysfunction is probably present in all horses after laparotomy, but most cases are subclinical and necessitate minimal intervention. In symptomatic animals, clinical signs are typically observed within 24 hours of recovery; these signs include colic, tachycardia, dehydration, decreased borborygmi and fecal output, and sequestration of fluid within the stomach. Rectal examination and ultrasonography may reveal small intestinal distention with rare or no wall movement. The severity and duration of intestinal stasis is variable, lasting from minutes to days.

The development of small intestinal POI, but not cecal emptying dysfunction, is influenced by the duration of surgery.[27,38] Technique may have a weak influence on small intestinal POI after jejunojejunostomy. The duration of intestinal ileus was shorter in animals that received a side-to-side stapled anastomosis than in those that had a hand-sewn end-to-end procedure.[41] The duration of ileus after stapled end-to-end anastomosis was no different from that after either of the other procedures.

Reported risk factors for the development of POI in horses include age (>10 years), small intestinal resection and anastomosis, breed, heart rate at admission, large volume (>8 L) reflux at admission, and duration of anesthesia and surgery.[37,38,43,44] Jejunocecostomy and side-to-side jejunojejunostomy have been associated with an increased risk of POI.[36,45] Pelvic flexure enterotomy and intraoperative and postoperative lidocaine infusion have been associated with a decreased incidence of POI.[38,43-45]

Miscellaneous Motility Disruptions

Other disruption of normal intestinal motility can occur in horses. Many, but not all, are associated with analgesic or sedative drug administration. The inhibitory effects of α_2-adrenergic agonists, such as xylazine and detomidine, on intestinal motility in horses are well described.[46-54] The activation of postganglionic cholinergic nerves in the myenteric plexus by this class of drugs results in reduced release of acetylcholine from autonomic and enteric nerves. Intravenous xylazine inhibits cecal and large colon motility for 20 to 30 minutes without seriously disrupting

VetBooks.ir

small intestinal myoelectric activity, and detomidine can reduce large intestinal myoelectric activity for up to 3 hours. The α_2-antagonist yohimbine has a weak but positive effect on cecal emptying in normal ponies, which suggests that normal motility is under constant α_2-adrenergic tone.[48]

Other analgesic medications can also decrease gastrointestinal motility. Opioids such as morphine have long been associated with decreased motility in humans.[55] Morphine has been shown to delay gastrointestinal transit and decrease gastrointestinal moisture content in horses.[56,57] Butorphanol administered alone appears to reset the antroduodenal MMC without substantial negative effects on motility, but it decreases duodenal motility when combined with xylazine more than does xylazine alone.[50,58] The roles of selective or preferential μ- and κ-receptor agonists vary different regions of the equine gastrointestinal tract: κ-Receptor agonists appear to have a more inhibitory effect in the jejunum, whereas μ-receptor agonists appear to inhibit the large colon more significantly.[59,60] Ketamine has also been shown to increase total gastrointestinal transit in healthy horses.[61]

Atropine is a postganglionic blocking agent that binds to muscarinic receptors. When administered at 0.04 mg/kg, individual small intestinal, cecal, and colonic contractions are inhibited for approximately 120 minutes, but small intestinal and colonic MMCs are suppressed for up to 8 hours.[62] The negative effect of atropine on gastrointestinal motility in horses can also be evident with topical ophthalmic administration of atropine.[63] This effect, in combination with pain and other management factors, probably relates to the high reported risk of colic in horses hospitalized for ocular disease.[64]

Gastric and small intestinal ileus, with no identifiable mechanical or physical disruption of motility, have also been identified as causes of acute colic in postparturient mares.[65] The origin of this condition has not been identified, but most mares responded well to decompression.

Diagnosis

The diagnosis of ileus is based on history and physical examination findings. Important tests include determination of pulse rate and rhythm, auscultation and percussion of the abdomen, rectal palpation, and passage of a nasogastric tube. CBC with fibrinogen estimation and cytologic analysis of peritoneal fluid may improve the accuracy of diagnosis. Affected animals may be colicky because of accumulation of fluid in the upper gastrointestinal tract (classical POI) or cecal contents (cecal emptying defect). Decompression of the stomach is important diagnostically and therapeutically in horses with POI after small intestinal surgery. The presence of intragastric fluid upon nasogastric intubation is a commonly applied diagnostic criterion, but little information is available to define the parameters that increase the predictive value of nasogastric reflux either alone or in combination with other clinical findings. Proposed criteria include gastric reflux of 4 L or more upon any single intubation or of more than 2 L/h on serial intubations; gastric fluid pH higher than 4.0; persistent tachycardia (>40 beats/min); signs of mild to severe abdominal discomfort; and rectal or ultrasonographic evidence of multiple loops of fluid-distended small bowel.[40] Failure to relieve pain with gastric decompression could indicate mechanical obstruction, severe inflammation of the intestine, or peritonitis. Most animals with ileus are depressed and have reduced fecal output and intestinal borborygmi. Intestinal sounds should, however, be interpreted with caution, because the presence of borborygmi does not always equate to progressive intestinal motility and may merely reflect local, nonpropagated contractions. Cecal distention with either firm or soft contents can be palpated rectally in horses with cecal dysfunction.

It is important to distinguish functional ileus from mechanical obstruction. This can be extremely difficult, but horses with mechanical obstruction typically have sustained high volumes of gastric reflux that vary little over time. Distinguishing mechanical obstruction from POI is especially important because horses with mechanical obstruction in the postoperative period may benefit from early repeat laparotomy.[39]

Treatment

SUPPORTIVE CARE. The management of gastrointestinal ileus is dependent on the segment of gastrointestinal tract involved. Therapy for ileus of the proximal gastrointestinal tract typically involves a combination of gastric decompression, fluid and electrolyte therapy, and antiinflammatory drugs. Nasogastric decompression is the mainstay of management to prevent excessive distention of the stomach and small intestine. This often necessitates placement of an indwelling nasogastric tube, a procedure that some authors have speculated may in itself delay gastric emptying. In one study, the placement of an indwelling tube for 18 hours did not adversely affect the emptying of liquids, but in another study, a delay was noted when the tube was left in place for 72 hours.[66,67] Both studies used apparently healthy animals.

Electrolyte balance is important, particularly with regard to maintaining adequate extracellular concentrations of potassium, calcium, and magnesium. Calculation of appropriate fluid replacement volume should include maintenance requirements (40 to 60 mL/kg/day) and an estimate of losses, especially nutrients lost through gastric decompression. Overhydration should be avoided to prevent intestinal edema. Intravenous colloidal fluids may be useful in addition to crystalloid fluids to prevent overhydration. Whereas medical therapy with fluid replacement and antiinflammatory drugs may be helpful for horses with primary cecal impaction, surgical therapy is probably required for horses with secondary cecal emptying defect.[33,34,68] Surgical management may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.[33,68] If affected horses survive postoperatively to discharge from the hospital, chances of long-term survival appear good.[33]

Evidence in experimental models and in human medicine suggests that early refeeding after surgery helps prevent POI.[69] Early refeeding was found to be beneficial in equine surgical cases.[36] Many clinicians offer small (one or two handfuls) meals of good-quality roughage frequently to reduce the risk of POI. A significant clinical or economic benefit of parenteral nutrition in adult horses with gastrointestinal disease also has yet to be demonstrated.[70-72] Parenteral nutrition should be considered when feed has been withheld for more than 96 hours, particularly in horses with a surgical wound, increased metabolic demands, or risk of hyperlipidemia. Limited exercise, in the form of hand-walking, may provide some benefit to these animals, although there is no evidence that exercise has a direct effect on intestinal motility in either horses or humans with POI.[73]

The pivotal role of intestinal inflammation provides a strong rationale for the use of antiinflammatory drugs in affected animals. Flunixin meglumine is widely used in equine practice as an analgesic and antiinflammatory agent, and ameliorates many of the adverse systemic effects of endotoxin. A potential negative effect of NSAIDs on large intestinal contractility has been suggested on the basis of results of in vitro studies[74]; however, a similar response has not been reported in whole animal studies.[46,48,75] There is some concern that non–cyclooxygenase-selective drugs such as flunixin meglumine inhibit anastomotic site healing and mucosal repair. An alternative may be firocoxib, which is highly selective for COX-2 and is as effective as flunixin in controlling colic pain.[76] Lidocaine is also an alternative or adjunct analgesic and antiinflammatory drug. The use of lidocaine is discussed in more detail later in this chapter.

Broad-spectrum antimicrobial drugs are indicated when sepsis is suspected or if the immune system is compromised, as

VetBooks.ir

in cases of moderate to severe endotoxemia. Theoretic concerns have been raised regarding the use of aminoglycoside antibiotics in animals with ileus. Inhibition of intestinal contractions occurred when sections of intestine were exposed to high concentrations of aminoglycoside antimicrobial drugs, but this inhibitory effect is unlikely to occur at clinically relevant doses.[77] The administration of benzylpenicillin or ceftiofur was associated with an increased risk of colic in the week after anesthesia for diagnostic imaging or nonabdominal surgical procedures.[78] Potassium penicillin G appears to have a modest, positive effect on large intestinal motility and frequency of defecation in horses.[79]

MOTILITY MODIFICATION. Motility-modifying drugs could play an important role in the prevention and treatment of gastrointestinal ileus. An effective prokinetic agent could shorten the length of hospitalization, thereby reducing the cost of treatment and the number of potential complications such as weight loss, thrombophlebitis, and laminitis. There is also evidence that the development of abdominal adhesions could be minimized with the use of an effective prokinetic drug.[80,81] A potential negative effect of prokinetic use in the postoperative period after anastomosis is increased predisposition to dehiscence.[82]

For most motility-modifying drugs to be effective, the intestinal wall must be healthy in order to enhance intestinal contraction. There are several examples in horses in which the expected contractile response to certain drugs is blunted in the presence of disease. It is reasonable to assume that many putative prokinetic drugs would be partially or totally ineffective in horses with abdominal disease. Such disease would include intestine that has undergone prolonged or excessive distention or that is in any inflammatory condition, such as after intestinal manipulation or in association with primary inflammatory diseases such as DPJ or *Salmonella* enteritis. Numerous drugs have been investigated in humans with POI, but no prokinetic agent has yet been found to be safe and effective.[83] The financial pressures associated with equine patient management often compel attending veterinarians to experiment with a range of putative prokinetic drugs.

Lidocaine, an aminoamide local anesthetic, appears to be the most commonly used putative prokinetic agent in the management and prevention of POI.[84] Intravenous administration of lidocaine increases gastrointestinal transit time in normal horses.[85] However, evidence regarding the efficacy of lidocaine in treating or preventing POI in horses is limited and conflicting (see below). Intravenous infusion of lidocaine may suppress primary afferent neurons, thereby limiting reflex efferent inhibition of motility. It is also possible that lidocaine may block the inhibitory effect of nonadrenergic, noncholinergic neurotransmitters on smooth muscle.[86] Lidocaine also has significant antiinflammatory properties, including amelioration of the cytokine response to endotoxemia, reduced neutrophil free radical production, impaired leukocyte phagocytic function, and inhibition of leukocyte migration through suppression of chemokines.[87,88] In addition, lidocaine has been shown to decrease clinical scores after experimental endotoxin administration in healthy horses, in comparison with untreated controls.[88] Lidocaine administration can also ameliorate the inhibitory effects of flunixin meglumine on jejunal mucosal barrier recovery after ischemia.[89,90] Because systemic administration of lidocaine was shown to increase somatic thermal antinociceptive threshhold, but not visceral distention threshold, the beneficial effect of lidocaine in horses with gastrointestinal disease may not be associated with analgesia.[91]

A combination of intraoperative and postoperative lidocaine infusion is commonly used as a preventive strategy against POI on the basis of evidence suggesting that treatment with lidocaine during colic surgery improves postoperative prokinetic activity in ischemic intestine[92] and is associated with a decreased risk of POI.[38] Postanesthetic treatment typically involves a slow intravenous bolus of 2% lidocaine (1.3 mg/kg) followed by a constant infusion at 0.05 mg/kg/min for 24 hours, with a target serum concentration between 1 and 2 mg/dL. In a prospective study of horses undergoing laparotomy for colic, the authors failed to demonstrate any difference between lidocaine and saline infusion with regard to return of borborygmi, time to first feces, or gastric reflux.[93] The study was limited by a low incidence of small intestinal strangulating lesions and POI. A large prospective study in the United Kingdom did not demonstrate an effect of lidocaine treatment on the prevalence, volume, or duration of postoperative gastric reflux.[94] Lidocaine infusion was associated with a reduction in reflux duration, time to fecal passage, and hospital stay for survivors in a study of 32 horses with POI or DPJ.[86] In a larger retrospective study of 126 horses undergoing surgery for small intestinal colic, lidocaine administration was associated with a reduced incidence of POI and increased rate of short-term survival.[43]

The rate of lidocaine infusion requires close monitoring because infusion can be associated with reversible side effects that include muscle fasciculations, ataxia, and seizures. The drug is highly protein bound, so hypoproteinemic horses may be more susceptible to toxic effects.

Bethanechol is a methyl derivative of carbachol and is an acetylcholine receptor agonist. The drug acts both at the level of the myenteric plexus and directly on intestinal smooth cells through muscarinic receptors. The actions are primarily mediated through activation of M_3 receptors; M_2 receptors are also involved but to a lesser extent.[95] There is evidence in other species that activation of M_2 receptors not only facilitates intestinal contraction but also may lead to antinociception.[96] Bethanechol is not degraded by the enzyme anticholinesterase. As anticipated, the drug has a range of cholinergic side effects, including abdominal discomfort, sweating, and salivation, although these are minimal when the drug is administered subcutaneously at 0.025 to 0.05 mg/kg of body weight.

Bethanechol is one of the most useful prokinetic agents in equine practice, inasmuch as it exerts effects throughout the gastrointestinal tract; however, it does not appear to be commonly used for that purpose.[84] It is most commonly used in the management of delayed gastric emptying and slowed small intestinal transit. The drug has been shown experimentally to significantly increase gastric contractility and hasten the emptying of liquid- and solid-phase markers from the stomachs of normal horses.[97] The drug has potent effects in the hindgut as well. Bethanechol increases both the relative strength and duration of wall contractions in the cecum and right ventral portion of the colon and consequently speeds up cecal emptying.[48] When given to ponies at a dose of 0.05 mg/kg SC, the drug increased electrical activity in the large colon for approximately 80 minutes.[75] Reported rates of bethanechol dosing have ranged widely; the doses most commonly recommended range from 0.025 to 0.05 mg/kg SC.

Neostigmine increases receptor levels of acetylcholine by inhibiting cholinesterase. The drug (0.022 to 0.025 mg/kg IV) promotes cecal and colonic contractile activity and enhances cecal emptying in normal ponies.[48] Neostigmine has been used in the management of small intestinal ileus but significantly delayed the emptying of 6-mm beads from the stomach of normal adult horses.[37] A survey of prokinetic use indicated that neostigmine was more commonly used in the management of large intestinal disease.[84]

Metoclopramide is a moderate partial 5-hydroxytryptamine 4 (5-HT_4) receptor agonist, a moderate 5-hydroxytryptamine 3 (5-HT_3) receptor antagonist, and an antagonist of both dopamine 1 and dopamine 2 receptors. It has been suggested that the 5-HT_4 receptor agonist properties are primarily

VetBooks.ir

responsible for the prokinetic effects of metoclopramide. Antagonism of prejunctional dopamine 2 receptors facilitates acetylcholine release and smooth muscle contraction. The effect on dopamine receptor antagonism is absent in newer benzamides. Metoclopramide crosses the blood-brain barrier, where its antagonist properties on central dopamine 2 receptors can result in extrapyramidal signs, including seizure. These signs were observed when the original reported dose of 0.25 mg/kg, given by intravenous infusion over 30 minutes, was used in practice,[98] and they were responsible for poor acceptance of the drug in equine practice. An experimental bolus of endotoxin caused a delay in gastric emptying, as assessed in the acetaminophen absorption test; this delay was partially ameliorated through pretreatment with metoclopramide (0.125 mg/kg in 1 L infused over 15 minutes), but, again, the investigators reported adverse side effects.[99] Most investigators have failed to demonstrate significant effects of metoclopramide in experimental animals, but constant intravenous infusion (0.04 mg/kg/h) in a population of horses after surgery significantly decreased the volume and duration of gastric reflux in comparison to control horses and horses receiving intermittent drug infusion.[100] Infusion was well tolerated and was superior to intermittent infusion and to no treatment at all.

Cisapride is a second-generation benzamide that is commonly reported to act as a primary 5-HT_4 receptor agonist and 5-HT_3 receptor antagonist. Furthermore, stimulation of 5-HT_4 receptors within the enteric nervous system enhances release of acetylcholine from the myenteric plexus, thereby promoting intestinal contraction. In vitro studies of equine jejunum concluded that the contractile actions of cisapride in the species were mediated primarily through 5-HT_2 and not 5-HT_4 receptors and that the response was noncholinergic.[101] Several reports suggested efficacy of cisapride in the management of intestinal disease in horses, including the resolution of persistent large colon impaction, treatment of equine grass sickness, and prevention of POI in horses after small intestinal surgery.[102-105] Cisapride has the potential to cause adverse cardiac effects, mediated through blockage of the rapid component of the delayed rectifier potassium current; those effects include lengthening of the QT interval and development of torsades de pointes, a potentially fatal arrhythmia. As a result, the drug has been withdrawn in the United States and in many other countries.

Another benzamide, mosapride, resulted in increased myoelectric activity of the small intestine and cecum of horses after oral administration. The authors reported that mosapride is a selective 5-HT_4 receptor agonist; consequently, the reported effects are surprising given that the actions of 5-HT on the equine jejunum were reported to be primarily mediated through activation of 5-HT_2 and 5-HT_3 receptors.[101] Further work has demonstrated increased gastric emptying, jejunal and cecal motility after mosapride administration (2 mg/kg PO) to healthy horses.[106] Mosapride (1.5 mg/kg PO) was also shown to increase electrointestinographic maximum amplitude within the small intestine, in comparison to untreated controls, after jejunocecostomy in normal horses.[107]

Tegaserod, a selective 5-HT_4 receptor agonist, is used in humans for the treatment of irritable bowel syndrome.[104,108] In horses, tegaserod has been shown to decrease total gastrointestinal transit time[109] and increase pelvic flexure contractile activity in vitro.[110,111] Tegaserod appears safe when administered orally to horses, and plasma concentrations considered therapeutic, according to in vitro work, were obtained after administration of a single dose orally at 0.27 mg/kg.[110]

Domperidone acts as a competitive antagonist at peripheral dopamine 2 receptors; these receptors are inhibitory. The drug has been used to manage gastroparesis in humans for many years.[112] The primary use in equine practice is in the management of mares grazing endophyte-infected tall fescue (1.1 mg/kg/day PO), principally because of drug-enhanced prolactin release from the anterior pituitary gland. The potential prokinetic effects of domperidone have not been studied extensively in horses, but modest efficacy of domperidone (0.2 mg/kg IV) was demonstrated in a model of experimental ileus in two ponies.[113]

Erythromycin is a direct motilin receptor agonist acting directly on smooth muscle cells, as well as within the enteric nervous system, to facilitate the release of acetylcholine and motilin. Erythromycin enhances gastric emptying in normal horses but, in contrast to most other species, has a more pronounced effect on the hindgut.[97,114] This is somewhat surprising because a higher density of motilin receptors was reported in the duodenum than in either the cecum or pelvic flexure of adult horses.[115] Erythromycin lactobionate (1 mg/kg IV) hastens cecal emptying in normal animals and induces propagating colonic MMC-like activity across the colon. Administration is often followed by defecation and abdominal discomfort. Several problems limit the use of erythromycin as a prokinetic agent in equine practice. Its principal use in human medicine has been restricted to management of acute exacerbations of diabetic gastroparesis, facilitation of feeding tube placement, and upper gastrointestinal endoscopy.[116] Although it has been shown to enhance emptying in normal horses, it was not as effective as bethanechol.[97] Because of its potent prokinetic effects in the cecum, erythromycin may help prevent cecal impaction in horses after anesthesia. However, its effectiveness on cecal motility appears to be markedly reduced in the immediate postoperative period.[32] High doses, constant infusion, or prolonged use of erythromycin also induces receptor tachyphylaxis, and its efficacy is thereby reduced. There is also evidence that intraluminal distention for as little as 2 hours leads to a reduction in the total number of motilin receptors and in the amount of motilin receptor messenger RNA, although erythromycin binding to remaining motilin receptors is not affected.[117] Erythromycin can induce diarrhea in adult horses; therefore administration over many days should be avoided. The diarrhea induced by erythromycin is probably mediated by *C. difficile* overgrowth and toxin elaboration.[118]

Because opiates have an inhibitory effect on normal intestinal motility, opioid antagonists may have the potential for prokinetic activity. Naloxone (0.05 mg/kg IV) has been shown to induce contractile activity in the cecum and the left portion of the colon.[119] The administration of naloxone was often followed by defecation within 15 to 20 minutes. Naloxone has not been beneficial in preventing POI in human beings.[120] Peripherally acting opioid antagonists, such as *N*-methylnaltrexone, can improve gastrointestinal tract function in humans who require opioids for pain management. An in vitro study in horses demonstrated a direct contractile effect of *N*-methylnaltrexone on the circular muscle layer of the jejunum and large colon.[121] In healthy horses, *N*-methylnaltrexone therapy increased daily fecal weight and, when administered concurrently with morphine, partially prevented morphine-associated increases in intestinal transit time and decreases in fecal production.[122]

α_2-Adrenoreceptor antagonists, such as yohimbine and tolazoline, counteract increased sympathetic outflow in response to nociceptive stimulation. Yohimbine (75 µg/kg by slow intravenous infusion) hastens cecal motility and emptying in normal ponies and also attenuates the negative effects of endotoxin on motility.[23,48]

Prevention and Early Identification Close monitoring is essential when horses have multiple risk factors for either POI or other forms of ileus, such as being on a regimen of opioid agonists, α_2-adrenergic agonists, or atropine, or combination of these. Monitoring fecal output closely can often help owners and practitioners identify horses developing impaction, thus allowing for early medical therapy. Similarly, close postoperative monitoring and gastric decompression are important for early detection of POI.

For horses at risk of cecal impaction or other miscellaneous motility disorders, limiting the number of drugs likely to inhibit motility and altering the diet to include increased water consumption and decreased bulk may be beneficial.

Nonsteroidal Antiinflammatory Drug Toxicity

Samuel L. Jones

Use of NSAIDs is common in equine practice because of their antipyretic, analgesic, and anti-inflammatory properties. These drugs are used to treat horses with colic, sepsis/endotoxemia, musculoskeletal disorders, and other medical problems. In addition to these therapeutic properties, NSAIDs also produce unwanted toxic side effects. NSAIDs have a relatively narrow therapeutic range, and when they are administered at excessive doses, toxicosis can occur within a few days. Although they are generally safe when administered at recommended doses,[1] some horses may exhibit signs of toxicosis at these doses within days or weeks.[2,3] The risk of toxicity is exacerbated in animals that are dehydrated or septic (e.g., endotoxemic patients). Recommended doses for NSAIDs commonly administered to horses include the following:

- Phenylbutazone, 2.2 to 4.4 mg/kg IV or PO q12h
- Flunixin meglumine, 1.1 mg/kg q12h or 0.25 mg/kg IV or PO q8h
- Ketoprofen, 2.2 mg/kg IV q24h
- Naproxen, 5 to 10 mg/kg IV or PO q12-24h
- Aspirin, 12 to 25 mg/kg PO q12-48h
- Meloxicam, 0.6 mg/kg IV q24h
- Firocoxib, 0.1 mg/kg PO q24h or 0.09 mg/kg IV q24h

Pathophysiology and Predisposing Factors

The principal mechanism of the therapeutic and toxic effects of NSAIDs is related to their inhibition of prostaglandin synthesis by inhibition of the COX enzyme. Two isoforms of the COX enzyme, COX-1 and COX-2, have been identified.[4] COX-1 is generally expressed constitutively and is thought to play an important role in maintaining physiologic homeostasis; it is found in such tissues as the gastrointestinal mucosa and kidneys and in the endothelium and platelets. In contrast, COX-2 is primarily an inducible enzyme that has a critical role in inflammation and is produced by a variety of cells, including monocytes, neutrophils, epithelial cells, fibroblasts, synoviocytes, and chondrocytes.

It has been postulated that drugs that nonselectively inhibit both COX-1 and COX-2 have greater toxic potential because they inhibit prostaglandins necessary for physiologic homeostasis, as well as prostaglandins that mediate inflammation and pain.[4] Both COX-1– and COX-2–dependent prostaglandins play an important role not only in maintaining the epithelial barrier in the gut but also in healing the epithelium when the mucosa is damaged (e.g., because of ischemic injury or infection). Most of the commonly used NSAIDs in horses are considered to be nonselective. Exceptions include meloxicam (3.8 to 10 times more selective for equine COX-2 versus COX-1[5,6]) and firocoxib (268 to 643 times more selective for COX-2 than for COX-1[7]). NSAIDs that are COX-2 selective are less ulcerogenic than those that are COX-1 selective in other species and may be so in horses. For example, COX-2 selectivity decreases the adverse effects of NSAIDs in a model of epithelial repair in horses.[8]

Although the COX-1 versus COX-2 scheme is currently considered valid, some evidence indicates that it may be overly simplistic. For example, COX-1 may play an important role in inflammation and is at least partly inducible.[9] In contrast, COX-2 can be induced physiologically in various organs and tissues and by stimuli other than inflammation.[4,10] In horses, gastric ulcerogenicity of even the nonselective NSAIDs varies (phenylbutazone is more ulcerogenic than flunixin meglumine, which is more ulcerogenic than ketoprofen).[11] This difference in toxicity among drugs may relate not only to the COX selectivity but also to other factors such as tissue distribution.

The gastrointestinal tract and the kidneys are the most common targets for NSAID toxicity. NSAID-induced injury can develop anywhere in the gastrointestinal tract (from the mouth to the rectum). Two well-recognized syndromes may be attributed, at least in part, to NSAID toxicity. The first is gastric ulceration: In the stomach, inhibition of COX can increase acid secretion, decrease output of mucus and bicarbonate, impair vasodilation, and diminish epithelial restitution, cell division, and angiogenesis.[12] Inhibition of COX also impairs the healing of existing ulcers. The second syndrome attributed to NSAID toxicity is right dorsal ulcerative colitis (RDUC). Although the right dorsal segment of the large intestine is most commonly affected, other segments may also be involved. Ulcerative lesions in the large intestine can be particularly troublesome because they can cause chronic debilitation, are difficult to diagnose, and can be refractory to treatment. In the kidney, prostaglandin E_2 and prostacyclin (prostaglandin I_2) produce vasodilation in the autoregulatory response of renal blood flow to hypoperfusion; consequently, hypovolemia, hemorrhage, or renal disease increases the risk of renal NSAID toxicosis. Damage is greatest at the renal crest (papilla), and papillary crest necrosis may be associated with subsequent nephrolithiasis or ureterolithiasis and chronic renal failure.[13] In humans the most common side effect of NSAIDs is bleeding, caused in part by reduced function of platelets and in part by gastrointestinal hemorrhage.

Not all of the adverse effects of NSAIDs are attributable to COX inhibition. The NSAIDs also cause injury through a variety of mechanisms, including microvascular damage, increased intracellular concentration of reactive oxygen and other free radicals, direct local injury (particularly with ion trapping in the stomach), inhibition of cell division, and reduced hydrophobicity of the gastric mucous coat.[10,12] Inhibition of COX may cause arachidonic acid metabolism to be shunted toward the lipoxygenase pathway, thereby producing other biologically active eicosanoids. The clinical significance of this shunting is unclear, but it has the potential for deleterious effects.

Although the toxicity of NSAIDs is related to the dose and duration of administration, some horses develop toxicosis at recommended doses. Predisposing factors such as dehydration, renal disease, hepatic disease, or sepsis may contribute to the development of NSAID toxicity. Dehydration, renal disease, and hepatic disease predispose horses to NSAID toxicosis because of reduced tissue perfusion and reduced drug elimination. Sepsis may predispose horses to NSAID toxicosis because of secondary hypovolemia, decreased tissue perfusion, and direct and indirect effects of various mediators produced in response to sepsis (e.g., platelet-aggregating factor). In humans, risk of NSAID-induced ulceration is increased among those with various gastrointestinal disorders (e.g., IBDs). NSAIDs inhibit the ability of injured equine intestinal mucosa to repair, which may increase the risk of ulceration in horses with ischemic damage or intestinal infections. Body weight may be a predisposing factor in that NSAIDs are often administered to ponies, miniature horses, and small horses at doses higher than those recommended for their body weight. Inadvertent overdosing can occur regardless of body weight or size (e.g., administration of a 12-g tube of phenylbutazone paste when administration of an anthelmintic paste was intended).

Some horses may have an idiosyncratic predisposition for ulceration, particularly that of the right dorsal portion of the colon. In experimental conditions, arthritic laboratory animals were more susceptible to NSAID-induced gastropathy than were healthy animals.[14] This finding may have relevance to

VetBooks.ir

horses because NSAIDs are often administered to chronically lame horses. Two or more NSAIDs are used concurrently in some situations. It is important to recognize that the effects of combining NSAIDs are additive, so that administering two NSAIDs at each of their recommended doses is similar to giving twice the recommended dose of one NSAID. Combination of two NSAIDs prolongs their pharmacologic effect but increases the risk of toxicity.[15]

Clinical Signs Clinical signs of NSAID toxicity are usually referable to the alimentary system and vary, depending on the segment involved. Oral or lingual ulceration may lead to difficulty in prehension and mastication. Esophageal ulceration may result in excessive salivation and apparent signs of pain (stretching of the neck, groaning) during swallowing. Gastric ulceration may result in slow consumption of feed, inappetence (particularly for grain in some horses), or anorexia. Horses that have gastric outflow obstruction associated with gastroduodenal ulceration may exhibit ptyalism, reflux esophagitis, and, in severe cases, spontaneous nasogastric reflux. Horses with ulceration anywhere in the gastrointestinal tract may exhibit signs of colic, which may be intermittent and may vary in severity. Horses with colonic ulceration may have soft stool or diarrhea and ventral edema secondary to enteric protein loss. Diarrhea can be severe, even fatal. Sepsis may result from intestinal mucosal damage caused by NSAIDs. Clinical signs of sepsis (e.g., tachycardia, altered appearance of mucous membranes, fever, and dehydration) may be seen in some horses with NSAID enteropathy. In some horses, hematuria may be seen.

Horses may have clinical signs days to weeks after NSAID therapy. Such horses are typically brought to medical attention because of recurring colic, weight loss, or loose manure. It is particularly important in these horses to determine any history of NSAID administration, even if it was several weeks before the time of presentation.

Diagnosis Diagnosis is usually made on the basis of history of NSAID use, clinical signs, and clinicopathologic findings. The most consistent clinicopathologic abnormalities in horses with NSAID toxicosis are hypoproteinemia and hypoalbuminemia, presumably resulting from loss of protein through inflamed or ulcerated intestinal mucosa. These findings are more commonly observed with damage to the distal intestinal tract and are not reliable for diagnosis of NSAID gastropathy. Some horses have decreased serum concentration of calcium, presumably attributable to intestinal loss of protein-bound calcium. In horses with severe NSAID-induced diarrhea, hyponatremia, hypochloremia, hypokalemia, acidemia, and hypovolemia may be observed. In such cases, hypovolemia may make the serum protein concentration appear to be higher than its actual value would be if the horse were adequately hydrated.

In chronic cases, horses may be anemic from inflammation, intestinal loss of blood through ulceration, or reduced function of platelets. Occult blood may be found in the feces of horses with lesions in the more distal portions of the intestinal tract. Tests for occult blood often lack sensitivity, and false-positive results may be expected for up to 24 hours after rectal palpation.

The concentration of leukocytes is usually within the reference range, although leukocytosis and hyperfibrinogenemia, associated with inflammation, and leukopenia and neutropenia, presumably caused by sepsis, can occur in some horses with acute NSAID toxicosis that affects the distal intestine. In general, results of peritoneal fluid analysis are within reference ranges, but concentration of nucleated WBCs, total protein, and fibrinogen may increase in the presence of advanced intestinal damage or intestinal vascular infarction. When findings of cytologic examination of peritoneal fluid are abnormal, results are more consistent with nonseptic than septic inflammation; however, septic inflammation may be observed when severe intestinal ulceration leads to transmural lesions and septic peritonitis.

Several clinicopathologic changes may accompany NSAID-induced renal damage. The most consistent finding is a decrease in urine specific gravity, from 1.008 to 1.020. Inability to properly dilute urine can occur with acute NSAID toxicosis for years after the original insult. This results from preferential damage to areas of the kidney that contribute most to concentrating urine (medulla, papilla). In chronic cases, urine specific gravity typically ranges from 1.013 to 1.020. Some horses with NSAID toxicosis are azotemic. In acute cases azotemia can result from dehydration, NSAID-induced alterations in renal blood flow, and tubuloglomerular feedback mechanisms. Chronic azotemia, in which serum creatinine levels range from 2.1 to 3.5 mg/dL, results from tubuloglomerular feedback mechanisms that reduce glomerular filtration to compensate for reduced reclamation of solutes in the medullary collecting ducts. In acute NSAID toxicosis, affected animals may have overt hematuria. In other cases, urinalysis may reveal occult blood, increased renal cells, and increased WBCs. In chronic cases other than those involving decreased urine specific gravity, urinalysis results are typically normal.

Endoscopy can be useful for visualizing the location and extent of esophageal and gastric lesions. NSAID-induced gastric lesions are more common in the glandular epithelium, although nonglandular lesions can be observed. Contrast radiography or scintigraphy may be useful for documenting delayed gastric emptying in some horses. Lesions of the jejunum, ileum, cecum, and colon can be difficult to identify without celiotomy and enterotomy. Isotope-labeled WBC scintigraphic scans may identify colonic ulceration[16]; the sensitivity and availability of the procedure, however, are limited. Ultrasonography may reveal thickening of the right dorsal portion of the colon or other colonic segments, but the technique appears to lack sensitivity.[17] Horses with renal crest necrosis may exhibit increased ultrasonographic echogenicity of the renal crest and echogenic debris in the renal pelvis.

Management Administration of NSAIDs should be discontinued if NSAID toxicosis is suspected. Gastric lavage and administration of 1 gallon of mineral oil per 450 kg of body weight via nasogastric tube may be of benefit in horses with acute NSAID overdose to reduce the absorption of the administered NSAID. Treatment for gastric ulceration with a proton-pump inhibitor (e.g., omeprazole, an H_2-receptor blocker such as ranitidine, or sucralfate, or a combination of these) should be implemented in horses with gastric ulceration. Sucralfate (10 to 20 mg/kg PO q8-12h) may also have a benefit in more distal segments of the equine intestine affected by NSAID toxicity. Sucralfate reduced ulceration in the stomach, small intestine, and colon and reduced protein loss in weanling-aged horses treated with an overdose of phenylbutazone.[18]

Regardless of the site of NSAID toxicity, administration of prostaglandin E analogs, or drugs that mimic their effects, may be of benefit. Administration of a synthetic analog of prostaglandin E_2 has been demonstrated to prevent phenylbutazone-induced gastrointestinal lesions in horses.[19] Misoprostol, a synthetic analog of prostaglandin E_1, ameliorated the effect of flunixin and promoted in vitro repair of equine intestinal mucosa damaged by ischemia.[20] The beneficial effects of misoprostol are probably due in part to the beneficial effects of prostaglandin E on the gastrointestinal mucosa (reducing injury and increasing repair) but may also be attributed to the antiinflammatory properties of misoprostol, particularly in the stomach, where misoprostol concentrations are high after oral administration.[21,22] Misoprostol can be administered orally starting at doses of 5 µg/kg q12h or 2 µg/kg q6h. Some horses develop signs of abdominal discomfort or diarrhea at these doses; another protocol is to start at 1.5 µg/kg q8h for 2

VetBooks.ir

to 4 days and increase at increments of 0.5 µg/kg q8h every 2 to 4 days until a maintenance dosage of 2.5 to 3 µg/kg q8h is achieved. Because of the paucity of experimental and clinical data for this drug, dosage schedules should be individually tailored to a horse's illness and tolerance of the drug.

For horses with hypovolemia secondary to colitis, administration of crystalloid fluids is indicated. Infusion of plasma may benefit horses with NSAID-induced enteropathies and signs of sepsis. The aim of plasma transfusion in a hypoproteinemic horse with colitis need not be to increase the plasma concentration into the reference range, because this may be cost-prohibitive and infused protein may be lost rapidly via the intestinal tract. Smaller volumes of plasma (1 to 3 L in an average-size horse) may exert beneficial effects by increasing colloid oncotic pressure and perhaps by modulating the effects of sepsis. Alternative colloidal fluids may be beneficial as well. Hetastarch (5 to 10 mL/kg IV q48-72h) may maintain plasma colloid oncotic pressure in the acute stages of the NSAID toxicity. Administration of broad-spectrum antimicrobial drugs may be indicated when signs of sepsis are observed. Parenteral administration of antimicrobial drugs is preferable to oral administration in horses with colitis because of the presumed increased risk of antimicrobial-associated diarrhea with the oral route. Oral administration of metronidazole (10 to 15 mg/kg PO q8-12h) might be an exception to this guideline, because evidence indicates that metronidazole may exert an anti-inflammatory effect and enhance healing in NSAID-induced intestinal ulceration.[23]

For horses with RDUC, dietary management directed toward providing a low-bulk diet in the form of a pelleted concentrate and restricting or eliminating ingestion of roughage is recommended. The aims of this approach are to decrease the mechanical and physiologic load of the colon. A complete pelleted diet (i.e., a diet that contains both concentrate and adequate but relatively low dietary roughage) decreases intestinal fill in the colon. A diet lower in fiber should decrease the physiologic load of the colon because in horses the cecum and large colon are the primary sites of fiber digestion and exchange of fluid and electrolytes. Concentrate should be fed in smaller amounts and frequently (four to six feedings per day). Addition of corn oil may provide additional calories and may also aid in healing of the damaged intestinal mucosa by promoting prostaglandin E_2 production. Some horses will not eat complete pellets, and some horses that have roughage withheld will eat bedding or wood as a consequence. Such horses should be allowed to eat fresh grass in small amounts on a frequent basis (four to six times daily). The importance and optimal duration of restriction of roughage are unknown, but it probably requires months for the colon to heal. Horses should be changed from, and returned to, their usual diet over a period of several days to decrease the risk of inducing other digestive disorders.

Feeding psyllium mucilloid may promote colonic healing in horses with RDUC. In other animal species, psyllium mucilloid has been demonstrated to increase the concentration of short-chain fatty acids of the large bowel, and increased short-chain fatty acids can promote colonic mucosal repair.[24] The amount and duration of psyllium mucilloid administered orally that are necessary to alter the colonic concentration of short-chain fatty acids and the role of short-chain fatty acids in repair of RDUC in horses are unknown. Continuous feeding according to manufacturer's recommendations for 3 to 6 months is suggested, or feeding 1 to 2 oz of psyllium mucilloid once or twice daily for the same duration may be considered.

Horses with strictures of the pylorus, duodenum, jejunum, or colon may require surgical management. Bypass or resection of affected intestinal segments may be necessary.

Limiting the extent of predisposing factors, such as dehydration, should decrease the risk of NSAID toxicosis. Avoiding use of NSAIDs or limiting the dose and duration of treatment to the minimums necessary to control the primary problem is recommended to decrease the risk of NSAID toxicosis. Other approaches to analgesia, such as regional anesthesia (epidural or perineural nerve blocks of distal limbs) or administration of butorphanol or lidocaine via constant-rate infusion should be considered.

Fluid Therapy for Horses With Gastrointestinal Diseases

Tiffany L. Hall

Most horses with acute gastrointestinal disturbances require fluid therapy to address decreased intake or excessive loss of fluids and to correct any alterations in acid-base and electrolyte balance. Conditions such as high-volume diarrhea and gastric reflux necessitate aggressive fluid therapy to correct hypovolemia, whereas other conditions (including intraluminal impactions) may necessitate a more conservative approach to maintain appropriate hydration. Assessment of hydration status and acid-base balance in horses presenting with gastrointestinal disease, as well as an understanding of the primary gastrointestinal condition, is critical for developing a fluid therapy plan. This section focuses on fluid therapy in horses with gastrointestinal disease. (For a more in-depth discussion of critical care and fluid therapy for horses, including selection of fluid types, monitoring and assessing fluid resuscitation, and complications associated with fluid therapy, see Fluid Therapy for Horses With Gastrointestinal Diseases section and Chapter 44.)

Identifying Patients Requiring Fluid Therapy

Clinical assessment begins with distinguishing hypovolemia from dehydration (Fig. 32.75). Hypovolemia is an emergency caused by an acute decrease in circulating blood volume that results in decreased tissue perfusion, anaerobic metabolism, organic acidosis, and ultimately shock. Clinical diagnosis of hypovolemia is based on altered perfusion parameters, including increased jugular refill time, prolonged capillary refill, tachycardia, poor peripheral pulse quality, decreased extremity temperature, decreased urine production, altered mentation, or a combination of these. Dehydration, on the other hand, is associated with a more insidious decrease in total body water and is reflected by clinical signs such as decreased skin turgor, decreased tear film, sunken eyes, and tacky mucous membranes.

Laboratory parameters are beneficial for evaluating hydration status, developing a fluid plan, and monitoring response to therapy. PCV and measurement of plasma total solids are commonly used to assess hypovolemia; however, these are neither sensitive nor specific. Splenic contraction and protein loss are two conditions common in horses with acute abdomen that affect the clinical utility of PCV/total solid values alone in assessing hydration. PCV/total solid values are most useful when greatly increased or when measured serially to monitor the response to fluid therapy.

An increase in the concentration of blood lactate serves as an indicator of decreased tissue perfusion. The most common causes of increased lactate in horses with gastrointestinal disease are hypovolemia, sepsis, and intestinal ischemia secondary to strangulation. Lactate can be measured in the field on whole blood with handheld analyzers. Increased blood lactate concentrations were associated with worse outcomes in equine colic[1] and should be suspected in cases of metabolic acidosis (decreased pH, negative base excess) in the absence of hyperchloremia or hyponatremia.[2]

Plasma or serum creatinine concentrations are useful for assessing hydration status in the absence of renal dysfunction. Creatinine concentrations up to 3.5 mg/dL (310 µmol/L) are common with moderate to severe hypovolemia and can be as high as 5 mg/dL (450 µmol/L) with prolonged or

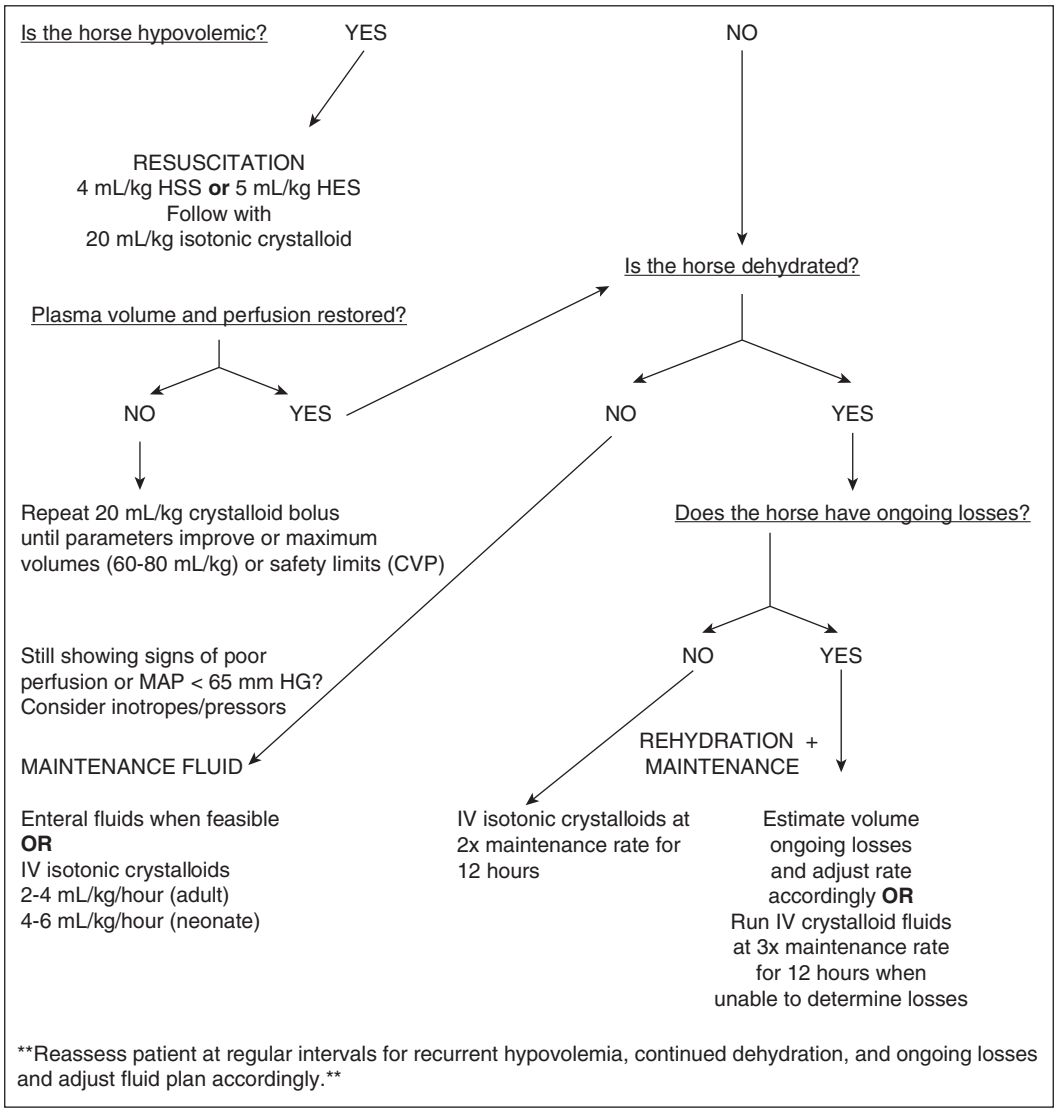

FIG. 32.75 Clinical assessment of perfusion parameters and hydration status. *CVP*, Central venous pressure; *HES*, hydroxyethyl starch solution; *HSS*, hypertonic saline solution; *MAP*, mean arterial pressure.

marked hypovolemia. Even in severe hypovolemia, the creatinine concentration does not increase by much more than 2.3 mg/dL (200 µmol/L) per day.[3]

Urine specific gravity provides valuable information regarding renal function and hydration status. High urine specific gravity (>1.040) indicates probable dehydration and normal renal function. Isosthenuria (levels of 1.010 to 1.015) indicates possible renal damage or a recent high fluid load. Urine specific gravity is especially useful in monitoring hydration status of neonates, inasmuch as neonates are normally hyposthenuric (<1.010) when well hydrated, although this can be affected by the types of fluids administered (colloids versus replacement fluids cersus maintenance), medications, inappropriate antidiuretic hormone secretion, and glucosuria.

CVP is an indirect measure of the quantity of blood returning to the heart, or preload, and is often studied in the hospital setting to assess restoration of circulating volume, in the presence of normal cardiac function. The normal CVP of adult horses is 7 to 12 mm Hg. Assessment of CVP is one of the more accurate, readily available methods of evaluating response to fluid therapy; however, measurement is affected by a number of factors, including catheter placement, head position, and presence of distributive shock.[4]

Measurement of blood pressure, particularly MAP, is also important in determining efficacy of fluid resuscitation for improving tissue perfusion. Blood pressure in horses may be determined directly or indirectly with the use of oscillometric devices. When CVP is normalized, which indicates restoration of blood volume, but MAP is decreased (<60 to 65 mm Hg), inotropes and pressors are often used to improve vascular tone and restore normal tissue perfusion.[4]

Formulating a Fluid Therapy Plan

The goals of fluid therapy are to increase cardiac output, by increasing and then maintaining cardiac preload; improve oxygen delivery; and correct electrolyte and acid-base disturbances. The plan for fluid therapy consists of four overlapping phases: (1) resuscitation, (2) rehydration, (3) maintenance, and (4) ongoing loss replenishment. Frequent monitoring of the patient and adjustment of the fluid plan are also important to a successful outcome. The fluid plan should be based on the clinical status of the affected horse, an understanding of the primary disease process, and any laboratory information available.

RESUSCITATION. Rapid fluid resuscitation is indicated in horses with clinical signs of hypovolemia. Reversal of hypovolemia is

VetBooks.ir

associated with improved outcome in human medicine and is shown to improve cardiovascular parameters in horses.[5-7] Balanced polyionic, isotonic crystalloid solutions are frequently used to restore circulating volume in hypovolemic equine patients; however, the use of colloids or hypertonic crystalloid solutions, or both, may provide more rapid results when available and indicated.

Small-volume resuscitation with hypertonic crystalloid or colloid solutions, or both, has been promoted to rapidly restore plasma volume in horses presenting with signs of hypovolemia.[8] The administration of hypertonic saline solution (HSS) was found to restore plasma volume and induce urination more rapidly than administration of an equal volume of isotonic crystalloids.[9] Hetastarch has been shown to increase circulating blood volume and improve tissue perfusion, as evidenced by decreases in heart rate and urine concentration after administration of hetastarch (10 mL/kg) with concurrent isotonic saline (10 mL/kg) to horses with colic.[10] Moreover, in horses undergoing exploratory laparotomy, cardiovascular indices were significantly improved after preoperative administration of 10% pentastarch (4 mL/kg), in comparison with 7.2% saline (4 mL/kg).[11] The administration of HSS is associated with development of an inorganic acidosis and hypokalemia, and the plasma expansion effects of small-volume resuscitation are short-lived; thus fluid therapy with hypertonic or colloid solutions should include concurrent administration or immediate follow-up with polyionic, isotonic crystalloid solutions.[8,9]

During resuscitation, isotonic crystalloid solutions are administered at doses of 20 to 40 mL/kg in adult horses (10 to 20 mL/kg in neonates) as rapid boluses. After each 20-mL/kg bolus, clinical evaluation of the patient, including evaluation of perfusion parameters, is performed in order to assess the need for repeat boluses. If perfusion parameters and blood pressure have not normalized on obtaining a normal CVP or at the completion of a total maximum "shock dose" of 60 to 80 mL/kg crystalloids, then inotropes and pressors are often incorporated in treatment, and the fluid rate is adjusted to maintenance rates. In horses and foals presenting for gastrointestinal disorders, alterations in vascular permeability and decreases in protein concentrations must be considered in determining the volume of crystalloid to be administered.

REHYDRATION. In horses that do not present with signs of hypovolemia or in whom hypovolemia has been reversed, dehydration is corrected over the first 12 to 24 hours of hospitalization. To rehydrate patients, isotonic crystalloids are administered at rates in excess of ongoing losses plus maintenance requirements. Clinically, this is accomplished in most patients with gastrointestinal disease by administration of isotonic crystalloid fluids at two to three times the maintenance rate. Once dehydration is corrected, according to clinical parameters such as PCV/total solids and urine specific gravity, this rate is slowed to that needed to maintain hydration. Horses with urine specific gravities below 1.020, and foals with urine specific gravities below 1.010, are unlikely to be dehydrated.

MAINTENANCE. Depending on the gastrointestinal disease, free-choice feed and water may be withheld from horses with acute abdomen for a period of time, during which fluid requirements must be supplemented to maintain hydration. The mean daily water intake (including the water content of feed) of normal resting adult horses is 57 to 64 mL/kg/day at ambient temperatures of 5° C to 25° C (41° F to 77° F). Mares restricted to 40 mL/kg/day demonstrated significant dehydration.[12] Maintenance fluid rates for adult horses (2 to 4 mL/kg/h) and neonatal foals (4 to 6 mL/kg/h) can be met through enteral administration when appropriate for the diagnosis and when gastrointestinal function is normal. When enteral administration is contraindicated, polyionic, isotonic crystalloids are most frequently used in the parenteral administration of fluids.

Electrolyte concentrations and hydration status should be monitored frequently as part of the maintenance fluid plan. Replacement crystalloid solutions higher in electrolyte concentrations are usually administered over maintenance crystalloid solutions according to the size of equine patients, the volume of fluids required, and availability. (See Chapter 44 for a comparison of commercially available fluid solutions.) Some patients, particularly neonates or those losing large volumes of fluid, are at risk for developing a free water deficit and subsequent inorganic acidosis when maintained on isotonic, replacement, crystalloid solutions. Monitoring of electrolytes, particularly sodium and chloride, helps identify such patients. In adult horses, physical examination and monitoring of body weight, PCV/total solids, creatinine concentrations, and urine specific gravity are useful in evaluating the efficacy of a fluid treatment plan. Overhydration in adults with normal renal function may be indicated by frequent urination, urine specific gravity lower than 1.013, and development of dependent edema. In neonates, body weight, urine production, urine specific gravity, and perfusion parameters are evaluated to monitor hydration status; detection of excessive fluid supplementation can be difficult because nursing neonates normally produce hyposthenuric urine. Development of preputial or stifle edema is an indication of overhydration in neonates. It is important that the volume of all intravenous solutions and enteral feedings be accounted for when fluid rates in neonates are calculated to prevent volume overload.

ONGOING LOSS REPLENISHMENT. Horses that present with gastrointestinal conditions that result in excessive fluid losses such as gastric reflux and diarrhea require supplementation in excess of maintenance fluid rates. Calculating the volume of fluid lost is the most accurate method of determining how much fluid will need to be replaced. Whereas the volume of nasogastric reflux can be tracked, determining the volume of fluid lost in adults and ambulatory foals with diarrhea is not possible; therefore frequent assessment of the patient by clinical examination and determination of relevant laboratory parameters are useful in evaluating the fluid plan to prevent continued dehydration or recurrence of hypovolemia.

Special Considerations in the Fluid Therapy Plan

The selection of fluids to be administered, rate and route of administration, parameters to be monitored, and frequency of monitoring are based on thorough individual case assessment. In addition to the various phases of fluid therapy, special circumstances encountered in horses with gastrointestinal disease must also be considered in the fluid therapy plan. These include commonly observed electrolyte disturbances, acidemia, hypoproteinemia, and endotoxemia. Table 32.11 lists common fluid choices and additives for conditions observed in horses with gastrointestinal disease.

Enteral Fluid Administration

Enteral fluid therapy may be sufficient to correct and maintain hydration in horses with gastrointestinal disease that have mild dehydration and normal small intestinal function.[13] In horses with gastrointestinal disease but no apparent dehydration, administration of an electrolyte paste and provision of fresh drinking water may be sufficient to supplement water and electrolytes.[14] However, enteral fluid therapy is contraindicated in horses with small intestinal obstruction or ileus and is not sufficient to treat hypovolemia.

Enteral fluids are often included in the treatment of impaction colic. Nasogastric administration of a balanced electrolyte solution (5.27 g NaCl + 0.37 g KCl + 3.78 g $NaHCO_3$ per L water) at 5 L/h is superior to enteral administration of magnesium sulfate, sodium sulfate, or magnesium sulfate with IV crystalloids in promoting hydration of colonic contents, and

VetBooks.ir

TABLE 32.11

Fluids and Additives for Electrolyte Disturbances in Horses

Metabolic Disturbance	Recommended Fluid	Dosage
Lactic acidosis	Polyionic crystalloids with or without small-volume resuscitation (HSS/HES)	Up to 60 mL/kg/h
Hyponatremia	Isotonic crystalloids	Sodium level should be corrected no faster than 1 mEq/L/h
• With hypochloremia	Polyionic crystalloids or sodium chloride	
• Without hypochloremia	Sodium bicarbonate	
Hypernatremia	5% Dextrose or 2.5% dextrose/0.45% sodium chloride	Sodium level should be corrected no faster than 0.5 mEq/L/h
Hypochloremia	Polyionic crystalloids or sodium chloride	0.9% or 7.5%, to effect
Hyperchloremia	Increased free water intake or administration	
• With hypernatremia	Polyionic maintenance crystalloid or 5% dextrose	Sodium level should be lowered no faster than 0.5 mEq/L/h
• Without hypernatremia	Sodium bicarbonate	5%, slowly, to effect
Hypokalemia	Potassium chloride	10 to 40 mEq/L or 0.5 mEq/kg/h Maximum, 1 mEq/kg/h
Hyperkalemia		
• With clinical signs	Calcium gluconate	1 mL/kg IV over 10 min 250 mL/1 L sodium chloride
• Potassium concentration >7 mEq/L	Sodium bicarbonate	1 to 2 mEq/L IV over 15 min
• Without clinical signs	5% Dextrose in polyionic crystalloids	2 mL/kg IV over 5 min
Hypocalcemia	Calcium gluconate	250 to 500 mL of 23% solution/5 L
Hypercalcemia	Polyionic crystalloids (without calcium)	4 to 16 mg/kg as an initial dose
	Magnesium sulfate	10 mL/5 L (maximum, 50 mg/kg)
Hypomagnesemia	Magnesium sulfate IV	4 to 16 mg/kg as an initial dose
Hypermagnesemia	Calcium gluconate	250 to 500 mL of 23% solution
Hypoalbuminemia	Fresh or fresh-frozen equine plasma	To effect, not to exceed 10 mL/kg
	HSS/HES	5 to 10 mL/kg to increase COP

All disturbances present must be taken into account before treatment begins.

COP, Colloid oncotic pressure; *HSS/HES*, hypertonic saline solution/hydroxyethyl starch solution (hetastarch); *IV*, intravenously; *PO*, by mouth.

it does not alter plasma electrolyte concentrations.[15,16] An isotonic solution for enteral administration can be made without the use of weight scales by measuring salt crystals in the barrel of a syringe (15 mL of Lite salt and 15 mL of table salt added to 4 L of water).[17] In a prospective clinical trial, 8 to 10 L of enteral fluids administered every 2 hours was successful in the treatment of 99% of colonic impactions and 83% of left-sided colon displacements.[18] Because enteral fluids are significantly less costly than commercially available intravenous fluids, this is an ideal treatment in some gastrointestinal conditions.

Electrolyte Disturbances In many horses with gastrointestinal disturbances, plasma electrolyte concentrations are altered, which may need to be addressed during fluid therapy. Portable equipment for measuring blood gases and electrolytes allows the field veterinarian to easily obtain information necessary to guide electrolyte supplementation and selection of appropriate fluids. Without case-specific determination of electrolyte concentrations, maintenance phase fluids in gastrointestinal disease should be limited to administration of isotonic, polyionic crystalloid fluids supplemented with 10 to 20 mEq/L of potassium chloride.

Generalized changes in electrolytes among horses with gastrointestinal disease are related to decreased feed intake, increased loss, and sequestration. Decreased sodium and chloride concentrations may be observed in cases of acute colitis, peritonitis, or intestinal torsion.[19] Hypochloremia without hyponatremia is also observed in proximal enteritis and grass sickness associated with loss of hydrochloric acid in gastric reflux.[20] Hypokalemia is common in horses after colic surgery because of decreased feed intake, enhanced mineralocorticoid release, and kaliuresis associated with administration of sodium-containing fluids. Hypokalemia also occurs with colitis and metabolic alkalosis. Potassium is primarily an intracellular ion, and decreases in whole body potassium may not be detected through plasma measurements; therefore it is common to add supplemental potassium to maintenance fluids. Hypocalcemia is commonly observed in horses presenting with gastrointestinal disorders, including those with surgical colic, colitis, functional disorders of the small intestine, organic acidosis, and endotoxemia.[21] Plasma ionized calcium provides a better indicator of physiologic calcium status, inasmuch as hypoalbuminemia occurs in many gastrointestinal conditions. In one report, 44% of horses with gastrointestinal disease had low plasma magnesium concentrations.[22] Hypomagnesemia may be associated with refractory hypocalcemia and hypokalemia; thus supplemental magnesium may be beneficial in those situations. Hypophosphatemia has been reported in horses with strangulating intestinal lesions or intestinal ileus.

ACIDOSIS. Inorganic and organic metabolic acidoses occur frequently in horses with gastrointestinal disorders. Inorganic acidosis occurs with hyponatremia (colitis, peritonitis, intestinal torsion) and relative or absolute hyperchloremia (colitis, free water deficit). Many affected patients have a normal anion gap. Organic acidosis in horses with gastrointestinal disease is common, secondary to elevated lactate concentrations and associated with an increased anion gap. Increased blood or plasma lactate concentrations in these cases are usually a result of poor tissue perfusion or inappropriate anaerobic metabolism in endotoxemia.

Metabolic acidosis in horses with gastrointestinal disease usually resolves with correction of hypovolemia and restoration

of tissue perfusion. In the case of inorganic acidosis, electrolyte abnormalities are occasionally severe enough to necessitate selection of a particular commercially available fluid. Administration of sodium bicarbonate to correct acidemia is reserved for cases in which the blood pH falls below 7.2 or for cases of severe hyponatremia with relative hyperchloremia, and only in patients with normal respiratory function.

Less frequently observed acid-base disorders in horses with gastrointestinal disorders include inorganic metabolic alkalosis (hypochloremia or hypoalbuminemia), respiratory alkalosis (hyperventilation associated with pain), and respiratory acidosis (hypoventilation caused by extreme abdominal distention or respiratory center depression).[2]

Hypoproteinemia Hypoalbuminemia occurs in horses with moderate to severe compromise of the colon, parasitism, intestinal malabsorption, or third spacing (peritonitis). Endotoxin exposure and ischemia-reperfusion injury induce capillary damage that allows plasma albumin to leak out into the interstitium. Clinical signs of hypoalbuminemia are peripheral, tissue, and organ edema, which lead to reduced oxygen uptake by cells and, in severe cases, organ failure. Albumin is a weak acid; thus severe hypoalbuminemia may contribute to metabolic alkalosis or mask concurrent metabolic acidosis.[2] Determination of the colloid oncotic pressure (COP) of the plasma is most useful in guiding colloidal fluid therapy, particularly when synthetic colloids have previously been administered.[23] COP and total protein concentrations were found to decrease over the course of anesthesia in horses undergoing colic surgery.[24]

Hypoalbuminemia and decreased COP should be treated when acute or if there are clinical signs. Options for colloidal support in horses include plasma transfusion and synthetic colloid solutions, such as hetastarch. Approximately 6 to 8 L of fresh-frozen plasma is necessary to effectively treat significant hypoproteinemia in adult horses, which makes plasma cost prohibitive in the treatment of decreased COP.[25] However, plasma has a role in treatment of SIRS by providing AT-III and other cofactors. The administration of 6% hetastarch at 8 to 10 mL/kg to conscious hypoproteinemic horses significantly improved COP for 6 hours after infusion and maintained an oncotic effect for 24 hours; however, administration of 2.5 mL/kg 6% hetastarch did not alleviate the decrease in COP observed in healthy horses receiving crystalloid during general anesthesia.[26,27] Hetastarch should be used with caution in patients with conditions of decreased renal perfusion, systemic inflammation/sepsis, or underlying renal insufficiency because it has been associated with development of acute kidney injury in humans.

Endotoxemia Horses with gastrointestinal disorders, particularly ischemic lesions and conditions involving inflammation of the bowel, are at risk of exposure to endotoxin as damage to the intestinal mucosa allows intraluminal bacteria to gain systemic access. During endotoxemia, capillary damage leads to increased vascular permeability, altering fluid dynamics and contributing to tissue edema. HSS has been shown to reduce the capillary endothelial swelling associated with SIRS and to improve tissue microcirculation and oxygen delivery.[28]

Studies of the effects of HSS in horses with experimentally induced endotoxemia have yielded mixed results. One study in conscious horses found that administration of 5 mL/kg HSS after administration of a low dose of endotoxin (1.64 ± 0.22 μg/kg) improved cardiac output and decreased peripheral vascular resistance in comparison with isotonic saline.[29] These findings were not supported by those of another study in anesthetized horses that received higher doses of endotoxin. In that second study, administration of combined 5 mL/kg HSS and 10 mL/kg hetastarch to horses with hyperdynamic shock induced by administration of 50 μg/kg endotoxin did not improve cardiopulmonary parameters.[30] The combination of HSS and hetastarch may protect against hypocalcemia associated with endotoxemia without negatively affecting coagulation beyond that seen in control horses.[31]

Nutritional Support Many horses with gastrointestinal disease are inappetant or are held off feed as part of their treatment for a variable amount of time. An enteral diet based on a horse's normal diet is the first choice for nutritional support; however, in adult horses are were held off enteral feeding for over 3 days because they have gastric reflux, ileus, esophageal obstruction, or anorexia should be supplemented parenterally.[32] In addition, horses with moderate obesity that are not eating may be at increased risk of developing hyperlipidemia and should receive supplementation earlier. Parenteral nutrition can range from the administration of 1% dextrose in intravenous fluids to the administration of a combination of dextrose, amino acids, and lipids that is based on the maintenance energy requirements for the individual patient. (See Chapter 50 for a complete discussion of nutritional support in horses.)

Ruminant Alimentary System

Gilles Fecteau, *Consulting Editor*

Ruminant Alimentary Disease

Dental and Oral Diseases

Sylvain Nichols • Guy St. Jean

Digestion of forage, silage, and grains starts with proper mastication and rumination. To be efficient, ruminants depend on a properly functioning mouth, which includes teeth, bones (mandible, maxillary, palatine and hyoidal apparatus), synovial structures (temporomandibular joint), muscles (tongue, masseter) and salivary glands (parotid, mandibular, and buccal). Many arteries, veins and nerves are present to allow the normal function of all those structures for prehension, mastication, swallowing, and rumination. An insult to any one of those structures has a significant effect on digestive efficiency and overall performance of the animal.

Tooth Anatomy

To understand dental and periodontal diseases, it is mandatory to understand the anatomy of those structures (Fig. 32.76). The anatomy of the tooth varies from tooth to tooth, depending on the number of roots and infundibula.[1] Teeth are the strongest tissue in a living animal. They consist mainly of enamel, cement, and dentine. The enamel covers the labial, lingual, rostral, and caudal surfaces of the crown. On the occlusal surface of a tooth, the enamel forms ridges and crests. In the early life of a tooth, the ridges and the crests are connected. As dental wear occurs, the dentine becomes exposed between the ridges and the crests, which results in creation of the infundibulum. The center of the infundibulum is blackened cement. The neck is the connection between the crown and the root and is the junction between the enamel and the cement. The gum connects to the tooth at the point where the periodontal ligament attaches the cement to the alveolar bone (alveolar socket), which forms

a shallow gingival sulcus. The inside of the tooth consists of dentine and the pulp cavity, where blood vessels and nerves are located. The nerves travel through the root canals.

Eruption of Teeth

Determining an animal's age by examining the teeth is not an exact science because the appearance of the teeth can be affected by inherited factors, nutrition, and geographic location.[2,3] At birth or within 2 weeks, four deciduous incisors usually are present in ruminants. All eight deciduous incisors erupt within the first month.[4] The fourth incisor (corner) is a modified canine tooth. The incisors meet with the dental pad of the upper jaw for the purpose of gripping and cutting herbage. Usually, all three pairs of deciduous premolars have erupted at birth or shortly afterward.[2,3] In cattle, the formula for the deciduous teeth is as follows: 2(incisors 0/4, premolars 3/3) = 20.

The age at which permanent teeth erupt is often the best criterion for determining the animal's age if a registration certificate is not available. However, systemic illnesses and malnutrition can retard dental development and cause retention of the deciduous teeth.[5] The first molars erupt at 8 months of age and are fully exposed at 12 months. At 18 months, the second molar is fully exposed. The third molar erupts at 24 months and is fully exposed at 30 months. The permanent premolar teeth start to replace the deciduous at 24 months and are usually present at 3 years.[2,3] The first pair of permanent incisors (central incisors) erupt at 18 to 24 months of age. The second pair of incisors (medial incisors) appears at 24 to 30 months of age. At 3 years of age, the third pair of incisors (lateral incisors) erupt. Between 3.5 and 4 years of age, the fourth pair of incisors (corner teeth) erupt.[4,5] Consequently, cattle have a complete set of permanent teeth at 4 years of age. Cattle have a shallow alveolar socket and associated tooth root. This may lead to dental attrition more readily than in horses. The formula for the permanent teeth in cattle is as follows: 2(incisors 0/4, premolars 3/3, molars 3/3) = 32.

The deciduous and permanent dental formulas of the sheep and goat are identical to those of cattle.[4] In sheep and goats, the periods of eruption are as follows: The incisors are present at birth or within the first 4 weeks. The premolars erupt 2 to 6 weeks after birth. The first pair of permanent central incisors replaces the deciduous pair at 12 to 18 months of age. The second pair erupts at 18 to 24 months of age; the third pair erupts at 30 to 36 months of age; and the fourth pair appears at 3.5 to 4 years of age. The three permanent premolars erupt at 18 and 24 months of age; the first molar, at 3 months of age; the second molar, at 9 to 12 months of age; and the last molar, at 18 to 24 months of age.[4]

FIG. 32.77 Photograph of a 2-year-old Holstein cow, with a Hau'Sman mouth gag in place to allow an oral examination. The cow was sedated with a "ketamine stun" (butorphanol, 0.05 mg/kg; xylazine, 0.025 mg/kg; ketamine, 0.1 mg/kg intramuscularly). The cow tolerated the gag and the examination well. *(Courtesy Sylvain Nichols, Université de Montréal.)*

Examination of Teeth

Dental disease in ruminants should be considered first on a flock or herd basis.[6,7] Determining dental health is particularly useful when unconventional feeds are incorporated into the herd nutritional program.[8,9] The clinical manifestations of dental diseases include inadequate food intake, inadequate calf development, weight loss, unthriftiness, low body condition score, quidding, low pregnancy rate in replacement heifers, decreased milk production, and mandibular or maxillary swellings or draining tracts.[4,7-10] Dental examination is especially of concern when animals are grazing on short grass. Examination of the herd should then be followed by dental examination of individual animals. For examination of the premolars and molars, the tongue should be withdrawn from the mouth and held at the commissure of the mouth opposite the teeth being examined. Use of a headlight or flashlight helps with performing a good oral examination. A small dose of xylazine (0.03 to 0.05 mg/kg IV) or a "ketamine stun" (butorphanol 0.05 mg/kg, xylazine 0.025 mg/kg, ketamine 0.1 mg/kg IV) and the use of a mouth gag allows for much a more thorough dental examination, including manual palpation in cattle (Fig. 32.77). A rigid endoscope is useful for evaluating the crown and the occlusal surfaces of the cheek teeth. Radiographic examination can also be important in certain cases. Oblique views are mandatory to evaluate the roots of each cheek tooth completely.

The incisors have a sharp edge in front and are used for gripping and cutting herbage.[4,7] The incisors should be aligned closely with little space between them.[4,7] In sheep, the periodontium of the incisor allows a movement of up to 2 mm rostrocaudal to accommodate rotating or turning forces during grazing.[10] This makes the sheep incisor very prone to loss after periodontal damage. The length of the premolar and molar teeth and their firm placement in the alveolar bone means that they are lost less often than the incisors.[2,3,7]

Dental and Periodontal Diseases

Sylvain Nichols • Guy St. Jean

Dental Attrition and Erosion

Rapid wearing of teeth is most common in grazing sheep older than 5 years of age. Many sheep and cattle grazing forage-deficient or sandy pastures and arid ranges in Africa, Australia, New Zealand, and the southwestern United States display accelerated tooth wear.[7,11] In Rhodesia, the incisors of Hereford

cattle had an increased rate of wear because of softer enamel, in comparison with those of indigenous cattle.[12]

Examination of an animal with dental attrition reveals worn incisor or molar teeth (or both); often only short stumps are seen. The teeth also may be loose, fractured, or missing. Dental attrition from excessive wear must be differentiated from periodontal disease that causes tooth loss.[7,13,14] The pathogenesis of excessive tooth wear relates to tooth hardness and diet quality. Ingestion and mastication of soil and sand with forage abrades and wears the incisor and molar teeth. In New Zealand, dental attrition in sheep was attributed to acids and enzymes in the herbage consumed, which acted on the tooth dentine.[11] A calcium deficiency or calcium/phosphorus imbalance, causing softness of the tooth enamel and dentine, may accelerate the rate of wear.

In the United States feeding fermented sweet potato cannery waste to cattle resulted in substantial increases in incisor erosion.[8,9] Cattle producers feeding sweet potato cannery waste noticed poor growth rate, inadequate calf development, low pregnancy rates in heifers, and worn, mottled, discolored incisors.[8,9] Sweet potato cannery waste is highly acidic (pH, 3.2) and causes calcium loss and tooth erosion. Deciduous teeth are etched more rapidly, which places young cattle at higher risk for severe tooth wear and dental infection. In addition, the distance between the original enamel surface and the pulp chamber is less in deciduous teeth than in permanent teeth, which is, again, more significant in younger cattle.[8,9] Mixing 10% broiler litter with sweet potato cannery waste raised the pH to 4 and thus provided a palatable high-quality feed and prevented the severe dental problems associated with sweet potato cannery waste alone.[8] It is important to allow a withdrawal time of 21 days before slaughter of cattle fed broiler litter to avoid the presence, in the meat, of pharmaceutical residues used in the poultry industry.

A syndrome involving excessive wear of deciduous incisor teeth, maleruption of permanent incisors, and an increased prevalence of dentigerous cysts in sheep has been reported in New Zealand.[15] Excessive wear of the incisor teeth of cattle was also recorded on the same farms. Ingestion of soil during winter because of the inclement weather, overgrazing of pastures, and the presence of low copper levels in the blood of affected animals were the main causes for the syndrome.[15] Dental attrition is prevented by providing supplemental feed to avoid overgrazing of pastures. The addition of 1% ground limestone to the feed in calcium-deficient areas is recommended.[16]

Periodontal Disease

Periodontal disease involves the supporting tissue that surrounds the teeth.[17,18] Periodontal disease of sheep is endemic in parts of New Zealand. A periodontal disease known as *cara inchada*, or "swollen face," has caused losses of cattle in Brazil.[19,20] Periodontal disease is characterized by protruding and loose incisors.[7,13] With time, incisors, premolars, and molars may be missing. Periodontal disease seems to be more prevalent in sheep than in cattle. However, an abattoir investigation in West Scotland revealed periodontal diseases in 12% of the heads evaluated. The disease was located mainly on masticatory teeth and was more frequent on beef cattle heads.[21] Periodontal disease results in pain during mastication, which leads to poor rumination and reduction in food digestibility.

Periodontal disease has been associated with bacterial plaque–induced gingivitis.[17,20,22,23] The acute gingivitis is replaced progressively by a chronic inflammation in the gingival sulcus. The periodontal ligament is destroyed by plaque-forming oral microorganisms and host enzymes. At this stage, periodontal pockets are formed, which cause loosening of teeth. This process may take months or years. Over time, the infection extends to the apical area. The gum margin begins to recede over the lesion, food accumulates within the pocket, and the entire alveolus becomes infected. At that point, the tooth becomes a sequestrum. The alveolar pyorrhea causes a periostitis of the external surface of the alveolar process, and swelling is observed. Once a tooth is lost from an affected alveolus, granulation tissue fills the alveolus and the alveolar bone undergoes remodeling.

Bacteria such as *Truperella pyogenes*, *Bacteroides* spp., *Actinomyces* spp., and spirochetes; metabolic or immune disorders in the host; and mechanical or chemical agents have been implicated in the pathogenesis of periodontal diseases in sheep.[7,22,24,25] Bacterial invasion in the gingival pockets has been associated with a defect of host immune competence.[26] Hypomagnesemia has been a common finding in sheep with periodontal disease, but this may be a secondary condition.[25] Gingival trauma may have a causal role.[27] Dissolution of the enamel at the attachment of the gingival epithelium by organic acids from microorganisms of the soil may be a predisposing factor.[28] The serum values for calcium, albumin, ALP, and citrate were lower for sheep with periodontal disease than for sheep not affected by dental disease.[29]

A postmortem examination of Scottish-Hill sheep revealed that 60% of 478 aged sheep had either loose or missing teeth. Gingival pockets were present in 87% of the population and were correlated with tooth looseness.[30] In the United States, a 25% rate of mortality caused by dental disease in a herd of 300 ewes was reported.[31] The clinical signs were depression, anorexia, and emaciation.[31] Necropsy revealed dental disease of the mandibular teeth with plaque, plant fibers in periodontal pockets, and osteomyelitis of the mandibular bone. An initial trauma to the gingiva from cheatgrass awns in the hay field was implicated.[31]

A particular type of periodontal disease in cattle was reported in Brazil.[19,20] This condition involves an inflammatory process of the periodontium of calves and older Zebu cattle that results in alveolar periostitis of the maxilla or, less often, the mandible.[19,20] Examination reveals deep periodontal pockets and loss of or loosened teeth. Affected animals suffer from malnutrition, diarrhea, and loss of condition, and many die. *Bacteroides* and *Actinomyces* organisms often are found in the lesion and are suspected of causing the disease.[19] This disorder is seen only in certain areas of Brazil, and the cattle improve if moved to unaffected areas. In one trial, the development of periodontal disease in calves was avoided by administration of the antimicrobial drug spiramycin.[20]

The assumption that incisor condition is a good indicator of future productivity is not well founded. Little scientific evidence exists to support the culling of sheep affected by periodontal disease. Three farms with a high prevalence of periodontal disease were selected, and the body score and weight of affected sheep were compared with those of sheep with no signs of periodontal disease. A significant association between periodontal disease and body condition or weight was identified on only one farm. It was concluded that periodontal disease in sheep may impair productivity on some farms but not others.[32,33]

Treating periodontal disease on a flock basis often proves impractical. Dental treatment, drug therapy, and management change have been tried in sheep. One form of dental treatment, tooth grinding, consists of trimming the incisors to the level of the lower dental pad.[13] Two trials of the productivity effects of tooth grinding were conducted; neither showed any positive benefit from the procedure.[32] An attempt to influence the development of periodontal disease in sheep by long-term treatment with tetracycline and metronidazole was also found ineffective.[23] In commercial sheep, surgical treatments could improve conditions such as periapical and gingival abscesses, but these treatments are not economically feasible.

Sheep can live without incisors if they do not have to graze too closely. Supplementary feeding should provide a net gain to the owner. When premolar and molar teeth are involved, this approach is unlikely to be effective because of the inability to chew and ruminate efficiently.

Dentigerous Cysts

Dentigerous cysts have been described in ruminants, particularly sheep.[15,33] These are odontogenic cysts of unknown cause that

VetBooks.ir

manifest as localized, bony swellings. Radiographs demonstrate the cystic nature of the swelling and reveal one or more teeth in the cyst.[15,33] For valuable animals, treatment is surgical.

Developmental Anomalies and Retention of Deciduous Teeth

Developmental anomalies have been reported in cattle.[6] Occasionally, tooth buds fail to develop. The fourth pair of permanent incisors is the set most often absent. The mandibular premolar on one or both sides also occasionally fails to form. The permanent incisor teeth have been observed to be rotated up to 180 degrees in the alveolus. Rotation of a first permanent mandibular premolar was observed as well; the rotation was 90 degrees, and no precise cause was identified. Retention of a deciduous premolar is common in 12- to 18-month-old cattle. This results in difficulty in masticating food and excessive salivation. The treatment consists of removing the deciduous premolar with a molar-extracting forceps.

Overgrown or Loose Molar Teeth

Overgrown molar teeth are found most commonly in older ruminants. The opposite tooth is often missing. Food accumulates between the affected tooth and the cheek, causing obvious swelling of the face. Interference with mastication is often noted. The offending tooth should be rasped regularly or removed. A power tool to grind cheek teeth works well. Premolar or molar teeth can become loose in advanced cases of actinomycosis affecting the jaw. It may be difficult to determine whether the loose tooth is a cause or result of the bony abnormalities. One cow with maxillary lymphoma and loose teeth has been reported.[34]

Broken Teeth

Broken incisors are not common because of the loose alveolar attachment of these teeth. Broken premolars and molars are more common because these teeth are more solidly attached in their alveoli; breakage usually results from attempts to masticate hard objects. Most fractures usually involve only a portion of the tooth, do not involve the root, and are asymptomatic. A sagittal tooth fracture that includes the root causes pain and may result in reduced feed intake and loss of condition. (Treatment is described later in the Tooth Root Abscess section.)

Dental Caries

Dental caries, or decay, creates areas of decalcification of the tooth.[4] Dental caries is rare in ruminants,[4] but it sometimes occurs in both deciduous and permanent teeth and in both dentin and enamel.[6] Interference with prehension is rare. On oral examination, an orange or black pigment is seen in the defective enamel or exposed dentin; these areas should be probed with a fine dental pick or needle. Frequently, the caries fills with food material until it reaches the pulp cavity, which creates a tooth root abscess (Fig. 32.78). At that time, the productivity of the animal decreases, and a swelling on the mandibular or maxillary bone, or purulent discharge secondary to sinusitis appears. A head scan or oblique radiograph is useful for confirming the diagnosis (Fig. 32.79). The infected tooth should be removed. Because the infection is located at the apex of one or multiple roots, the periodontal ligament holds the tooth firmly in the alveolar socket, which makes oral extraction difficult. A surgical repulsion is often necessary. (See the Tooth Root Abscess section.)

Osteodystrophia Fibrosis

Osteodystrophia fibrosa is caused by resorption of calcium from bone and its replacement by connective tissue.[35] It is most common in goats. Osteodystrophia fibrosa can result from calcium, phosphorus, or vitamin D deficiencies or from hyperparathyroidism. Usually a growing animal with osteodystrophia fibrosa has a bilateral, soft, nonpainful, and swelling of the maxilla or mandible or both jaws.[35] The diagnosis is based on radiographic evidence of poorly mineralized bone and inward rotation of the premolar and molar teeth. The treatment consists of supplementing the ration with adequate mineral levels while maintaining a 2:1 ratio of calcium to phosphorus.

FIG. 32.79 A right lateral oblique radiograph of the mandible of a 3-year-old Holstein cow shows a radiolucency center over the caudal root of the third molar. Lysis of the apex of the root is present. *(Courtesy Université de Montréal.)*

Tooth Root Abscess

A tooth root abscess can be a complication of periodontal disease or dental caries. It can be diagnosed in aged cattle but seems

VetBooks.ir

more frequent in younger cattle. Periodontal disease at the time of permanent tooth eruption could explain the presence of this condition in young cattle. Early on, the repercussions on the health of the animal are minimal. Chewing behavior might change, and growth or milk production could be reduced. With time, a swelling appears around the infected tooth. Eventually, a draining tract becomes evident. If the molars or the caudal root of the fourth premolar is infected on the maxillary arcade, unilateral nasal discharge associated with halitosis appears because the roots of those teeth are located in the maxillary sinus. With time, the mandible or the maxilla becomes distorted from the severe periosteal reaction and the bony proliferation caused by the chronic infection. In some cases, the external appearance of the jaw resembles cases of osteomyelitis caused by *Actinomyces bovis* (actinomycosis). The oral examination may reveal periodontal disease (exposed roots), a fractured tooth, or caries. A rigid endoscope is useful for evaluating the caudal cheek teeth. The final diagnosis is confirmed by a head scan or oblique radiographs. Medical therapy fails to resolve the infection because the tooth has become a sequestrum; therefore the tooth should be removed. Oral extraction is possible in chronic cases or in cases secondary to periodontal disease. With the animal under sedation or general anesthesia, a mouth gag is used to open the jaw. The affected tooth is located, and the gingiva is elevated on the lingual and buccal side of the tooth. If the tooth is not already mobile, a molar spreader can be used to loosen the periodontal ligament. Molar-extracting forceps are placed on the crown, and the tooth is moved slowly from left to right until the periodontal ligament is completely broken. Finally, the tooth is removed by means of a fulcrum effect. The procedure is, in the author's opinion, difficult when caudal cheek teeth are involved. The limited mobility of the temporomandibular joint reduces the working space in the back of the oral cavity in cattle.

Dental repulsion is done, preferably with the animal under general anesthesia, with the affected tooth uppermost. Mandibular teeth are removed through a ventral or a lateral approach. With the ventral approach, a Galt trephine is used to remove the bone covering the roots of the infected tooth. Then a straight dental punch is placed over the roots before the tooth is hammered out. With the lateral approach, the lateral mandibular bone plate lateral to the infected tooth is removed with a pneumatic burr or with a bone rongeur and curette. The roots are freed from the bone, and a curved dental punch is used to hammer the infected tooth out. In the author's experience, the lateral approach works best to remove mandibular molars. The surgical approach is more challenging, and care must be taken to preserve the facial artery and vein that travel just over the third molar.

Maxillary premolars are removed through a dorsal approach by trephining the maxillary bone above the infected tooth. To remove maxillary molars, a maxillary bone flap is made above the maxillary sinus. Straight or curved dental punches are used to hammer the tooth out. It is important to seat the punch perfectly on the tooth to prevent the punch from slipping and fracturing the hard palate or lacerating the palatal artery. Intraoperative imaging is essential to identify the proper position of the dental punch and to ensure that no tooth fragments are left behind.

The alveolus is packed with dental wax, gauze, or dental acrylic, such as Optosil (Heraeus Kulzer GmbH, Hanau, Germany).[8] On the mandible, the ventral aspect of the incision can be left open for drainage. If sinusitis is present at time of surgery, a Foley catheter is left in the sinus postoperatively to allow daily flushing. Antibiotics are administered for 1 to 2 weeks, according to culture antimicrobial sensitivity results. The dental plug is removed 3 to 4 weeks after surgery. Sedation and the use of a mouth gag may be necessary to remove the dental plug safely. The prognosis after oral or surgical extraction is good.

Dental Fluorosis

Dental fluorosis is associated with continuous ingestion of small but toxic amounts of fluorine in the diet or drinking water. Most reported occurrences of fluorosis are in cattle. Sheep are less susceptible. Developing teeth are very sensitive to the ingestion of excess fluorides. Fluorides inhibit the action of ameloblasts and odontoblasts during tooth formation, which results in failure of the tooth to incorporate minerals. Fluorosis causes striations or patches (yellow, brown, green, or black) in enamel. Some erosion of the permanent tooth can occur. Cattles are susceptible to dental fluorosis during enamel matrix formation from approximately 6 months to 3 years of age. Severe dental fluorosis results in dental wear, inability to graze properly, and difficulty with mastication and food intake because of tooth pain. In addition to clinical signs, the fluorine concentration in the blood and urine can be analyzed to confirm the diagnosis. Normal cattle have blood levels of up to 0.2 mg/dL of blood and 2 to 6 mg/kg in urine. Cattle with fluorine intakes sufficient to cause intoxication may have bloods levels of 0.6 mg/dL and urine levels of 16 to 68 mg/kg. Treatment usually entails removing the animals from the source of fluorine.

Rostral Mandibular Masses

Vascular gingival hamartomas are defined as disorganized and excessive proliferations of vascular tissue that are present at birth (Fig. 32.80).[36,37] They are considered a developmental anomaly rather than a true neoplasm because of their limited growth. En bloc excision combined with rostral mandibulectomy is curative.[38]

Odontogenic tumors are not common in cattle. They occur generally on the rostral mandible but can be found more caudally on the mandible and maxillary. [39] Ameloblastic tumors are the most frequent odontogenic tumor.[40] Depending on the tissue involved in the mass, they are called *ameloblastic fibroma* (dental epithelium), *fibrodentinoma* (dental epithelium and small island of dentine), or *fibroodontoma* (dental epithelium, dentine and enamel). They are benign tumors with continuous growth and are found in younger cattle. A mass of variable

FIG. 32.80 Photograph of a vascular gingival hamartoma in a 3-day-old calf. *(Courtesy Sylvain Nichols, Université de Montréal.)*

size covered with gingival mucosa with distorted deciduous and permanent incisors is present (Fig. 32.81). The mass has no effect on the health of the animal. Eventually, ulcerations appears from rubbing while eating. Rostral intraoral radiographs help determine the extent of the tumor in the mandible (Fig. 32.82). En bloc excision is curative. To obtain clean margins, a rostral mandibulectomy is necessary.[41]

Odontoma is a benign tumor composed of normal dental tissue that grows in an irregular way. It affects permanent teeth before eruption and is therefore found in younger cattle. It does not appear to be common in cattle, however.

Other masses affecting the rostral mandible are fibrosarcomas and osteosarcomas. Those malignant tumors occur in older cattle. Rostral mandibulectomy, if performed early, may be curative.

FIG. 32.81 Photograph of an ameloblastic fibroma in a 4-year-old Holstein cow. *(Courtesy Sylvain Nichols, Université de Montréal.)*

FIG. 32.82 An intraoral radiograph of the cow in Fig. 32.6. The tumor has changed the normal anatomy of the rostral mandible. *(Courtesy Université de Montréal.)*

ROSTRAL MANDIBULECTOMY. This procedure is best performed with the animal under general anesthesia in sternal recumbency. With a mouth gag in place, the gingiva is incised at the predetermined site of the mandibulectomy. A periosteal elevator is used to retract the gingiva attached to the periosteum rostrally and caudally. An oscillating saw or a Gigli wire is used to amputate the rostral mandible. The saved gingival mucosa is sutured to cover the bone. Bleeding is to be expected during the dissection of the gingival mucosa and from the mandibulectomy site. Bone wax helps control bleeding from the mandible. A pressure bandage may be needed postoperatively. It incorporates the lower lip and the remaining rostral mandible.

The surgery site heals rapidly without complications. Because cattle graze mainly with their tongue, no repercussions have been observed with regard to food intake after rostral mandibulectomy.

Salivary Gland Diseases

Sylvain Nichols • Guy St. Jean

The parotid, mandibular, and sublingual glands are the three largest salivary glands in ruminants.[1] In cattle, the mandibular gland is larger than the parotid gland. The parotid gland is located behind the caudal border of the masseter, from the zygomatic arch to the most ventral aspect of the mandible's vertical ramus. Its duct enters the gland at its most ventral location. It travels along the facial vein to enter the oral cavity abaxial to the second maxillary molar. The mandibular gland lies medial to the caudal portion of the mandible from the basihyoid bone to the paracondylar process. The duct exits the mandibular gland axially and travels rostrally between the deep mylohyoideus muscle and the sublingual gland. It enters the oral cavity rostral to the frenulum of the tongue. The sublingual gland has two parts: the monostomatic and the polystomatic portions. The monostomatic portion is 10 cm long, and its main opening is near the entrance of the mandibular gland's duct. The polystomatic portion has multiple microscopic ducts along the base of the tongue.[2]

A dairy cow in lactation produces 100 to 200 L of saliva in 24 hours. Saliva is secreted continuously, but the rate of secretion is increased by feeding, rumination, and the presence of coarse feed in the rumen.[1] The saliva provides a fluid medium for transport of ingesta during deglutition and regurgitation. It also maintains adequate phosphate for bacterial digestion of cellulose in the rumen and contains bicarbonate, which acts as a buffer to maintain ruminal pH above 5.5. Ruminant saliva contains approximately 90 to 140 mmol/L of bicarbonate. The normal pH is around 8.2.[3]

Excessive Salivation

Excessive salivation (ptyalism) is a sign of many pathologic conditions. The volume of saliva may be normal, but if it is not swallowed, salivation can appear excessive. As a precaution against exposure to rabies, gloves should be worn to examine the mouth of any animal that is salivating excessively. Excessive salivation may be seen with dental disease, stomatitis, foreign objects in the mouth or pharynx, or esophageal obstruction. It also has been seen with ruminal disorders, in cows that have eaten spoiled silage, and with impaction of the abomasum. Ptyalism may be a clinical sign in rabies, pseudorabies, meningoencephalitis, listeriosis, tetanus, and slaframine toxicity.[1,4] Mercury, iodine, lead, copper, and arsenic also can stimulate secretion by the salivary glands. Treatment depends on the underlying causes.

Salivary Duct Atresia or Agenesia

This condition is diagnosed in younger animals. A soft swelling is palpable along the normal location of the duct. Sialography

VetBooks.ir

may be performed to highlight the obstruction. If possible, creating an opening in the oral cavity allows the saliva to drain in the mouth. This procedure is performed with the animal under general anesthesia. A 1.5-cm opening is created by suturing the oral mucosa to the salivary duct mucosa.[5] This procedure is difficult to perform when the obstruction is located distally from the oral opening. Other therapeutic options include chemical débridement or surgical removal of the affected gland and duct (see Sialocele section, as follows).

Sialocele

A sialocele develops when saliva escapes from a duct or salivary gland and enters the surrounding tissue. The saliva contains enzymes that irritate the tissue. The accumulation of saliva is surrounded by inflamed tissue, which gives the lesion a cystic appearance. A soft, fluctuant swelling usually is seen. Pain may be observed during mastication. Trauma or a foreign body is usually the cause of a sialocele. The diagnosis is based on the history, palpation findings, ultrasound evaluation, fluid aspiration and cytologic evaluation, and sialography. Needle aspiration may yield yellow mucoid saliva. Two treatments have been described.[6,7] The first involves removal of both the involved glands and duct.[6] Surgical extirpation of the mandibular salivary gland in the caudal area of the mandibular spaces has been performed successfully in cows, sheep, goats, and buffaloes.[1] Exposure of the tissue by opening the capsule of the gland facilitates the process of extirpation and prevents trauma of the surrounding nerves and blood vessels.[6] In the second treatment option, the sialocele is opened, drained, and chemically débrided with a caustic agent such as iodine or copper sulfate.[7] Post-débridement analgesia is mandatory after chemical resection.

Sialoadenitis

Inflammation of the salivary glands usually is caused by an ascending infection from a traumatized duct, by penetrating wounds or plant awns, or by a hematogenous embolization. Diffuse swelling of the salivary glands may be observed, and the swelling may be hot and painful on palpation. Abscess formation is a common complication. The pain may interfere with mastication and swallowing. Treatment consists of systemic antibiotics, antiinflammatory drugs, and analgesic drugs. Abscesses should be drained when they localize. Salivary fistulas can be sequelae to salivary abscesses. Surgical extirpation is also possible. However, because of the inflammation surrounding the gland, the dissection is more challenging, and the odds of traumatizing neurovascular structures are increased.[5]

Parotid Gland Carcinomas

In three cows at slaughter that had parotid gland carcinomas, the neoplastic cells appeared to originate from ductal and acinar epithelium.[8] Ocular squamous cell carcinoma may spread locally to the parotid or mandibular lymph nodes.[9]

Actinobacillosis (Woody Tongue, Wooden Tongue)

Bradford P. Smith

Definition and Etiology

Actinobacillus lignieresii, a Gram-negative rod, is a normal inhabitant of the rumen and mouth of cattle and sheep and probably goats. When the organism enters the soft tissues through a lesion, actinobacillosis results in a granulomatous abscessation. Ruminants of all ages can be affected, and the disease appears to have a worldwide distribution. The classic site of infection is the bovine tongue; because the condition causes a very hard, diffuse nodular swelling, it has been given the name "woody tongue" or "wooden tongue." The prevalence of woody tongue in bovines at slaughter is 0.7% to 3.6%.[1] Atypical actinobacillosis lesions of cattle can occur in the lips, nose, or lymph nodes of the head or neck or at other sites. Although the lesions ordinarily occur sporadically, herd outbreaks with morbidity rates of up to 73% have been reported.[1,2] Sheep are most commonly affected by hard swellings of the lips, often with fistulous tracts. Actinobacillosis has also been reported to cause tongue lesions in sheep and horses. These lesions appear to be rare in goats.

Clinical Signs and Differential Diagnosis

Actinobacillosis lesions usually involve soft tissues. When the tongue is affected, the major clinical signs are inability to prehend food normally, excessive salivation, and sometimes visible enlargement of the tongue, which protrudes from the mouth. The submandibular area often is enlarged and firm. On palpation the tongue is firm to very hard, painful, and nodular (Fig. 32.83). Nodular lesions are often slightly ulcerated. The base of the tongue is most frequently affected, but the shaft may also be involved. An ulceration filled with plant awns or stems often is seen in the sulcus lingualis at the junction of the base and shaft of the tongue. Because cattle use the tongue to prehend food, anorexia results when the tongue is painful and inflexible. Actinobacillosis must be differentiated from dental disease, oral foreign bodies, pharyngeal trauma, and other diseases that cause oral pain.

Atypical lesions in cattle involve sites other than the tongue.[3] Lymph nodes of the head and cranial cervical area are most frequently affected, but where any abrasion is present, granulomas or abscesses may develop, followed by licking or contact with pus draining from a lesion on another animal. Because plant awns and stems create entry sites for the organism in the mouth, most lesions are in the head. Granulomas in the nose and eyelids and needle puncture wounds over the left jugular vein have been reported. These granulomas may be confused with tumors, polyps, or cysts. Granulomas have been reported in the esophagus, pharynx, palate, flank, internal iliac lymph nodes, and testes; multiple subcutaneous lesions with regional lymph node involvement also have been reported. Three cases involving cutaneous lesions of the facial tissues were described as extensive swollen plaques under alopecic areas. Most granulomatous abscesses in a herd outbreak of actinobacillosis involved the tongue, muzzle, and lips and the submandibular, parotid, and cranial cervical areas. Generalized involvement or granuloma formation in internal organs may also occur.

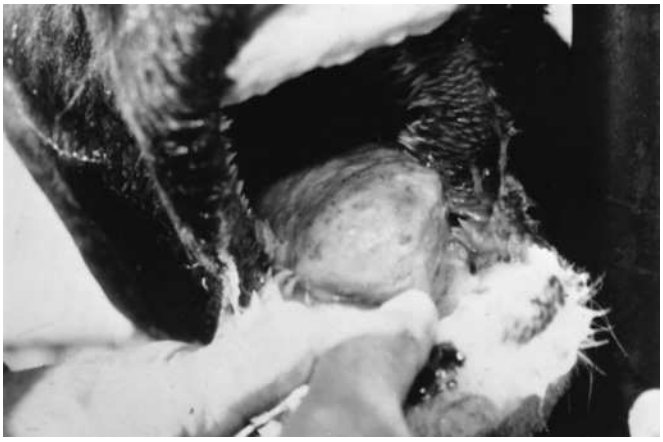

FIG. 32.83 Firm, enlarged bovine tongue typical of woody tongue caused by *Actinobacillus lignieresii*. Partly ulcerated areas of mucosa overlie hard nodules.

VetBooks.ir

Lesions in sheep typically involve the lips and face or parotid and submaxillary regions. The nasal cavity and internal organs are occasionally involved. Soft tissues of the head may be infected through fight wounds. Lesions of the lips must be differentiated from those of contagious ecthyma, and granulomatous abscesses in other sites must be differentiated from caseous lymphadenitis lesions. Lesions of the tongue in sheep, essentially identical to those found in cattle, have been reported as a cause of green staining of the lips and "cud-dropping" in sheep.

Clinical Pathology

Diagnosis of actinobacillosis requires biopsy and culture of the lesion. The pus usually is not malodorous. Pus crushed between two glass slides shows "sulfur granules," "clublike rosettes," or "club colonies." Similar colonies may be found in actinomycosis and some staphylococcal infections. *A. lignieresii* organisms are small, Gram-negative rods. Definitive diagnosis relies on culture. No reliable serologic test is available for actinobacillosis, and the hematologic and biochemical findings may be normal or typical of a chronic infection.

Pathophysiology

A. lignieresii is a normal inhabitant of the mouth in ruminants and can be found in many plant awns. When mucosal lesions occur as a result of plant awns (e.g., foxtails), thistles, or particularly stemmy coarse feed, actinobacillosis may occur. Many affected cattle have a small ulcer in the sulcus lingualis at the junction of the base and shaft of the tongue. Plant fibers are sometimes found in the granulomatous lesions of actinobacillosis. Once inoculated into tissues, the organism may cause a local lesion, lesions in draining lymph nodes, or both. Lesions elsewhere on the body may be contaminated by saliva or by pus from other draining lesions or directly by plant awns on which *A. lignieresii* resides.

Epidemiology

Most cases of actinobacillosis are sporadic. Herd outbreaks may be associated with abrasive feedstuffs and crowded conditions in which the organism is spread rapidly to wounds on other animals by way of saliva. In one herd outbreak, 73% of a group of heifers (4 to 24 months of age) were affected 1 month after feeding of a coarse, stemmy haylage had begun.[2] Atypical lesions often are associated with a previous wound at the site, such as a nose lead wound, multiple needle punctures, or a head butting wound. Outbreaks of actinobacillosis in wounds of the head, neck, body, and limbs have been reported.

Necropsy and Biopsy Findings

Actinobacillosis lesions typically are firm, pale, gritty, granulomatous abscesses. On gross examination, they appear similar to exuberant granulation tissue and connective tissue, often appearing to have a yellowish granular (1- to 3-mm) surface. Masses contain multifocal necrotic foci, often filled with nonodorous, thick, yellow-white pus. Histological examination reveals that the lesion is a granulomatous abscess. An outer capsular region of connective and granulation tissue surrounds an area of leukocytes and rosettes ("club colonies"). Mononuclear cells, plasma cells, and eosinophils predominate. Many neutrophils are seen at the center of the lesion. Multinucleated giant cells or plant fibers, or both, may be present.

Treatment and Prognosis

Treatment usually is successful, and the condition has an excellent prognosis when only the tongue is involved. The prognosis may be only slightly less optimistic when internal organs and atypical sites are involved. Sodium iodide (70 mg/kg given IV as a 10% to 20% solution) is the treatment of choice. Intravenous treatment is given once and repeated at least one more time 7 to 10 days later. In refractory cases, intravenous therapy may be repeated more often (2- to 3-day intervals). In severe cases, daily organic iodides can be administered orally at a rate of 60 mg/kg/day[4] in addition to the intravenous iodide. If signs of iodinism develop (excessive tearing, coughing, inappetence, diarrhea, or dandruff), iodine administration should be halted; the adverse signs normally disappear shortly thereafter.

The onset of therapeutic benefit of sodium iodide is remarkably rapid. Within 48 hours after treatment, the tongue is flexible enough to allow the animal to eat. Although the mode by which iodides exert their beneficial therapeutic effect in actinobacillosis is not well understood, they probably exert some antiinflammatory effect on the granulomatous inflammation. Iodides have little in vitro bacteriostatic or bactericidal effect at the concentrations given,[5] but the onset of action is very rapid. They probably act in some other way than by direct antimicrobial effect. The old belief that iodides cause abortion at the recommended dose has been cast into doubt by the author's clinical experience and by reports of others,[6] who gave 1.5 to 2 times the recommended intravenous dose without inducing abortion. Nevertheless, there are anecdotal reports of the association, and when products are labeled with a contraindication to their use in pregnant cattle, due caution should be exercised. Iodides should be given slowly and with caution to horses because of the possibility of severe generalized adverse reactions to intravenous sodium iodide.

Most strains of *A. lignieresii* are sensitive in vitro to a number of antimicrobial drugs, including ceftiofur, ampicillin, penicillin, florfenicol, sulfa drugs, certain approved aminoglycosides, and tetracyclines. Each isolate should be tested for antimicrobial sensitivity. Therapy with an antimicrobial drug to which the isolate is sensitive is recommended in severe, generalized, or refractory cases of actinobacillosis. Therapy should also include iodides.

Surgical debulking of lesions, particularly if they interfere with airflow, is also possible for atypical cases in which a large granulomatous mass is present and the mass has proved refractory to medical therapy. Hemostasis may be a problem after surgical debulking.

Prevention and Control

Prevention relies mainly on avoidance of coarse, stemmy, scabrous feeds and pastures full of hard, penetrating plant awns (e.g., foxtails) or thistles. If an outbreak occurs, immediate change to a softer feed is advised, and affected animals should be treated individually. Rapid resolution of the outbreak can be expected once these steps have been taken. If atypical lesions occur, a cause of skin wounds in the area should be sought and resolved.

Actinomycosis (Lumpy Jaw)

Bradford P. Smith

Definition and Etiology

Actinomycosis is caused by *A. bovis*, a Gram-positive, nonencapsulated, branching, filamentous bacterium that is a normal inhabitant of the ruminant mouth. The disease occurs mainly in cattle, but on rare occasions it affects sheep or goats, and one report of the disorder in a horse involving *Actinomyces viscosus* and *Actinomyces odontolyticus* has been published.[1] The bacterium enters the tissues and bone through oral abrasions, openings, and punctures associated with dental or gingival disease, hard plant awns (e.g., foxtails), thorns, stickers, or dry, coarse, stemmy feeds. Lesions may begin as cavities (caries) in the dentin or dental pulp.[2] They are sporadic and occur mainly in the mandible and less commonly in the maxilla. Because of the preponderance of mandibular lesions, with the development of periosteal new bone and fibrosis, the disease is commonly known as "lumpy jaw." Lesions occasionally occur

VetBooks.ir

FIG. 32.84 Hard swelling on the distal mandible of a cow infected by *Actinomyces bovis*. Loss of teeth and bone destruction, along with fibrosis and callus formation, are seen in this advanced case. The oral mucosa is secondarily ulcerated by trauma.

in soft tissues of the head, esophagus, forestomachs, and trachea. *A. bovis* occasionally causes granulomatous abscesses in other soft tissues. Most of the early reports of esophageal groove and forestomach involvement incriminate actinobacillosis rather than actinomycosis.

Clinical Signs and Differential Diagnosis

Bovine actinomycosis typically causes a hard, immovable, painless, bony mass on the mandible (Fig. 32.84). The lesion is most common on the horizontal ramus. Initially it is nondraining (has no fistulous tracts), but fistulous tracts may develop and involve tooth roots as the condition progresses (Figs. 32.85 and 32.86). When teeth become involved, the animal shows evidence of pain during chewing, and weight loss may result. A careful examination of the mouth is necessary to detect loose teeth, plant awns, or severe gingivitis and to rule out a pathologic fracture. If a fistula is present, the tract should be flushed with organic iodine and contrast radiographs obtained to determine whether it communicates with the mouth. The differential diagnosis includes tooth root abscess, fracture, tumors, and osteomyelitis caused by other organisms. If a mandibular swelling continues to enlarge despite therapy, radiographs should be examined for evidence of a fracture or sequestrum. Atypical actinomycosis with lesions in soft tissue causes a variety of clinical signs, depending on the location.

Clinical Pathology and Diagnosis

Hematologic and clinical chemistry findings may be normal or may reflect a chronic infection. Radiographs of the lesion are helpful in determining dental involvement or a pathologic fracture. The radiographic lesion consists of multiple central radiolucent areas of osteomyelitis surrounded by periosteal new bone and fibrous tissue. If a fistulous tract is present, a contrast study performed while the tract is flushed may help

FIG. 32.85 Hard swelling and draining tract on the mandible of a cow, typical of *Actinomyces bovis* lesion.

determine the extent of the fistula. Before flushing, material from the core of the lesion should be aspirated or examined in biopsy. A Gram stain and culture of pus should be performed. The organism is Gram-positive, filamentous, and branching. "Sulfur granules" similar to those described for actinobacillosis may be seen. Many authors report that they were unsuccessful at culturing the organism.

Pathophysiology and Epidemiology

A. bovis appears to enter the bone through mucous membrane punctures caused by foreign bodies, plant awns, or coarse, stemmy feeds or through a diseased tooth or areas of gingivitis that allow oral bacteria access to the bone. Cases usually are sporadic.

Necropsy and Biopsy Findings

Actinomycosis causes a granulomatous abscess. Scattered through the mass of tissue are basophilic clumps of bacteria surrounded by eosinophilic clublike projections. The bacteria appear as long, filamentous, branching rods. Surrounding them is evidence of cellular reaction, composed of neutrophils,

epithelioid cells, macrophages, and occasional multinucleated giant cells. In the outer fibrous tissue are plasma cells.

Treatment and Prognosis

Treatment of actinomycotic bone lesions usually results in arrest of the lesion, but seldom does the size of the hard mass regress significantly. The prognosis for arrest of the lesion with vigorous treatment is good. If the mass does not have any fistulous tracts and no affected teeth are loose, medical therapy alone may be sufficient. If the mass has fistulous tracts, it should also be vigorously curetted and flushed with povidone-iodine or other organic iodine. The lesion has a rich blood supply, and curettage can result in severe hemorrhage. If the cavity is large, it may be necessary to flush and pack with iodine-soaked gauze daily for several days and then less frequently as healing progresses. Three cases of actinomycosis were treated successfully with a repeated regimen of curettage followed by cryotherapy with liquid nitrogen poured into the lesion. The authors repeated the treatment on days 2, 9, and 16.[3] If there is an open fistula into the mouth (as judged by vigorous flushing) or if teeth are involved, the affected tooth or teeth should be carefully removed or repaired endodontically.[2] Care must be taken to prevent mandibular fracture, and the animal must be sedated or anesthetized to allow for proper intraoral manipulation. The empty alveolus should be carefully packed with gauze or a dental acrylic to which a wire or umbilical tape is attached and pulled through the fistula. The wire is tied externally to a small gauze roll to keep the alveolar packing firmly in place. The wire should be untied daily and the tract flushed thoroughly with povidone-iodine until the wound is completely granulated. Once granulation begins, it may not be necessary to check and flush the lesion more than once a week. The alveolus will take several weeks to close, pushing the gauze or acrylic out as it does so.

Medical treatment of actinomycosis involves the use of sodium iodide and penicillin or another antimicrobial drug to which the organism is sensitive. Sodium iodide is given IV at a dose of 70 mg/kg as a 10% to 20% solution. It can be given every 7 to 10 days or more often until signs of iodinism occur (i.e., lacrimation, cough, inappetence, diarrhea, and dandruff). If repeated intravenous treatments are difficult, oral organic iodides (total powder) can be given at the rate of 60 mg/kg/day for 3 weeks. As with actinobacillosis, the beneficial therapeutic effects of iodides appear to arise from their ability to reduce granulomatous inflammation rather than from direct antimicrobial effects. Iodides do not appear to cause abortion and can be safely given to pregnant cows,[4] although care should be used because there are anecdotal reports to the contrary, and products are labeled with a contraindication for pregnant cattle.

Isoniazid (10 mg/kg/day given PO for 1 month) is effective at arresting actinomycosis of the mandible in cattle.[5] It is inexpensive and readily consumed in a small amount of grain. A prolonged withdrawal period before slaughter for human consumption is required. The drug appears to be nontoxic at this dosage, but it may cause abortion and should not be used in pregnant cattle. The Food Animal Residue Avoidance Databank (FARAD; www.farad.org/vetgram/) should be checked before isoniazid is used.

Penicillin (22,000 U/kg IM twice daily) or another antimicrobial drug such as florfenicol or ampicillin can be added to the treatment regimen in cases involving valuable animals or when twice-daily treatment for 7 to 14 days is possible. Streptomycin can be given twice daily, but because of the prolonged persistence of tissue residues, aminoglycosides generally are considered unacceptable in food animals.

Prevention and Control

A. bovis is a normal mouth inhabitant of ruminants; therefore the only possible means of prevention is to avoid feeding coarse, stemmy feeds; feeds with hard, penetrating plant awns; and feeds with other sharp materials. The recommendations in this regard are similar to those for actinobacillosis.

Pharyngeal Trauma and Abscess

Bradford P. Smith

Definition and Etiology

Pharyngeal trauma occurs relatively frequently in cattle, which results in cellulitis, abscessation, or hematoma formation. One case resulted in megaesophagus. Pharyngeal trauma is almost always associated with use of a balling gun, long dose syringe, speculum, paste wormer gun, rigid probe of calf esophageal feeder, or rigid stomach tube.[1] A foreign body such as a sharp stick or wire occasionally perforates the pharynx. Hematomas may result from unidentified blunt trauma. The puncture or laceration may be very small and usually is located in the area near the origin of the esophagus. The result is that feed and saliva enter the retropharyngeal area, and inflammation develops (also see Chapter 31, Retropharyngeal Lymph Node Abscessation section).

Clinical Signs and Differential Diagnosis

The clinical signs include anorexia, drooling of saliva, malodorous breath, extended head and neck, localized or diffuse pharyngeal pain, feed coming from the external nares, and forestomach stasis or bloat. Severe cases may involve obvious pharyngeal swelling, fever, easily elicited cough on laryngeal palpation, dyspnea, and aspiration pneumonia. Intraluminal submucosal pharyngeal abscesses with similar clinical signs have been reported. The differential diagnosis in cattle must include retropharyngeal abscesses (also see Chapter 31, Retropharyngeal Lymph Node Abscessation section), pharyngeal foreign body, actinobacillosis, megaesophagus, and lymphosarcoma or other tumors that involves the pharyngeal lymph nodes.

Careful digital palpation of the pharynx via the mouth often reveals the diagnosis, although restraint is difficult because the area is painful and swollen, causing dyspnea and struggling. A well-lubricated stomach tube should be gently passed to relieve bloat and ascertain that no esophageal obstruction is present. Pharyngeal trauma is rare in sheep and goats, and retropharyngeal abscesses caused by *Corynebacterium pseudotuberculosis* (caseous lymphadenitis) are the most common cause of pharyngeal swelling.

Clinical Pathology and Laboratory Aids

Endoscopy and radiography may be of great help in diagnosing the site of the lesion, the extent of cellulitis, and the presence of a foreign body. Endoscopy reveals a swollen, collapsed pharyngeal air space. The wound may be visible, and it may have exudate at its origin. Endoscopy can help rule out intraluminal masses and foreign bodies. Retropharyngeal cellulitis, abscess, or hematoma often can be visualized radiographically, and radiopaque foreign bodies can be seen (Fig. 32.87). Gas in the soft tissues or a discrete mass can be seen with cellulitis and abscess, respectively. Gas can often be seen in the lumen of the esophagus as well. Radiographs of the lungs and thorax may be helpful if aspiration pneumonia or mediastinitis is suspected. In some cases in which no appropriate treatment is instituted early or treatment fails, the infection can reach the mediastinum via the thoracic inlet, and the prognosis becomes more guarded. The results of hematologic analysis may reflect an infectious inflammatory process.

Pathophysiology

Inflammation, swelling, and necrosis in the retropharyngeal tissues interfere with normal swallowing by causing pain when swallowing is attempted, by causing physical interference with

VetBooks.ir

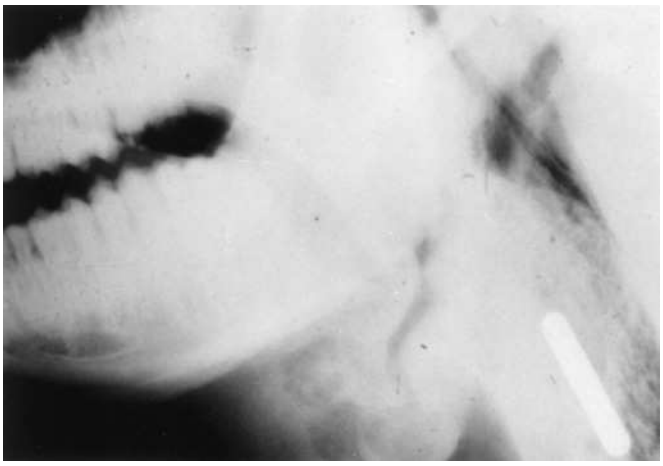

FIG. 32.87 Pharyngeal trauma in a 2-year-old bull caused by a magnet that was given forcefully with a balling gun 24 hours previously. The magnet is visible in the retropharyngeal tissues surrounded by cellulitis, with swelling and gas in the tissues. The area is swollen and painful.

passage of a bolus, and by causing neurologic involvement. The resultant dysphagia may predispose the animal to inhalation of feed and saliva.

If the retropharyngeal inflammation affects the pharyngeal branch of the vagus nerve on the dorsolateral surface of the pharynx, the esophageal and pharyngeal phases of swallowing and eructation are disturbed.[1] The resultant pharyngeal paresis may lead to reflux of feed through the nares. Involvement of the adjacent cranial laryngeal nerve makes the laryngeal mucosa less sensitive to foreign material and thus diminishes the cough reflex. Severe inflammation may involve the vagus nerve itself and cause forestomach stasis with bloat and laryngeal motor dysfunction.[1-3] Eructation also involves pharyngeal muscular activity, and the maneuver is likely to be quite painful when cellulitis is present in the area.

Treatment and Prognosis

In spite of the fact that affected animals often are completely anorexic and febrile and look very ill, most cases of pharyngeal puncture or laceration resolve successfully if the animal can be vigorously treated with broad-spectrum antimicrobial drugs for 7 to 14 days, if aspiration pneumonia can be controlled by limiting access to feed, and if adequate supportive care can be given. Tetracyclines, ampicillin, ceftiofur, trimethoprim-sulfonamide, and florfenicol have been used successfully. NSAIDs should be given for analgesia and for their ability to reduce inflammation. Oral administration of boluses should be avoided. FARAD must be checked before drugs are given off label (www.farad.org/vetgram/).

Affected animals should have access to water; if they cannot drink, and if passage of a tube is possible, a soft stomach tube should be used several times daily to gently administer a total of 30 to 50 L (8 to 13 gallons) of water plus electrolytes daily. If tolerated, it can be passed nasally and left in place securely sutured or taped in place to a halter. Alternatively, a rumen fistula may be surgically placed and used to water and feed the animal. The most important electrolyte to administer is potassium: 60 to 100 g of potassium chloride should be given daily with the water. Once the animal can drink without coughing or nasal reflux, soft green grass or a soft mash should be offered. If this is well tolerated, it should be continued for 2 weeks, after which green pasture or soft, green, leafy alfalfa hay or other equally palatable feed should be gradually and carefully introduced into the diet.

If a discrete retropharyngeal abscess forms, it is best first to attempt drainage into the pharynx through the original laceration by pushing a finger into the healing wound until pus escapes. If this fails, a surgical approach to the area may be necessary. Surgery is rarely required in cases of pharyngeal trauma or laceration with cellulitis.

Prevention and Control

Careful use of balling guns, paste wormer guns, and other equipment that can damage the pharynx is the best prevention. Adequate restraint of the head of any animal that is to be orally treated also helps prevent pharyngeal trauma. Care should also be taken to ensure that no wire, thorns, or sticks are incorporated in hay.

Contagious Ecthyma (Sore Mouth, Orf, Contagious Pustular Dermatitis, Scabby Mouth)*

Bradford P. Smith

Definition and Etiology

Contagious ecthyma (CE) (sore mouth, orf, contagious pustular dermatitis, scabby mouth) is a common disease of sheep and goats that is transmissible to humans and has a worldwide distribution. The disease has a short 2- to 14-day incubation period and tends to be more severe in goats; Boer and Boer crossbred goats are most likely to have severe generalized persistent infections with proliferative dermatitis, chronic pneumonia, arthritis, and lymphadenopathy.[1,2] A good review of human lesions was published in 2005.[3] The colloquial name *sore mouth* describes the most common presentation of the disease in sheep and goats; the name *orf* (possibly from the old Norse term *hrufa*, meaning a crust or scab) is more commonly used for the disease in all species in England and for human disease in the United States. The agent is a DNA poxvirus of the parapoxvirus subgroup, which includes several closely related parapoxviruses; these include pseudocowpox (another cause of orflike "milker's nodules" in humans), bovine papularstomatitis (BPS), parapoxvirus of red deer in New Zealand, squirrel parapoxvirus, and parapoxvirus of gray seals. Biological and genetic differences exist among strains of CE virus, and so cross-protection may be limited; vaccines must target the field strain. Wild ruminants (e.g., reindeer, musk ox) and camelids are also affected. A study demonstrated that the sheep orf virus does not cause lesions in camels, and the camel orf virus does not affect sheep, so it is likely that no infection is transmitted between camels and sheep or goats. Other species that can be affected include various wild ruminants, dogs, and cats.[4] The virus is epitheliotropic, usually creating proliferative lesions in the skin of the lips, nostrils, oral mucosa, teats, and occasionally the vulva.

Clinical Signs and Differential Diagnosis

The most common presentation is of a young animal with crusting, proliferative lesions of the mucocutaneous junctions of the mouth and nose (Fig. 32.88). Proliferative lesions may be seen on the gums (Fig. 32.89). Older immunologically naive animals may be affected, and lesions may occur at the coronary band, on the tongue, interdigitally, on the conjunctiva of the eye, on the external genitalia, or on the udder or teats, with the last site affected especially in does or ewes nursing affected kids or lambs. The disease progresses through papular, vesicular, and pustular stages, which are rarely seen, before the characteristic presentation of proliferative, coalescing, scabbed lesions

*Paul G.E. Michelsen contributed to writing this chapter in previous editions. His contribution to this section is acknowledged.

VetBooks.ir

FIG. 32.88 Typical scabby lesions of contagious ecthyma (sore mouth, orf) on the lips of a young goat. Lesions tend to be proliferative rather than ulcerative.

FIG. 32.89 Typical proliferative lesions of contagious ecthyma (sore mouth, orf) on the gums of a young sheep.

appears. In one report, the characteristic proliferative scabs appeared on the margins of healing burn wounds. Affected animals may be reluctant to nurse, eat, walk, or be nursed, depending on the location of lesions.

Secondary bacterial infection or myiasis of affected parts may occur. The disease usually runs its course in 3 to 6 weeks, but chronic cases have been reported. Complete healing without scarring is the norm as scabs fall off. Severe infections may result in stunting of growth, particularly in goats. Overwhelming infection has been noted on rare occasions, with extension of lesions into the deeper respiratory or gastrointestinal tracts. Does and ewes with severe udder infection may develop mastitis from secondary bacterial infection. Sheeppox and goatpox occasionally produce lesions similar to those of CE, but they are virulent diseases with systemic signs, including conjunctivitis, pyrexia, anorexia, and rhinitis. One report from China documented an outbreak in goats consisting of mixed infections with goatpox, orf, and *Mycoplasma capricolum*, subspecies *capripneumoniae*, which together resulted in a 60% mortality rate.[5]

Animals with bluetongue may have a crusted mouth and nose and eye lesions in the convalescent phase, but bluetongue is a disease with more evidence of oral erosive rather than proliferative lesions and systemic signs, including pyrexia, reluctance to move, lesions on the tongue, and conjunctivitis. Bluetongue has a seasonal incidence (late summer, early fall) that coincides with the activity of its insect vector. CE may occur at any time but typically occurs in spring in the lamb or kid crop. Ulcerative dermatosis (lip and leg ulcer) is an uncommon disease caused by a virus similar to that of CE, but the lesions are crusted ulcers, to be distinguished from the crusted proliferations of CE. The author has observed a series of cases of what appeared to be mild CE of long duration (several years in one individual) in a family of Nubian goats; this was confirmed by an immunofluorescence assay. Smith and coworkers[6] reported on five sheep, 4 months to 3 years of age, that developed severe refractory distal limb lesions resembling warts. Two also had lesions on the head. The sheep were from three different flocks; one was a Hampshire and four were Suffolk. Lesions were confirmed as orf by electron microscopy and immunohistochemistry.[6] A report from Texas described severe multifocal persistent orf lesions in 16 Boer or Boer crossbred goat kids 2 to 5 months of age, from two different farms. Some of the kids had been vaccinated with live-virus vaccine at 1 day of age, others at 2 weeks of age. Lesions were found on lips, nose, ears, body, legs, and feet.[7]

Laboratory Diagnosis

The diagnosis usually is made in the field by recognition of the typical lesions in a naive flock or in a naive group (young lambs or kids) in a disease-endemic flock. Definitive diagnosis usually involves identifying the distinctive cross-hatched virus particles in typical early lesions with electron microscopy, PCR, immunohistochemistry, or inoculation into known protected or susceptible animals. Minced biopsy tissues have been used as a source of virus that is identified by fluorescent antibodies after it has been growing in embryonic ovine kidney cell cultures. Complement fixation tests to detect antibodies (with patient serum) or antigen (with vesicular fluid or a suspension of scabs) have also been used.

Pathophysiology

The disease follows a similar time course in animals and human beings: approximately 6 weeks. Six stages have been described,[8] which begin after an incubation period of 3 to 14 days. Each stage lasts approximately 1 week.

1. *Maculopapular stage:* An erythematous spot becomes elevated. Histological study of this stage reveals vacuolization of cells in the upper third of the epidermis with intracytoplasmic eosinophilic inclusions in the affected cells.
2. *Target stage:* A red halo of dilated blood vessels and inflammatory cell infiltrates surrounds a white ring of vacuolated epidermal cells with intracytoplasmic and intranuclear inclusions, which surrounds a red center of pyknotic epidermal cells.
3. *Acute stage:* The lesion is a red, weeping nodule. Microscopic study reveals reticular degeneration of the epidermis with vesicles. The dermis is infiltrated with macrophages and lymphocytes and is denuded of epidermis in places. The hair follicles are distended with pyknotic epidermal cells.
4. *Regenerative stage:* The nodule is now dry with small black dots (the pyknotic follicle cells, now extruded to the surface) in a thin yellow surface.
5. *Papillomatous stage:* The surface of the nodule is roughened with papillomas, which microscopic study proves to be fingerlike, downward projections of epidermis through a full thickness of dermis.
6. *Regressive stage:* The lesion decreases in size and elevation above the surface, the papillomas regress, and several crusts may come off. Microscopic study reveals that the papillomas and infiltrates regress, leaving normal architecture.

Orf virus encodes for a protein that is apparently homologous to mammalian vascular endothelial growth factors. This family of molecules mediates vascular permeability, angiogenesis,

VetBooks.ir

and endothelial cell proliferation, which may account for the swollen, proliferative nature of orf lesions.[9] Transient fever and lymphadenopathy are occasionally seen in humans. Lesions in humans that are not excised and from which no biopsy sample is taken heal without a scar.

Orf virus encodes a range of immunomodulatory genes that interfere with host antivirus immune and inflammatory effector mechanisms, allowing time for virus replication in epidermal cells.

Epidemiology

The naturally occurring disease is primarily one of sheep, goats, and human beings, but it has also been reported in a variety of wild ruminants. Experimental transmission has been achieved in cattle, rabbits, horses, and monkeys. No naturally occurring clinical cases in these species have been reported. All ages and classes of sheep and goats are affected, and clinically normal sheep can infect naive individuals.[10] In herds and flocks in which the disease is endemic, it usually is seen in the lamb or kid crop and on the udders and teats of some of the nursing mothers. Animals that have had a bout of disease are solidly immune for 1 to several years, but the rate of morbidity is high (often 80%) among naive individuals. Humans are infected through contact with affected animals or fomites that have contacted affected animals (including one report of transmission by a pickup truck that had been used to haul sheep).[8] Effective disinfectants include hypochlorite, alkalis, glutaraldehyde, and Virkon. Virkon is a multi-purpose disinfectant containing oxone and inorganic buffers and has a wide spectrum of activity against viruses.

Human-to-human transmission can occur. The mortalityrate among animals is low except when young individuals are severely affected and quit nursing or when mothers have severe udder lesions. Overwhelming infections are rare except in Boer or Boer crossbred goats, but some outbreaks are more severe than others.

The virus is quite resistant to many environmental conditions and persists from year to year on infected premises. Dried scabs allow the virus to persist for years, but wet conditions are less hospitable to it. Reports of PI sheep in wet climates point to another possible source of infection.

Treatment, Prevention, and Control

The infection usually is self-limiting and of minor consequence. Young individuals may need to be tube-fed if the lesions are severe enough to preclude suckling. Secondary infections, myiasis, or mastitis may be treated with topical disinfectants, antibiotics, or insecticides as appropriate. The hard crusts should not be removed because removal may delay healing and promote scarring. Also, humans should limit contact with affected animals and should wear gloves when handling them as necessary. Anecdotal reports, each consisting of one case, have claimed good results for treatment of human orf with intralesional corticosteroids, IFN, idoxuridine in DMSO, diethyl ether, or cryotherapy. An immunosuppressed human with a huge orf lesion on the finger was successfully treated with topical cidofovir antiviral cream. Similar good results were obtained in a group of 12 severely affected, bottle-fed lambs with painful intraoral lesions. The proliferative tissues were débrided and cauterized with a portable diathermy unit. The exposed submucosa was then frozen twice with liquid nitrogen spray. Healing occurred by second intention, and the lambs recovered rapidly.

The infection is prevented by keeping a herd or flock virus free by not introducing or contacting infected animals or humans. Lesions often are not apparent on carriers.[10] Once established, the disease persists on the premises because of virus in scabs. Vaccination should be undertaken only if the infection is persistent, because the vaccine consists of virulent live virus. Vaccination can also be achieved with dried scabs from the previous year's outbreak because there are distinct antigenic differences among orf viruses[11]; the scab material is rubbed into scarified skin in an inconspicuous location (inner thigh, under the tail, in the axilla). A localized inflammatory reaction at the site 1 week after vaccination indicates that inoculation was successful. Infected or vaccinated animals should not be allowed contact with unexposed animals until the lesions have healed. Lambs born to immunized ewes may not be protected by colostral antibodies even though their levels of antibody after suckling are high[12]; this points to the importance of cell-mediated immunity in protection from the disease. Lambs should be vaccinated at 6 to 8 weeks of age and are immune 3 weeks later. Yearly vaccination of the new lamb or kid crop and of new additions to the herd with farm-specific strains of orf should prevent devastating outbreaks on infected farms. At a minimum, it appears that goat isolates should be used for kids and sheep isolates for lambs.[11-13]

Bovine Papular Stomatitis (BPS, Proliferative Stomatitis)

Bradford P. Smith

Bovine papular stomatitis (BPS) is a worldwide disease principally of young cattle caused by a parapoxvirus closely related to those of CE and pseudocowpox. BPS, CE, and pseudocowpox have many similarities, and they may represent a single virus adapted to different species.[1] There are as many antigenic differences among strains of BPS as among CE and pseudocowpox.[1] Local strains therefore are recommended for vaccination. Infection usually is asymptomatic, and one study of cattle in Virginia demonstrated that 31 of 45 samples from asymptomatic cattle were virus-positive.[2] In the same study no asymptomatic deer, goats, or sheep were found to be positive for parapoxvirus, which suggests that cattle are the reservoir host. Lesions consisting of raised papules may be noted on the muzzle, nose, oral mucosa (particularly the hard palate), or esophagus; the differential diagnosis includes *Vaccinia* virus[3] (an Orthopoxvirus found in cattle only in South America), vesicular stomatitis, foot-and-mouth disease (FMD), and bovine viral diarrhea (BVD). In young feedlot cattle, 2- to 10-mm lesions of BPS are common for the first 4 weeks after arrival.[4] The rate of morbidity may approach 100%. BPS also occurs as a chronic disease in young cattle.[5] It may be the same disease as proliferative stomatitis, muzzle disease, mycotic stomatitis, erosive stomatitis, ulcerative stomatitis, and necrotic stomatitis. In addition to cattle, water buffalo and wild ruminants can be affected.

Ulcerative esophagitis caused by BPS virus in a 5-month-old, unthrifty calf was associated with a 20% morbidity rate in a group of 25 calves.[6] Outbreaks of severe disease associated with BPS with a mortality rate over 50% have been reported. Weight loss and diarrhea accompanied by papular lesions are commonly associated with the severe syndrome. Many lesions are erosions or shallow ulcers with elevated borders, whereas others are obvious raised papules. Lesions are found in the mouth, esophagus, and rumen. There are no lesions on the feet. BPS is commonly seen in calves 1 to 12 months of age and is rare in adult cattle, but outbreaks of confirmed BPS in Brazil and Japan involved the teats of dairy cows as well as the hands of milkers.[7,8] A confirmed case of severe esophageal lesions in an adult bull that died after 2 months has also been reported.[9] The disease is spread by animal contact and appears to be worldwide in distribution.

The first evidence of the disease is the appearance of 2- to 4-mm hyperemic foci, most commonly in the ventral margins of the nares. Similar lesions next appear in the mouth. Within 18 hours they become raised papules. Some lesions enlarge to

form raised plaques over 1 cm in diameter. Lesions regress in 1 day to 3 weeks, leaving a yellow, red, or brown spot that persists for several weeks more.[10] Secondary lesions come and go; some calves are visibly infected for 4 months.[10] Most affected animals have no fever or obvious clinical signs, and they continue to eat normally. Leukopenia was not seen in experimentally infected calves.[10] Secondary lesions appear to be spread through the blood; intravenous inoculation results in similar upper alimentary tract lesions.[11]

Histologic lesions consist of hydropic degeneration of the epithelial cells of the oral mucosa, hyperplasia of the papillae of the lamina propria, and eosinophilic inclusions in the cytoplasm of the degenerating epithelial cells. Lesions reaching the ulcerative stage show secondary necrosis, bacterial invasion, and sloughing of epithelium. These are described in detail in the Contagious Ecthyma (Sore Mouth, Orf, Contagious Pustular Dermatitis, Scabby Mouth) section.

BPS has been associated with the "rat tail" syndrome of feedlot cattle.[12] Of 84 Texas feedlots, 36 reported the problem, with a morbidity rate of 1% to 10%. The syndrome consists of diarrhea, excessive salivation, poor weight gain, and loss of hair from the end of the tail. Sarcocystosis has also been mentioned in association with "rat tail" syndrome.

BPS is capable of causing painful proliferative lesions in human beings.[1] The lesions resemble those caused by CE or pseudocowpox, so they are often described as parapox virus infection. Most often the affected individual has a recent history of examining the mouths of cattle, often with cuts or abrasions on the hands. Lesions in humans apparently are limited to the primary site of inoculation on the hands.

Although ovine ecthyma vaccines are commercially available, no vaccine is marketed for protection against BPS. Local strains of parapoxviruses would be most likely to be more protective than commercial vaccine strains.

Bluetongue

Christie E. Mayo • N. James MacLachlan

Definition and Etiology

Bluetongue is an arthropod-transmitted viral disease of domestic and wild ruminants.[1,2] Clinical disease is largely restricted to sheep and certain wildlife (notably white-tailed deer, mule deer, pronghorn, bighorn sheep, American bison), but other ruminants, including cattle, may show disease in some circumstances. Cattle are considered to be especially common reservoir hosts of bluetongue virus (BTV).

BTV occurs throughout tropical and temperate regions of the world, where different constellations of BTV serotypes are transmitted by different species of *Culicoides* midge vectors in relatively distinct global "episystems."[3,4] Whereas infection often occurs year-round in tropical climates, it is distinctly seasonal in temperate areas, occurring only in the late summer and fall months. Bluetongue is usually manifested only in the temperate areas at the upper and lower limits of the global range of the virus. The global distribution of BTV has altered, perhaps as a consequence of the effect of climate change on the *Culicoides* midges that serve as biological vectors of the virus.[5-7] In particular, since 1998 multiple BTV serotypes spread throughout the Mediterranean Basin and, in 2006, additional virus serotypes invaded and spread throughout extensive portions of northern Europe to precipitate an economically devastating epidemic.[8] Coincident with this invasion of multiple serotypes of BTV into Europe, at least 10 novel BTV serotypes have also appeared in the southeastern United States.[2,9] BTV infection of sheep was detected for the first time in Ontario in 2015, which represents farther northward expansion of the range of BTV in North America.[10]

Although BTV has been isolated from ruminants or *Culicoides* midge vectors, or both, from all continents except Antarctica, the international movement of ruminants is highly regulated, and often severely restricted, for fear of importing BTV into bluetongue-free countries or regions.[11] The continuing occurrence of disease outbreaks globally, the wide host range, the potential for establishment of endemic infection (as has occurred in extensive portions of Europe that previously were free of the virus), and the similarity of some clinical signs of bluetongue to those of vesicular diseases have all made BTV infection the subject of intense regulatory interest worldwide. Import regulations promulgated in reaction to the disease have been more of a threat than the disease itself to the livestock industries of some countries.[12]

BTV is the prototype virus in the genus *Orbivirus* within the family Reoviridae.[13] Other closely related viruses in this genus include epizootic hemorrhagic disease of deer and African horse sickness viruses. The genome of BTV includes 10 distinct segments of double-stranded RNA, each of which encodes at least one protein. The serologic classification of BTV into serotypes is based largely on the protein product of just one genomic segment (the *L2* gene that encodes the VP2 outer capsid protein), but virulence and other characteristics of individual virus strains may not be related to this protein.[14] There is marked genetic variation among field strains of BTV, even viruses of the same serotype and from the same region.[15] The genetic diversity and heterogeneity of field strains of BTV arises as a consequence of both genetic shift and drift. Specifically, genetic shift occurs by reassortment of the individual viral gene segments during infections of cells with more than one virus serotype or strain. Individual genes also evolve by genetic drift during alternating replication in the insect and animal hosts of the virus.[16]

The genetic determinants of BTV virulence are uncertain. At least 30 BTV serotypes are recognized worldwide, but virus strains of the same serotype may have markedly different virulence even to highly susceptible ruminants.[1,2,11,17,18] For example, BTV serotype 8 (BTV-8) is present in the Caribbean Basin, where it has not been associated with major outbreaks of disease, whereas the strain of BTV-8 that appeared in northern Europe in 2006 was highly pathogenic and caused significant production loss and mortality in a variety of livestock species, including cattle.[3,8,17] Some serotypes of BTV (BTV-25 to BTV-27) infect small ruminants but can have properties quite different from those of the "traditional" serotypes (BTV-1 to BTV-24), notably the capacity for truly persistent infections of ruminants and for contact transmission [19-21]

Clinical Signs and Differential Diagnosis

Clinical bluetongue disease is manifested in two ways: (1) as reproductive syndromes and (2) as bluetongue per se, a systemic hemorrhagic viral fever that affects multiple organs but especially the upper gastrointestinal tract, skin, and lungs.[1,2,17] Sheep most commonly are affected, particularly European fine-wool breeds such as the merino and crossbreeds thereof. Bluetongue also occurs in cattle, goats, and South American camelids, but less commonly than in sheep and only after infection with especially virulent virus strains.

In susceptible sheep, the first clinical signs of bluetongue appear after an incubation period of 3 to 7 days or sometimes longer. These signs include a transient fever (up to 41.1°C [106°F] or higher); edema of the face, lips, muzzle, and ears; excessive salivation; and hyperemia of the oral mucosa (Fig. 32.90). Affected sheep usually have a profuse serous nasal discharge that becomes mucopurulent after a few days, leaving crusts around the nostrils and muzzle. The tongue may be cyanotic (hence the name), although this is a relatively infrequent manifestation. The oral lesions progress to petechial hemorrhages, erosions, and ulcers, which are especially prominent on the dental pad and the commissures of the mouth. The oral lesions can be sufficiently painful that affected animals

VetBooks.ir

FIG. 32.90 Face of a sheep with severe bluetongue; note submandibular edema and hyperemia and cyanosis of the lips and tongue (bluetongue).

will not eat, and severely affected sheep will stand over water without drinking. Lameness and stiffness caused by coronitis and myopathy can be severe, and the coronary band characteristically shows petechial hemorrhages and hyperemia. Hemorrhages also may be evident in the subcutis of nonhaired skin such as the inguinal region. Lameness may progress to "knee walking" or recumbency. The hooves may slough, and breaks in the wool are common. Diarrhea, with or without blood, can occur. Many sheep become depressed, are unable to rise, and die, but some severely affected sheep make a full recovery. Pulmonary edema is often marked, especially in fatal cases, and some cases appear to livestock owners to be pneumonia. In fact, acute secondary bacterial bronchopneumonia is often superimposed on the characteristic pulmonary edema of bluetongue. Sudden death, presumably as a consequence of mediator-driven hypovolemic shock or cardiac necrosis and failure, may occur at any time, even in an animal that appears to be recovering. Although the lesions and signs of bluetongue are somewhat characteristic, as is the seasonal occurrence of disease in temperate regions such as much of the United States, the differential diagnosis for sheep showing some of these signs includes sore mouth (contagious ecthyma), FMD, peste des petits ruminants (PPR), and sheeppox.

The reproductive and teratogenic effects of BTV in sheep and cattle vary, depending on the virus strain, the host, and other factors. Reproductive effects, including abortions, stillbirths, and weak but live "dummy lamb" births, were profoundly evident when live attenuated vaccine was administered to pregnant ewes in California in the 1950s.[22,23] In South Africa, where BTV infection has been recognized as endemic since the first descriptions of the disease before 1900, teratogenic effects have not been commonly linked to the virus despite the use of polyvalent live attenuated vaccines and nearly continuous exposure to the virus.[1] However, fetal infections were documented in cattle after these same vaccines were more recently introduced into Europe. Furthermore, it was unquestionably established that these vaccine viruses also circulated naturally after they were introduced into Italy.[24] With the notable exception of circulation of live attenuated vaccine viruses, abortion and teratogenic defects are uncommonly associated with natural BTV infection of livestock in endemic areas.[25] However, major outbreaks of abortion have occurred after the introduction of virulent BTV into immunologically naive populations of sheep.[26-28] Moreover, the strain of BTV-8 that was responsible for the 2006 epidemic in northern Europe crossed the placenta in a substantial proportion of pregnant ruminants, including cattle.[8,17] Some authors have questioned whether this remarkable property of this northern European strain of BTV-8 might imply that it was, at some time in its history, propagated in cell culture, as live attenuated vaccine viruses.

Clinical disease is uncommon among cattle infected with most BTV strains, particularly in BTV-endemic areas.[1,2,11] However, as evidenced emphatically by the 2006 BTV-8 epidemic in northern Europe, disease certainly can occur in BTV-infected cattle. Severely affected cattle exhibit many of the same signs as do affected sheep. Excessive salivation may be the first clinical sign. Hyperemia and necrosis of the muzzle ("burnt muzzle") and a patchy dermatitis may also occur, along with necrosis of the skin of the teats. In cattle, depending on which signs are exhibited, the differential diagnosis should include mucosal disease (BVD), malignant catarrhal fever (MCF), vesicular diseases, rinderpest, photosensitization, BPS, and infectious bovine rhinotracheitis. Clinical disease in cattle can also be difficult to distinguish from FMD and vesicular stomatitis, and appropriate regulatory officials should be notified in such outbreaks. Outbreaks in the United States, North Africa, and the Middle East confirm that the related epizootic hemorrhagic disease virus can also cause a bluetongue-like disease syndrome in cattle that also mimics FMD.[29]

Ocular lesions occur in some BTV-infected ruminants. The syndrome was well characterized during the 2006 BTV-8 epidemic in northern Europe when calves infected transplacentally in late gestation developed transient corneal opacity (blue-eye) after ingestion of colostrum that contained BTV-8–specific antibody.[30] Similarly, non-African ungulates such as European bison at the Berlin Zoological Gardens developed similar ocular lesions after BTV-8 infection.[31] "White eye calf" syndrome was described in Oregon in the 1970s and associated with BTV or epizootic hemorrhagic disease virus infection.[32] It may be that the lesions result from deposition of immune complexes in the eye, analogous to the immune complex–mediated uveitis that follows immunization of dogs with certain canine adenovirus vaccines.

Laboratory Diagnosis and Immunology

BTV infection in livestock is routinely diagnosed serologically by competitive ELISA that detects antibodies to the core VP7 protein of BTV. The test is highly sensitive and specific and detects antibodies to most if not all BTV serotypes. These antibodies persist for long periods after natural infection, although it is not currently possible to distinguish animals that were naturally infected from those that were immunized with live attenuated vaccine. The presence of antibody indicates only prior exposure to BTV and implies nothing about disease causality. Serotype-specific antibody is currently assessed only with laborious and expensive virus-serum neutralization assays.

Identification of BTV infection in animals is most readily accomplished with a group-specific quantitative PCR assay. Such assays are routinely available in diagnostic laboratories and can identify all known serotypes of BTV. Furthermore, the amount of viral nucleic acid can be quantitated, which can be useful in determining the cause of disease. Acutely affected animals generally have large amounts of BTV nucleic acid in their blood and tissues, which is reflected by low cycle threshold values on the assay. Because ruminants remain positive for BTV nucleic acid for up to 6 months or longer after infection, the detection of either viral nucleic acid by quantitative PCR or of antibody to BTV by competitive ELISA is not proof of disease causality. Serotype-specific PCR assays can be used to serotype the virus present. The availability of these assays has largely obviated the need for virus isolation, which is cumbersome, laborious, and expensive and typically takes several weeks. Virus isolation also requires specialized laboratory facilities because some virus strains require initial propagation in

VetBooks.ir

embryonated chicken eggs before they will grow in cell culture systems. Advances in sequencing technologies have facilitated the characterization of the full BTV genome. Full-length sequencing approaches have helped identify novel serotypes (BTV 25-30), as well as characterize the genetic diversity of the virus. In developing a growing database of full-genome BTV sequences has facilitated the design of conventional and real-time PCR assays. [33]

The development of immune tolerance to BTV (in utero infection that results in antibody-negative, virus-positive individuals), as recognized in BVD infections, now is regarded as unimportant in the natural epidemiology of BTV infection, although some controversy persists.[17] Fetuses infected with BTV in late gestation are born viremic (virus positive) and, potentially, before they have had the time necessary to develop an immune response. The fact that these animals are born viremic and antibody-negative should not erroneously be interpreted as immunologically tolerant. However, it has been shown that BTV-25 causes persistent infection in goats, although these animals do develop immune responses to the infecting virus that are detected by standard serologic assays. [20]

Pathophysiology Bluetongue is proposed to be a hemorrhagic viral fever analogous to viral hemorrhagic fevers of humans such as Ebola.[17,34] Specifically, BTV replicates within the endothelium and mononuclear phagocytic cells of infected animals. Vascular injury, particularly to small vessels, is responsible for the manifestations of clinical sigms. Release of cytokine and vasoactive mediators from infected cells leads to capillary leakage and, subsequently, the edema and hemorrhage that are characteristic of fulminant cases. Direct virus-induced vascular injury leads to thrombosis and subsequent infarction of tissues, causing ulcers and manifestations such as the characteristic cyanotic (infarcted) tongue in some severely affected sheep. Teratogenic effects result from direct virus-mediated destruction of proliferating progenitor cells within the central nervous system of the developing fetus after transplacental transmission of the virus in pregnant ruminants. Teratogenic defects occur only when the fetus is infected at critical stages of organogenesis, which is before midgestation (approximately 150 days in cattle and 70 days in sheep). Transplacental infection soon after conception can lead to early embryonic death and cause infertility.[23]

Epidemiology

The development of clinical bluetongue disease is the product of a complex interaction among host, virus strain, vector, and environmental influences.[1,2,11] For example, many of the virus strains that circulate in endemic areas such as California are mildly pathogenic for livestock in the region. Epizootics typically occur when a new virus strain or new animals are introduced into a previously stable ecosystem. For example, the 2006 epidemic in northern Europe was the result of the introduction of a highly virulent strain of BTV-8.[8] In addition to sheep, this virus caused serious disease in cattle, South American camelids, goats, non-African wild ungulates such as yaks and European bison, and even some carnivore species.[31] Environmental alterations that favor the proliferation of midge vectors in a region also promote disease epidemics.

BTV infects wild and domestic animals primarily through the bite of the vector midge of the genus *Culicoides*. There are more than 1400 *Culicoides* species globally; however, only a few have been identified as BTV-competent vectors.[1-3,5,6,11,35] In temperate regions of the world, *Culicoides* midges are abundant in midsummer to early fall, and outbreaks of bluetongue in livestock occur during this time when temperatures support both midge activity and BTV replication within the vector. Other routes of virus transmission are possible even during the interseasonal period in temperate regions (winter, spring, and early summer). For example, it has been shown that BTV can be spread to newborn ruminants via the ingestion of infective colostrum.[36,37] Lastly, although BTV can be transmitted sexually in infected semen and transplacentally from dam to offspring, the importance of these potential routes of virus transmission remains conjectural; they are unlikely to have a major role.[17] Specifically, animals infected in early gestation develop teratogenic brain defects and have cleared infectious virus by the time of birth. Fetuses infected in late gestation can certainly be born viremic and potentially contribute to virus amplification and circulation. Embryo transfer currently is not viewed as a significant risk of BTV transmission if the embryo is washed at least 10 times. In summary, dissemination of BTV by vector *Culicoides* midges is by far the most common method of transmission in endemic areas; however, some serotypes of BTV (notably BTV-26 and BTV-27, and probably BTV-25) can be spread by direct contact transmission without requirement for the insect vector. [19]

In much of North America, the prevalence of bluetongue closely mirrors the distribution and abundance of *Culicoides sonorensis*, with lower rates in northern climates that are less hospitable to the midge and higher prevalence in California and other warmer southern regions.[3,4] However, the vector species in the southeastern United States, where 10 additional serotypes of BTV have appeared, are less defined. Similarly, vector species other than *C. sonorensis* are important elsewhere in the Americas as they are in different regions of the world. In the absence of competent vector populations, animal-to-animal transmission appears to be incapable of maintaining endemic BTV infection; thus BTV-8 disappeared quickly from most of northern Europe.

It remains uncertain as to how BTV is maintained (overwintered) in temperate areas where infection is highly seasonal.[2,11] Although viremia can be prolonged in both cattle and sheep, BTV infection is not persistent in domestic ruminants and insufficient to sustain the virus through the several months of the overwintering period (approximately December through June in the northern hemisphere). Infection of vector midges is persistent and lifelong; however, the life span of midges is relatively short, and so it is unlikely that infected individuals could survive the entire overwintering period. Studies in California have confirmed the presence of BTV-infected parous female *Culicoides* midges in midwinter without concurrent infection of adjacent sentinel cattle, which suggests that long-lived vectors infected in the prior seasonal period of transmission sustain BTV throughout the overwintering period in seasonally endemic areas. [38,39]

The severity of clinical signs in BTV-infected sheep varies by breed. Early in the history of the bluetongue investigation, it was noted that African breeds showed few if any signs of infection, whereas imported European breeds showed fulminant disease. [1,2] More recently, breed differences in immunologic response and susceptibility to disease expression after vaccination with live attenuated BTV vaccine have been reported.[40]

Necropsy Findings

The lesions of bluetongue are characteristic, particularly in sheep.[1,17,41] These include ulcers and hemorrhage throughout the oral cavity, including the dental pad and tongue. These lesions may extend from the esophagus into the forestomachs. Coronitis and subcutaneous hemorrhages and edema, along with edema between the fascial planes of the neck and abdominal musculature, are also common. Other typical findings are pulmonary edema, hemorrhages on the endocardial and epicardial surface of the heart and pulmonary artery, and necrosis of both skeletal and cardiac muscle. Especially characteristic

VetBooks.ir

lesions include gelatinous edema around the nuchal ligament (in addition to the other sites previously listed), subintimal hemorrhages in the pulmonary artery, and discrete focal areas of acute myocardial necrosis in the papillary muscle of the left ventricle. Microscopic study reveals cuffing of inflammatory cells around small vessels in the affected skin and gastrointestinal mucosa with pronounced hypertrophy of the endothelium lining affected vessels, acute and focally extensive necrosis within the musculature of the heart and some skeletal muscles, and pulmonary edema.

Treatment, Prevention, and Control

Treatment of bluetongue in affected ruminants is nonspecific and aimed at supportive and nursing care. Animals with severe oral lesions are reluctant to eat or drink. Valuable animals can be fed gruels of alfalfa pellets by stomach tube and can be encouraged to eat soft feeds or green grass. Muscle and coronary band pain may limit mobility; therefore water and shade must be close at hand. Sulfa drugs or other relatively broad-spectrum antimicrobial drugs can be administered in an attempt to prevent or treat secondary bacterial pneumonia. Antiinflammatory medications that include but are not limited to NSAIDs, aspirin, and flunixin are commonly given.

Elimination of *C. sonorensis* (or other midge vectors) from the environment is usually not practical, but housing sheep indoors during the peak of activity (dusk, early evening) to minimize exposure to biting midges may be beneficial with regard to some vectors. Grazing wet areas such as irrigated pasture only during the heat of the day also may help, as most insects are not active in extreme temperatures. Midges that feed on ivermectin-treated cattle die, but the exchange of virus may occur before the insect's demise. *C. sonorensis* larvae develop in fine-grained mud with high organic matter content, such as those around farm reservoirs, overflowing watering troughs, and shallow septic systems. Elimination of these breeding grounds along with with larvicidal treatments may help in some situations. Especially valuable animals can be housed in insect-proof enclosures to prevent any contact with vector midges during outbreaks, or they may be treated with repellants to minimize the likelihood of vector attack.

Both inactivated and modified live BTV vaccines are available in some parts of the world, and these logically should be based on the local strains and serotypes.[1,2,42,43] Inactivated vaccines are inherently safer than live attenuated ones because the latter have the potential for transmission in nature, reversion to virulence, and the capacity to cross the placenta. There is little cross-protection between BTV serotypes, so animals need to be vaccinated against all serotypes of the virus circulating in a given region. A live attenuated vaccine is available in some western states of the United States for immunization of sheep, but there currently are no vaccines to other endemic serotypes such as BTV-2, BTV-3, BTV-11, BTV-13, and BTV-17.[37] Live attenuated vaccines should be given at least 2 weeks before breeding season to avoid teratogenic effects, and vaccination should be done before the seasonal period of virus transmission (late summer and fall) to avoid infection of vectors and so minimize the likelihood of recombination of vaccine and field viruses. Ewes may be vaccinated late in pregnancy, but there is some risk of inducing abortion. Vaccine should not be administered in early or midgestation because of potential teratogenic defects. Vaccinated breeding rams may have some risk of transiently decreased fertility. Vaccinated and naturally infected animals cannot readily be distinguished by current serologic diagnostic tests. New-generation BTV vaccines have been developed, including recombinant vector vaccines, and virus-like particle vaccines. In addition to being very safe, these vaccines also have the potential to allow vaccinated animals to be distinguished from infected animals (so-called DIVA).[44]

Diseases Caused by Bovine Viral Diarrhea Virus (BVDV)

Paul Walz

Definition and Etiology

Infections with bovine viral diarrhea virus (BVDV) are endemic worldwide, and BVD is recognized as one of the most important infectious diseases of cattle. Not simply confined to causing disease in cattle and the alimentary system as the name would imply, BVDV is a pathogen capable of infecting other ruminants and pigs and affecting multiple physiologic systems, including the reproductive, respiratory, circulatory, immunologic, integumentary, musculoskeletal, and central nervous systems.[1] Reproductive losses and respiratory tract disease are the most consequential economically, and infection of the reproductive system is critical for maintenance and transmission of BVDV within and among cattle populations through the generation of persistently infected (PI) offspring.[2] Infection of pregnant cattle before day 125 of gestation can result in the birth of calves that are immunotolerant to and PI with BVDV.[3] PI calves are the most significant reservoir of BVDV and are at risk for the sporadic, usually fatal mucosal disease.

BVDV is the prototypic member of the genus *Pestivirus* within the Family Flaviviridae. The pestiviruses are enveloped, single-stranded, positive-sense RNA viruses. Historically, the genus *Pestivirus* contained four recognized species that include the two genotypes of BVDV (BVDV-1 and BVDV-2), classical swine fever virus and border disease virus. Genetically distinct pestiviruses that had not been designated as unique species included giraffe virus, Bungowannah virus, pronghorn virus, and HoBi-like viruses. The genus *Pestivirus* has undergone a change in nomenclature by the International Committee on Taxonomy of Viruses, with new species designations of *Pestivirus* A through *Pestivirus* K. The designations *Pestivirus* A through *Pestivirus* D correspond to the classic four species, BVDV-1, BVDV-2, classical swine fever virus, and border disease virus, respectively; the designations *Pestivirus* E through *Pestivirus* K correspond to pronghorn antelope pestivirus (E), Bungowannah virus (F), giraffe pestivirus (G), HoBi-like pestivirus (H), Aydin-like pestivirus (I), rat pestivirus (J), and atypical porcine pestivirus (K).[4] A part of the logic for this new classification scheme is the knowledge that not all BVDV strains are host restricted to cattle.

As in many RNA viruses, mutations can occur within BVDV genomes and lead to genetic, antigenic, and pathogenic variation. BVDV exists as quasi-species, which are different but closely related mutant viral genomes subjected to continuous competition and selection. Nucleotide sequence differences are the most reliable criteria for differentiation of BVDV species. Subgenotypes of BVDV are described within BVDV-1 and BVDV-2 species: 21 among BVDV-1 viruses (1a to 1u) and 4 among BVDV-2 viruses (2a to 2d).[5] Within the North American cattle population, there are three major subtypes, BVDV-1a, BVDV-1b, and BVDV-2a; the BVDV-1b subtype predominates in diagnostic laboratory submissions and prevalence studies of persistent infection.[6] Predominance of the BVDV-1b strains in North America is noteworthy because most vaccines licensed and marketed in the United States contain BVDV-1a and BVDV-2 strains.[7] Strains of BVDV can be also be further subdivided into cytopathic (CP) or noncytopathic (NCP) biotypes on the basis of their effect on cultured cells: CP strains cause vacuolation and death of cultured cells. The effect of the virus in cultured cells is not correlated with virulence, inasmuch as NCP BVDV are associated with cases of severe clinical disease, and only NCP strains of BVDV have been demonstrated, both naturally and experimentally, to induce persistent infection.[8] The NCP biotype predominates in the

cattle population, accounting for approximately 65% to 90% of BVDV isolates.[9] The NCP biotype is often the source of CP strains, which arise by mutations and recombination in the NCP strain.

Epidemiology

PREVALENCE. BVDV is distributed in cattle populations throughout the world as indicated be serologic surveys that test for the presence of neutralizing antibodies to the virus. Exposure to PI animals or vaccination against BVDV can cause seropositivity in an animal within a population. Prevalence of seropositive cattle varies among countries, with differences in seroprevalence rates largely dependent on management of cattle populations examined. Use of vaccines, open versus closed cattle production units, population densities, indoor versus pasture housing, communal grazing, and presence of PI animals greatly influence the numbers of seropositive cattle. Surveys in North America have indicated high seropositive rates in cattle, approaching 90%.[10] In contrast, the number of PI cattle is much lower and is generally believed to account for fewer than 1% of all cattle. In randomly selected beef herds in five U.S. states, the prevalence rates of BVDV persistent infection in individual animals and in herds were 0.17% and 2.7%, respectively.[11] Other persistent infection prevalence studies in beef cow-calf operations within more geographically focused areas in the United States have demonstrated rates between 0.09% and 1.7%, respectively[12,13]; however, not all studies performed have involved randomly selected herds, which can affect prevalence rates considerably. Surveys conducted on United States dairy operations have demonstrated individual animal prevalence rates of 1.9%[14] and 0.13%.[15] PI cattle can be found in clusters within groups of cattle as a result of BVDV exposure in cows at similar times in pregnancy, and this can elevate the prevalence within a studied population. Although it is generally believed PI calves have poor survivability, they can survive to adulthood, become pregnant, and give birth to PI offspring. Of PI calves identified from randomly selected beef herds, 61% survived to weaning and thus were capable of providing a source of virus throughout the breeding season and early gestation.[11] The numbers of PI calves arriving at United States feedlots represent a prevalence rate between 0.1 and 0.4%.[16,17]

HOST RANGE. Cattle are considered the natural host of BVDV; however, BVDV is not strictly specific about hosts.[18] Historically, pestiviruses were assigned according to the species from which they were isolated; BVDV, classical swine fever virus, and border disease virus isolates were recovered from cattle, pigs, and sheep, respectively. Through serologic evidence, BVDV infections have been identified in more than 50 species within 7 of the 10 families of the mammalian order Artiodactyla. Species other than cattle that have been reported to be susceptible to BVDV infection include pigs, sheep, goats, bison, captive and wild cervids, and Old World and New World camelids.[18] Of the heterologous hosts, sheep and goats are considered to have high potential for BVDV infections because they are phylogenetically most closely related to cattle, and sheep and goats can have close contact with cattle under certain management conditions such as subsistence agriculture and hobby farming. Alpacas and white-tailed deer have received attention as heterologous hosts for BVDV infections because of the identification of PI animals. PI alpacas can survive for several months, but low birth weights, failure to thrive, and chronic respiratory and gastrointestinal infections are described in such animals.[19] The BVDV-1b strain is most frequently isolated from PI alpacas and could be the result of introduction and intraspecific spread and maintenance of BVDV1b into North American alpaca populations; an alternative explanation is that unique BVDV1b subgenotypes are able to establish transplacental infections in alpacas.[20]

Infection of wildlife with BVDV has been demonstrated by several serosurveys and, less frequently, virus identification in individual animals. The livestock-wildlife interface is of great concern for a number of infectious diseases, including the related classical swine fever virus in wild boars. Wildlife may become infected with BVDV, but other factors, including shedding of the virus, intrapopulation maintenance, and amount of interspecific contact may influence the establishment of BVDV wildlife reservoirs. Persistent infections of white-tailed deer with BVDV have been demonstrated both by experimental and natural exposure.[21] As in cattle, the most dramatic effects of BVDV infections in white-tailed deer involve the reproductive system. Shedding of BVDV through nasal or rectal routes has been demonstrated in acutely infected and PI white-tailed deer, and shedding has resulted in transmission to other white-tailed deer.[22,23] Apparent prevalence rates of persistent infections in United States cervid populations were between 0.03 and 0.3% in tested populations.[24-26] Whether BVDV infection in these populations originated from contact with cattle or was the result of an endemic cycle is unknown.

Identification of heterologous PI hosts may have important implications for the epidemiologic behavior of BVDV; of most importance is that nonbovid PI animals may serve as reservoirs for BVDV. As reservoirs, nonbovid PI animals could threaten the health and well-being of other artiodactyls, including cattle, and adversely affect outcomes and ultimate success of organized BVDV control and eradication efforts.[27]

TRANSMISSION. Methods of BVDV transmission can be classified as vertical and horizontal. With BVDV, horizontal and vertical transmissions are closely related, as horizontal transmission to a pregnant cow can result in vertical transmission to the developing fetus (Fig. 32.91). As stated previously, PI cattle can reach adulthood. Calves delivered from PI dams are themselves PI; however, the status of most PI offspring is the result of an acute infection, or horizontal transmission, in the dam.[11] BVDV can be horizontally transmitted continuously by PI animals and briefly by animals during an acute infection. As with other viral diseases, factors controlling BVDV transmission in a susceptible population are the infectiousness of the virus, the contact rate between infectious and susceptible animals, the duration of infectiousness, and the proportion of the population that is naive and susceptible.[28] Cattle PI with BVDV shed large amounts of virus their entire life and are the major source of BVDV transmission both within and among herds. They are capable of shedding virus from nasal secretions, urine, feces, milk and colostrum, uterine fluids, saliva, tears, and semen.[29] Direct contact with these body fluids from PI cattle is the most efficient method of horizontal BVDV transmission, inhalation and ingestion being the most common routes. Although heterologous PI hosts are capable of BVDV in nasal secretions in amounts equivalent to those shed by PI cattle,[21] they are assumed to play a reduced role in BVDV transmission because rates of contact rates between infectious heterologous hosts and susceptible cattle are lower.

Acutely infected cattle also have a limited role in BVDV transmission because levels and duration of virus shed are considerably lower; however, potential for transmission of BVDV after acute infection can be greatly influenced by the virulence of the acutely infecting strain of BVDV, the proportion of naive animals being exposed, and the immune cross-protection acquired through either vaccination or exposure to field strains of virus. Calves acutely infected with a highly virulent strain of BVDV shed greater amounts of virus and for a longer duration,[30] and so they theoretically are a source of transmission. However, an experimental study demonstrated no spread of infection from acutely infected to susceptible animals even though they were in close contact, which further emphasizes the importance of virus and host characteristics during

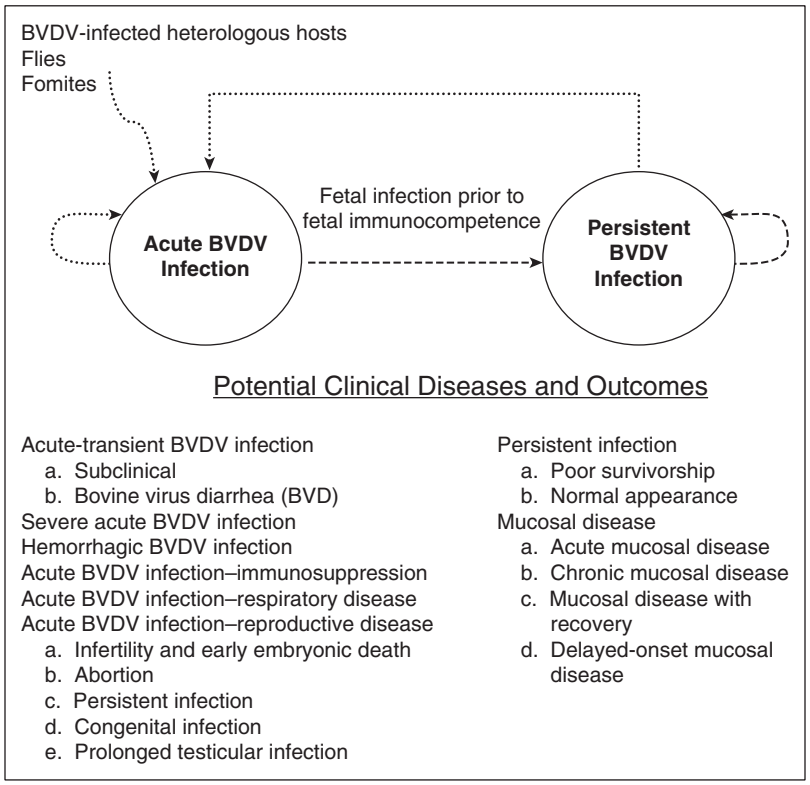

FIG. 32.91 Two forms of bovine virus diarrhea virus (BVDV) infection: acute and persistent. Routes of horizontal transmission are indicated by *dotted lines* (most consequential is from persistently infected [PI] cattle to naive cattle); routes of vertical transmission are indicated by *dashed lines* (most consequential is acute BVDV infection in pregnant cattle). Potential clinical diseases are not exclusive, and multiple clinical forms can be observed in the same population of cattle.

transmission.[31] After acute BVDV infection, virus can be found in nasal secretions usually for only a few days between 4 and 10 days after exposure.

Although contact with PI cattle is the most widespread cause of BVDV transmission, infections with BVDV in the absence of PI cattle have been described in seronegative herds.[32] Spread of BVDV can occur in the absence of PI cattle as a result of direct contact with acutely infected animals, contact with heterologous hosts, or indirect contact. Because BVDV is an enveloped virus, it is unstable at low or high pH and at high temperatures but can survive in a cool, protected environment for several weeks.[29] Temperature has a major influence on BVDV survival in manure slurry: The virus can remain infective for more than 6 weeks at 5°C but less than 2 weeks at 20°C.[33] According to research with the related classical swine fever virus, BVDV is probably susceptible to common disinfectants such as chlorhexidine, phenols, iodophors, aldehydes, and hypochlorites.[34] Indirect transmission through contaminated needles and equipment and through insect vectors has been demonstrated experimentally.[35,36] Insects such as stable flies, horse flies, and face flies can serve as potential sources of BVDV infection[35,37]; however, the horn fly, a common fly species affecting cattle, cannnot transmit BVDV between PI cattle and BVDV-naive cattle.[38]

Bulls acutely infected and PI with BVDV are capable of shedding virus in semen and have the potential for horizontal and vertical transmission.[39-41] The virus may survive cryopreservation and processing of semen for artificial insemination.[42] Although acutely infected bulls shed lower concentrations of BVDV in semen than do PI bulls, infection of artificially inseminated heifers may result from the use of semen from acutely infected bulls before seroconversion.[40] Prolonged, localized testicular infections have also been described after experimental BVDV infection of postpubertal bulls; however, their prevalence and epidemiologic significance are probably low.[43]

Herd-to herd transmission usually occurs through acquisition of PI cattle or pregnant cattle that are carrying PI fetuses. Introduction of pregnant adult females carrying PI fetuses, aptly named "Trojan dams," have been recognized as an important source of infection transmission to BVDV-free herds.[44] Cattle operations that have purchased cattle within the past 5 years are at highest risk for having PI animals.[45] Purchase of new cattle incubating an acute infection or exposure to other cattle through fence line contact, communal pastures, and animal exhibitions can also enable BVDV introduction into a herd.

Clinical Signs and Differential Diagnoses

BVDV infection in cattle may result in a complex spectrum of clinical manifestations ranging from subclinical to fatal disease. The virus is capable of infecting multiple organ systems, often concurrently. Clinical manifestations are dependent on the interplay of host factors, environmental stress levels, and viral factors.[46] Host factors influencing the outcome of viral infection include immune status, pregnancy status, gestational age of the fetus at the time of infection, and whether the host is immunotolerant or immunocompetent. Viral factors include biotypic variation, genotypic variation, and antigenic diversity. With regard to the clinical manifestations of BVDV infection in cattle, both BVDV-1 and BVDV-2 strains can be involved in the entire spectrum of clinical disease, including acute and persistent infections. Two states of infection (acute and persistent) are possible with BVDV infections in ruminants, and this is the basis for discussion of clinical signs and pathogenesis within this text (see Fig. 32.91).

VetBooks.ir

Disease Associated With Acute BVDV Infection

The terms *acute*, *primary*, and *transient* have all been used to describe BVDV infection in postnatal cattle. Although postnatal cattle are able to respond immunologically to BVDV, immunosuppression induced the by virus is an important contribution to pathogenesis and clinical disease. For discussion of clinical disease states, acute BVDV infections can be further subdivided into six disease categories: acute-transient BVDV infection, severe acute BVDV infection, hemorrhagic BVDV infection, acute BVDV infection/immunosuppression, acute BVDV infection/respiratory disease, and acute BVDV infection/reproductive disease.

ACUTE-TRANSIENT BVDV INFECTION. Acute-transient BVDV infection occurs in postnatal cattle. In most situations, the disease occurs in cattle considered BVDV naive, but disease could potentially occur in cattle seropositive for BVDV that become infected with a heterologous BVDV strain. Most acute BVDV infections occur without clinical manifestations; up to 90% of BVDV infections are estimated to occur without clinical signs.[46] If cattle are observed closely, however, mild fever, leukopenia, and a decrease in milk production can be observed. Exposed cattle develop BVDV-specific neutralizing antibodies. If a pregnant animal has even subclinical BVDV infection, deleterious effects can be manifested in the fetus.

Bovine viral diarrhea is the term used to describe the clinical form of BVDV infection in immunocompetent cattle, and digestive tract disease manifested by severe diarrhea was part of the original description of BVD in 1946.[47] The incubation period for acute BVDV in naive cattle is 5 to 7 days. After oronasal uptake, BVDV initially replicates in nasal mucosa and tonsils. Viremia typically lasts for several days starting around day 3 after infection, but it can last for up to 15 days. During this period of viremia, spleen, thymus, lymph nodes, gastrointestinal epithelium, and the respiratory tract can become sites of further viral replication. Clinical signs of BVD include depression, oculonasal discharge, anorexia, fever, oral erosions and ulcerations, diarrhea, and, in lactating cows, decreased milk production. The respiratory rate may be rapid, which may be interpreted incorrectly as pneumonia. Clinical pathologic changes such as leukopenia are observed in calves acutely infected with BVDV.[46] The major decreases in the total leukocyte count have been in the numbers of neutrophils and lymphocytes.

One of the most important determinants for the outcome of acute BVDV infection in susceptible animals is the virulence of the infecting BVDV strain.[48] Experimental infections with BVDV strains of low and high virulence reveal similar initial infection and patterns of dissemination through the body but differences in the amount of virus in tissues and in speed of dissemination.[49] Virulent strains of BVDV result in widespread distribution of virus in tissues, and BVDV strains that induce high levels of viremia result in more severe clinical signs. Viral replication and antigen distribution can be detected in the thymus, lymph nodes, Peyer's patches, tonsils, and spleen with all strains of BVDV. In contrast to strains of BVDV with low virulence, in which antigen is found only outside of lymphoid tissues in the intestinal mucosa, antigen against high virulent strains can be found in bone marrow, intestinal mucosa, respiratory tract, endocrine tissues, and nervous system tissues after acute infection.[49] The HoBi-like viruses have received considerable attention because of their emergence and detection in South America, Europe, and Southeast Asia, and natural descriptions and experimental reproductions of infection with HoBi-like viruses have revealed very mild disease signs in cattle. Most description of HoBi-like virus infection in natural settings are related to either respiratory disease or reproductive disease, specifically abortion. During experimental reproduction of the disease, clinical signs associated with HoBi-like virus infection can be indistinguishable from those of BVDV infection with strains of low virulence.[50]

Disease associated with acute BVDV infection is often observed in seronegative cattle between the ages of 6 to 24 months. It is generally believed that maternally derived BVDV-specific antibodies have waned and acquired immunity is not yet formed, and thus calves as young as 4 to 6 months of age are susceptible. Maternally derived BVDV-specific colostral antibodies are thought to be protective unless sufficient antigenic diversity exists between the challenge strain and strain against which the maternally derived colostral antibodies were developed. Disease as a result of acute infection can be observed in preweaned calves.[51] Acute disease in neonatal or preweaned calves can result in signs of pneumonia or enteritis, often in association with failure of passive transfer. In studies of the duration of maternal colostrum-derived antibodies against BVDV-1 and BVDV-2, a major finding is the variability in duration between calves as a result of colostrum quality and consumption. Estimated mean time to reach seronegative status in dairy calves receiving maternal colostrum was 117.7 ± 37.7 days for BVDV-1 and 93.9 ± 61.9 days for BVDV-2.[52] In another study, the mean duration for colostrum-derived antibodies in beef calves was 185.6 ± 59.8 days for BVDV-1 and 157.8 ± 56.1 days for BVDV-2.[53]

Diarrheal diseases considered in the differential diagnosis for acute BVDV infection in adults include salmonellosis, winter dysentery, paratuberculosis, intestinal parasites, MCF, arsenic poisoning, and copper deficiency (molybdenosis). The differential diagnoses for acute BVDV infection for the neonatal period includes other causes of diarrhea in young calves, such as rotavirus or coronavirus infection, cryptosporidiosis, enterotoxigenic *E. coli* infection, salmonellosis, and coccidiosis. Other causes of calf pneumonia such as bovine respiratory syncytial virus, pasteurellosis, hemophilosis, or mycoplasma infection should also be considered.

SEVERE ACUTE BVDV INFECTION. An atypical and significantly more severe form of BVDV infection was first described in cattle in the late 1980s.[54] The disease had a peracute course, caused morbidity in high rates, and resulted in substantial numbers of deaths in all age groups. In Quebec, mortality due to BVDV in veal operations was estimated at 25% of 143,000 calves for 1993.[55] The outbreak in Ontario involved 150 dairy, 600 beef, and 100 veal herds. The severity of disease varied among herds; in some herds, mortality rates were 10 to 20% in all age groups of cattle. Clinical manifestations of severe, acute BVDV infections include diarrhea, pyrexia, decreased milk production, and, frequently in older cattle, oral ulcerations. Because of the presence of severe clinical disease in combination with oral ulcerations, mucosal disease was a primary part of the differential diagnosis in the late 1980s and early 1990s. Other diseases that cause oral lesions in cattle include MCF, vesicular stomatitis, papular stomatitis, FMD, and bluetongue. Abortions in cattle also were common. These outbreaks of severe clinical disease were reported to be associated with the introduction of cattle to the herd or history of inadequate vaccination programs.[54] BVDV isolates from outbreaks in Canada and the United States were analyzed, and NCP isolates were obtained from affected cattle. Nucleotide sequencing of the RNA genome of these isolates revealed a distinct group of BVDV, which were designated as BVDV-2,[56] which is now considered a separate species within the genus *Pestivirus*.

The outbreaks of severe BVDV infections clearly demonstrated that some BVDV strains can cause severe life-threatening disease in postnatal, immunocompetent cattle. Before 1993, it was believed that the majority of BVDV infections in immunocompetent, adult cattle resulted in subclinical or mild

VetBooks.ir

disease. Although BVDV-2 strains were associated with severe acute BVDV infections, not all BVDV-2 strains cause severe disease. Furthermore, it is likely that some BVDV-1 strains are capable of inducing severe clinical disease under unfortunate conditions involving host, agent, and environment factors.

HEMORRHAGIC BVDV INFECTION. The hemorrhagic syndrome, which is characterized by thrombocytopenia, is an additional form of severe acute BVDV infection in immunocompetent cattle.[57] Hemorrhagic syndrome was first described in both calves and adult cattle naturally infected with BVDV; severe depressions in platelet counts and high case fatality rates were reported.[58] Clinical manifestations of the hemorrhagic syndrome are related primarily to thrombocytopenia and include bloody diarrhea, epistaxis, petechial hemorrhages, ecchymotic hemorrhages, hyphema, and bleeding from injection sites or insect bites. Fever, diarrhea, rumen stasis, and dehydration are also common. In addition to thrombocytopenia, leukopenia characterized by severe neutropenia and lymphopenia are clinical pathologic abnormalities. Thrombocytopenic BVDV infections have been experimentally reproduced, almost exclusively with NCP BVDV-2 strains[57,59]; however, hemorrhagic syndrome has been reported after experimental inoculation of colostrum-deprived calves with a BVDV-1b strain.[60] Platelet dysfunction has also been described with experimental BVDV infection[61]; thus quantitative and qualitative platelet defects contribute to the hemorrhagic diathesis observed in infected cattle. Bone marrow infection, specifically BVDV infection in bone marrow megakaryocytes, may be important in the origin of BVDV-induced thrombocytopenia.[30,62] Diseases that can mimic hemorrhagic syndrome include septicemia with subsequent development of disseminated intravascular coagulation, sweet clover poisoning, and bracken fern poisoning.

ACUTE BVDV INFECTION/IMMUNOSUPPRESSION. Although the majority of BVDV infections in immunocompetent cattle are transient and self-limiting, it is apparent that when infection occurs in the presence of other microorganisms, BVDV can contribute to disease that becomes clinically evident. Numerous studies, under both natural and experimental conditions, have demonstrated the relationships between BVDV and other infectious agents. The virus has been reported to enhance the pathogenicity of bovine herpesvirus-1 (BoHV-1), actinomycosis, papular stomatitis, enteritis caused by *Salmonella* spp., colibacillosis, metritis, and mastitis. The role of BVDV in synergistic or mixed infections with other agents is probably to cause immunosuppression.[63] Mechanisms responsible for BVDV-induced immunosuppression are probably multifactorial; however, critical information on mechanisms of the suppression, the duration and extent of recovery, and the long-term effects are undetermined.[27] The ability of BVDV to induce quantitative and qualitative defects in leukocytes could provide some contribution to immunosuppression.

The defects involve immune system cells of both the innate and adaptive immune responses. A transient leukopenia occurs in most cattle acutely infected with BVDV that may be more severe with BVDV-2 than with BVDV-1. Decreases in helper ($CD4^+$), cytotoxic ($CD8^+$), and gamma/delta T-lymphocytes, as well as B-lymphocytes and neutrophils, have been reported and these decreases are often strain dependent.[64] The mechanism of leukopenia has been explained in several possible ways; these include immune system removal of BVDV-infected immune cells, destruction of immune cells by BVDV, and increased trafficking of immune cells into tissue sites of viral replication. During acute infection, various levels of lymphoid depletion are observed in the thymus, spleen, lymph nodes, and gut-associated lymphoid tissues (Peyer's patches).[65] The NCP BVDV strains are lymphotrophic, and lymphocyte apoptosis in lymphoid tissues results in cytolysis and lymphoid depletion.

Decreased functional responses in immune system cells have also been described during acute BVDV infection, and affected cells include lymphocytes, neutrophils, monocytes, and macrophages.[66,67] Dysfunction in both B and T cells has been demonstrated by poor culture response to phytohemagglutinin, pokeweed mitogen, and concanavalin A stimulation and by decreased production of interferon.[68] Infection of peripheral monocytes in vitro caused a significant decrease in the chemotactic responses to lymphokine.[69] Immunohistochemical and flow-cytometric studies have demonstrated that BVDV infects and replicates in antigen-presenting cells.[70] Infection of monocytes with BVDV has been shown to stimulate the synthesis of cytokines that may reduce their ability to stimulate T cell responses to specific antigens and mitogens. A decrease in the secretion of TNF-α from LPS- or *Salmonella*-stimulated bone marrow–derived macrophages that had been infected with BVDV has been reported.[71] These abnormalities, in combination with environmental or management stressors, or both, contributes to immunosuppression and concurrent infection with other pathogens. Increased susceptibility to other secondary infections is a consequence of BVDV-induced immunosuppression.

ACUTE BVDV INFECTION/RESPIRATORY DISEASE. Substantial data demonstrate that BVDV infection plays an important role in polymicrobial disease, and the bovine respiratory disease complex in feedlot animals and intensively housed calves is the best example of this type of disease process. In North American feedyards, bovine respiratory disease is the most frequently reported cause of morbidity and mortality. The role of BVDV in the bovine respiratory disease complex is debatable as to whether BVDV-induced immunosuppression or primary infection of the respiratory tract plays the major role, but BVDV can be isolated from pneumonic cattle more frequently than other viruses.[72] Certain BVDV strains may be pneumotrophic, as evidenced by some BVDV strains that cause interstitial pneumonia in experimentally inoculated calves.[73]

BVDV may play a secondary role in bovine respiratory disease complex through immunosuppression. Although BVDV is frequently isolated from cattle with pneumonia, it is often isolated with the other infectious agents typically associated with bovine respiratory disease complex. Reports from disease outbreaks and experimental studies have supported a synergistic role of BVDV with BoHV-1 and bovine respiratory syncytial virus.[74,75] Calves experimentally inoculated with BVDV 7 days before inoculation with BoHV-1 developed more severe clinical disease, with dissemination of BoHV-1 into nonrespiratory tissues such as intestinal and ocular tissues, than did calves inoculated with BoHV-1 alone.[74] Initial BVDV infection may impair the ability of calves to clear BoHV-1 from the lungs and to contain BoHV-1 at the local infection site. Synergism between BVDV and bacterial pathogens, specifically *Mannheimia haemolytica* and *Mycoplasma bovis*, has also been described.[76,77] Viral-bacterial synergy in bovine respiratory disease complex probably is the result of BVDV compromise of the host defense mechanisms. Viral damage of nasal turbinate and tracheal epithelium alters mucociliary clearance of bacteria with subsequent bacterial attachment and colonization. The innate defenses of the lung are compromised with BVDV infections of macrophages and neutrophils, which results in depletion, destruction, or impairment in function. B and T cell–mediated immune responses can also be suppressed as a result of BVDV infection.[63]

ACUTE BVDV INFECTION/REPRODUCTIVE DISEASE. Reproductive tract infections have been described for male and female cattle. The importance of BVDV on the male reproductive tract has not received attention equivalent to the effects on female reproduction for a number of reasons, but from a

VetBooks.ir

transmission standpoint, acutely infected bulls and PI bulls are capable of shedding virus in semen.[39] Either acceptable or unacceptable semen quality may be observed in bulls acutely infected with BVDV. Although acute BVDV infections generally result in a transient viremia with subsequent clearance of the virus by the host immune system, a localized, prolonged infection of testicular tissue with NCP BVDV has been described in both natural and experimental conditions.[39,41] The original description of prolonged testicular infection with BVDV was identified in the testes of a seropositive, nonviremic bull at an artificial insemination center.[41] Despite absence of viremia, the bull continuously shed infectious BVDV in semen throughout his life, and the semen of this bull resulted in infection and subsequent seroconversion of an inseminated seronegative heifer.[78] Furthermore, this bull displayed a consistently high concentration of circulating serum antibodies that neutralized the specific viral strain that was persistently shed in the semen. Since that original description, prolonged testicular infections with BVDV have been reproduced in post-pubertal bulls. Viral RNA has been detected in semen for 2.75 years after BVDV exposure, and infectious virus grown from testicular tissue has been detected up to 12.5 months after BVDV exposure.[39] Protection from a systemic immune response due to a blood-testes barrier is believed to be the mechanism for the localized, prolonged testicular infection.

Infection with BVDV can cause significant reproductive problems in nonimmune pregnant cattle, including fertilization failure, embryonic death, abortion, persistent infection, and congenital defects (Fig. 32.92). Transplacental infection is a common event in pregnant cattle exposed to BVDV, and in experimental studies, transplacental infection occurs with almost 100% efficiency.[79] As discussed previously, most acute BVDV infections are subclinical, but infection in pregnant cattle may result in significant disease. The economic damage caused by BVDV in susceptible herds is associated mainly with the outcomes of intrauterine infections. The outcome of fetal infection with BVDV is dependent on three main factors: (1) time of infection (i.e., gestational age of the fetus at the time of infection); (2) organ system involved in the infection; and (3) properties of the virus (i.e., biotype, virulence, and target cell range). Of importance is that BVDV-1 and BVDV-2, as well as CP and NCP strains, can result in reproductive disease, although only NCP strains are capable of resulting in PI cattle.

Infertility and Early Embryonic Death. Infection of cattle before insemination can result in impaired conception rates.[80] This may be due in part to ovarian infection and dysfunction as a result of BVDV viremia. Viral antigen in macrophage-like cells and ovarian stromal cells and oophoritis have been described in cattle acutely infected with NCP BVDV[81] and in cattle vaccine with modified live-virus vaccines containing CP BVDV.[82] Of particular interest is that pathologic change and BVDV antigen were detected in some cattle up to 60 days after infection.[83] The first 45 days of gestation are the embryonic period, and conception and pregnancy rates are lower if cattle are exposed at the time of insemination and become viremic during the first 3 weeks of pregnancy.

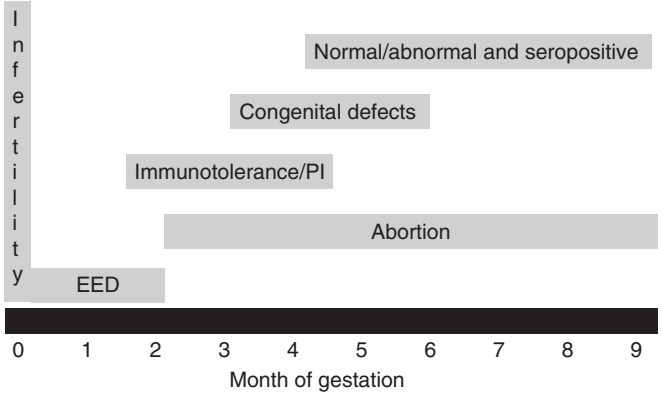

FIG. 32.92 Potential reproductive outcome after infection with bovine virus diarrhea virus during different stages of gestation. *EED*, early embryonic death; *PI*, persistent infection.

Abortion. BVDV infection can cause abortion at any time during gestation. Fetal resorption, mummification, or expulsion can occur after fetal death, depending on the gestational age of the fetus at the time of infection.[84] Although fetal death and abortion are most common during the first trimester, material from middle- and late-term abortions and stillbirths should be examined for BVDV. Diagnostic laboratory surveys indicate that BVDV isolation prevalence from aborted animal fetuses in the United States is quite variable; BVDV has been isolated in as few as 0.1% and as many as 27.2% of submitted fetuses.[85,86] After BVDV infection, expulsion of the fetus may occur shortly or may be delayed for several months after infection. As a result of delayed expulsion after fetal death, isolation of BVDV from aborted fetuses may not be successful. This has also been demonstrated experimentally, whereby abortion was observed 30 to 50 days after experimental infection at approximately days 100 to 120 of gestation.[87]

Persistent Infection in Offspring. Gestational days 45 to 125 are the period of fetal development during which fetal immunocompetence for BVDV develops. The most outstanding outcome of infection during this period is the development of persistent infection. Immunocompetence for BVDV is not absolute at day 125 of gestation, and the dams of most PI calves were exposed before gestational day 100. By definition, cattle that are PI with BVDV are immunotolerant to BVDV. Biotype plays an important role in infection during this period of gestation. Abortion can occur with infection with both CP and NCP strains of BVDV; however, only NCP strains are capable of causing persistent infection.[8] The PI animal's body cannot recognize the infecting NCP BVDV as foreign. Immunotolerance is specific to the infecting NCP strain of BVDV, and after birth, PI animals can respond immunologically to heterologous strains of BVDV. For this reason, PI animals may be seropositive for BVDV, and seropositive status cannot be utilized diagnostically to rule out persistent infection.

Congenital Defects. Congenital malformations are associated with BVDV infection during the gestational period of organogenesis, which occurs approximately between days 100 and 150 of gestation.[79] Congenital malformations that have been reported in association with BVDV infection include cerebellar hypoplasia, hypomyelinogenesis, hydranencephaly, alopecia, cataracts, optic neuritis, brachygnathism, hydrocephalus, microencephaly, thymic aplasia, hypotrichosis, pulmonary hypoplasia, and growth retardation. Congenital malformations may be due to the direct result of viral infection on developing cells, or the host immune response in destroying virally infected cells. During a point-source of exposure of BVDV into a bred population of cattle, congenitally malformed calves will be born just before the birth of PI animals, and this information can be useful for determining sampling of calves for BVDV.

BVDV Infection During Later Stages of Pregnancy. Fetal infections can occur in the last trimester, but at this stage of gestation, organogenesis is often complete and fetuses are considered immunocompetent to BVDV. Congenital infection during this period usually results in the birth of a calf that is seropositive on a precolostral blood sample. Detrimental effects of BVDV infection in late gestation seem to be less common; however, weak calves and abortions have been reported.[79] It has generally been accepted that infection in late gestation results in the birth of calves that are clinically normal; however, calves congenitally infected with BVDV may

VetBooks.ir

be at greater risk for increased morbidity and mortality postnatally.[88] The congenitally infected calves that are born with neutralizing antibody titers to BVDV have been shown to be twice as likely to experience a severe illness during the first 10 months of life as are calves born free of BVDV antibody titers.[88] The prevalence and importance of congenital infections remains to be determined.

Disease Associated With Persistent BVDV Infection

PI cattle are the main reservoir for BVDV. Cattle PI with BVDV are characterized by a wide distribution of BVDV throughout their organs as a result of lacking an immune response to the persisting BVDV strain. In PI animals, the virus is present throughout all organs and tissues; therefore BVDV is shed in multiple body excreta, including nasal discharges, urine, semen, colostrum/milk, and feces. Some PI calves are born weak and stunted and die shortly after birth[46]; however, many PI calves are born without any observable abnormalities and can survive for at least several months. This is important for beef cattle herds because these animals can survive into the start of the subsequent breeding period and thus become an important source of horizontal transmissions. PI cattle can have decreased survival, as evidenced by reports documenting a mortality rate higher than 50% in the first year of life.[89] This mortality may be due in part to the fact that PI cattle may have an impaired immune response, which makes them more susceptible to opportunistic pathogens. The rate of vertical transmission is 100% as PI cows give birth to PI offspring.

PI cattle are at risk of developing mucosal disease. Mucosal disease is the most dramatic of BVDV-associated clinical disease because of the severity and characteristics of lesions. Mucosal disease occurs when cattle that are immunotolerant and PI with NCP BVDV become infected with a CP BVDV.[90] Because mucosal disease occurs only in PI cattle and PI cattle are less than 1% of the cattle population, it is characterized as a disease with low case attack rate and high case fatality rate. Although the origin of the CP BVDV can be external, such as after the use of modified live-virus vaccines, current theory holds that in the majority of cases of mucosal disease, the CP BVDV represents a mutation of the NCP BVDV (the persistently infecting biotype).[90] There are multiple clinical forms of mucosal disease; the variations are due to the antigenic relationship between the persistently infecting NCP strain and the superinfecting CP strain.[90] The multiple clinical forms of mucosal disease can be categorized as acute (fatal) mucosal disease, chronic mucosal disease, chronic mucosal disease with recovery, and delayed-onset mucosal disease.[90]

ACUTE MUCOSAL DISEASE. Acute mucosal disease occurs when the superinfecting CP strain shares close antigenic homology to the PI NCP strain. The CP strain may arise de novo by a mutational event from the NCP strain in the PI animal. The mutational event affects the viral biotype but does not affect the viral antigenicity.[91] The clinical findings associated with acute mucosal disease include pyrexia, depression, anorexia, decreased milk production, profuse diarrhea, ptyalism, mucopurulent oculonasal discharge, and oral erosions.[46] Oral erosions are present on the lips, gingival margins, tongue, dental pad, and the hard palate. Experimental reproduction of acute mucosal disease indicates an incubation period of 7 to 14 days.[90] Acute mucosal disease is considered 100% fatal.

CHRONIC MUCOSAL DISEASE. Chronic mucosal disease and mucosal disease with recovery are forms of mucosal disease in which the superinfecting CP strain is heterologous to the PI NCP strain. The likely source of the superinfecting CP strain is external, rather than a mutational event in the PI NCP strain. The clinical manifestations of chronic mucosal disease are anorexia, weight loss, diarrhea, chronic bloat, alopecia, erosive lesions on the mouth and skin, and lameness.[46] The lameness may develop as a result of laminitis, interdigital necrosis secondary to erosive lesions, and hoof deformities. In rare cases, a PI animal may mount an immune response to the superinfecting, heterologous CP strain and clear the superinfection; this situation has been referred to as *mucosal disease with recovery*.[90] Although recovery may be possible, a PI animal will always remain PI with the NCP strain.

Necropsy Findings

Pathologic lesions associated with BVDV infection can be quite diverse in types and degree and, like the clinical manifestations, are dependent on host and viral factors. Age of animal, immune status at the time of infection, and the presence of concurrent infections greatly influence the pathologic observations. Many lesions observed are not specific to BVDV infection; thus laboratory testing becomes an important component in the diagnostic process. Occasionally, only microscopic lesions are present, and unless histopathologic study is performed, a lesion can be unnoticed and infection undiagnosed.

ACUTE BVDV INFECTION. Animals that die of acute BVDV infection have less severe lesions. In addition, lesions, when present, can often be nonspecific and subtle. Edematous intestines, occasionally with ecchymotic hemorrhages and mild reaction in mesenteric lymph nodes, can be observed. Occasionally, linear erosions in the alimentary tract and proximal colon are present, along with atrophy of gut-associated lymphoid tissues (Peyer's patches). Secondary bacterial infections such as enteritis, pneumonia, or mastitis are present and have contributed to death. Animals that die of hemorrhagic syndrome can have evidence of hemorrhage in many organ systems, including the gastrointestinal, cardiovascular, respiratory, and urinary systems. Petechial or ecchymotic hemorrhages are often apparent on mucosal surfaces, and hemorrhage in the gastrointestinal submucosa and Peyer's patches may be significant. Lesions associated with cases of severe acute BVDV infection can be similar to lesions associated with mucosal disease. Because of this and the severe clinical signs observed, it is usually not possible to differentiate the two forms of disease without supporting laboratory testing.

MUCOSAL DISEASE. Postmortem examination of cattle dying of mucosal disease usually reveals gross abnormalities most prominent in the alimentary system. Animals that die of mucosal disease usually have severe, necrotizing erosive or ulcerative lesions involving the mouth, tongue, esophagus, ruminal pillars, omasum, abomasum, intestines, and cecum.[92] Erosive lesions may extend onto the external nares and into the nasal cavity. Ulcers involving the esophagus typically are linearly elongated. Peyer's patches in the small intestine often are necrotic and hemorrhagic. Bowel contents are watery, hemorrhagic, and foul smelling. Pathologic gastrointestinal conditions may be absent or very mild in cattle with chronic mucosal disease, although histopathologic lesions usually are present with atrophy of Peyer's patches. Skin lesions are often found and include patchy hyperkeratosis around the neck, shoulder, and perineal areas. Erosive lesions involving the perineal area, the prepuce, and the interdigital cleft and coronary band of the hoof may be present. Skin lesions are most apparent in cattle suffering from chronic mucosal disease.

ABORTIONS AND CONGENITAL DEFECTS. Pathological criteria for the diagnosis of BVDV as a cause of abortion are not established. Fetuses aborted as a result of in utero BVDV infection often are autolytic when expelled. Lesions found in aborted fetuses and the accompanying placentas are nonspecific

VetBooks.ir

for BVDV. Under experimental conditions or when aborted fetuses are expelled soon after death, lesions observed include conjunctivitis, peribronchiolar and interalveolar pneumonia, and nonspecific myocarditis. A significant decrease in cerebellar mass may be evident in calves affected by cerebella hypoplasia as a result of in utero infection with BVDV during the second trimester of gestation. Other common congenital defects associated with BVDV infection that may be noted at necropsy include cataracts and thymic hypoplasia.

Diagnosis

Numerous methods are available for detecting BVDV infection. The choice of test depends on the clinical problem, the availability of tests by different diagnostic laboratories, and financial considerations (Table 32.12). Because the clinical manifestations of BVDV are diverse, accurate diagnosis of BVDV infection relies on laboratory testing. Sample selection and handling for BVDV testing is critical because the initial test material largely defines success or failure of the diagnostic test.[93] The introduction of PCR has transformed viral diagnostics, and real-time PCR technology has further improved the already significant benefits of traditional PCR. Real-time PCR has become the tool often used by diagnostic laboratories for the detection of BVDV.

VIRUS ISOLATION. Virus isolation is a basic, reliable, and widely used method for diagnosis of BVDV infection, and remains the "gold standard" of BVDV diagnostic tests. The BVDV may be cultured and isolated from many samples, including serum, whole blood, semen, nasal swabs, and various

TABLE 32.12

Diagnostic Testing for Bovine Virus Diarrhea Virus (BVDV)

Clinical Form	Diagnostic Test	Specimen	Comments
Acute-transient BVDV infection	Virus isolation PCR	Serum, whole blood or nasal swabs	Whole blood is preferred. Viremia may be too transient for successful virus detection.
	Virus isolation PCR	Nasal swabs	This is useful for establishing role of BVDV in bovine respiratory disease complex.
	Serum virus neutralization	Serum	Pair sera 3 to 4 weeks apart. Serologic testing for both types 1 and 2 BVDV should be performed.
	Fluorescent antibody immunohistochemistry virus isolation PCR	Postmortem tissues	Tissues of choice include ileum, mesenteric lymph nodes, spleen, thymus (calves), lung (pneumonia).
Infertility	Serum virus neutralization	Serum	Serum bank for at-risk animals may be needed as seroconversion is complete when reproductive problem is noticed, or titers of affected cattle should be compared with those of unaffected cattle. Serologic testing for both types 1 and 2 BVDV should be performed.
Abortion	Serum virus neutralization	Serum	Pair sera 3 to 4 weeks apart. Serologic testing for both types 1 and 2 BVDV should be performed.
	Serum virus neutralization	Fetal fluid	Presence of antibodies or BVDV is suggestive but not definitive for BVDV-induced abortion. Serologic testing for both types 1 and 2 BVDV should be performed.
	Fluorescent antibody immunohistochemistry virus isolation PCR	Fetal tissues	Tissues of choice include ileum, mesenteric lymph nodes, spleen, thymus, liver, and lung.
Persistent infection	Virus isolation (IPMA) Antigen capture ELISA PCR	Serum or whole blood	Testing should be repeated in 2 to 4 wk to confirm persistent infection. For virus isolation, buffy coats should be used in these studies for calves younger than 6 months of age.
	Antigen capture ELISA immunohistochemistry PCR	Skin biopsy	Blood samples should be retested in 3 to 4 wk to confirm persistent infection. Pools of skin or blood may be tested initially with PCR.
Mucosal disease	Virus isolation PCR	Serum or whole blood	Both CP and NCP BVDV must be isolated.
	Fluorescent antibody immunohistochemistry Virus isolation PCR	Postmortem tissues	
Herd screening	PCR	Bulk milk tank Skin biopsy	Milk test screens only lactating cows; 300 cows per milk pool can be tested.
	Serum virus neutralization	Serum from sentinel cattle	Unvaccinated cattle 6 to 12 months of age should be tested. Serologic testing for both types 1 and 2 BVDV should be performed

CP, Cytopathic; *ELISA*, enzyme-linked immunosorbent assay; *IPMA*, immunoperoxidase monolayer assay; *NCP*, noncytopathic; *PCR*, polymerase chain reaction.

VetBooks.ir

types of tissues.[94] Although their use is time consuming and expensive, mononuclear cells in the buffy coat from whole blood are an ideal sample for individual virus isolation when an acute BVDV infection is suspected because BVDV is highly cell associated and neutralizing antibodies to BVDV in serum do not interfere with the virus isolation.[94] Sample handling is very important for virus isolation with mononuclear cells because they need to be viable when inoculated in the cell culture.[93] The ideal tissue samples for virus isolation from deceased animals at postmortem examination include lymphoid organ–related tissues such as spleen, Peyer's patches, mesenteric lymph nodes, and thymus.[94] In addition, pooled tissues from the same animal can be applied to virus isolation. NCP BVDV strains are detected, and CP strains confirmed as BVDV, by immunofluorescence or immunoperoxidase staining techniques or reverse transcriptase PCR (RT-PCR).

BVDV ANTIGEN DETECTION. Direct antigen detection methods with blood and a variety of fresh, frozen, or fixed tissues have been described for BVDV. These methods include immunohistochemistry, antigen-capture ELISA (ACE), and immunofluorescence. Because of standardization of methods, ACE testing kits have largely replaced the use of immunohistochemistry in diagnostic laboratories. Viral antigens can be detected from BVDV infected tissue, whole blood, serum, milk, or nasal swab samples.[94] These tests are advantageous in that they allow rapid and inexpensive detection in comparison to virus isolation. In addition, amplification of antigen is not needed, so these tests are ideally suited for the detection of animals with considerable amounts of antigen: namely, PI carriers.

ACE methods on skin samples have become widely used to detect BVDV antigen and are applied for the detection of cattle PI with BVDV.[95] Skin biopsy samples may be obtained easily and inexpensively. A major advantage of testing by ACE on skin samples is that sampling can be performed on young PI calves, which could test negative by virus isolation, microplate virus isolation, and other serum or buffy coat testing because of inhibition by acquired colostral antibodies.[96] Both the immunohistochemistry and ACE tests are ideally suited for the detection of PI animals, and reports indicate these tests very rarely detect acute infection in cattle.[97,98,99] With immunohistochemistry testing, PI animals can be differentiated from acutely infected cattle on the basis of location of viral antigen in the skin.[100] In cattle vaccinated with modified live-virus vaccines, immunohistochemistry or ACE methods do not yield positive results.[98,101]

REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION. Since sequences of BVDV isolates became available, molecular techniques have been developed for diagnosis of BVDV, and this method of BVDV diagnosis has gained widespread use as a routine diagnostic method.[95] An additional advantage of RT-PCR for diagnostics is that sequencing information can be readily and economically obtained, thus determining the BVDV species involved in the animal infection or herd problem. In comparison with traditional virus detection methods, PCR offers rapid results with high sensitivity and specificity. Development of commercial kits, with rapid and simple viral RNA extraction techniques, has made molecular techniques ideal for detection of viral genomic nucleic acids from many types of samples, including serum, whole blood, tissues, and bulk tank milk. The RT-PCR is more sensitive than virus isolation.[102] Because of the high sensitivity of RT-PCR, it is used for pooled testing, and pooling of whole blood, serum, or milk samples is an economical way to detect BVDV infection in herd screening assays. A U.S. Department of Agriculture (USDA)–licensed PCR testing protocol and kit are now available for the pooling of ear notch samples.

SEROLOGY. Detection of antibodies to BVDV is another method of demonstrating virus infection; however, it is often difficult to distinguish antibodies produced in response to a natural infection, after vaccination, or as a result of transfer of maternal antibodies from dam to offspring. Interpretation of serologic results is difficult without important information about the herd being tested, such as the vaccination history. Serologic testing may be used to assess vaccine efficacy and vaccine protocol compliance, as well as to determine whether BVDV exposure has occurred in the herd.[94] The BVDV-specific antibodies can be divided into two groups: neutralizing and nonneutralizing antibodies. Although there are several applicable methods, serum utilization, more appropriately called *virus neutralization*, and ELISA have been most commonly used for serologic diagnosis of BVDV. Because of numerous technical and logistical challenges, the virus neutralization test is less useful than the ELISA.[103]

Treatment and Prognosis

No specific treatment is available for animals showing clinical signs of BVDV infection. Owners should be informed that severely ill animals may have mucosal disease, which ordinarily is fatal. The goals of therapy for cattle suspected of having acute BVDV infection are supportive care and prevention of secondary bacterial infection. Broad-spectrum antimicrobial agents, fluids, electrolytes, and vitamins may be indicated.

Prevention and Control

Control of any infectious disease relies on eliminating the reservoirs of the pathogen and limiting transmission from infected individuals to susceptible animals. PI animals are the reservoirs, and eliminating the potential for the birth of PI calves is key to prevention and control. The goal of BVDV control is to ultimately reduce production losses associated with BVDV infection. Development and implementation of herd health programs that involve vaccination and biosecurity to limit exposure of pregnant cattle to PI cattle are important for success of control. Therefore for prevention and control of BVDV, three major actions should be instituted: (1) identification and elimination of PI animals, (2) enhancing immunity through vaccination, and (3) implementing strict biosecurity measures to prevent introduction of PI carrier animals into a population of susceptible cattle. Each of these three principles has been applied[104]; however, BVDV continues to be a major problem to the cattle industry worldwide. Some European countries have successfully eradicated BVDV,[105] and voluntary BVDV control programs have been implemented in the United States. Control and eventual eradication of BVDV can be possible in defined areas, even those with large and dense cattle populations.

IDENTIFICATION AND ELIMINATION OF PERSISTENT INFECTION IN CATTLE. The primary source of BVDV is cattle PI with BVDV because PI animals have a high and persistent viremia and shed BVDV from nearly all secretions throughout their lifetime. PI animals ideally should by identified and removed from breeding herds. In beef cow-calf operations with a controlled breeding season, PI animals should be removed before entry of a bull into the breeding herd.[106] In this situation, all calves, replacement heifers, bulls, and nonpregnant dams without calves should be tested for BVDV PI status. Because PI cows always produce PI calves, a negative test result for a calf indicates a negative PI status of the dam.[107] For any calves that test positive, the dam must be tested for BVDV PI status. Most PI calves result from an acute infection in the dam, rather persistent infection in the dam. Dams with negative test results may reenter the breeding herd; they possess high natural immunity to BVDV. In beef herds with a controlled breeding season, the BVDV status of all animals can be

VetBooks.ir

determined if no animals are pregnant at the time of testing. If cattle are pregnant at the time of testing, those animals must be segregated, and their calves' test results must be negative before return to the breeding herd.

In dairy herds and beef herds without a controlled breeding season, young calves should be tested and removed as soon as possible to avoid possible transmission to the breeding herd. Screening young calves for PI status is best accomplished with ACE or RT-PCR methods on skin biopsy samples. The use of skin samples for testing young calves is advantageous over other methods in that it is relatively easy for laymen to collect the samples, samples may be taken from calves that possess circulating maternal antibodies, and a single positive test result usually indicates PI status. Because acutely infected animals can produce positive RT-PCR results and occasionally positive ACE results, valuable breeding stock should be retested 30 days later with virus isolation on blood samples or ACE or RT-PCR assays on blood or ear notches.[99]

Screening all individuals in a herd for BVDV is very costly, especially considering the low prevalence of PI animals among cattle herds. Instead of whole-herd testing, monitoring strategies may be initiated, and these include evaluation of production records, BVDV evaluation of aborted fetuses, use of sentinel animals, pooling strategies for RT-PCR testing, and BVDV testing on sick or deceased individuals within the herd.[106] Monitoring breeding records, calf morbidity and mortality rates, and weaning proportions are considered the minimal level of surveillance, and these involve the least expense, but this level of surveillance is not very sensitive for evaluating the presence of persistent infection with BVDV within a herd.[11,106] As an example of the difficulty in utilizing clinical suspicion as a reason to perform herd testing, BVDV was isolated from cattle in 53% of herds in which there was no suspicion of the infection,[108] and animals PI with BVDV were not identified in 81% of herds where veterinarians suspected BVDV was present.[11] On the other hand, identifying BVDV in sick or dead animals or in aborted fetuses provides the justification for further whole-herd testing for animals PI with BVDV.

Because of high sensitivity, RT-PCR assays with pooled samples have been developed and tested to screen populations of animals for BVDV persistent infection.[102,109] Sample types that have been utilized in RT-PCR assays of pooled samples include serum, whole blood, bulk tank milk, and skin. With pooling whole blood samples, a single PI animal is detectable in pools of up to 250 negative samples. RT-PCR assays have also been developed and evaluated for testing pools of skin biopsy samples.[109] Pooled sample testing by RT-PCR is a rapid and cost-effective method for screening populations of cattle for animals PI with BVDV. Individuals within the positive pools may be tests subsequently with ACE, immunohistochemistry, virus isolation, or RT-PCR methods, depending on the class of animals being tested. When testing young beef calves, it is important to perform all testing before the breeding season to identify and eliminate animals PI with BVDV that pose a risk for bred cattle.

ENHANCING IMMUNITY THROUGH VACCINATION. Many vaccines are commercially available for BVDV, and the majority of these USDA-licensed vaccines contain BVDV in combination with other bovine respiratory and reproductive pathogens, including BoHV-1, parainfluenza type 3, bovine respiratory syncytial virus, *Leptospira* spp., *Campylobacter* spp., *M. haemolytica*, *Histophilus somni*, and *Pasteurella multocida*. Because of antigenic diversity among BVDV 1 and BVDV 2 strains, modified live-virus and inactivated vaccines containing both species are now widely available. Advantages and disadvantages of BVDV modified live-virus vaccines and inactivated vaccines have been described.[110] One disadvantage of inactivated BVDV vaccines is that two doses are required for the initial immunization. A major problem with using inactivated vaccines is the widespread lack of compliance among producers.[111] Failure to give a booster during the primary series and failure to regularly administer annual boosters with inactivated vaccines are common.[111]

Vaccines are an important component to BVDV prevention and control, and their effectiveness has been to limit disease from BVDV infection. In discussing BVDV vaccination with owners and producers, it is important to discuss reasonable expectations after vaccination and to remember that *disease* and *infection* are not synonymous terms. Experimental and field data indicate vaccination with either inactivated or modified live BVDV vaccines are effective at reducing or obviating clinical disease.[54,112] In addition, modified live-virus vaccines containing BVDV 1 strains are effective at limiting or preventing clinical disease when vaccinated animals are subsequently challenged with a virulent BVDV 2 strain.[113,114] Protection from clinical disease is important for stocker/backgrounder and feedlot operations, and immunity to BVDV has been demonstrated to be protective against bovine respiratory disease complex.[115] Preconditioning cattle by vaccination against BVDV before an expected exposure (commingling and shipping) reduces the effects of exposure of cattle to BVDV.

Protection against viremia is the true measure of BVDV vaccine efficacy. To be truly efficacious, vaccination against BVDV should protect against viremia to prevent dissemination of virus throughout the host, including preventing infection of target cells of the reproductive tract that result in fetal infection. Since 2005, the focus for vaccine efficacy has shifted from protection against clinical disease to protection against fetal disease or infection. Published studies indicate the protection against fetal infections after BVDV vaccination varies from 60 to 100%. This wide degree of variation depends on whether the vaccine is inactivated or modified live-virus, the timing of challenge, and the degree of homology between the vaccine strains and the challenge strains. Although both modified live-virus and inactivated BVDV vaccines have been demonstrated to provide fetal protection, modified live BVDV vaccines provide greater protection, according to a meta-analysis of clinical trials.[116] Fetal protection studies have been performed to evaluate commercial vaccines containing only BVDV 1 strains[117,118] and commercial vaccines containing both BVDV 1 and BVDV 2 strains.[119,120] From published studies, it appears that protection is superior when animals are challenged with strains from the same genotype.[114,121] An extremely important observation regarding these fetal protection studies is that although protection may not be 100% against all strains of BVDV, the level of protection is far superior to that observed when proper vaccination is not utilized, as evidenced by very high numbers of PI animals among unvaccinated cattle.[116]

BIOSECURITY. Although BVDV prevention and control starts with identification and elimination of PI animals, strict biosecurity is essential to prevent reintroduction of the virus. Strict biosecurity is difficult for most cow/calf and dairy operations to achieve and is even more difficult or impossible for most stocker/backgrounder and feedlot operations to achieve. Biosecurity systems with isolation and testing of all incoming cattle are necessary to ensure that BVDV does not enter the farm. All purchased cattle should be isolated and tested for persistent BVDV infection before entry into the herd. In addition, isolation of new additions for three weeks before entry into the resident breeding herd should prevent transmission of BVDV from acutely infected animals. Most lapses in herd biosecurity involve purchasing cattle that are PI with BVDV or purchasing pregnant cattle in which the BVDV status of the fetus is unknown. If pregnant cattle are purchased, these animals should be isolated and their offspring should be tested to ensure that they are free of BVDV. Semen should be used only from bulls that have test results negative for BVDV infection.

For purebred herds marketing genetically valuable embryos and livestock, it is important to test embryo transplantation recipients to ensure that they are not PI with BVDV. Exposure of cattle to other cattle or small ruminants at exhibitions should be limited, and animals should be quarantined for 3 weeks before reentry into the breeding herd. Most biosecurity principles instituted for BVDV control have the added benefit of disease control with other pathogens of cattle.

Malignant Catarrhal Fever (Bovine Malignant Catarrh, Malignant Head Catarrh)

Robert J. Callan

Definition and Etiology MCF is a severe lymphoproliferative disease caused by a group of herpesviruses collectively referred to as *malignant catarrhal fever viruses.*[1-6] The most recent taxonomic nomenclature places these viruses in the order Herpesvirales, family Herpesviridae, subfamily Gammaherpesvirinae, genus *Macavirus.*[7,8] Ten genetically and antigenically related viruses have been identified and constitute the group of MCF viruses. Six of these viruses are associated with clinical disease, and the remaining four viruses have not yet been associated with disease (Table 32.13).[5-9] Each virus has a reservoir host in which infection is typically asymptomatic. Clinical disease occurs in aberrant hosts and is characterized by acute onset of fever, inappetence, profuse ocular and nasal discharge, ocular signs such as corneal opacity and conjunctivitis, alimentary erosions, enteritis, and enlarged lymph nodes. The disease is typically progressive and often fatal.

Clinical MCF is observed in cattle, deer, bison, buffalo, several other domestic and wild ruminants[5,6] (>33 species to date), pigs,[10-13] and alpaca.[14] It has worldwide distribution and can be a problem in zoos and game parks. There are two primary etiologic forms of MCF that are designated by the host reservoir of the virus. Wildebeest-associated MCF is caused by alcelaphine gammaherpesvirus 1 (AlHV-1). The principal reservoir of AlHV-1 is the blue wildebeest *(Connochaetes taurinus)* and the black wildebeest *(Connochaetes gnou).*[5,15] Wildebeest-associated MCF occurs primarily in Africa or in zoologic parks where other ruminants have contact with wildebeest. Sheep-associated MCF is caused by ovine gammaherpesvirus 2 (OHV-2). Domestic and wild sheep and goats are asymptomatic reservoirs of the virus. Sheep-associated MCF is the primary form of MCF that is observed outside of Africa and affects primarily domestic and wild ruminants. MCF caused by OHV-2 has also been identified in pigs.[10-13] Goats are a reservoir for caprine gammaherpesvirus 2,[16] which has been isolated from cases of MCF in white-tailed deer,[17-20] sika deer,[21-24] roe deer,[25] moose,[25] pudu,[26] and water buffalo.[27] Both AlHV-1 and OHV-2 can be experimentally transmitted to rabbits and hamsters, in which infection causes an acute, fatal lymphoproliferative disorder similar to natural MCF.[28,29]

Clinical Signs and Differential Diagnosis The clinical signs and pathologic process of MCF have been reviewed.[5,6] Cattle from 4 weeks of age to adulthood can be infected and develop clinical illness. After an incubation period of 2 to 30 weeks, the disease attacks vascular endothelium, causing a lymphocytic vasculitis. The incubation period can be prolonged; in at least one case, the incubation period was 200 days. High fever, alimentary erosions, diarrhea, dysentery, corneal opacity, anterior uveitis, conjunctivitis, mucopurulent nasal discharge, thickened cracking skin, encephalitis, lymphadenopathy, and hematuria may be present (Fig. 32.93). Oral and nasal erosions may be evident but are often too far back in the nasal or

TABLE 32.13

Ten Antigenically and Genetically Related Viruses in the Malignant Catarrhal Fever Virus Group and Their Respective Reservoir and Clinical Hosts[5-8]

Current Name	Previous Name	Primary Reservoir Host	Clinically Susceptible Hosts
Ovine gammaherpesvirus 2 (OHV-2)	Ovine herpesvirus type 2 (OvHV-2)	Domestic and wild sheep	Cattle, bison, deer and other cervids, swine, moose, alpaca, and other domestic and wild ruminants
Alcelaphine gammaherpesvirus 1 (AHV-1)	Alcelaphine herpesvirus type 1 (AlHV-1)	Wildebeest (*Connochaetes* spp.)	Cattle, deer, and other domestic and wild ruminants
Alcelaphine gammaherpsevirus 2 (AHV-2)	Alcelaphine herpesvirus type 2 (AlHV-2)[64,65]	Jackson hartebeest *(Alcelaphus buselaphus lelwel)*, topi *(Damaliscus lunatus)*	Barbary red deer *(Cervus elaphus barbarus)*, bison
Caprine gammaherpesvirus 2 (CHV-2)	Caprine herpesvirus type 2 (CpHV-2)[9,16,21,23,25,27]	Goat	White-tailed deer, sika deer, roe deer, moose, pudu, water buffalo, pronghorn
Unassigned	MCFV of white-tailed deer (MCFV-WTD)[19], Caprine herpesvirus 3	Goat	White-tailed deer, red brocket deer
Unassigned	Ibex-MCFV[66]	Ibex *(Capra nubiana)*	Bongo *(Tragelaphus eurycerus)*, anoa, pronghorn antelope
Hippotragine gammaherpesvirus 1 (HHV-2)	HiHV-1[67,68]	Roan antelope *(Hippotragus equinus)*, scimitar-horned oryx *(Oryx dammah)*	None identified
Unassigned	Oryx-MCFV[4,9], or Gemsbok MCFB	Gemsbok *(Oryx gazella)*	None identified

Unassigned	Aoudad-MCFV[4]	Aoudad, Barbary sheep *(Ammotragus lervia)*	None identified

MCFV, Malignant catarrhal fever virus.

FIG. 32.93 A yearling steer with malignant catarrhal fever. Note the corneal opacity, lacrimation, and mucopurulent nasal discharge.

oral cavity to be observed externally. Ocular lesions are often present and consist of corneal opacity that originates in the periphery (centripetal) and progresses to the center. Corneal ulceration is generally not present, and there is no uptake of fluorescein dye. Affected animals exhibit generalized weakness and dyspnea. Ropy saliva may be dropped from the painful mouth, and scabs may develop on the muzzle. Swelling and hyperemia of the coronary bands may be observed, characteristic of coronitis. The hoof or horns may be shed, and lameness may be pronounced. Hematuria often is present and caused by a hemorrhagic cystitis. Nonsuppurative arthritis can also be observed. Neurologic signs include ataxia or altered mentation and are caused by a nonsuppurative encephalitis. Cutaneous lesions consist of multifocal coalescing alopecia with dermatitis and necrosis. When particular signs predominate, the condition may be labeled the alimentary form, the encephalitic form, the head and eye form, or the skin form. One strain of virus can cause all forms, and animals with most of these signs can be identified in a given outbreak. Clinical signs in any single animal may progress rapidly or over a course of weeks. Disease in Sitka deer (and perhaps other species) may consist primarily of dermatitis and alopecia.[21,23,24,30,31]

The course of the acute disease is usually 3 to 7 days; some animals survive longer. Disease is generally more severe and progresses more rapidly in bison than in cattle. The mortality rate is very high. Peracute deaths without any visible symptoms can also occur. A mild form, with transient fever and mild oral and nasal mucosal erosions followed by recovery, has been observed in experimentally infected cattle. Some animals survive clinical disease and, in a few cases, may return to normal productivity. The case mortality rate is generally high and may exceed 90%. However, chronic and recovered cases have been described, and in one report, recovery occurred in 50% of cases.[32]

MCF must be differentiated from BVD-related mucosal disease, rinderpest, bluetongue, vesicular stomatitis, and FMD. The last two diseases are not usually associated with diarrhea, and with vesicular stomatitis and FMD, morbidity rates tend to be high and mortality rates low. Clinical bluetongue is rare in cattle and not usually associated with dysentery. Arsenic toxicity and chlorinated naphthalene toxicity have some clinical similarities to the intestinal forms of MCF. Ocular signs, including corneal opacity, conjunctivitis, and discharges, must be differentiated from bovine keratoconjunctivitis (pinkeye), in which the lesion starts at the center of the cornea and corneal ulceration is present. In contrast, the corneal opacity of MCF starts at the limbus and is caused by edema secondary to the loss of the internal endothelial layer of the cornea.[33,34]

Clinical Pathology and Serology Some affected animals show leukopenia caused by lymphopenia and neutropenia if tested early in the course of disease, but this is an inconsistent finding in natural outbreaks.[35] Joint fluid is cloudy and may contain increased protein and mononuclear cell numbers. Cerebrospinal fluid may have elevated protein concentrations and elevated WBC counts with mononuclear pleocytosis in animals displaying neurologic signs. Serologic tests include ELISA, indirect immunofluorescence, complement fixation, and virus neutralization.[1,5] Virus isolation can be attempted for cases of MCF caused by AlHV-1. Serologic tests identify antibodies directed to a conserved MCF virus glycoprotein and do not discriminate between the different MCF viruses. Serologic tests are best used to screen the infection status of reservoir animals or to identify asymptomatic infection in clinically susceptible hosts. Diagnostic PCR tests have been developed for AlHV-1 and OvHV-2.[1,5] PCR tests are best used to distinguish between AlHV-1 and OvHV-2 in animals with clinical MCF. PCR tests for the identification of other MCF viruses, including a multiplex PCR assay, are available from specific research laboratories.[1,5]

A presumptive diagnosis is based on a history of exposure, clinical signs, and evidence of infection supported by serologic or PCR results. A definitive diagnosis can be made only if characteristic histopathologic lesions, including lymphocytic vasculitis, are present, along with supportive diagnostic test results demonstrating infection.[1,5]

Pathophysiology Natural infection occurs through inhalation of aerosolized virus or through direct or indirect contact with ocular or nasal secretions from reservoir hosts. The exposure dose plays a role in the likelihood of developing clinical MCF and the duration of the incubation period.[1,5,6,36-40] Experimental transmission studies in sheep and bison show initial replication of the virus in respiratory epithelium.[1,5,6,36,37,39,40] OvHV-2 DNA can be identified in the respiratory tract 9 to 12 days after infection in bison experimentally infected by intranasal inoculation.[41] OvHV-2 infection of lymphocytes is observed 14 to 21 days after infection. The incubation period for clinical MCF is highly variable and ranges from 14 to more than 200 days. MCF virus infection causes infiltration of lymphocytes, particularly T cells, into tissues.[2,5,6] This T cell proliferation is predominated by $CD8^+$ gamma-delta T cells and, to a lesser extent, $CD4^+$ T cells.[5,42] There is also an increase in large granular lymphocyte cells that appear to have cytopathic activity. It is believed that the fundamental disease is caused by an autoimmune-like process involving dysregulation of cytotoxic T cells associated with expression of specific viral transcripts.[2,5,42,43]

Epidemiology Wildebeest-associated MCF remains an important disease in cattle and other ruminants that encounter wildebeest.[5,6] AlHV-1, unlike OvHV-1, can be isolated in cell culture, and this has aided the ability to study the disease epidemiologic behavior and transmission. Wildebeest calves are generally infected with AlHV-1 in utero or soon after birth and shed the virus in ocular and nasal secretions until the age of 4 to 6 months.[5,15] Adult wildebeest become latently infected and transmit the virus to their offspring. Recrudescence and shedding of AlHV-1 in wildebeest can occur after treatment with corticosteroids. Cattle are infected with AlHV-1 when exposed to young, actively shedding wildebeest calves. The incubation period of wildebeest-associated MCF under natural exposure conditions in cattle can range from 2 weeks to 6 months and perhaps longer. In general, the incubation period of wildebeest-associated MCF is shorter than that of

sheep-associated MCF. Some cattle that become infected with AlHV-1 do not develop clinical MCF. Diseased cattle do not shed free infectious virus and thus are not a risk to contact animals.[5]

Sheep-associated MCF is the predominant form of MCF outside of Africa. The prevalence rates of OvHV-2 infection determined by PCR or competitive inhibition ELISA in healthy adult North American domestic sheep is reported to be 99% and 94%, respectively.[44] Sheep serve as the primary reservoir of OvHV-2, although sheep do not show clinical signs of infection. Less than 5% of lambs are infected at birth.[5,45] The majority of lambs remain uninfected up to 2.5 months of age. After 3.5 months of age, the lambs develop infections through close contact with adult sheep; the prevalence rate approaches 100% by the age of 5.5 months. OvHV-2 is shed and transmitted through nasal and ocular secretions.[46,47] Seroconversion and detection of OvHV-2 DNA in nasal secretions lags behind the detection of viral DNA in blood by several months.[5,45] Lambs separated from adults at 2 months of age remain reliably OvHV-2 free.[5,48] These findings indicate that newborn lambs are not a major source of virus infection for cattle. Nasal viral shedding peaks at approximately 6 to 9 months of age, and it is these infected adolescent lambs that pose the greatest transmission risk to other animals.[5,46]

Infected adult sheep continue to shed low numbers of virus throughout life.[5,46] Adult sheep may shed OvHV-1 in larger amounts during the periparturient period or while they feed in feedlots, which raises the risk for commingled cattle. OvHV-2 is readily transmitted between in-contact sheep; however, transmission by inoculation of whole blood or peripheral blood mononuclear cells is inconsistent.[49] This suggests that infectious virus is produced and shed primarily in nasal or ocular secretions and that infection of blood cells may be largely nonproductive.

Positive results of competitive inhibition ELISA tests have been identified in bison (2% to 23%), domestic goats (74%), elk (9%), mule deer (2%), white-tailed deer (3%), pronghorn antelope (25%), bighorn sheep (37%), muskox (40%), and mouflon sheep (62%). Black-tailed deer, llamas, and mountain goats have been tested and were not found to be seropositive for MCF.[50] However, it is not clear whether these species play any role as reservoir species.

Sheep-associated MCF can be acute or chronic, and infected animals may recover. Cattle and American bison *(Bison bison)* are the two primary species affected by sheep-associated MCF. The disease usually occurs sporadically, with only one or a few animals affected, but many large outbreaks have been reported.[5,6,51-55] Transmission probably occurs through direct contact, indirect contact, and aerosol of nasal secretions from sheep. In one report, exposure of bison to sheep for less than a day at an auction resulted in a high mortality rate.[55] There is evidence of transmission from sheep to cattle or bison extending over distances of 70 m up to 5.1 km.[53,56,57] In one example of natural infection of bison, the incidence rates of disease and mortality were inversely related to the distance of exposure.[53] The incubation period after experimental or natural exposure ranges from 14 to 220 days.[6,38,41,51,54,55] Cattle and bison are considered dead-end hosts and do not spread the infection to other animals.[2,5,55]

Bison are more susceptible to developing clinical MCF than are cattle by both experimental inoculation studies and natural exposure.[5,36,38,54] In bison, OvHV-2 infection and clinical MCF is observed with intranasal nebulization at doses as low as 10^3 DNA copies of OvHV-2.[5,36,37] Cattle become infected with doses as low as 10^6 OvHV-2 copies but require at least 10^8 copies to become infected with clinical MCF.[5,38] In contrast, the minimum infectious dose for sheep is between 10^2 and 10^3 DNA copies, but sheep require a dose of 3×10^9 copies to develop nonfatal clinical signs of MCF.[5,39,40] Several studies have shown that both cattle and bison can be infected with OvHV-2 and not develop clinical MCF.[5,52,56,58] These studies show that infection, morbidity, and mortality are related to species susceptibility, inoculation dose, and probably other factors not yet determined. Both asymptomatic and clinically affected cattle and bison do not shed infectious virus and are considered dead-end hosts.[5]

Necropsy Findings In an infected animal, the nasal mucosa is hyperemic and may have hemorrhagic superficial erosions. The oral mucosa has necrotic papillae and large areas of necrosis and ulceration. Multiple focal ulcerations are seen in the esophagus. Parts of the forestomachs and intestines are thickened, edematous, and occasionally ulcerated and hemorrhagic. The lymph nodes, tonsils, and Peyer's patches are enlarged, moist, and friable. Splenic lymphoid follicles are prominent, and the liver is swollen. The adrenal glands are hemorrhagic. The mucosal surface of the bladder has focal areas of hemorrhage. The eyes are hyperemic and show severe corneal edema. The brain may have intersulcal cloudiness and meningeal petechiation consistent with encephalitis. Joints may have swollen and reddened synovia with an increased quantity of cloudy fluid.[6,59]

Histologically, there is a marked lymphoid accumulation around blood vessels, as well as necrosis of the tunica media and intima in multiple tissues. Generalized lymphoid hyperplasia and lymphoid infiltrates are present in subepithelial and intraepithelial locations, in association with epithelial necrosis and sloughing. Similar changes occur in all epithelial tissues.[59] Chronic cases develop chronic obliterative arteriopathy.[32]

Treatment and Prognosis There is no specific treatment for MCF beyond supportive care. Fluid therapy and nursing care may allow some animals to survive and recover from disease. Antimicrobial treatment to help prevent secondary bacterial pneumonia or septicemia may provide some benefit. Treatment with NSAIDs may provide comfort but could increase the degree of alimentary erosions or decrease their healing. Gastrointestinal protectants such as bismuth subsalicylate (Kaopectate) may provide support to the gastrointestinal tract and help maintain appetite. Maintenance of appetite seems to be one of the key prognostic indicators in clinical cases of MCF. Although some animals that exhibit mild disease may survive, close to 100% of those with severe clinical signs die.

In one report, the severity and progression of ocular lesions associated with MCF in cattle were evaluated in relation to disease outcome.[33] The degree of corneal edema at presentation did not show prognostic value in predicting disease outcome (death versus survival). However, improvement of corneal edema over the course of the disease was associated with a better outcome. In addition, animals in which anterior uveitis worsened were more likely to die or be euthanized.

Prevention and Control The primary method of control is to reduce the exposure of susceptible hosts to reservoir hosts.[5,6] Transmission is related to the distance between reservoir hosts and susceptible hosts, so these groups of animals should be physically separated. This can be particularly difficult because, as mentioned, transmission from sheep to bison over distances as far as 5 km have been reported.[53] Adult wildebeest and sheep pose a lesser risk of transmission than do neonatal wildebeest and adolescent sheep, which shed higher amounts of virus from nasal secretions than do the adults. These younger groups of reservoir animals should be kept at a greater distance from susceptible hosts. Feedlot sheep from 6 to 9 months of age pose a significant risk. Natural transmission of OvHV-2 between feedlot sheep and dairy cattle or bison has been reported and is probably related to the younger age of the feedlot sheep in comparison with adult breeding animals.[53,54,56]

VetBooks.ir

VetBooks.ir

Currently, no commercial vaccines are available for prevention of wildebeest-associated or sheep-associated MCF. Attenuated AlHV-1 vaccines have demonstrated some protection against virulent AlHV-1 challenge and natural infection in cattle.[60,61] Respiratory tract mucosal immunity appears to be critical in preventing initial infection and development of clinical MCF.[2,60,62,63] Further research identifying critical antigens and methods to induce strong, long-lasting mucosal immunity for both AlHV-1 and OvHV-2 are necessary for developing effective vaccines for bison and cattle.

Vesicular Stomatitis

Pamela J. Hullinger • Danelle A. Bickett-Weddle

Definition and Etiology

Vesicular stomatitis virus (VSV) is a rhabdovirus in the genus *Vesiculovirus* that causes sporadic (cyclic) outbreaks in cattle, horses, donkeys, mules, and pigs. Clinical signs include vesicles, erosions, and ulcers. Although deaths are rare, these lesions can result in pain, anorexia, and secondary bacterial mastitis. Some animals may lose their hooves after developing laminitis.[1] Affected cattle younger than 1 year of age rarely show clinical signs. Affected sheep and goats rarely have clinical signs, and South American camelids are intermediate in susceptibility. Humans can become infected with VSV and develop a mild influenza-like disease.

Vesicular stomatitis viruses are endemic from southern Mexico to northern South America, but they regularly spread north and south from these regions, causing outbreaks and epidemics. Although these viruses are no longer endemic in the U.S., they are introduced periodically into the southwestern states and can sometimes spread further north.[1]

Four distinct viruses are now recognized: VS Indiana (formerly called *Indiana 1*), VS New Jersey, Alagoas virus (formerly called *Indiana 3*), and Cocal virus (formerly called *Indiana 2*). Indiana 1 and New Jersey occur in the United States.[1] Viral strains vary in virulence.

Historically, epizootic waves of vesicular stomatitis tended to occur at approximately 10-year intervals, usually in the summer or fall. However, outbreaks have become more frequent since the 2000s. An outbreak of vesicular stomatitis in the United States lasted from April 29, 2015, to March 4, 2016. A total of 823 premises were confirmed or suspected to have VSV infections (VS New Jersey serotype) in eight U.S. states: Arizona (36 premises in three counties), Colorado (441 premises in thirty-six counties), Nebraska (38 premises in ten counties), New Mexico (52 premises in thirteen counties), South Dakota (50 premises in seven counties), Texas (4 premises in four counties), Utah (56 premises in eight counties), and Wyoming (146 premises in ten counties).[2]

Although the VS New Jersey serotype has at least 14 distinct genotypes, only a few of these have been found in outbreaks in the United States. The VS New Jersey serotype should be considered a collection of serologically related but genetically variant viruses.

State and federal regulatory veterinarians should be contacted immediately when vesicular stomatitis is suspected so that quarantine and disease identification measures can quickly contain an outbreak.

Clinical Signs and Differential Diagnosis

The incubation period is usually 3 to 7 days but can be shorter or longer, depending on route of transmission and viral load. In the 1984 California outbreak, it was unusually long (9 days).[1] Vesicles occur in the mouth, on the teats, and in interdigital areas. Vesicles are only occasionally visible because the epithelium rapidly becomes necrotic and turns into painful ulcers. Lesions on the gums and tongue may coalesce to form large eroded areas that cause dysphagia and reluctance to eat, frothing at the mouth, drooling, and weight loss (Figs. 32.94 and 32.95). Milk production falls quickly. In dairy cattle, teat lesions are common and cause mastitis. Small ulcers in the interdigital area and on the coronary band are occasionally present and cause lameness. Recovery varies from 2 to 21 days, depending on the severity of the lesions and management factors such as the type of feed and milking sanitation.[3] Actual healing of the lesions may take 34 to 59 days.[4]

FIG. 32.94 Severe ulceration of the tongue of a dairy cow caused by vesicular stomatitis. A plaque of dying mucosa covered by fibrin is visible at the tip of the tongue, and excessive salivation is obvious. *(Courtesy Dr. Mark Thurmond.)*

FIG. 32.95 Tongue of horse with vesicular stomatitis, demonstrating severe lingual erosions. *(Courtesy Dr. Skip Aaroe.)*

In cattle, morbidity rates are generally high (5 and 60%)[3,4] and low mortality rates (1% to 5%). Although many exposed cattle do not show obvious clinical signs of disease, many more are found to have oral lesions if closely examined, and most animals in the herd seroconvert.

The major differential diagnostic consideration is FMD, which causes identical clinical signs, except that VSV can affect horses. Other diseases of cattle that result in oral lesions include BVD, BPS, bluetongue, and epizootic hemorrhagic disease. These usually appear, not as epidemics in herds, but rather in one or a few animals in the herd (although with BPS, morbidity rates may be high). Other causes of oral lesions such as bristle grass irritation and toxins should be ruled out.

Clinical Pathology and Laboratory Diagnosis

VSV can be found in vesicular fluid, swabs of ruptured vesicles, the epithelium of unruptured vesicles, and epithelial flaps from

VetBooks.ir

freshly ruptured vesicles.[1] Many cell lines and other methods can be used to isolate VSV from clinical samples. The identity of cultured virus can be accomplished by RT-PCR, immunofluorescence, complement fixation tests, or antigen-capture ELISA. Antigen-capture ELISA can also be used for serotyping.[1] Electron microscopy of tissue samples may be helpful in distinguishing VSV from some other viruses that cause vesicular lesions, such as the FMD virus. [1]

Vaccination with inactivated virus results in a rapid rise in titer, followed by a gradual decline for a year.[5] Serum-neutralizing antibody titer rises rapidly after exposure and then gradually falls over the first year. Serum-neutralizing antibody titers that appear after natural exposure may persist for years. The presence of a serum-neutralizing antibody titer does not prevent reinfection or development of clinical signs. Hematologic and clinical chemistry findings generally reflect an acute to chronic inflammatory disease and are nonspecific.

Pathophysiology

After a short incubation period, fever occurs, and the virus invades the germinative layer of oral epithelial cells. Oral abrasions or trauma may increase susceptibility. Contact of virus with teats or feet can result in lesions in these areas, especially if the teats are chapped or cracked or the feet are traumatized. The lesions progress rapidly from blanched macules to vesicles and soon rupture, leaving sloughed epithelium and ulcerated areas. Healing occurs quite rapidly if feed is soft and does not cause oral trauma.

Epidemiology Older, high-producing dairy cows that have been in milk longer are more susceptible to clinical disease caused by VSV than are younger herdmates.[5] Because the virus cannot penetrate intact mucosa, cattle fed coarse feeds or hard pellets that traumatize the oral mucosa are at higher risk. Cows with chapped or cracked teats and those on farms with poor milking hygiene are more likely to get teat lesions.[5] Cow-to-cow contact is a major mode of transmission in outbreaks, and increased interpen movement of cattle, as well as sharing of feed and water troughs (unless cleaned frequently), increase the risk of exposure to VSV. The virus can be transmitted by milking machines and human hands during outbreaks. In addition to being biological vectors, insects can also contribute to the mechanical spread of the disease.

The transmission of VSV is not completely understood, and transmission routes in individual outbreaks are unclear. Outbreaks can be associated with the movement of animals from another area, but disease epidemics unrelated to introduction of new animals do occur. The infection tends to be seasonal (occurring in the summer and fall in temperate areas and at the end of the rainy season in the tropics) and behaves like an arthropod-borne virus. Insect vectors are thought to introduce VSV into populations of domesticated animals. Sand flies (*Lutzomyia* sp.), black flies (family Simuliidae) and *Culicoides* midges can act as biological vectors. Sand flies seem to be important vectors in endemic areas, but they have a limited flight range and are not thought to spread these viruses over long distances.[1] Black flies are believed to be particularly important vectors in parts of the western United States. It is still uncertain where the virus originates before entering livestock populations. Once animals develop lesions, however, insects may become infected by feeding on these lesions or contaminated secretions. Transovarial transmission has been demonstrated in sand flies and black flies in the laboratory and may be possible in *Culicoides* midges. It might contribute to virus overwintering in cold climates.[1] Both migratory western grasshoppers and the plants they eat can be infected with VSV,[6] which provides a means of livestock exposure. It is hypothesized that VSV may be a plant virus that strays into animals, in which it causes sporadic disease.

Other insects act as mechanical vectors. Antibodies have been found in a number of wild species of animals (deer, raccoons, bobcats, monkeys) that may serve as virus reservoirs. Active cases of vesicular stomatitis occur in Mexico between U.S. epidemics; it is possible that cattle from Mexico arriving in the United States may also be sources of VSV. Sheep and goats in contact often seroconvert, although clinical signs in these species are rare.

The virus survives several weeks in cool soils but is inactivated by sunlight and is very resistant to pH changes.

Necropsy Findings

Deaths from vesicular stomatitis are rare and usually attributed to secondary bacterial diseases, including environmental mastitis and pneumonia. Affected cattle become gaunt and weak as a result of dysphagia and anorexia. Erosive and ulcerative lesions are usually confined to the mouth. The teats are frequently involved in affected lactating cows, and lesions on the coronary band and interdigital area occasionally appear.

Histologically, intracellular and extracellular edema, ballooning and degeneration of epithelial cells, and vesicle formation accompanied by neutrophilic infiltration occur. There are no inclusion bodies. The characteristic bullet-shaped structure of the VSV can sometimes be seen with electron microscope examination of fresh lesions or vesicular fluid.

Treatment and Prognosis

Mortality can be almost completely prevented if ill cattle are offered shade, fresh water, clean bedding, and soft feed. Offering soft feed hastens recovery and reduces the anorexic period. Judicious use of appropriate antibiotics to control secondary bacterial pneumonia may be warranted. Cattle with teat lesions are at high risk for developing mastitis and should be carefully milked last and monitored closely for mastitis. The prognosis for survival is very good, but agalactia and mastitis may necessitate the culling of animals.

Prevention and Control

The websites of World Organization for Animal Health (OIE)[7] and the USDA[2] provide the latest information on active vesicular stomatitis outbreaks. During an outbreak, regulatory officials implement a quarantine of the premises and require testing and isolation of sick animals. Leftover feed should be removed from feed bunks twice daily, and the bunks should be disinfected. Water troughs should be cleaned and disinfected daily. According to Spickler, "VSV is susceptible to numerous disinfectants including 1% sodium hypochlorite, 40-70% ethanol, 2-propanol, aldehydes (e.g., 0.5%-2% glutaraldehyde, formaldehyde), 1% cresylic acid, phenolic disinfectants and detergents. These viruses appear to be more susceptible to inactivation by acid (e.g., pH 2) than alkaline conditions. VSV are also susceptible to UV [ultraviot] light including sunlight, or heat (e.g., 4 minutes at 55°C, or one minute at 60°C)."[1]

Vaccination with killed[8] or live virus vaccines is rarely practiced preventively because the disease occurs as such rare epidemics in small areas and vaccination interferes with serologic testing and monitoring. Although VSV vaccine is available in some South American countries, it is not currently available in the U.S.

Foot-and-Mouth Disease (Aftosa, Aphthous Fever)

Pamela J. Hullinger • Danelle A. Bickett-Weddle

Definition and Etiology

FMD is an acute, highly contagious viral disease of cloven-hoofed livestock that is characterized by vesicular lesions,

VetBooks.ir

erosions, and ulcers in the mouth and interdigital areas and on the muzzle, teats, and coronary bands. Natural hosts include cattle, sheep, goats, swine, water buffalo, bison, deer, elk, antelope, wild ruminants, bears, llamas, camels, giraffes, elephants, rats, yaks, capybaras, and hedgehogs.[1] Of these, cattle and swine are generally the most susceptible, shed the most virus, and display the most severe clinical signs. Affected mature sheep and goats usually have mild clinical signs, and horses are not susceptible. Livestock of all ages are susceptible, and the mortality rate is higher in young animals because myocarditis can occur.[1]

FMD is caused by a picornavirus of the genus *Aphthovirus*. At least seven immunologically distinct types of FMD virus have been identified: A; O; C; SAT 1, 2, and 3; and Asia 1. Within the seven types, at least 60 subtypes have been recognized.[1] African buffalo can be a maintenance host of SAT serotypes in sub-Saharan Africa and may harbor the virus for at least 5 years. They have not been shown to play an epidemiological role outside of Africa or to transmit the virus naturally to domestic cattle.[2] Vaccination against one subtype generally does not protect adequately against another. This fact, together with the fact that immunity is generally short term, means that developing effective vaccination programs is challenging.

The virus is rapidly inactivated by pH above 9.0 or below 6.0 and by very high temperatures. For example, the OIE Terrestrial Animal Health Code recommends that deboned, defatted meat products be subjected to 70°C for a minimum of 30 minutes. Organic material and protection from sunlight promote virus survival. Sodium hypochlorite, citric acid, and a number of proprietary products are effective disinfectants.[3]

Clinical Signs and Differential Diagnosis

FMD is clinically indistinguishable from vesicular stomatitis except that the latter also affects horses. Clinical signs of FMD in cattle include fever, depression, anorexia, listlessness, occasional shivering, excess salivation, lip smacking, nasal discharge, and lameness. Milk production may be reduced. In addition to vesicular stomatitis, the differential diagnosis includes BPS, BVD, bluetongue, rinderpest, MCF, and severe cases of infectious bovine rhinotracheitis. Teat lesions can be confused with those caused by bovine herpes mammillitis or parapoxviruses.

Vesicular lesions (blisters) 0.5 to 5 cm in diameter rupture within 48 hours, followed by a mucosal slough and large erosions. These lesions appear to be very painful, and affected animals are reluctant to eat or move. In general, the morbidity rate is high, but the mortality rate is low. Death may occur in young animals, mainly from myocardial necrosis and secondary bacterial pneumonia. Because of the response to the disease and its effect on trade, it is economically devastating, and its rapid spread and clinical signs (e.g., weight loss, mastitis, lameness) have significant effects on animal health and productivity. An outbreak of FMD in a country previously free of the disease can cost billions of dollars in trade loss over ensuing years.

Laboratory Diagnosis

FMD is clinically indistinguishable from vesicular stomatitis and other viral mucosal diseases. Therefore laboratory confirmation is obtained through demonstration of FMD viral antigen or nucleic acid in samples of tissue or vesicular fluid, either by RT-PCR or by virus isolation. Detection of virus-specific antibody can also be used for diagnosis, and the presence of antibodies to viral nonstructural proteins is an indicator of infection, irrespective of vaccination status. When vesicular stomatitis or FMD is suspected, state and federal authorities should be contacted immediately (see Chapter 47).

Pathophysiology

In cattle, the usual incubation period is 2 to 14 days. The primary sites of infection and replication by FMD virus are the pharyngeal and digestive mucosa and alveolar epithelium of the udder. The virus replicates in the cells of the stratum spinosum. It spreads locally and also enters the circulation and is carried to other susceptible tissues. The mucosal cell disruption results in separation of superficial epithelium from basal epithelium, which fills with tissue fluids. Within 2 to 21 days, a fever begins and some vesicles appear. Vesicles develop in the mouth, on ruminal pillars, and in coronary bands. When the epithelial layers slough, erosions are left behind that take days to weeks to heal, depending on their size.

Necropsy Findings

In addition to oral erosions and ulcerations, ulcers may be seen on the ruminal pillars. In young cattle, myocardial and skeletal muscle degeneration and necrosis may be noted. The vesicles are characterized histologically by ballooning, cellular degeneration, intracellular and extracellular edema, and separation of the basal epithelium. There are no inclusion bodies. Myocardial and skeletal muscle degeneration characterized by Zenker necrosis may occur in young cattle.

Epidemiology

Transmission occurs primarily through animal contact, inasmuch as the virus is shed in bodily fluids (saliva, feces, urine, milk, semen). Contaminated fomites such as clothing, footwear, tires, equipment, and bedding spread the virus, and aerosol transmission can occur in favorable environmental conditions. Recovered cattle usually stop shedding the virus within 2 weeks. Detection of virus for longer periods from the oropharynx of cattle has been documented, but such "carriers" have, to date, not been shown to transmit disease to other cattle in natural environments. African Cape buffaloes can be lifelong carriers, but outside of Africa, they have not been shown to play a role in the transmission of the disease.[2]

The virus exists in milk, and at low levels, it may survive high-temperature short-time pasteurization (72°C [161°F] for 15 seconds or more). Uncooked or partly cooked meat products or garbage scraps, hides, or other tissues contaminated with the FMD virus from an endemic area of the world may transmit the disease long distances. The virus can persist in frozen meat for years.

FMD is endemic in Asia, Africa, the Middle East, and small regions in South America and southern Europe (Turkey), where losses involve not only those caused by the disease itself but also the monetary losses resulting from loss of export markets. Noteworthy are some outbreaks in previously FMD-free regions, including Great Britain in 2001 and 2007, Uruguay in 2001, Japan in 2010, South Korea in 2011, and Bulgaria and Turkey in 2011. A 2012 outbreak involving an SAT 2 strain in the endemic regions of Egypt produced an unusually high rate of mortality in adult cattle.

Treatment and Prognosis

Where FMD is endemic, understanding the epidemiology of the disease can provide insights on how to reduce and possibly eliminate the disease through management, movement control, and targeted vaccination. Good nursing care and judicious use of systemic antimicrobial drugs to limit secondary bacterial pneumonia and mastitis can be beneficial. Soft feeds such as chopped green grass (or soaked hay) are much more palatable than dry hay to sore-mouthed animals. The prognosis for survival is good, although affected animals may lose weight, have reduced milk production, and experience mastitis secondary to viral teat lesions.

VetBooks.ir

Prevention and Control

The OIE and USDA websites contain information about current global disease status, which changes frequently. In FMD-endemic areas, managed movement and vaccination can reduce disease incidence. In FMD-free areas (Great Britain, the United States, Canada, Mexico, Japan, New Zealand, and Australia), control programs are based on rapid detection and response, including quarantine, biosecurity, managed movement, depopulation, vaccination, or a combination of these.[4]

The current vaccination strategy used globally is to use a serotype-specific, killed FMD vaccine. Immunity, both vaccine induced and naturally occurring, is short-lived, and vaccination usually must be repeated two or three times a year.[1] Vaccine provides partial protection, and subsequent infections usually result in subclinical or mild disease. Calves nursing immune dams are likewise partially protected by passive antibody for up to 5 months. Molecular vaccines are currently under development globally and in 2012, an adenovirus-vectored FMD vaccine was approved for conditional license in the United States. This vaccine does not require live virus production and could be used in the event of an outbreak in the United States. The decision to use FMD vaccine to control an outbreak is complex, and strategies related to production, distribution, and animal identification require adequate resources for effective implementation.

Peste des Petits Ruminants (PPR, Sheep and Goat Plague) and Rinderpest (Cattle Plague)

Bradford P. Smith

Definition and Etiology

Peste des petits ruminants (PPR) and rinderpest are acute, highly contagious, and usually fatal viral diseases of ruminants. PPR is still active and threatens goats and sheep, but OIE and the Food and Agriculture Organization have the goal of eradication by 2030.[1,2] Rinderpest was officially declared by the OIE to be globally eradicated in 2011, mainly through vaccination. It is the second disease after smallpox to be eliminated.[3] Cattle and water buffaloes were most frequently affected by rinderpest, but the disease also occurred in yaks, gaur, sheep, goats, pigs, and other cloven-hoofed animals, in which it is usually less severe. It was rarer in camelids. Many wild animals in Africa are susceptible, including buffalo, lesser kudu, eland, giraffe, warthog, and wildebeest.

The viruses causing PPR and rinderpest are closely related RNA viruses in the Paramyxoviridae family, genus *Morbillivirus*. The viruses can remain viable for at least 1 year in frozen tissue but are killed by direct sunlight in 2 hours. Other morbilliviruses pathogenic for animals include canine distemper and the Hendra virus, which caused disease in horses and humans in Australia in 1994.

PPR is a highly virulent virus of goats, sheep and occasionally camels. There is only one serotype. It occurs in Africa, the Near East, Middle East, and Asia; outbreaks have occurred in approximately 76 countries. In 2016 it reached the edge of Europe in Georgia.[1] There do not appear to be any carriers or reservoirs besides domestic goats and sheep.[1] PPR has important negative economic effects in agricultural societies. An effective single-dose vaccine that confers lifelong immunity is available. There are also accurate diagnostic assays. Thus it is hoped that massive vaccination programs in domestic animals can eradicate PPR by 2030.

PPR morbidity rates can reach 100%, and the mortality rate can be between 50% and 100% in goats and sheep. Cattle and pigs develop inapparent infections. The disease also occurs in wild species, including several gazelles, gemsbok, ibex, and wild sheep. In 2015, a massive outbreak occurred among Mongolian wild Saiga antelope, triggering a die-off due to PPR. The reader is referred to the OIE website[1] for current information.

Clinical Signs and Differential Diagnosis

Clinical signs of PPR in goats and sheep are similar to those of rinderpest in cattle. For both PPR and rinderpest, the incubation period is usually 3 to 10 days, which is followed by sudden onset of fever, depression, and anorexia. The nose is dry, and mucous membranes are congested. Within days oral erosions appear where necrotic foci have sloughed. Purulent occular and nasal discharge occurs. Diarrhea is severe and may be bloody. Interstitial pneumonia occurs, and secondary bacterial bronchopneumonia is common. Dehydration and starvation often lead to death.

In small ruminants with signs of PPR, bluetongue and Nairobi sheep disease must be ruled out.

In endemic areas, rinderpest is suspected in cattle when the signs described earlier occur in groups of animals. In nonendemic areas diseases that appear similar clinically are BVD-related mucosal diseases, MCF, arsenic poisoning, severe coccidiosis, and severe fulminating infectious bovine rhinotracheitis, as well as FMD and vesicular stomatitis.

Laboratory Diagnosis

A rapid strip test for PPR can be used in the field.[4] Laboratory confirmation of PPR or rinderpest virus can be accomplished by virus isolation; PCR; ELISA; detection of viral antigen by fluorescent antibody testing, virus neutralization, or agar gel immunodiffusion; counterimmunoelectropheresis; detection of rising antibody titer by ELISA or virus neutralization[5]; and histopathologic evaluation, including immunohistopathologic study. Virus isolation is most successful in the first days of infection (often before the onset of diarrhea). Blood should be taken in heparin. The lymph nodes and spleen are reliable sources of virus, as are tears and ocular discharges. Lymph node biopsy after day 3 of infection is the most reliable means of diagnosis in a living goat. Tissues should be shipped frozen on ice to the laboratory for virus isolation or detection of antigen. Detection of a rising antibody titer can help diagnose the disease retrospectively. Leukopenia may be noted in the acute early stages.

Pathophysiology

The virus usually enters through the respiratory mucosa. Lymphoid tissue and epithelial cells of the GI and respiratory systems are the primary targets of rinderpest virus. Lymphocytes are destroyed in the germinal centers of the lymph nodes, Peyer's patches, tonsils, splenic corpuscles, and cecal lymphoid tissue. Immunosuppression occurs as lymphoid tissue is destroyed. The virus also attacks the alimentary tract mucosa; Peyer patches are the most severely affected. As alimentary mucosa is lost, diarrhea and emaciation become severe, and secondary bronchopneumonia usually develops as the respiratory epithelium is destroyed.

Epidemiology

PPR and rinderpest are highly contagious and spread mainly through airborne droplets, direct contact, feces, and contaminated fomites such as human beings. All secretions and feces of infected animals are contagious throughout the course of the disease. Wild ruminants with active disease may be a source of infection for livestock. Because the mortality rate is high, treatment is unrewarding and the prognosis is poor, although individual animals can be helped by good nursing, fluid therapy, and antimicrobials to control bronchopneumonia. Innate or specific resistance may protect individuals or herds from clinical signs after infection. Recovered animals do not appear to act as carriers for more than a few months.

VetBooks.ir

Necropsy Findings

Lesions are found mainly in the alimentary tract, lymphoid tissues and lungs. Subendocardial hemorrhages may also be seen in animals that die of acute illness. Oral erosions, edema, and congestion of the abomasum are typical, and ulcers and hemorrhagic to necrotic Peyer's patches occasionally are present. The cecal and colonic mucosae are hemorrhagic, ulcerated, or necrotic. The lymph nodes are enlarged and have necrotic germinal centers. Severe interstitial pneumonia frequently occurs,[5] and secondary bronchopneumonia is common.

Prevention and Control

Because there is only one known strain of PPR and one of rinderpest virus, protection after infection or vaccination usually is lifelong. Vaccination of susceptible animals at 6 months of age and older in endemic areas with a live attenuated virus is an effective means of control.[1,6] The vaccine does not produce adverse reactions, has a long shelf life if refrigerated, and produces solid immunity. Its major disadvantages are that the lyophilized virus has to be kept cold, and once a vial has been reconstituted, it must be used quickly before the virus dies. Research is yielding more stable vaccine without a cold chain for up to 30 days. [7]

Control of epidemics in areas where the disease is not endemic involves quarantine and slaughter of infected and exposed animals, as well as other contact ruminants and swine. Disinfection of premises while they are under government quarantine is essential for controlling the disease. The virus is susceptible to most disinfectants and survives in the environment for only 2 to 3 days. A comprehensive review was published in 2014.[8]

Choke and Esophageal Disorders

Bradford P. Smith • Charles L. Guard

Definition and Etiology

Choke is the term used for esophageal obstruction. In ruminants it is most common in cattle because of their eating habits, but it has even been reported in a goat that ate thread with a needle attached.[1] If the obstruction is complete, the condition is rapidly fatal (except in neonates) because of the inability to eliminate the gases of fermentation produced in the rumino-reticulum. Partial obstruction produces dysphagia or anorexia. Obstruction may be caused by the ingestion of foreign objects or large chunks of solid feedstuffs such as apples, potatoes, beet tops, corn cobs, or even a mango.[2] Dry grain, particularly in pellet form, may be consumed so rapidly that sufficient saliva is not produced to lubricate the passage of the feed boluses. This is more common in sheep than in other ruminants; with grain, spontaneous resolution usually occurs within minutes to hours. Obstruction also may be the result of space-occupying lesions in or near the esophagus. Choke must be differentiated from diseases that cause dysphagia by means of pharyngeal lesions and resultant neuromuscular dysfunction. Congenital or acquired lesions of the esophagus, such as aortic arch anomalies and diverticula, may cause signs similar to those of esophageal obstruction.

Clinical Signs and Differential Diagnosis

The earliest signs of complete esophageal obstruction from intraluminal objects are anxiety and ptyalorrhea (i.e., saliva dripping from the mouth because of an inability to swallow). The animal may violently swing the head from side to side and make repeated attempts to swallow. Staggering (which must be differentiated from ataxia caused by neurologic diseases) may be observed. Bloat develops soon after at a rate that depends on the nature of the ruminoreticular contents.

Intraluminal objects commonly causes obstruction in the cranial part of the cervical portion of the esophagus, at the thoracic inlet, or at the base of the heart. In a 2-week-old calf with a cloth foreign body obstructing the distal esophagus at the cardia, regurgitation after drinking milk was observed.[3] External palpation may localize the site of obstruction in the cervical portion of the esophagus. With more slowly developing and incomplete obstruction, anorexia and dysphagia may be observed. Bloat may occur repeatedly and resolve spontaneously or after passage of a stomach tube. The underlying cause may result in signs severe enough to mask the esophageal problem. Cellulitis along the cervical portion of the esophagus may result in a reluctance to lower the head or bend the neck laterally. Possible causes of cervical cellulitis include perivascular injection of irritating substances, abscesses, and reaction to *Hypoderma lineatum* larvae.

Esophageal stricture may follow a previous episode of esophageal obstruction or inflammation in adjacent tissues. If no site of obstruction is externally evident, careful attempts to pass a stomach tube usually reveal the site of the problem. Radiography with barium contrast material may help identify the site of strictures, perforations, and diverticula. Endoscopy of the esophagus may also aid in identifying the specific nature of functional or structural abnormalities. Megaesophagus has been observed after pharyngeal trauma, as a congenital disorder, and with hiatal hernia. An esophageal stricture or a diverticulum may cause reflux of boluses of feed mixed with saliva or regurgitation of liquid ruminal contents. Failure to gain weight or progressive weight loss accompanies the failure to swallow feed successfully. Signs may be seen only when forage is consumed, whereas water and grain are swallowed normally.

Systemic diseases may lead to esophageal dysfunction. Rabies must always be considered when dysphagia is present, and appropriate precautions must be taken. Botulism also leads to esophageal transport failure, although dysphagia and a weak tongue are more prominent in the affected animals that do not eat. Tetanus may be similar in appearance to esophageal obstruction because of the presence of bloat, dysphagia, and drooling. Several poisonous plants, including sneezeweed, larkspur, and milkweed, may cause excessive salivation, drooling, and bloat. Consumption of red clover infected with the fungus *R. leguminicola*, which produces the toxin slaframine, results in copious salivation. Pharyngeal trauma and subsequent cellulitis lead to dysphagia and drooling, but severe bloat does not occur unless the swelling is sufficient to occlude the esophagus. However, mild bloat frequently accompanies pharyngeal trauma caused by associated vagal nerve inflammation and dysfunction.

Clinical Pathology

Common features of long-standing choke are dehydration and metabolic acidosis resulting from continued loss of sodium bicarbonate and sodium phosphate in saliva. As sodium depletion develops, the composition of saliva shifts to include more potassium under the influence of aldosterone. Inflammatory diseases lead to predictable changes in the hemogram.

Necropsy Findings

Animals that die of acute esophageal obstruction are bloated and may have saliva and feedstuffs in the upper airway. Postmortem examination of animals with protracted esophageal dysfunction may reveal focal dilations or stenoses of the esophagus. Esophageal perforation may have occurred because of pressure around an intraluminal foreign body or necrosis caused by extension of an adjacent septic process.

Treatment and Prognosis

In cases of complete esophageal obstruction, relieving bloat is the first concern. Passage of a stomach tube may be attempted if the animal is not in respiratory distress. Trocharization of

VetBooks.ir

the rumen or installation of a temporary fistula may be required. Until the esophagus has been cleared, it is important to keep the muzzle level or pointed down to reduce the risk of aspiration of saliva. Sedative drugs such as acepromazine or xylazine may be useful for calming an animal and enabling careful examination. Suitable precautions should be taken if rabies is remotely possible. The history and an examination of the environment should enable the clinician to anticipate the nature of the obstructing object. Palpation of the neck along the left jugular furrow may reveal the site of obstruction in lean or thin-necked animals. A manual oral examination should precede probing attempts with a stomach tube. Gentle pressure on the stomach tube as it passes down the esophagus should allow localization of the obstruction. A small hand can reach into the cranial part of the esophagus and may retrieve some solid objects. If the object is solid (e.g., a potato), it may be possible to massage it into the pharynx by pressing in the jugular furrow on both sides of the neck. Specialized equipment, such as a probang, is available with a corkscrew-like or pincer-like end that can be used to grasp or engage a foreign body and expedite its retrieval. If a mass of grain is obstructing the esophagus, external massage, probing with the stomach tube, or pumping fluid against the mass through the tube may break it up.

If the choke is intrathoracic and probing with a stomach tube does not relieve the problem, several courses of action are possible. A small ruminal fistula can be inserted to prevent bloat, and the animal can simply be placed in a pen without bedding, feed, or water. Many masses consisting of grain or hay spontaneously pass within 24 hours, whereas solid objects rarely pass spontaneously. If the obstruction does not resolve in 24 hours, the animal can be heavily sedated, a cuffed endotracheal tube can be passed to prevent aspiration, and vigorous lavage with water through a stomach tube can be attempted. The head should be held lower than the body to minimize the risk of aspiration. If the obstruction still cannot be relieved or it is believed that the obstruction is a solid object, a rumenotomy can be performed. Access to the esophagus through the cardia should allow snaring of the object with a loop of stiff wire or breakup of a mass of grain.

The long-term prognosis after choke is good unless the esophageal mucosa has been damaged. Stricture formation may follow cellulitis or pressure necrosis at the site of the obstruction. Aftercare for the choked animal consists of a soft diet and antiinflammatory drugs to minimize tissue swelling. Well-soaked alfalfa cubes made into a mush may pass partly obstructed areas. Hay and grain should be moistened before feeding, and grain should be offered only in small amounts at each feeding. Broad-spectrum antibiotics should be given if mucosal damage is suspected. Maintenance of an indwelling nasogastric tube for feeding for up to 10 days after severe esophageal trauma may be helpful in preventing strictures during healing. Thick gruels made from soaked alfalfa cubes or pellets can be pumped into the rumen by a bilge pump designed for boats, or the animal can be fed and watered through a ruminal fistula. Surgical exploration may be required to determine the cause of esophageal obstruction from space-occupying lesions or strictures. Abscesses may be drained, and granulomatous lesions resected. Esophageal diverticula, aortic arch anomalies, and intrathoracic surgical problems are not easily treated.

Esophageal Dilation (Megaesophagus) and Hiatal Hernia

Bradford P. Smith

Megaesophagus rarely occurs in ruminants. It has been reported in association with pharyngeal trauma and resultant inflammatory involvement of the vagus[1] and with hiatal hernia (diaphragmatic hernia with herniation of the reticulum into the thorax) in which the megaesophagus was large (10 cm in diameter × 20 cm in length).[2] Vagotomy and hiatal hernia are recognized as causes of diminished esophageal pressure. A 4-month-old calf with megaesophagus lacked esophageal muscle cells and ganglion cells, and many fat cells were present.[3] The esophagus of a 12-month-old ram with megaesophagus was found to be heavily infected with *Sarcocystis arieticanis*, and eosinophilic inflammation and degeneration of muscle fibers were noted.[4] However, *Sarcocystis* spp. have been found in the esophagus of many sheep without megaesophagus, which makes the diagnosis difficult. An 18-month-old heifer with megaesophagus also had eosinophilic submucosal infiltration, but no sarcocysts were seen.[5] Megaesophagus due to unknown causes in a goat was also reported.[6]

The principal clinical signs of megaesophagus are regurgitation and vomiting, usually shortly after eating. Mild, recurrent bloat and discomfort when a stomach tube is passed are also observed. In other cattle with a hiatal (diaphragmatic) hernia or an esophageal diverticulum, regurgitation or vomiting and bloat have also been reported. Contortion of the neck while eating, apparently caused by pain, was seen in one cow and is reported in human beings with hiatal hernia. In some cases of herniation of the reticulum into the thorax, bloat and regurgitation are not seen; in others, diaphragmatic hernia resulted in chronic bloat.[7] Diaphragmatic hernias may be either congenital or acquired. It appears that acquired diaphragmatic hernias are most common.

A stomach tube should be passed to the rumen to rule out choke or an intraluminal mass obstructing the esophagus as a cause. If a tube can be passed freely to the rumen, plain and contrast radiographs of the esophagus should be taken. If this is not possible, the abdomen should be explored surgically for a diaphragmatic hernia, and the cardia and terminal esophagus should be palpated digitally by means of rumenotomy.

Megaesophagus associated with pharyngeal trauma has a good prognosis,[1] whereas megaesophagus associated with hiatal hernia has a more guarded prognosis.[2] Supportive treatments and stomach tubing with fluids may be required for 1 to 2 weeks until the animal is able to drink unaided. Longer-term support can be given to a valuable animal by surgical creation of a ruminal fistula fitted with a rubber cannula through which feed and water can be given until normal deglutition returns.

Ultrasonography of the Ruminant Abdomen

Sébastien Buczinski

Medical indications of ultrasonography in cattle and small ruminants have expanded since the 1990s. This ancillary test can be performed at the patient's side and gives valuable information to confirm a clinical hypothesis. As for any diagnostic test, it is important for the clinician to know what he or she is looking for before performing the procedure. The cattle abdomen is vast, and a complete abdominal screening (including reticulum, spleen, abomasum, small and large intestines, bladder, kidneys, and uterus in females or inguinal area in males) can be time consuming and not practical in field situations. Practical questions that the clinicians can have in mind when planning abdominal ultrasonography are numerous. To this author's knowledge, in dairy practice, the most common questions to be answered by this test are as follows: (1) Does the affected cow have cranial peritonitis? (2) If so, what is the main presumptive diagnosis, depending on the localization of fluid and effect on reticular motility? (3) Is the right-sided ping truly caused by abomasal dilation, or is another organ the source? (4) Where is the pyloric part of the abomasum when left displaced abomasum is suspected but no typical ping is heard? (5) Does a cow with colic (e.g., evidence of intestinal

obstruction) need immediate surgery? (6) Is the right kidney involved when left kidney pyelonephritis is suspected? (7) When peritonitis is suspected because of unsuccessful blind abdominal tap, can a better spot be chosen? All these questions can be answered rapidly (in less than 15 min) with a focused ultrasonographic examination

Units and Probes Required

The required characteristics of the ultrasound unit used for this examination depend on the size of the patient. For small calves (e.g., preweaned dairy calves weighing less than 100 kg [220 lb]) and small ruminants, a rectal linear probe (≥5 MHz) can generally be used for assessing abdominal structures and intraabdominal umbilical remnants. For larger animals, a lower frequency probe (<5 MHz) is needed to increase the penetration depth of the ultrasound beam (20 to 30 cm depth is obtained by a 2- to 3.5-MHz probe). The probe can be either linear, sectorial, or convex. Several portative ultrasound units are now available and produce good-quality images that can be used for medical diagnosis in ruminants.

Secondary characteristics of the ultrasound unit that may be suitable, especially in a teaching environment, are the ability to perform measurements (distance or area measurements), as well as the ability to store pictures and videos. These characteristics may help monitoring lesion progression and are very helpful if a second opinion is required and the examination has been performed on the farm.

Patient Preparation

The area of interest needs to be clipped or shaved. Then the skin can be rubbed with a moist towel before coupling gel that allows a good contact between the skin and the probe is applied. This standard preparation is the best way to obtain high-quality images. For a rapid screening, the author sometimes uses only direct spray application of 70° isopropyl alcohol on the skin (and only if hair is short and clean). The disadvantage of this preparation is premature wear of probe pad, which will eventually need to be replaced. In most situations, no specific containment other than head restraint (eg halter) is required, at least in dairy cattle, which are frequently manipulated for milking purpose. If the animal is not coooperative, another operator can be required to prevent injury or damage to the equipment.

General Comments About Ultrasonography Performance

Despite its more frequent use for medical purposes in cattle and small ruminants, there is a relative paucity of data concerning the accuracy of ultrasound examination (in terms of sensitivity and specificity). There are some reports as case-series or case-control studies from referral veterinary centers (eg university hospital). In many situations, ultrasonography is helpful for determining abnormal organ position, parenchymal anomalies or presence/extension of free abdominal fluid. The definitive diagnosis is generally reached by additional ancillary testing (e.g., clinical pathologic study, microbiological analysis, cytologic study, or biopsy). Ultrasonography is very helpful for selecting the best area to obtain these additional diagnostic samples.

Normal and Main Abnormal Ultrasonographic Aspects of Abdominal Organs in Calves and Cows

A thorough knowledge of the abdominal anatomy and normal ultrasonographic aspect of the abdominal organs is necessary to reach the confidence level necessary to perform this ancillary test. The major organs or structures that can be assessed with ultrasonography are the peritoneal space, reticulum, abomasum, small and large intestines, liver, kidneys, uterus, and ovaries. Other structures such as the omasum, rumen, pancreas, mesenteric lymph nodes, and abdominal vessels can also be assessed for specific purpose (Fig. 32.96) such as ruminitis, pancreatitis, and lymphadenomegaly.

THE PERITONEAL CAVITY AND PERITONEAL FLUID ASSESSMENT. Abdominal ultrasonography is a sensitive technique for detecting peritoneal fluid accumulation. The peritoneal fluid is generally present in small amount in the normal abdomen and serve as a lubricant. The peritoneal fluid quantity physiologically increases in late pregnancy because of hypervolemia and possible increased hydrostatic pressure on abdominal vessels secondary to mass effect of the fetus. Large quantities of free abdominal fluid can manifest as ascites (secondary to congestive heart failure or in the presence of caudal vena cava thrombosis; Fig. 32.97). Inflammation of the peritoneal cavity (peritonitis) is a common cause of focal or diffuse accumulation of free abdominal fluid. The typical findings in cases of peritonitis consist in the presence of heterogenic liquid content with various amounts of echoic to hyperchoic fibrin strands as shown in Fig. 32.98. Depending on the condition chronicity and the bacteria involved, secondary abscessation and images associated with gas-producing bacteria can also be observed, as with a retroperitoneal abscess in Fig. 32.99. The retroperitoneal abscess can be distinguished from peritonitis because the accumulation occurs between the parietal part of the peritoneum layer and the transverse muscle.

FORESTOMACHS. The reticulum, rumen and omasum have the same ultrasonographic aspect. They have a thick hyperechoic wall. Their content cannot be imaged because of the presence of small gas bubbles in the rumen fluid (reverberation artifact). The topography of the scanning area for the main abdominal organs is represented in Fig. 32.96.

The reticulum can be imaged mainly in the left cranioventral abdomen in the area between the xyphoid process of the sternum and cranial to the left mammary vein (Fig. 32.100). The reticulum is recognized by its periodic biphasic movements (Video 32-1) during contractions preceding ruminal contractions. These biphasic contractions generally occur at the frequency of 1 per minute. Initially, a low-amplitude contraction (reticulum pushed from 5 to 10 cm deep in the abdominal cavity) is observed; then the reticulum returns to its relaxed state. Immediately after, a complete contraction (>17 to 18 cm) occurs.[1] The general ultrasonographic landmarks that can be used to identify the reticulum is the musculophrenic vein, which is an anechoic tubular structure between the abdominal wall and the diaphragm (Fig. 32.100). The reticulum wall is smooth and slides easily along the abdominal wall. The honeycomb structure of the wall is occasionally observed.

The main abnormality seen during reticular assessment is associated with cranial peritonitis such as in hardware disease. In these cases, heterogenic fluid accumulation between the abdominal and reticular walls is generally observed (exudate with fibrin strands or clots; Fig. 32.101). In these cases, the motility of the reticulum is most often abnormal, with decreased frequency and amplitude of contractions due to pain and adherences. Other findings associated with hardware disease are deformation of the reticular wall Fig. 32.102, increased wall thickness due to fibrin deposit, and abscessation characterized by a cavitary lesion Fig. 32.103. The foreign body cannot be imaged in most cases. Therefore the definitive diagnosis is based on clinical findings, extension of the peritonitis findings (mainly left-sided), and other imaging tools such as abdominal radiographs.

The rumen and omasum are also seen as hyperechoic thick-walled viscera, but no content is visualized. The rumen occupies most of the left abdominal cavity, whereas the omasum is observed at the visceral border of the liver. The clinical value of specifically assessing these organs remains to be determined.

VetBooks.ir

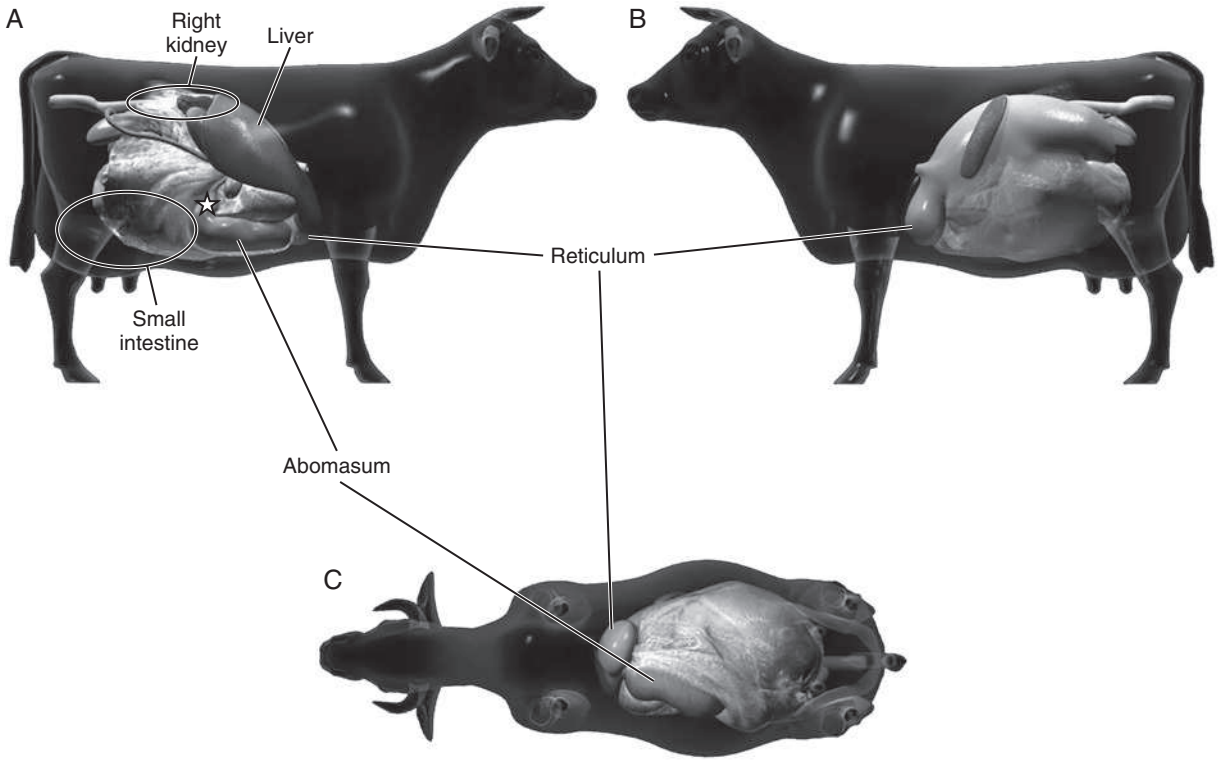

FIG. 32.96 Practical anatomic landmarks for abdominal ultrasonography in a cow. The right **(A),** left **(B),** and ventral **(C)** views of the abdomen. The reticulum, abomasum (and pyloric part of the abomasum *[star]*), liver, small intestine, and right kidney area of interest are represented in the three different views. *(Courtesy Dr. André Desrochers and Dr. Denis Harvey, from* Surgery of the abomasum in cattle, Version 2.0, *Université de Montréal.)*

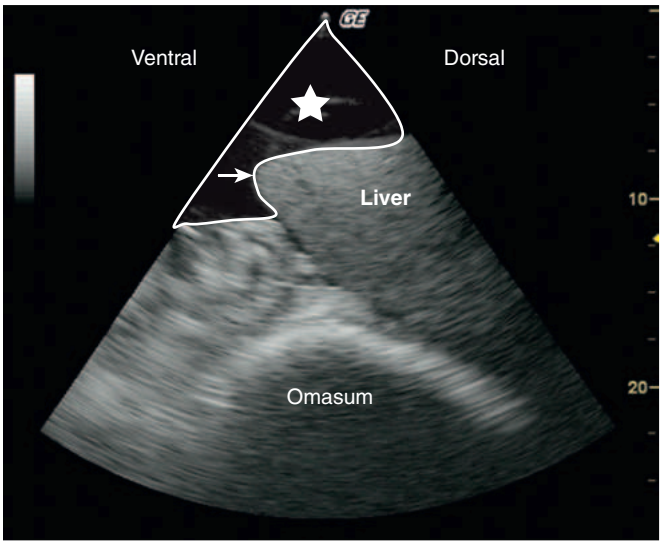

FIG. 32.97 Ascites secondary to congestive heart failure in a dairy cow. Large amounts of anechoic fluid are observed on right flank ultrasonography *(star)*. The ventral border of the liver is also observed. The liver ventral border is not as sharp as usual because of hepatomegaly *(arrow)*. Image obtained with a phased-array 2.5-MHz probe (maximal depth, 27 cm).

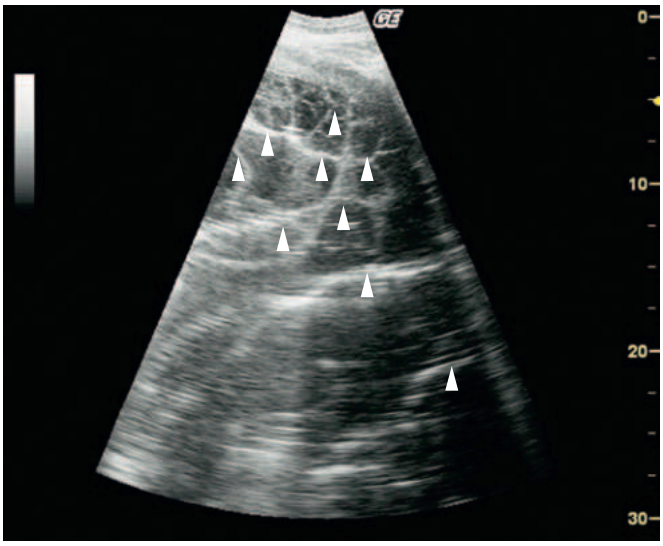

FIG. 32.98 Sonogram of caudal peritonitis in a cow secondary to uterine laceration. A large amount of peritoneal fluid is observed. The "spider-web" appearance is due to the multiple echoic fibrin strands *(arrows)*. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 30 cm).

The abomasum has a distinct ultrasonographic appearance in comparison with others. The abomasal wall is thinner and can sometimes be difficult to identify specifically with a low-frequency probe. The normal abomasum position varies greatly throughout the production phase of a dairy cow. This organ is pushed cranial to the left in late pregnancy and then is slowly displaced toward the right ventral part of the abdomen. The pyloric part of the abomasum has specific characteristics used to localize the abomasum position. This portion has a thick multilayered wall and is most often observed as a crescent shape structure oral to the cranial part of the duodenum (Fig. 32.104**)**. The posterior (deeper) wall of the pyloric part

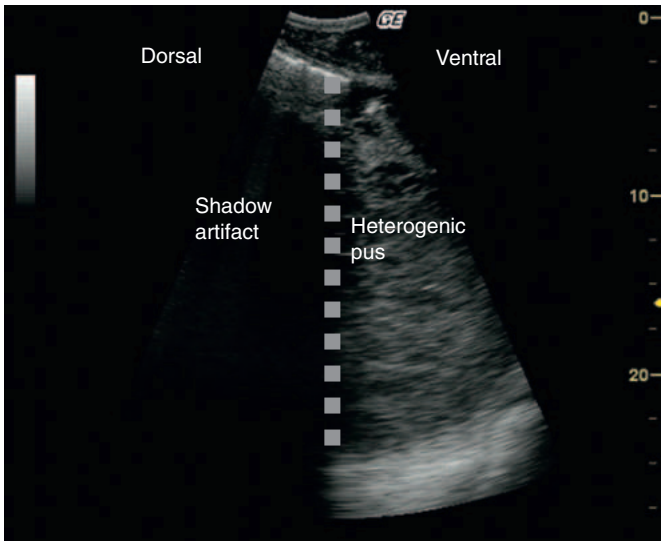

FIG. 32.99 Gas-liquid interface seen in a cow with retroperitoneal abscess secondary to right flank laparotomy. The gas-tissue interface *(gray dotted line)* was caused by gas-producing bacteria present in the abscess. The shadow on the dorsal part of the flank is an artifact. Heterogenic pus is visible on the ventral part of the sonogram. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 28 cm).

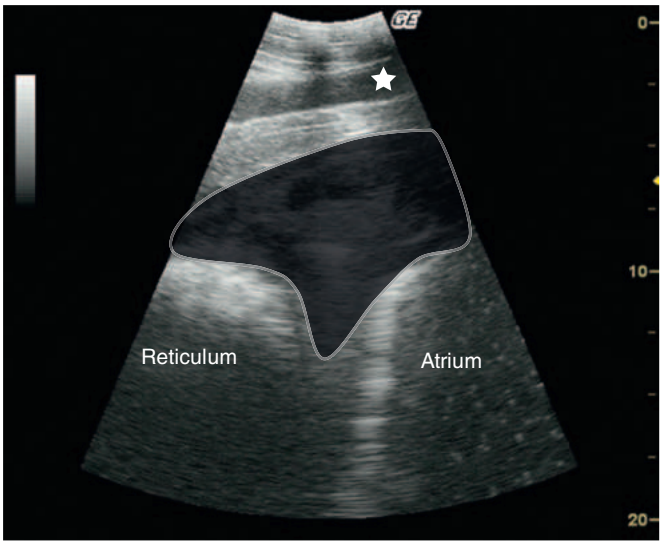

FIG. 32.101 Typical aspect of traumatic reticuloperitonitis in a dairy cow. The heterogenic peritoneal content *(shaded area)* between the diaphragm, reticular wall (left), and rumen atrium wall (right) is observed. The diaphragm is surrounded by the musculophrenic vein *(star)* and peritoneal fluid. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 20 cm).

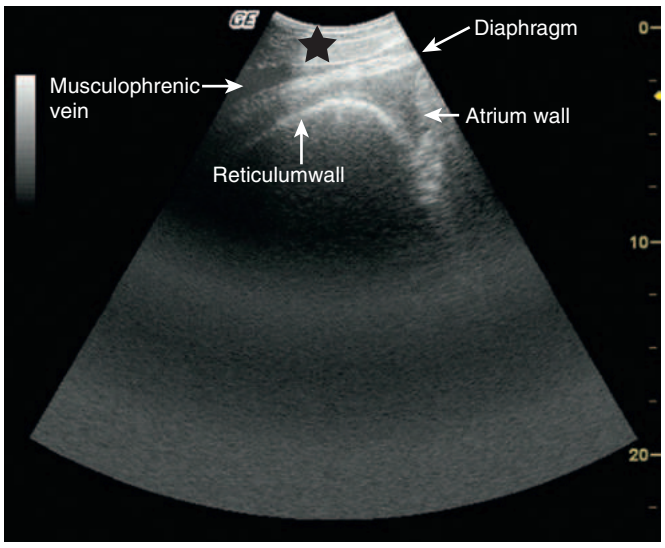

FIG. 32.100 Sonogram of the reticulum at the beginning of its first contraction. The reticulum wall is characterized by its hyperechoic aspect. Because of gas content, no forestomach content can be seen. The musculophrenic vein allows distinguishing the diaphragm and abdominal wall *(black arrow)*. The atrium wall is partially visible. At the beginning of the first contraction of the reticulum, the space between the reticulum and the diaphragm is slightly increased in comparison with the that between contractions. Better contrast enables easier reading of the sonogram. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 23 cm).

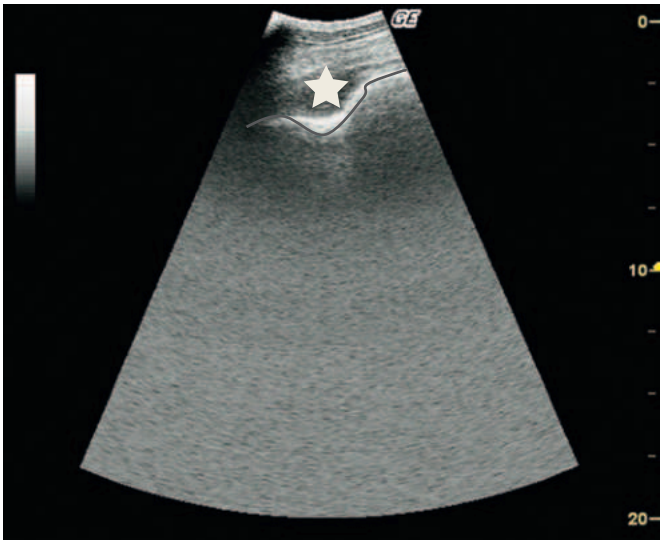

FIG. 32.102 Deformation of the reticular wall in association with hardware disease. The reticular wall (highlighted in *gray*) is different from its traditional smooth appearance due to the presence of peritonitis *(star)* and focal increased pressure. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 20 cm)

is generally not observed because of shadow artifact associated with gas content of the viscus.

Because of the difficulty in characterizing abomasal position, the pylorus position is a useful indicator of abomasal position when an abomasal displacement is suspected with no ping on auscultation or when right-sided ping indicates abomasal dilation. In these situations, the pylorus is not in its normal specific position, and secondary findings associated with abomasal dilation, such as the presence of a gas-liquid interface (on the left or right), can be observed (Fig. 32.105). When a "floating" displaced abomasum is suspected, the pylorus is generally found medial to the right mammary vein or close to the ventral midline. In these situations, ultrasonography may help in treatment decision. In case of abomasal dilation or volvulus of the abomasum, the distended abomasum precludes normal observation of the liver. The position of the pylorus is also interesting to distinguish abomasal dilation from volvulus because the pyloric part of the abomasum is observed more cranially in cases of volvulus. Infiltration of the abomasum by lymphomatous tissue can also be suspected when imaging the pyloric part of the abomasum (Fig. 32.106). In these conditions, transabdominal fine-needle aspiration or biopsy in the thickened wall may help determine the final diagnosis.[2]

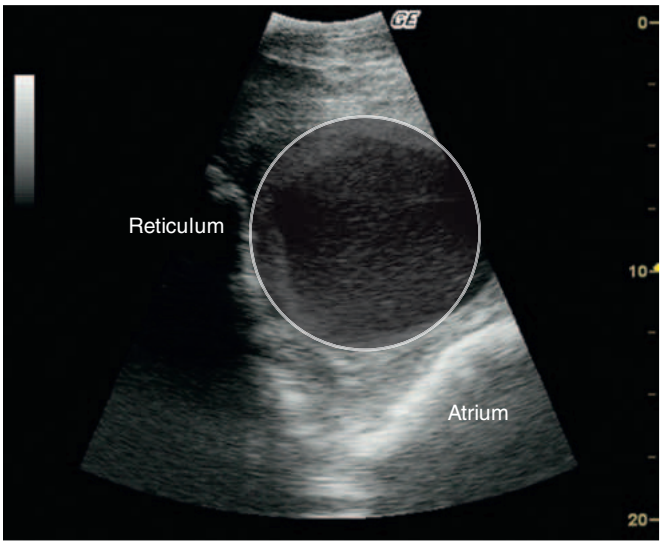

FIG. 32.103 Chronic traumatic reticuloperitonitis and abscessation. The reticulum and atrium walls are visible. The atrium is pushed dorsally because of a cavitary lesion with an heterogenic content and thick wall (abscess). Image obtained with a sectorial 3.2-MHz probe (maximal depth, 20 cm).

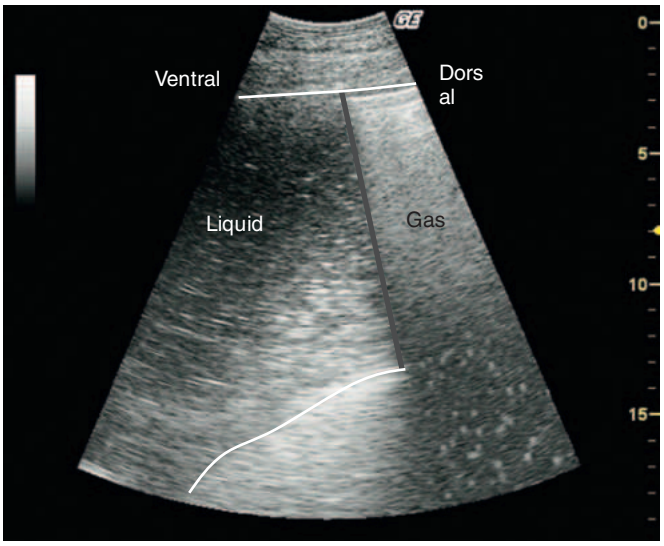

FIG. 32.105 Ultrasonographic appearance of a left displaced abomasum (or right abomasal dilation/volvulus) A gas-liquid interface is observed *(gray dotted line)*. The abomasal wall is indicated with *white lines*. The medial wall cannot be observed on the dorsal part because of the presence of gas within the distended abomasum. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 19 cm).

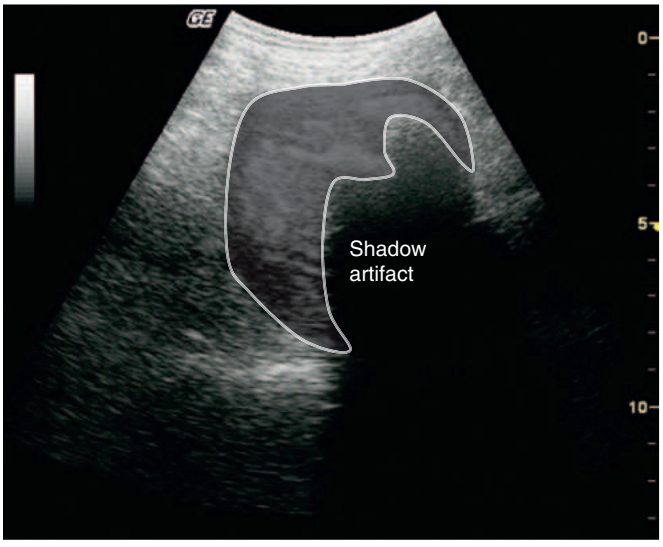

FIG. 32.104 Pyloric part of the abomasum in transverse section. The pyloric part of the abomasum has a thick layered wall. The characteristic crescent shape is visible because of residual gas within the abomasal lumen. A shadow artifact is therefore observed. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 13 cm).

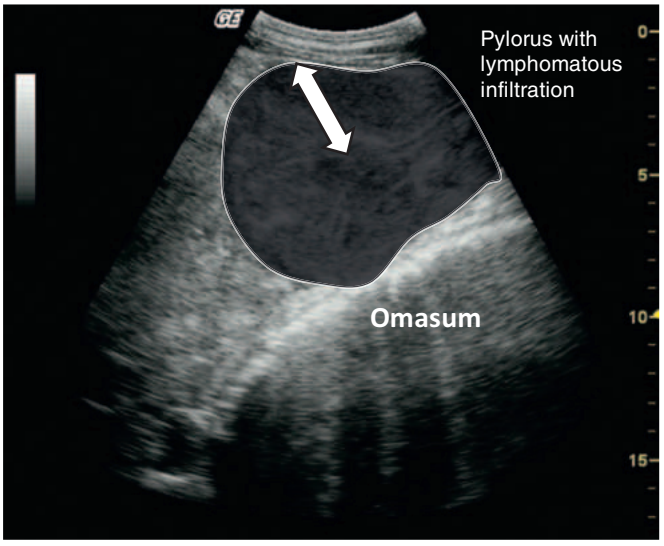

FIG. 32.106 Ultrasonographic aspect of the pyloric part of the abomasum in a cow with abomasal infiltration by lymphomatous tissue. The wall of the pyloric part is thickened (3 to 5 cm; *arrows*), as is the cross-section of the pylorus *(gray shaded area)*. The multilayered structure of the enlarged pylorus is also visible. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 17 cm).

Abomasal ulcers cannot be observed with ultrasonography. Perforating ulcers can be suspected when finding images compatible with peritonitis are close to the abomasal projection area (Fig. 32.107). However, these findings are not specific and can be associated with any cause of peritonitis.[3]

SMALL AND LARGE INTESTINES. Ultrasonography of the small and large intestines is generally straightforward. The small intestine is generally observed in the midventral part of the right flank. Multiples loops of small intestine are observed; constant movement indicates good peristalsis. The normal diameter of the small intestine is generally less than 4 cm, but its cross-sectional dimension varies constantly. The content of small intestine is generally visible as areas of variable echogenicity (Fig. 32.108, Video 32-2).

The most common abnormal findings during small intestine ultrasonography is ileus. In these situations (either paralytic or obstructive ileus), significant distention of the small intestine loops is observed with decreased motility (Fig. 32.109, Video 32.3). Secondary peritoneal effusion can be seen in association with impaired mesenteric blood flow and transudation. Edema of the intestinal wall can also be observed (e.g., wall thickness >2 to 3 mm)[3] (Fig. 32.110).

One of the main challenges during small intestine ultrasonography is to differentiate obstructive causes of ileus (i.e., necessitating surgical treatment) from medical causes. The exact cause of obstruction is rarely diagnosed on transabdominal ultrasonography because of the size of the bovine abdomen.

VetBooks.ir

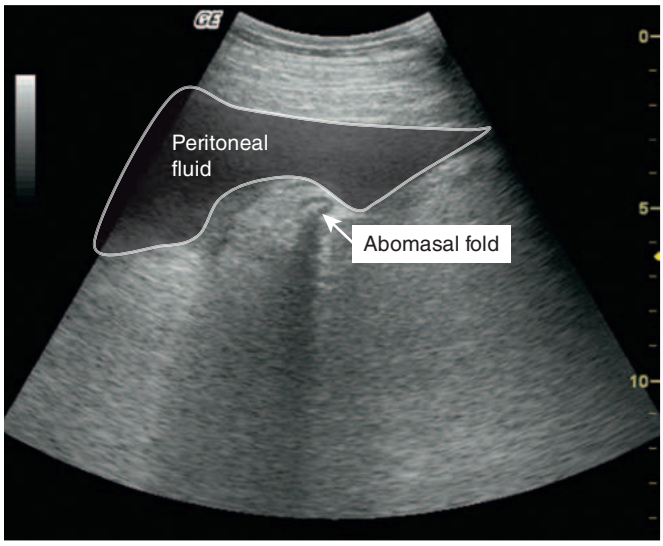

FIG. 32.107 Cranial peritonitis associated with perforating abomasal ulcer. Hypoechoic peritoneal fluid accumulation is visible close to the abomasum. The abomasum is recognized by hypoechoic abomasal fold. Abomasal ulcer was suspected because of the localization of peritonitis close to the abomasum. However, it cannot be definitively diagnosed without other ancillary testing (e.g., laparotomy or necropsy). Image obtained with a sectorial 3.2-MHz probe (maximal depth, 14 cm).

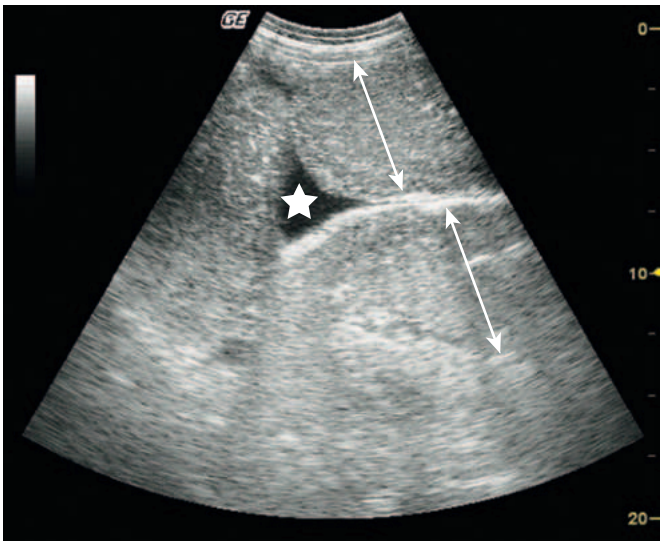

FIG. 32.109 Sonogram of obstructive ileus associated with hemorrhagic bowel syndrome. An important distention of the small intestine loops is observed (>6 to 7 cm in diameter). Secondary anechoic peritoneal effusion is also observed *(star)*. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 20 cm).

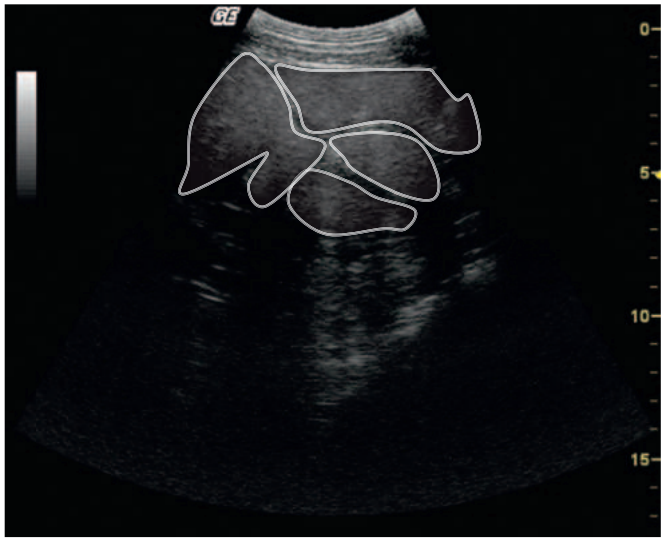

FIG. 32.108 Sonogram of normal small intestine loops in an adult Holstein cow. The intestine loops are characterized by their various shapes, hypoechoic wall, and echoic content. Their wall is delimited by a *white line*. When imaging is done in real time, constant movement of the loops and their content is observed. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 17 cm).

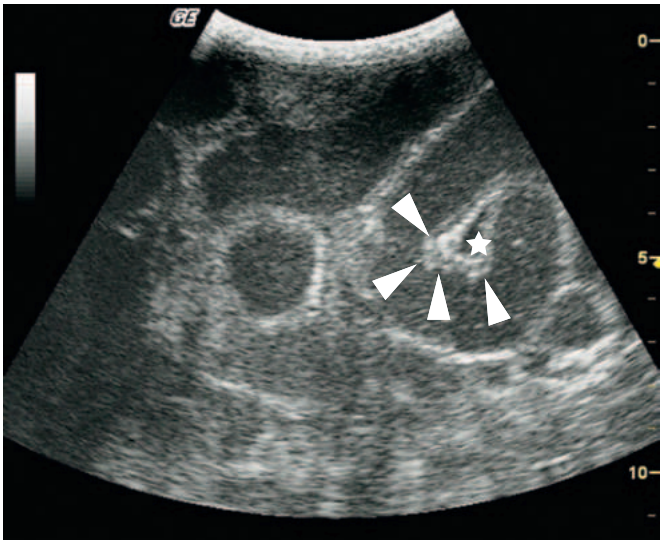

FIG. 32.110 Sonogram of obstructive ileus secondary to atresia coli in a 3-day-old Holstein calf. Besides intestinal loops dilation and peritoneal fluid accumulation *(star)*, thickening of the intestinal wall is also observed secondary to intestine wall edema *(arrowheads)*. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 12-cm).

However, identification of indirect consequences of obstructive ileus is an achievable goal that helps in the decision of medical or surgical treatment. In cases of obstruction, the visualization of distended (oral to the obstruction) and empty loops (aboral) of small intestine helps the clinician make the decision about whether surgery can be delayed.

The large intestine can be imaged by ultrasonography on the dorsal midright flank. However, limited information can be obtained. First, its content is full of gas and cannot be imaged. Second, it is difficult to identify each part of the large intestine. The thin large intestinal wall, which is close to the probe, can be observed. A shadow artifact hides deeper parts of the large intestine. The caecum can also be imaged with ultrasonography.[4] In general diagnosis of cecal problems relies on the transrectal examination findings. The general appearance of the caecum is the same as that of the large intestine (Fig. 32.111).

LIVER ULTRASONOGRAPHY. The liver can be imaged with transabdominal ultrasonography. A high-frequency probe can be used in calves, but a low-frequency probe is indicated for the assessment of the liver in adult cattle (especially if the caudal vena cava, which is located deep in the abdomen, is scanned). Prior knowledge of the liver anatomy is required, and the clinician must remember that an important part of liver parenchyma cannot be directly visualised because the diaphragmatic portion of the liver is surrounded by lung

VetBooks.ir

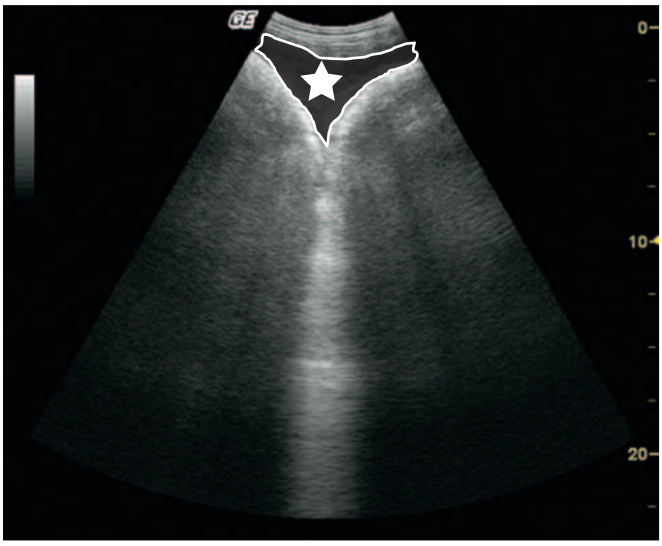

FIG. 32.111 Right flank sonogram of large intestine in a Holstein heifer with cecal dilatation and torsion. The cecal/colonic wall is visible as a thin echoic wall. Because of the gas content, no ultrasound beam is transmitted beyond the superficial wall. Secondary findings associated with peritonitis (increased peritoneal fluid with small echoic fibrin strands) are outlined *(star)*. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 25 cm).

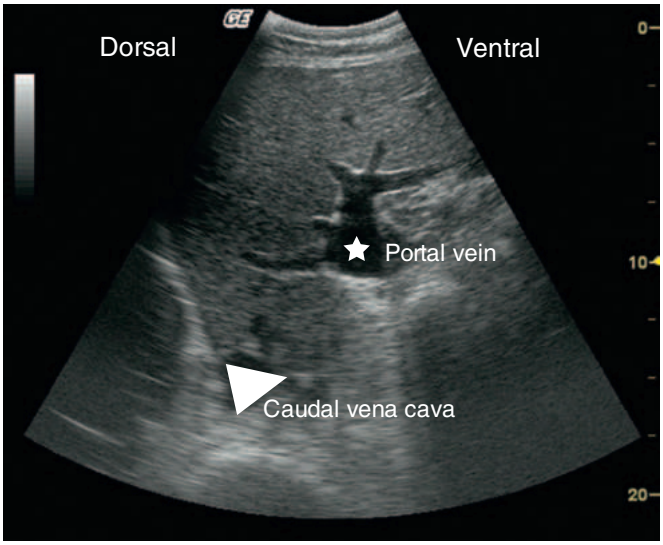

FIG. 32.112 Ultrasonogram of the liver, showing the relative position of caudal vena cava and portal vein in a Holstein heifer. The liver parenchyma has an homogenous echogenic texture. The portal vessels and major portal vein are characterized by a hyperechoic wall *(star)* in the midvisceral part of the liver. The caudal vena cava is visible in the dorsal and deep part of the liver as a triangular shape. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 20 cm).

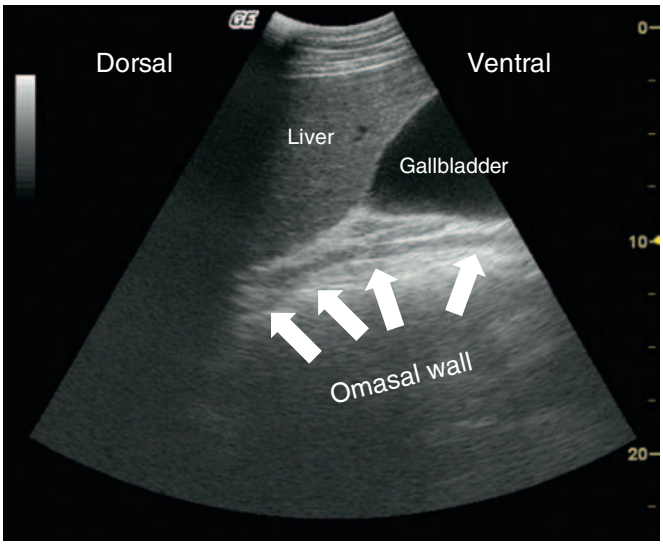

FIG. 32.113 Normal aspect of the gallbladder. The gallbladder, as observed from the ninth to eleventh intercostal spaces, appears as a pear-shaped structure with anechoic content, originating from the ventral visceral surface of the liver. Image obtained with a sectorial 3.2-MHz probe at the ninth intercostal space (maximal depth, 22 cm).

parenchyma. The screening area runs from the ventral fifth intercostal space to the last intercostal space.[5]

Different structures can be observed when the liver is scanned.[5,6] The liver parenchyma has a hypoechoic to echoic homogenous aspect. Small anechoic structures such as vessels or biliary ducts are visible within the parenchyma. The portal vein and major portal vessels, the caudal vena cava aspect (Fig. 32.112), and the gallbladder aspect (Fig. 32.113) are also observed during the ultrasonographic examination. Basic knowledge of the normal appearance of the liver and its structures is essential when ultrasonography is used on an animal with suspected liver disease. The right and caudate lobe of the liver can be observed, but a significant portion of the left lobe is not visible because of its relative position within the lung field. Pneumoperitoneum and abomasal right dilation/volvulus are also conditions that preclude a correct visualization of the liver parenchyma.

Liver ultrasonography is especially helpful for the diagnosis of liver abscesses, caudal vena cava thrombosis, and any focal or diffuse liver changes. Ultrasonography may help the clinician select the best area to perform liver biopsy or fine-needle aspiration for a definitive diagnosis.

Liver abscessation is a common hepatic condition in calves, dairy cows, and feedlot cattle.[7] The clinical signs are not specific, and liver ultrasonography is generally helpful if the affected site is not in the part of the organ beneath the lungs. Previous studies in feedlot calves have revealed the limited ability of ultrasonography to show lesions on the left hepatic lobe.[8] Cavitary lesions of various size and shape can generally be observed (Fig. 32.114). The abscess content can be homogenous to heterogenous. The definitive diagnosis is made through fine-needle aspiration to differentiate from liver neoplasm or cystic structures.[5] Liver neoplasms are uncommon in cattle, but the ultrasonographic aspect of hepatocellular adenoma, bile duct carcinoma, and adenocarcinoma have been reported.[9] The ultrasonographic changes are not pathognomonic and generally consisted in single to multiple circular structures. The definitive diagnosis necessitates biopsy or aspiration of the abnormal area. Liver metastasis secondary to the spread of a primary non hepatic tumor (e.g., lymphoma) has also been reported.[5]

Liver ultrasonography is helpful for the diagnosis of liver flukes and cholestastic disorders in cattle. In cases of chronic fasciolosis, calcified bile ducts are recognized by the acoustic shadowing below the mineralized duct.[10] Percutaneous puncture of the gallbladder to search for flukes' eggs is more a sensitive test than is fecal eggs testing for *Fasciola hepatica* and *Dicrocoelia dendriticum* infection.[11] Distention of the biliary tract is observed with any cholestatic disease. Establishing a differential diagnosis with liver vessels is not easy without color flow Doppler imaging. Distention of the gallbladder alone is not a specific sign of liver dysfunction because dilation may occur in anorexic cows without any primary liver disease.

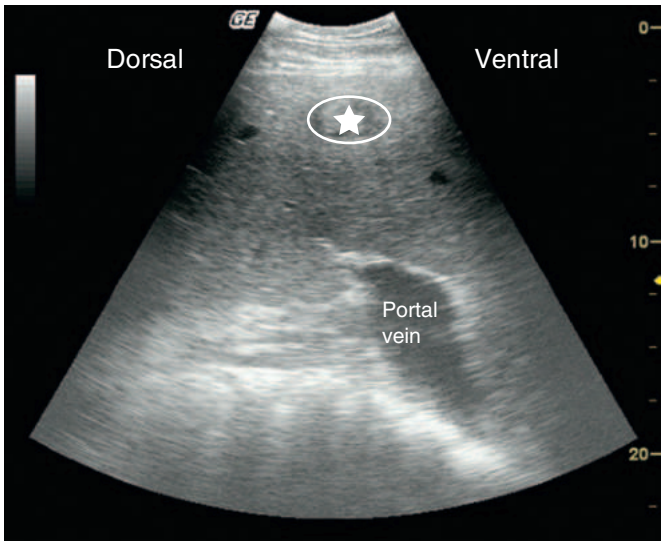

FIG. 32.114 Ultrasonographic aspect of liver abscess. The abscessation is represented by a cavitary lesion with heterogenic content *(star)* within liver parenchyma. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 22 cm).

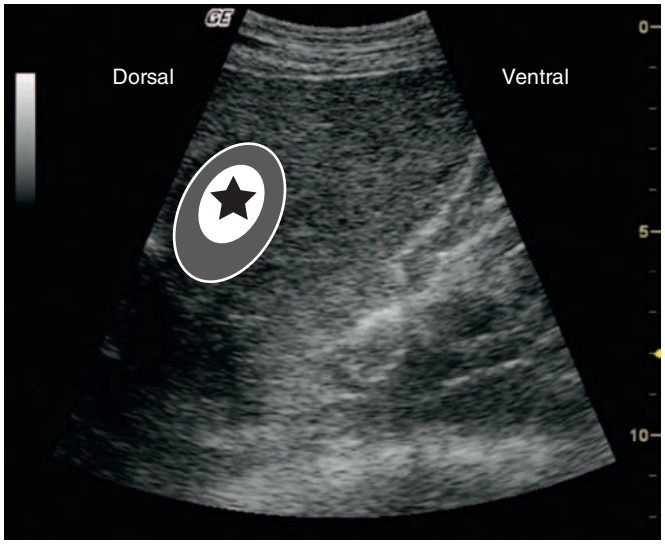

FIG. 32.115 Liver abscess secondary to omphalophlebitis in a 2-week-old Holstein calf. The abscess is characterized by a thick hypoechoic capsule *(gray colored zone)*. The pus appears with an hyperechoic aspect *(star)*. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 15 cm).

Liver ultrasonography can also be performed for the diagnosis of fatty liver syndrome (hepatic lipidosis). This diffuse liver disease is characterized by fat accumulation within liver parenchyma. The excess of fat within the liver cells increases their impedance and therefore attenuates the ultrasonography beam more rapidly.[5] Contrast in the image is decreased, which renders the quality of imaging vascular structures poor (vascular blurring). The specific diagnosis of fatty liver is difficult without software for automatic texture analysis.[12,13] However, this type of digital analysis is not routinely performed in a clinical setting. The ultrasonographer is able to detect only severe liver infiltrations.

Anomalies of the liver vessels mainly consist of caudal vena cava thrombosis and liver congestion secondary to heart failure. In young calves, omphalophlebitis with or without liver abscessation is also commonly reported (Fig. 32.115).[14] Caudal vena cava thrombosis is a common vascular condition in which subacute

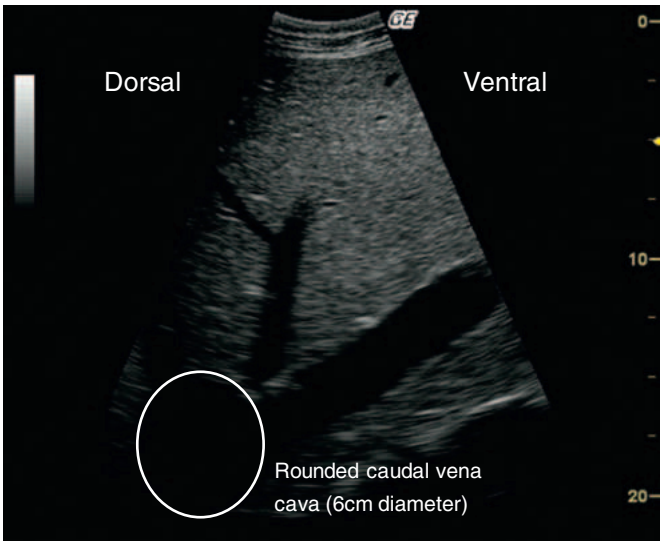

FIG. 32.116 Ultrasonographic aspect of distension of the caudal vena cava in a Holstein cow with thrombosis of the caudal vena cava. Congestion of the caudal vena cava is characterized by distention (diameter, >4.5 to 5 cm) and change of shape from triangular to circular as a result of thrombosis of the vessel. The thrombus is generally not seen because it is masked by the lung field. Image obtained with a sectorial 3.2-MHz probe (maximal depth, 20 cm).

ruminal acidosis is commonly observed (e.g., in feedlot calves and dairy cows). The thrombosed part of the caudal vena cava cannot be seen transabdominally because of interference with the lung field but can be imaged on intraabdominal ultrasonography during explorative laparotomy.[15] The main anomaly observed on transabdominal ultrasonography is associated with secondary changes of the caudal vena cava shape before the thrombosed area. The increased hydrostatic pressure is associated with a dilation and a shift in the shape of the caudal vena cava from triangular to round (Fig. 32.116). The reported range of the diameter of the caudal vena cava is 2 to 5 cm, depending on the intercostal space screened.[6] The portal vein normal diameter generally varies from 1.7 to 5.3 cm. All liver vasculature can be distended secondary to right-sided heart failure (Fig. 32.117). Because of hepatomegaly caused by liver congestion, the liver borders are less sharp than usual (see Fig. 32.97). In these situations, the clinical presentation typically differs from caudal vena cava thrombosis.

The pancreas can also be observed on abdominal ultrasonography.[16] However, its visualization is difficult because of its poorly defined shape and structure. Pancreatic diseases are uncommon in cattle, and little information about the use of ultrasonography to investigate pancreatic disease has been reported, except with regard to transabdominal biopsy[17] and induction of experimental pancreatitis by transabdominal chloroform injection.[18]

KIDNEYS AND URINARY TRACT. The urinary tract can be imaged on transabdominal and transrectal ultrasonography.[19] Ultrasonography can be especially helpful in the detection of pyelonephritis, hydronephrosis, and distention/rupture of the bladder secondary to urolithiasis. Infection of the urachus and umbilical arteries can also be diagnosed in calves.[14]

During transabdominal examination with a low-frequency probe in an adult cow, the clinician can observe most of the right kidney and occasionally part of the left kidney. In young calves, the transabdominal approach can also be used with a high-frequency probe because of the superficial position of the kidneys. The caudal part of the left kidney is traditionally imaged through a transrectal approach with a high-frequency probe.

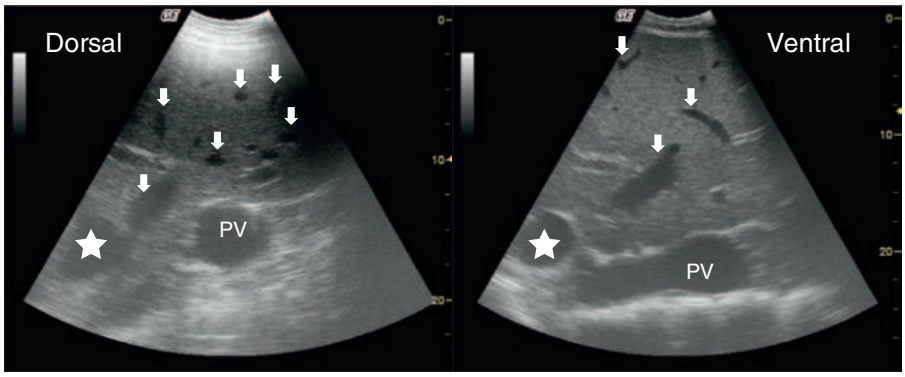

FIG. 32.117 Liver changes secondary to right-sided heart failure. The main changes are related to liver vasculature. Dilation of the caudal vena cava *(star)* and the portal vein *(PV)* is visible, as is the general increase in the vessels' sizes, especially in the superficial part of the liver *(arrows)*. Images obtained with a sectorial 3.2-MHz probe (maximal depth, 22 cm).

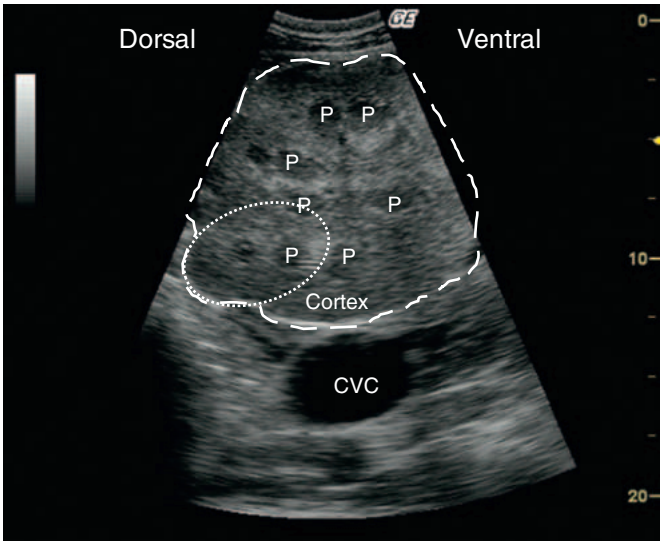

FIG. 32.118 Transverse view of the right kidney in a cow with caudal vena cava thrombosis. The lobulation of the kidney is visible (example: *dotted circle*). The hypoechoic pyramids *(P)* can be distinguished from the more echoic cortex. The distended caudal vena cava *(CVC)* is also seen on that image. Image obtained at the dorsal right paralumbar fossa with a sectorial 3.2-MHz probe (maximal depth, 20 cm).

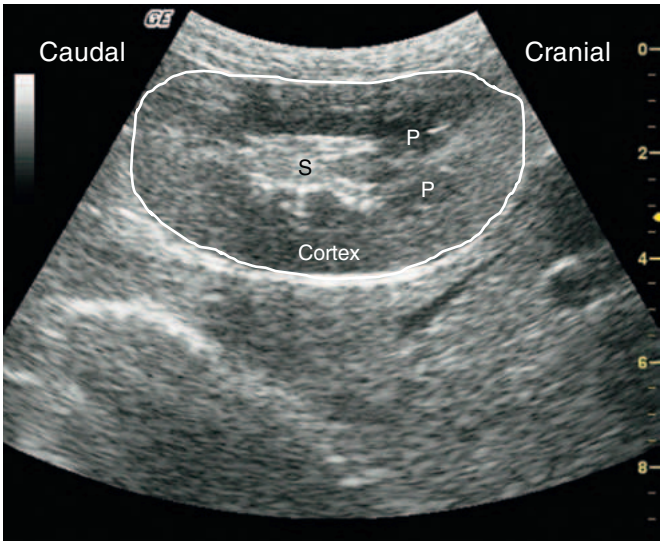

FIG. 32.119 Longitudinal view of the left right kidney in an adult Boer buck. The bean shape of the kidney is observed. The hypoechoic pyramids (P) can be distinguished from the more echoic cortex. The hyperechoic renal sinus (S) is also observed. Image obtained at the dorsal right paralumbar fossa with a sectorial 3.2-MHz probe (maximal depth, 10 cm).

Most of the right kidney is observed on the dorsal part of the paralumbar fossa and the last intercostal space (extending from the thirteenth rib to the third lumbar vertebra). Other approaches such as placing the probe between the transverse processes of the lumbar vertebrae can also be done. Visualization of the left kidney by transabdominal approach is limited because of the presence of gas-filled superficial loops of large intestine.

The normal kidney is characterized by its lobulated aspect in cattle (Fig. 32.118), which is in contrast to the bean-shaped appearance in small ruminants (Fig. 32.119). The cortex is more echogenic than the medullary pyramids. In the central part of the kidney, the renal sinus is seen as a hyperechoic structure (because of fat content; see Fig. 32.119). It is difficult to differentiate vascular and ureteral structures.

Ultrasonography can detect kidney changes associated with pyelonephritis, which is a common urinary tract disease in dairy cows. The main changes are associated with abnormal deposits in the collecting structures of the kidney (Fig. 32.120). Distention of the urethra can be distinguished from renal vessels if color-flow Doppler imaging is available (Fig. 32.121). Hydronephrosis secondary to ureteral obstruction can be observed as a dilation of collecting structures and compression of both the pyramid and cortex (Fig. 32.122). Ultrasonography is of particular interest for distinguishing unilateral from bilateral renal diseases, which is of prognostic importance. Other less important renal anomalies (nephrolithiasis or cysts; Fig. 32.123) can also be observed during the examination.

The urinary bladder can be imaged transabdominally in small ruminants and calves (Fig. 32.124) and by transrectal examination in adult cattle. The more common anomalies of urinary bladder are associated with infection (cystitis), which leads to increased urine echogenicity and heterogenicity. Urolithiasis-associated changes are also an indication of performing urinary bladder ultrasonography to evaluate bladder wall integrity (rupture). Severe distention is observed (see Fig. 32.124) before rupture occurs. In case of ruptured urinary bladder, the ultrasonographic findings are very similar to those of ascites or diffuse peritonitis. Analysis of fluid obtained by abdominocentesis is helpful for reaching the final diagnosis.

OTHER ABDOMINAL STRUCTURES. The genital tract (male and female), abdominal lymph nodes, and spleen can also be imaged during the ultrasonography of the abdomen. The genital anomalies are beyond the scope of this chapter. The primary

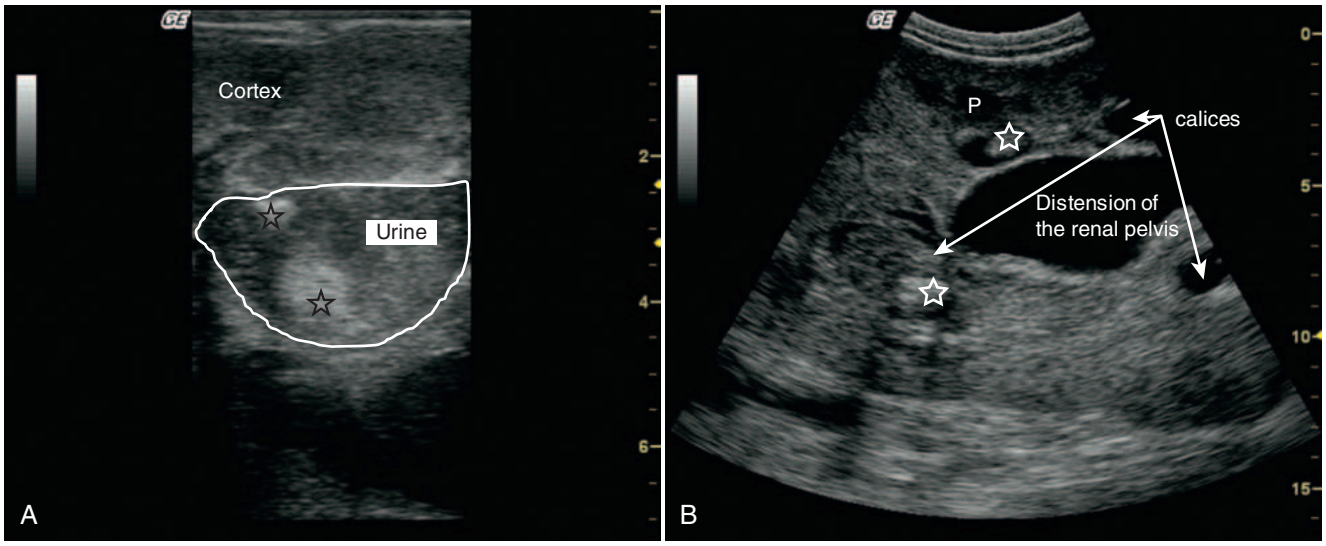

FIG. 32.120 Abnormal findings associated with pyelonephritis in dairy cows. A, Distention of calices is observed with the presence of heterogenic urine secondary to infection. Hyperechoic purulent material *(star)* is also observed. Image obtained transrectally at the caudal part of the left kidney with a linear 8-MHz probe (maximal depth, 8 cm). **B,** Long-axis view of the right kidney in a dairy cow with pyelonephritis. The main anomalies are dilations of the renal calices and pelvis. Heterogenic material is seen within the distended calices and is compatible with pus or fibrin deposits. Some pyramids *(P)* are visibles within the renal cortex. Image obtained at the dorsal right paralumbar fossa with a sectorial 3.2-MHz probe (maximal depth, 16 cm).

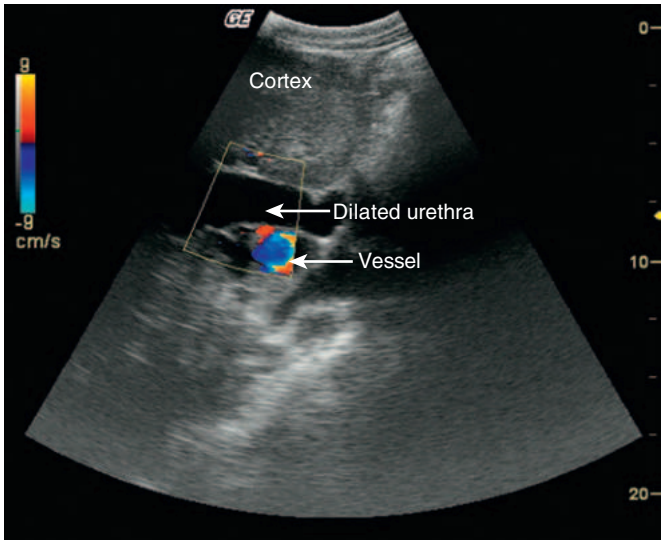

FIG. 32.121 Distinction between vessels and collecting structures in the renal sinus with color-flow Doppler imaging. Transverse view shows color in anechoic tubular structures seen within the renal sinus in the left kidney. The positive Doppler signal allows distinction between vascular structures (where Doppler signal is positive) and dilated pelvis/urethra (where Doppler signal is negative). Image obtained at the dorsal right paralumbar fossa with a sectorial 3.2-MHz probe (maximal depth, 22 cm).

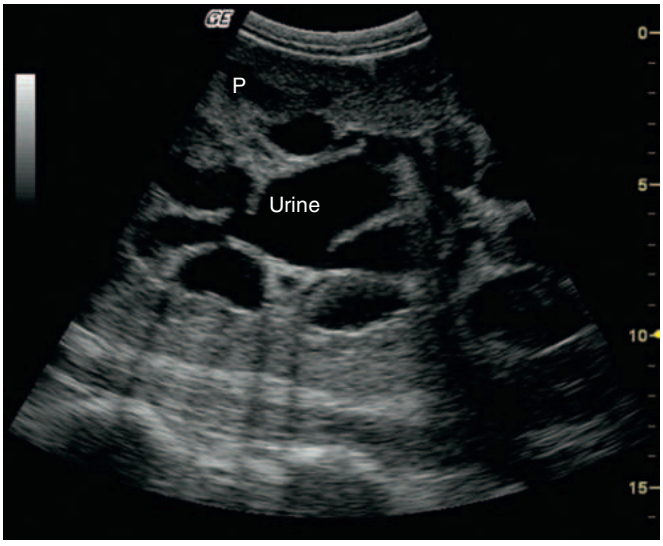

FIG. 32.122 Sonogram in a dairy cow with early-stage hydronephrosis secondary to pyelonephritis. Longitudinal section of the right kidney, showing significant dilation of collection structures (calices and pelvis), which are filled by anechoic urine. Several pyramids *(P)* are still visible. The renal parenchyma is compressed by urinary distention, which leads to irreversible renal failure. Images obtained at the dorsal right paralumbar fossa with a sectorial 3.2-MHz probe (maximal depth, 16 cm).

diseases of the spleen are uncommon and most of the time are caused by migration of a foreign body as a result of hardware disease. The mesenteric lymph nodes can also be observed during abdominal ultrasonography for various infectious and inflammatory conditions.

Acute Abdomen in Ruminants

David Francoz • Gilles Fecteau • André Desrochers • Sylvain Nichols

Abdominal emergencies in ruminants are both a therapeutic and a diagnostic challenge for veterinary practitioners. Some of them necessitate immediate surgical treatment, and others can be treated medically (Fig. 32.125). They are associated with numerous conditions that affect the abdominal cavity and can also be mimicked by diseases of extraabdominal origin (Fig. 32.126).

Different questions should be addressed during management of an acute abdomen in ruminants: Where does the pain originate? Is it a medical or surgical problem? Is it an urgent or nonurgent problem? Is medical treatment indicated before surgery? What is the likelihood for survival and productivity? To answer these questions, the clinician should use a systematic approach that is based on adequate signalment and history, complete physical examination, and judicious choice of ancillary

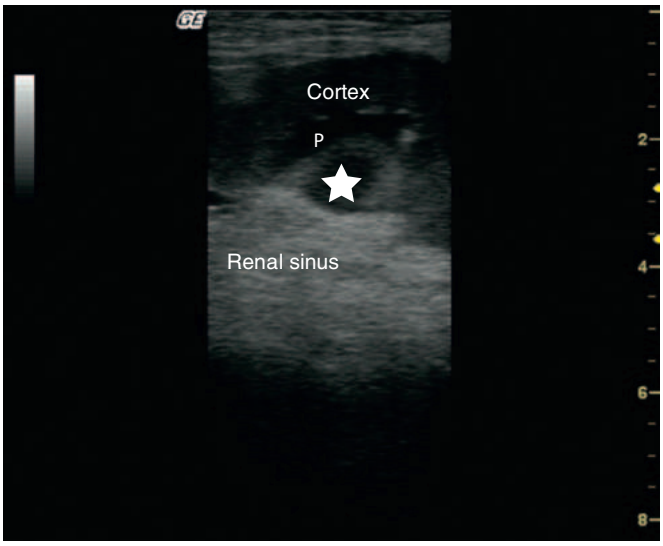

FIG. 32.123 Transrectal sonogram of a left renal cyst in an Holstein dairy cow. This was an incidental finding. The cyst *(star)* is surrounded by the hyperechoic renal sinus and hypoechoic pyramid *(P)*. Image obtained transrectally with a linear 8-MHz probe (maximal depth, 8 cm).

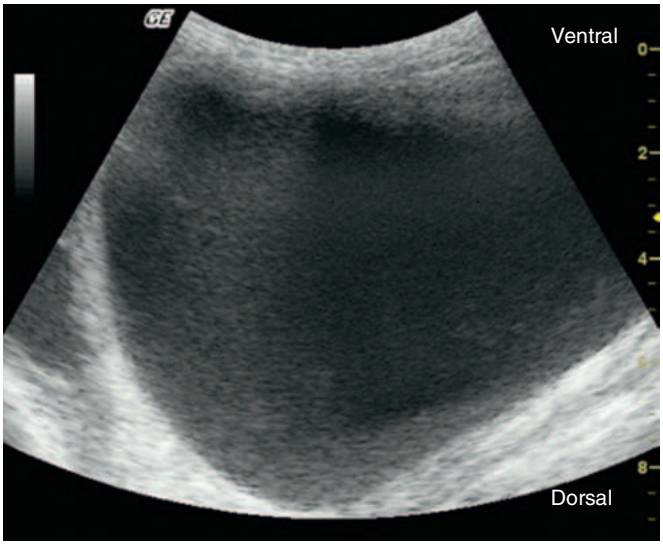

FIG. 32.124 Distended urinary bladder in a 4-month-old Boer buck with urolithiasis. The distended urinary bladder is a circular structure with anechoic content. This finding is compatible with the absence of major rupture of the urinary bladder. Images obtained at the ventral part of the abdomen with a sectorial 3.2-MHz probe (maximal depth, 10 cm).

tests. Precise information is not yet available for accurately determining the prognosis about the outcome of an acute abdomen in ruminants. In most cases, prognosis should be based on past experiences of other clinicians as well as one's own experience.

Even though a precise diagnosis facilitates the institution of appropriate treatment and helps better predict outcome, emphasis should not be placed solely on the diagnosis. In addition, contrary to other species, the cost and risk associated with standing laparotomy are minor in cattle. Consequently, it could be more economical to directly perform a laparotomy and avoid additional diagnostic tests and procedures.

Abdominal Pain

Abdominal pain may be a consequence of excessive distention of a hollow viscus (excessive intestinal distention), spasms of intestinal smooth muscles, stretching of the mesenteric supporting structure, intestinal ischemia, or chemical irritation of the visceral or parietal peritoneum.[1] Abdominal pain is classified into two main categories: visceral pain (hollow viscera and solid organs) and parietal pain (parietal peritoneum, abdominal muscles, rib cage).

Pain sensation from the parietal peritoneum travels through the peripheral spinal nerves and usually localizes over the affected area.[1] Because parietal pain is exacerbated by pressure and tension modification, affected patients are reluctant to move and have tonic reflex contractions of the abdominal muscles.[2] No active clinical signs of colic are present. This scenario is typically observed in cases of peritonitis. In addition to being reluctant the move, the animal has a splinted abdomen, and external palpation produces specific responses,[3] such as a positive result of a xyphoid grunt test or not dipping the back when pinched over the withers.

Some pain fiber endings are located in the submucosa and muscle layers of hollow viscera (intestines, bladder) and in the capsule of solid organs (kidneys, liver). Consequently, distention, forceful contraction, or traction produces pain in a hollow viscus. Capsule stretching creates pain in solid organs. Visceral pain is typically recognized by active manifestations of colic: kicking at the abdomen; treading with the rear feet; lying down, standing, and stretching out and grinding the teeth. Affected goats may also vocalize. Affected animals are anxious and have an apprehensive attitude. Contrary to parietal pain, visceral pain is transmitted via sensory fibers in the autonomic nerves.[1] Visceral pain is often diffuse and difficult to localize.[1]

A Concise but Precise Evaluation of the Animal

An animal with acute abdomen may need immediate medical assistance. Therefore the clinician should identify life-threatening problems and take appropriate action rapidly. Acute abdominal emergencies are often associated with either hypovolemic or septic shock, which should be treated promptly. Hypovolemic shock is characterized by increased heart rate, pale mucous membranes, slow capillary refill time, and dehydration. Increased heart rate and dehydration are also observed in case of septic shock, but mucous membranes are hyperemic or bluish in color, and scleral vessels are congested and dark. Intensive fluid therapy is the treatment of choice for both hypovolemic and septic shock. Pain control may also be necessary to allow a more complete physical evaluation (see Medical and Supportive Treatment, Fluid Therapy, and Control of Pain and Inflammation sections). However, documentation of a complete history and meticulous physical examination should be performed before emergency medical therapy if the patient is stable.

HISTORY. History documentation should be focused on the identification of risk factors of specific conditions, as well as the description of pain and associated clinical signs.

Signalment may identify an animal at higher risk of particular diseases. Age, sex, breed, and production stage are important parameters to consider in establishing the differential diagnosis. For example, abomasal volvulus develops more frequently in dairy cows than in beef cattle.[4,5] Similarly, uterine torsions are essentially observed at the time of parturition or in the last trimester. Colic in a wether or a buck goat should be considered a result of urolithiasis until proven otherwise. Specific nutrition programs and management systems have also been associated with specific conditions such as hemorrhagic bowel syndrome.[6] Paralytic ileus associated with hypocalcemia is reported to occur during estrus.[7] Previous history of surgery can be associated with the development of adhesions and colic. Recent calving and obstetric manipulations may cause a full-thickness uterine tear and subsequent peritonitis.

Description of the clinical signs observed by the owner and the chronologic sequence of events are of particular interest.

VetBooks.ir

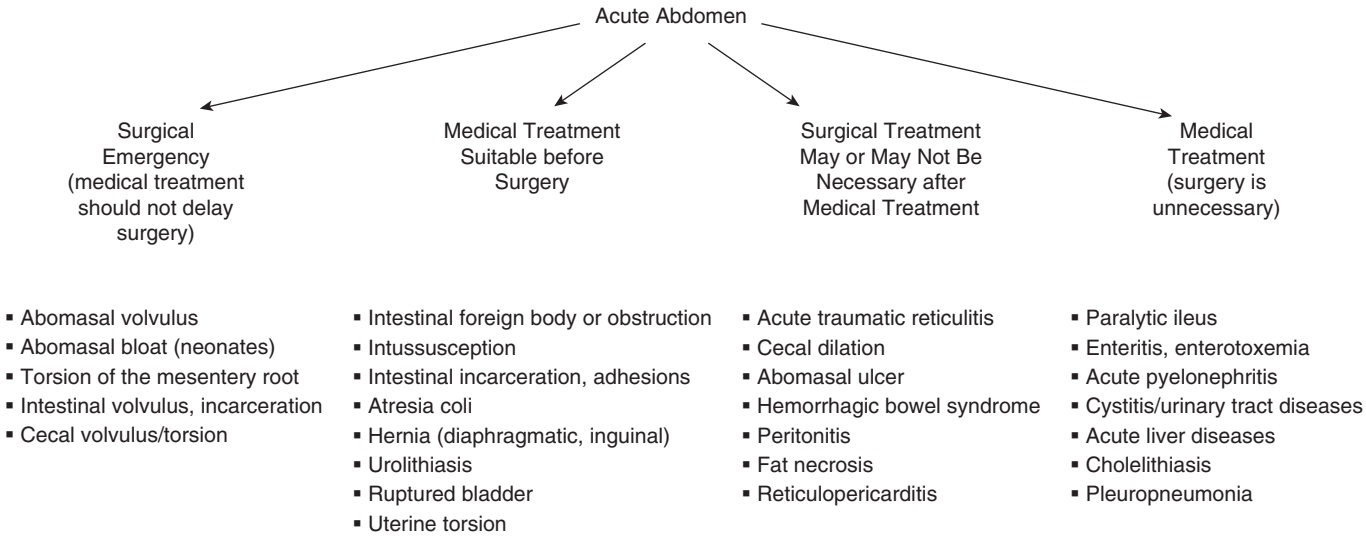

FIG. 32.125 Classification of abdominal causes of acute abdomen according to the need for surgical exploration or medical treatment.

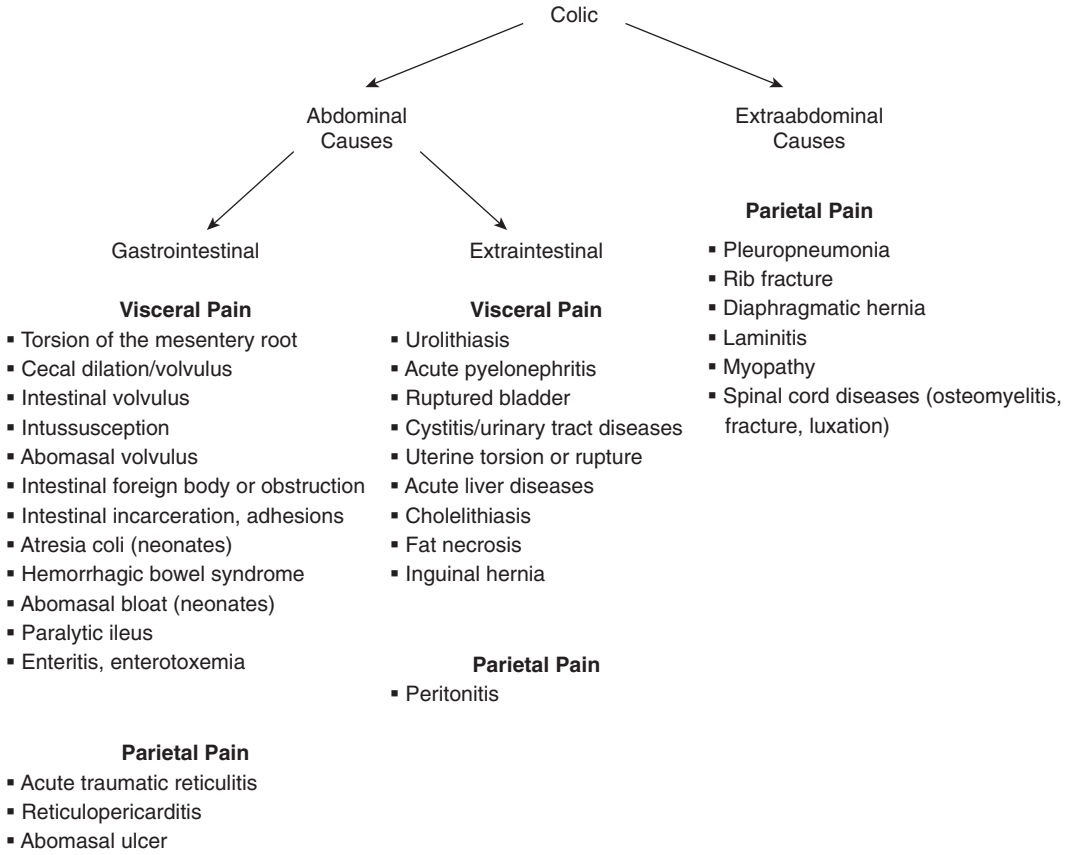

FIG. 32.126 Causes of colic (abdominal pain) in ruminants.

Abdominal pain is an important criterion in deciding whether surgery is necessary. Severe colic is classically associated with surgical intestinal conditions,[3,8] although some animals with severe jejunal distention secondary to acute enteritis may have a similar clinical presentation.[9] Intussusception in cattle is characterized by an acute onset of anorexia, decreased fecal output (often with dark feces containing blood) and milk production, and colic. However, even though the abdominal pain eventually becomes less severe, the depression progresses.[3,10] Torsion of the mesenteric root has an acute onset with severe colic and rapid deterioration.[3,11,12] Previous treatments, especially those that can modify clinical signs or the interpretation of laboratory results, should also be noted. Administration of analgesics such as NSAIDs may partially control abdominal pain, attenuate signs of colic, and decrease the heart rate.

Identification of associated clinical signs may help identify not only digestive but also nondigestive causes of abdominal pain. Fecal output, consistency, and appearance are relevant

information. Stranguria manifested by unsuccessful micturition efforts is associated with urolithiasis. Pleuritis, pleuropneumonia, or rib fractures may mimic abdominal pain.

COMPLETE PHYSICAL EXAMINATION. A thorough and complete physical examination is the most important step in evaluating an acute abdomen.

Evaluation of Vital Parameters. Assessment of cardiovascular status (heart rate, mucous membranes, capillary refill time, and dehydration) is essential in the evaluation of an animal with an acute abdomen and is part of the rapid initial evaluation of the animal. Determination of rectal temperature, pulse or heart rate, and respiratory rate (TPR) should always be performed first because manipulations during the physical examination of an abdominal emergency can elicit pain and modify the heart rate.

The TPR and amount of pain exhibited may also be used to monitor the evolution of the condition and the response to the initiated treatments, as well as prognostic factors. Normal to moderately elevated heart rate and adequate hydration status are considered good prognostic indicators in abomasal volvulus.[13] Combination of heart rate and lactate measurements has been reported to improve the ability to predict negative outcome of right-sided abomasal disorders.[14]

Once vital parameters have been evaluated and the animal appears hemodynamically stable, a thorough complete physical examination of all body systems is performed.

Visual Examination. The animal's abdominal profile or silhouette should be observed from the rear and both sides to detect and characterize abdominal distention. Bilateral ventral distention is associated with small intestine disorders, whereas distention in the right paralumbar fossa is associated with cecal and colon disorders. In cases of abomasal volvulus, the distended abomasum can be observed caudal to the last rib in the right paralumbar fossa. Gas in the rumen causes distention of the upper left abdomen, whereas some forms of chronic indigestion have a "papple" shape (pear on the right and apple on left). Lateral views of the abdomen help determine whether the distention arises primarily from the paralumbar fossa or extends cranially under the ribs. An affected animal may arch the back in cases of cranial abdominal pain, sole abscesses, or laminitis (sore feet).

Extraabdominal Examination. Examination of the thorax (pleuropneumonia, rib fractures) and the musculoskeletal system (laminitis, myopathy) are important in ruling out diseases that mimic abdominal pain.

Abdominal Examination. Abdominal examination is performed by auscultation, percussion, ballottement, and succussion of the abdomen. Pings are sounds of tympanic resonance caused by a gas-fluid interface in a distended organ and can be detected by simultaneous auscultation and percussion. Because rectal palpation may create an area of increased resonance on the right dorsal part of the abdomen, detection of pings should be performed before rectal palpation. On the right side of the abdomen, many organs may be responsible for pings. Determining the location, pitch characteristics, and variability of the ping is essential for establishing a differential and precise diagnosis. Pings localized from the thirteenth rib cranially to the ninth rib are typical of abomasal volvulus or rightward displacement of the abomasum.[3] Cecal dilation or volvulus causes a ping in the right paralumbar fossa and caudal quadrant,[3] often extending to the hip. Abomasal volvulus is more likely to cause a high-pitched ping, whereas animals with peritonitis may have a bilateral low-pitched ping in the upper paralumbar fossa. In normal animals, a monotone pinging area of 15 to 20 cm centered just under the last rib corresponds to gas in the spiral colon. Moving or constantly contracting viscera, such as gas in the descending duodenum or proximal colon, produce pings of changing pitch. For this particular reason, it is important to auscultate and percuss for a certain period of time to notice ping variation.

On the left side, pings are principally associated with left abomasal displacement, ruminal collapse, and pneumoperitoneum. Left abomasal displacement typically causes pings dorsally from the eighth to the thirteenth ribs. Pings associated with gas in the rumen, ruminal collapse, and pneumoperitoneum are localized dorsally in the left paralumbar fossa and extend cranially to the eleventh rib. Simultaneous auscultation and ballottement (succussion) of the abdomen may detect fluid-filled viscus with an interface of gas such as the rumen or the abomasum. The location of the fluid splashing sounds on auscultation-succussion may help confirm and differentiate among auscultation-percussion findings. Tense abdominal muscles, secondary to parietal peritoneum inflammation (parietal pain), may also be detected during succussion. Auscultation of ruminal contractions is also of importance. The number of rumen contractions should be counted and characterized over at least a 2-minute period. Three complete contractions per 2 minutes are considered normal. Incomplete and frequent contractions (>5 per 2 minutes) and complete absence of contraction for 2 minutes are abnormal. After initial treatment. the rumen auscultation should be repeated to evaluate the improvement.

Identification of Abdominal Pain. Differentiation between visceral and parietal pain. as well as pain localization. should be attempted in order to investigate the cause. However, the task is often difficult in animals such as cattle whose behavior in response to pain is unpredictable.

Cranial peritonitis, secondary to traumatic reticuloperitonitis (TRP) or abomasal ulcers, is a common cause of parietal abdominal pain. Affected cattle are reluctant to move; they stand with the elbows abducted and an arched back.[3] During examination, bruxism (grinding of the teeth) may be present.[3] Pain can be elicited by pinching over the withers or applying forceful movement with the knee or upward pressure with a bar or pole over the xyphoid area or anterior abdomen. In response to pain, an animal may grunt or kick and be reluctant to dip the back when the withers is pinched.[3] Sensitivity of this test may be increased by simultaneous auscultation of the trachea to better hear the subtle grunt.

As mentioned previously, the visceral pain is more diffuse and associated with active manifestations of colic.

Rectal Palpation. Rectal abdominal palpation of cattle is an essential part of the physical examination for acute abdomen. However, the size of the abdomen limits the systems or organs that can be palpated.

Cecal disorders are clearly diagnosed by rectal palpation. A firm mass palpated in multiple, dilated, turgid small intestine loops is a typical finding of intussusception[10] or hemorrhagic bowel syndrome.[6] Adhesions between the kidneys and the rumen, the intestinal convolutions, and decreased rectal mobility in the posterior abdomen are characteristics of a chronic peritonitis. Uterine wall integrity may be evaluated during rectal palpation, although examination per vagina may be necessary to confirm a full-thickness laceration in an early postpartum cow. In feedlot steers with urolithiasis, rectal palpation reveals a pulsatile pelvic urethra and a distended bladder. In cases of pyelonephritis, enlargement of one or both ureters may be palpated. Normally, only the left kidney can be palpated rectally: If infected, it will be painful to the touch and larger, and lobulation may become less obvious. Diseased right kidneys are exceptionally reached rectally especially if the animal is hydronephrotic. In small ruminants, urolithiasis is manifested by pulsations in the pelvic urethra that may be palpated by digital rectal examination. Bladder distention or kidney enlargement can be detected by deep abdominal palpation, and vocalization will be elicited during palpation of the distended bladder.

Fecal Output and Appearance. Presence and macroscopic appearance of feces can be evaluated during rectal palpation. Decreased or absence of feces is principally associated with intestinal stasis or obstruction, which may occur secondary to a direct mechanical obstruction (necessitating surgical treatment) or to gastrointestinal ileus (necessitating only medical treatment). However, feces may be present in the first few days after an intestinal obstruction.

ANCILLARY TESTS

Packed Cell Volume and Total Solids. Shock, sepsis, and toxemia cause hemoconcentration and dehydration and are associated with an increase in total solids. On the other hand, increased PCV and decreased total solids are observed during the formation of a third compartment filled with a protein-rich fluid, as in generalized peritonitis.[15] In one study, total protein concentration was significantly lower in cows with septic peritonitis than in cows suffering from nonseptic peritonitis.[16]

Blood Gas Analysis and Electrolytes. Blood gas analysis and electrolyte measurement results are helpful in the institution and monitoring of fluid therapy. Most adult ruminants with acute abdominal diseases suffer from metabolic alkalosis.[17] Metabolic alkalosis is often associated with abomasal volvulus, intussusception, cecal disorders, abomasal ulcers, peritonitis, renal diseases, and reticuloperitonitis.[17] Hypochloremia and hypokalemia are frequently combined with metabolic alkalosis.[18] Metabolic acidosis may be observed if urinary tract disease, small intestinal strangulation or obstruction, or enteritis with severe diarrhea is present.[17]

Some parameters could also be used as prognostic indicators. Serum chloride concentration, anion gap, and base excess have been proposed as preoperative prognostic indicators in dairy cattle suffering from abomasal volvulus. Poor short-term prognosis was associated with serum chloride concentrations lower than 79 mEq/L,[19] base excess values of –0.1 or less,[20] and anion gap values of more than 30 mEq/L.[21] However, a prospective study on the outcome of abomasal volvulus demonstrated that serum base excess and anion gap values did not differ between productive and nonproductive animals.[13] In that study, serum chloride concentration was significantly lower in nonproductive animals, but the prognostic test yielded numerous false-negative results.[13]

Blood Lactate Concentration. Blood lactate concentration is frequently used to assess a compromised cardiovascular or respiratory system, to monitor the response to treatment, and to establish a prognosis for survival. Portable analyzers are available for the measurement of L-lactate, and so this diagnostic test is easily doable at the farm. In cattle, blood lactate concentrations have been reported as a predictor of uterine torsion[22] and abomasal disorders.[14,23-26] Blood L-lactate concentrations exceeding 6.5 mmol/L before correction of uterine torsion[22] or exceeding 6 mmol/L before surgery for right abomasal disorders[14] were associated with a poor prognosis. In the author's clinics, an early measurement (before any treatment) and a follow-up measurement after initial therapy (IV fluids, NSAIDs, or other) are performed. The author and colleagues have found that an increase in blood lactate or a very marginal reduction in blood lactate, despite aggressive therapy, indicates that surgery is needed or the prognosis is poor. However, in one study, short-term change (preoperative and postoperative values) in blood L-lactate concentrations did not appear to be a useful prognostic indicator.[23]

Serum Biochemistry Profile. Evaluation of specific enzyme activity or markers (e.g., hepatic enzymes, BUN, and creatinine) along with physical examination and other ancillary tests may be useful in establishing a diagnosis and assessing progress.

Complete Blood Cell Count and Differential. Hematologic findings are rarely specific to a condition and reflect the underlying inflammatory process. In most cases a minimal to moderate inflammatory process characterized by a neutrophilic leukocytosis is observed. Hematologic findings may also provide information about the acuteness of the disease and the severity of associated sepsis and toxemia. Severe sepsis is associated with neutropenia, degenerative left shift, toxic changes in neutrophil structure, and lymphopenia. Hematologic study is also an important ancillary test for monitoring the response to treatment.

Fibrinogen. In ruminants, increased fibrinogen concentration is an early indicator of inflammation. Studies in cattle have demonstrated that fibrinogen concentration may increase within 1 to 2 days after induction of inflammatory conditions. Normal fibrinogen concentration despite severe visceral involvement should be observed only in peracute cases (within a few hours; e.g., torsion of the root of the mesentery). Moderate to marked increased fibrinogen concentration is also the signature of chronic active localized inflammatory conditions such as reticuloperitonitis, liver abscesses, and pyelonephritis.

Urinalysis. Urinalysis is helpful in differentiating between colic of urogenital origin from gastrointestinal disorders. Urinalysis can be performed rapidly with a urinary dipstick (Chemstrip 9, Roche Diagnostics Corporation, Indianapolis, Ind.) and gross morphologic examination. Renal diseases are associated with proteinuria (>1+), glucosuria, and positive blood reaction. In cases of acute urethral obstruction, hematuria and proteinuria are consistently observed. Determination of urinary specific gravity before fluid replacement may help characterize azotemia.

Abdominocentesis. Abdominocentesis is considered an essential ancillary test in the approach to acute abdomen in many species,[9,27] including cattle.[3] Because of the ability of cattle to wall off and localize infections in the abdomen, a four-quadrant method of abdominocentesis is suggested by some authors.[3] Ultrasonography can be used to find abnormal fluid location or quantity, which improves the precision of determining the abdominocentesis site. Fluid can be evaluated macroscopically for color, volume, odor, and turbidity. Normal and changes values are reported in the Peritonitis in Ruminants section of this chapter.

Different parameters may be evaluated in peritoneal fluid. Lactate, D-dimer, glucose, and ALP concentrations and pH of the peritoneal fluid have been reported to be indicators of intestinal ischemia and peritonitis in horses.[28,29] In one cattle study, decrease in glucose concentration in peritoneal fluid was a sensitive and specific marker of septic peritonitis.[16] D-Dimer level is also elevated in cases of ischemic and inflammatory abdominal conditions.[16,24] L-Lactate measurement could also be a useful diagnostic tool for the evaluation of various abdominal ischemic conditions in cattle.[24]

Diagnostic Imaging

Ultrasonography. Ultrasonography is a very helpful diagnostic tool for the management of acute abdomen. It helps in identifying the structures involved, the extension of the lesions, and the presence of abdominal fluid, as well as in the monitoring of the cases. With advances in multifrequency abdominal transducers, ultrasonography is used more frequently in ruminant medicine. More detailed information this type of imaging is available in the Ultrasonography of the Ruminant Abdomen section.

Radiography. Radiographic images in adult cattle are obtained with powerful machines available only in referral centers. They are among the most helpful ancillary examinations for the diagnosis of reticuloperitonitis.[30,31,32] Abdominal radiographs have been used for the diagnosis of intestinal atresia and intussusception in calves.[3]

A lateral view of the abdomen of small ruminants may help for the diagnosis of urolithiasis because stones in the urethra or in the bladder may be detected.

VetBooks.ir

Medical or Surgical Decision

A differential diagnosis and a decision for surgical or medical treatment should be established on the basis of clinical signs and ancillary tests results (see Fig. 32.126). If a definitive diagnosis is made, specific treatment can be instituted. When a definitive diagnosis cannot be established, attempts should be made to differentiate surgical and medical cases (see Fig. 32.125). Every animals with elevated heart rate, with organ distention found on rectal palpation, and that is producing little to no feces are surgical candidates even if a definitive diagnosis cannot be established. Intestinal obstructions necessitate immediate surgery. A mechanical obstruction may be suspected when there is a suspicion of intestinal or cecal torsion on rectal examination, pings indicating a right abomasal displacement or volvulus, peritoneal fluid indicating bowel devitalization, severe active colic, or rapid deterioration in the animal's condition.[8] If an intestinal mechanical obstruction is not suspected during the first examination, exploratory surgery may be delayed for up to 36 hours.[33] However, frequent monitoring should be performed and appropriate medical treatment provided to the animal.

SURGERY. Most abdominal surgery in adult cattle is performed with the animal standing and with local or regional anesthesia. Sedation may be necessary in some cases, but the risk of lying down during surgery have to be considered. Cattle can tolerate intestinal resection and anastomosis standing if adequate local anesthesia and systemic analgesia are provided. However, some animals are reluctant to stand because of the primary condition or as a result of electrolyte imbalance. Any traction on the mesentery root is painful enough to make an animal go down during the procedure. Surgery should be performed with the animal in recumbency if it is in extreme pain or weak and likely to lie down. Because a right paralumbar fossa celiotomy provides the best exposure to the intestinal tract, left lateral or sternal recumbency should be favored. Other than the general status of the animal, the suspected affected organ, presence of aggressive behavior, surgeon preferences, and facilities should be considered in the choice of performing the surgery with the animal standing or in recumbency. If the animal is dehydrated or manifests signs of shock, preoperative fluid therapy and analgesics are recommended. For the prevention of surgical infection, appropriate preoperative antibiotic administration is also recommended.

MEDICAL AND SUPPORTIVE TREATMENT. The goal of therapy in an animal with acute abdomen is to initially correct the hemodynamic and metabolic imbalances associated with hypovolemic or septic shock, to control pain, and to correct or treat the primary cause of the disease, when identified. Consequently, medical treatment often includes fluid therapy, NSAIDs, and antimicrobial drugs.

Fluid Therapy. Crystalloid solutions (0.9% NaCl, Ringer's solution) are indicated initially to replenish fluid loss and improve the circulating blood volume. To resuscitate critically ill neonatal patients, recommended intravenous fluid administration rates of isoosmotic crystalloid solution are 80 to 90 mL/kg of body weight per hour.[34] However, such rates are difficult to achieve through a catheter in adult ruminants. The maximal flow rate usually achieved through a catheter (14G catheter) in an adult cow is 15 to 20 mL/kg/h. Studies demonstrated that perfusion rates of 40 and 80 mL of an isoosmotic crystalloid solution per kilogram of body weight per hour can be used safely in adult ruminants and dehydrated calves, respectively.[35,36,37] If the animal is not critically ill, fluid and electrolyte deficits should be corrected over 2 to 8 hours.

Hypertonic solutions (7.2% or 7.5% NaCl) are also an alternative. Intravenous administration of hypertonic saline provides rapid resuscitation in dehydrated or endotoxemic ruminants.[38] A rate of 4 to 5 mL of hypertonic solution per kilogram should be administered IV through the jugular vein over 8 to 10 minutes. Animals should be provided with a supply of fresh water immediately after the treatment, or an intravenous infusion of an isotonic crystalloid solution should be instituted. Cattle not observed to drink within 5 minutes should have 20 L of water pumped into the rumen.[38] An administration rate for a hypertonic solution of over 1 mL/kg/min should be avoided because it induces a potentially fatal hypotension, coupled with a decrease in cardiac contractility.[38]

Correction of Acid-Base and Electrolyte Imbalances. Correction of electrolyte imbalances should be based on laboratory results when available. Previous treatments should be considered (e.g., intravenous calcium, orally administered magnesium hydroxide) to initiate the most appropriate fluid therapy if no laboratory results are available. Most animals with acute abdominal diseases suffer from metabolic alkalosis, hypochloremia, and hypokalemia.

Calcium homeostasis is fragile in postpartum dairy cattle. Hypocalcemia is common in ruminants with gastrointestinal disorders or simply anorexia, particularly in lactating cows.[17,34] Moreover, metabolic alkalosis, frequently observed in cases of acute abdomen, is strongly associated with subclinical hypocalcemia.[7,39] Calcium ions are of particular importance in gastrointestinal motility. First, in the gastrointestinal smooth muscles, the channels responsible for generating action potentials are calcium-sodium channels.[40] Second, gastrointestinal smooth muscle contraction occurs in response to the entry of calcium into the muscle fiber.[40]

The Ringer's solution containing 8.6 g of NaCl per liter, 0.3 g of KCl per liter, and 0.3 g of $CaCl_2$ per liter, yielding 147 mEq/L Na, 155 mEq/L Cl, 4 mEq/L K, and 4 mEq/L Ca, is the commercially available solution of choice. At the author's veterinary teaching hospital, a homemade solution (7.5 g of NaCl per liter, 1.5 g of KCl per liter, and 5.75 g of Ca^{2+} per liter [25 mL of 23% calcium borogluconate per liter], yielding 128 mEq/L Na, 148 mEq/L Cl, 20 mEq/L K, and 26 mEq/L Ca) is used for adult cattle. The author and associates usually begin fluid therapy with rapid administration of a 0.9% NaCl solution (15 to 20 mL/kg/h) for rapid ressucitation and then administer the homemade solution at a rate of approximately 4 to 5 mL/kg/h.

Control of Pain and Inflammation. Pain and inflammation are important causes of gastrointestinal hypomotility. Gastrointestinal pain increases sympathetic tone, causing general inhibition of the gastrointestinal tract.[40,41] Numerous inflammatory mediators are released during disease of the gastrointestinal tract and alter intestinal motility.[42] Peritoneal inflammation or irritation and associated pain may initiate ileus in several species.[42] Release of proteinases, vasoactive substances, free oxygen radicals, and endorphins secondary to ischemia and reperfusion injury, or endotoxemia, impairs cardiovascular function and decreases gastrointestinal motility.[42] Release of inflammatory mediators leads to a pain response and modulates the intensity of noxious stimuli.[41] Consequently, analgesic and antiinflammatory drugs appear essential in the management of acute abdomen. These drugs must be used with caution; NSAIDs may induce abomasal ulcers, particularly in an anorexic patient, and analgesics may mask clinical signs (pain, fever) and thereby compromise adequate case management through a delay in surgery.

NSAIDs are the most commonly used drugs for gastrointestinal pain management in cattle. There has been no comparison of the efficacy of the different NSAIDs available in food animal medicine specifically in relation to their use in the management of acute abdomen. In some countries, meloxicam is approved for the reduction of pain associated with abdominal surgery. Preoperative and postoperative

VetBooks.ir

administration of flunixin, ketoprofen and meloxicam was demonstrated to have positive effects on animal recovery and pain control after left abomasal displacement surgery[43,44] or fistulation surgery.[45,46] However, no recommendation can be made about which one is most effective.[44,47] Ketoprofen and flunixin appear to have similar activities in endotoxic calves.[48] Meloxicam has been reported to decrease the severity of clinical signs and to reduce the production of thromboxane B_2 in calves with experimentally induced endotoxmia.[49] The choice of NSAID becomes a matter of previous experience, comparative medicine, legislation, and cost. In equine gastrointestinal pain, a poor or short-duration response to NSAIDs indicates a need for surgery.[41] This principle can be applied to cattle with caution because of their different behavior in response to pain.

α_2-Agonists that function as sedatives and analgesics, such as xylazine, detomidine, and medetomidine, could also be used to relieve pain in cases of acute abdomen. All are considered strong analgesics that can alleviate most visceral pain, at least temporarily, in equine medicine.[41] There are few data on the use of α_2-agonists for the management of acute abdomen in cattle. In a cow with a large intestinal obstruction, signs of abdominal discomfort disappear immediately for at least 1 hour after the administration of a single dose of xylazine (0.05 mg/kg IV).[50] Different side effects must be considered before the administration of α_2-agonists. Xylazine is reported to have significant effects on the gastrointestinal tract in cattle, decreasing reticuloruminal and intestinal motility.[51] Because of the hemodynamic changes associated with the administration of α_2-agonists, these drugs must be used with caution in hypotensive patients and those suffering from shock.[52] α_2-Agonists can mask surgical pain and delay the decision for surgery. This is particularly critical with the use of detomidine.[41] Finally, dose and administration of α_2-agonists should be used with care if standing surgery is planned, as they may influence the animal to lie down.

Opioids, morphine or butorphanol can also be used alone or in combination to control abdominal pain. Information regarding their use in this situation in cattle is lacking. To the author's knowledge, opioid usage was studied in cattle in castration, dehorning, and preoperative analgesia but never for abdominal pain control. In the author's clinic, after the diagnosis of a nonsurgical process or correction of a surgical process, clinicians administer morphine (0.1 mg/kg, IM or SC), or butorphanol (0.05 to 0.1 mg/kg, IV, IM, or SC) or a continuous-rate infusion of a combination of ketamine (0.2 mg/kg/h) and butorphanol (0.02 mg/kg/h).

Finally, lidocaine may be used for its analgesic and anti-inflammatory effects, as well as its potential prokinetic effects. As described in horses, a continuous IV infusion of lidocaine at a rate of 3 mg/kg/h after an initial dose of 1 mg/kg (IV, over 15 min) can be administered. However, no data are actually available about its effect on the control of pain and inflammation and on the gastrointestinal motility in cattle.

Antimicrobial Drugs. Bacterial translocation from the intestines can occur in cases of mechanical or functional ileus secondary to bacterial overgrowth, inflammation, and impairment of barrier function of the intestinal wall. A systemic broad-spectrum antibiotic treatment should be instituted when a septic process is suspected. This initial antibiotic therapy should be effective against Gram-negative, Gram-positive, aerobic, and anaerobic pathogens. The choice of antibiotic should also take into consideration legal aspects and the cost of the treatment. β-Lactams, tetracyclines, and trimethoprim-sulfadoxine appear to be good choices. In ruminants, there is no accepted recommendation for the duration of treatment.

Other Medical Treatments. The use of laxatives (magnesium hydroxide, mineral oil, liquid paraffin) in cases of suspected gastrointestinal obstruction or ileus in cattle has no therapeutic basis. Moreover, these treatments may exacerbate the condition. Because the intestines are already filled with gas and fluid, laxatives only impose additional distention. In human medicine, laxatives are frequently used for the treatment of POI; however, no study could demonstrate their actual benefit.[53] Braun and colleagues reported that the use of laxatives for the treatment of cecal disorders delayed the time to first defecation.[54] Moreover, magnesium hydroxide may be responsible for detrimental effects such as decreased potassium absorption, metabolic alkalosis,[55] sedation caused by hypermagnesemia,[55] increased ruminal pH,[56] and decreased ruminal microbial activity.[56]

Motility-modifying agents may be used in the management of gastrointestinal disorders. In most cases, intestinal motility is restored when pain is relieved and electrolytic imbalances are corrected. Steiner[51] and Constable and colleagues[57] reviewed the different prokinetics that can be used in ruminant medicine and their clinical implications. In cattle, according to their reviews, erythromycin (10 mg/kg, IM, bid for 2 days [Erythro-200[51]] or 8.8 to 10 mg/kg IM[57]) is the most effective drug for the treatment of abomasal hypomotility and can be used for the postoperative treatment of abomasal displacement or torsion. However, in a context of antimicrobial stewardship, the use of antimicrobial drugs for purpose other than antibacterial activity is controversial and should not be recommended. Bethanechol (0.07 mg/kg, SC, tid for 2 days, not approved for food animal use in the United States) alone or in combination with metoclopramide (0.1 mg/kg, SC or IM, tid for 2 days, not approved for food animal use in the United States), increased the contractility of abomasal smooth muscles, but no data on in vivo efficacy are available.[51,57] Metoclopramide alone is ineffective in cattle and sheep for the treatment of abomasal hypomotility.[51,57] Bethanechol (0.07 mg/kg SC tid for 2 days; not approved for food animal use in the United States) can be used for conservative or postoperative treatment of cecal disorders and treatment of paralytic ileus.[51]

In contrast to cattle and sheep, in goats metoclopramide (0.5 mg/kg IM or IV; not approved in the United States) has been reported to significantly increase myoelectric activity of the duodenum.[51] Cisapride (0.5 mg/kg PO, not approved in the United States) was believed to be responsible for an increase in abomasal emptying rate in one study in calves.[58] However, in vitro, cisapride did not demonstrate any significant effect on the contractility of smooth muscle of cows from the pyloric antrum, proximal duodenum, and proximal colon.[59,60] Continuous infusion of neostigmine (87.5 mg in 10 L of sodium chloride-glucose infusion at 2 drops/sec per cow) was successfully used for the conservative and postoperative treatment of cecal disorders.[54] In that clinical report, this protocol was preferred to those previously reported (neostigmine SC every hour over 2 to 3 days in doses that gradually decreased from 12.5 mg to 2.5 mg).[54] Drug administration was easier and involved fewer disturbances for the animal.[54] However, no control group was included in this study. Also, neostigmine has been reported to have a pronounced effect on intestinal contractility, causing uncoordinated spikes to become more frequent, thereby compromising the potential beneficial effect.[60]

No prokinetic drug is reported to directly increase ruminal motility. In cases of prolonged anorexia or acute indigestion, ruminal flora can be disturbed and reduced. Transfaunation may help rapidly reconstitute the ruminal flora and hasten return to normal function of the rumen and the digestive tract. The technique for and beneficial effects of transfaunation (reduction of ketonuria, increased feed intake, and higher milk yield) have been reported in the postsurgical treatment of left abomasal displacement.[61]

FOLLOW-UP. When a definitive diagnosis cannot be made, close monitoring of the animal may be indicated (Fig. 32.127). Follow-up must also be performed after to surgery to ensure

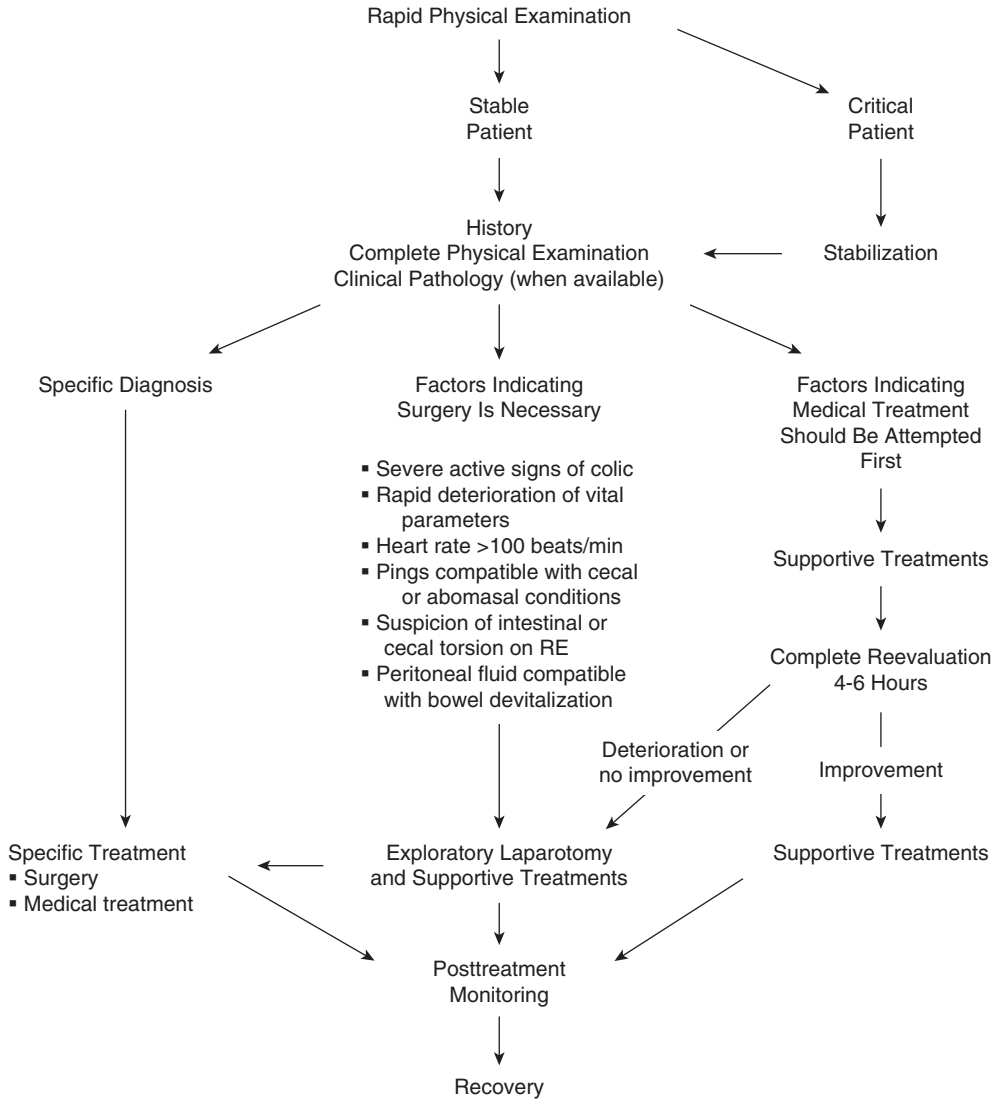

FIG. 32.127 Suggested decision tree for cattle with an acute abdomen. *RE*, Rectal examination.

adequate response to surgical treatment and to allow possible adjustment of treatment. In a referral hospital, the animal should be reevaluated every 4 to 6 hours. In field practice, vital parameters, rectal palpation, presence and consistency of feces, and pain may be reevaluated every 6 to 12 hours. A significant reduction of heart rate was observed 4 and 6 hours after the initiation of treatment in cases of cecal dilation.[54] Feces are usually passed within 4 to 6 hours after surgery in cases of intestinal volvulus or cecal disorders. Failure to defecate for 24 hours or more is abnormal in cattle and therefore indicates persistence of intestinal obstruction and may adversely affect the prognosis. Deterioration or persistence of clinical signs despite the initiation of supportive treatment is also an indication for surgery. Surgical exploration is indicated if the following clinical signs are observed: persistence of colic, development of abdominal distention, heart rate exceeding 100 beats/min, scant feces, typical abomasal or cecal pings, or paracentesis results that indicate bowel devitalization.

The decision for surgery or medical treatment remains challenging in cases of acute abdomen in ruminants. Optimal management of acute abdomen prevents any unnecessary delay in cases requiring surgery and avoids unnecessary surgery. Knowledge of diseases associated with signs of acute abdominal pain is important, but no clinical signs are specific for a particular problem, and a specific diagnosis cannot be established postoperatively in many cases. On the basis of a systematic approach to clinical examination and a judicious use of ancillary tests, the clinician may be able to identify cases that necessitate immediate or delayed surgery, avoid unnecessary surgery, and establish a cost-effective management plan.

Indigestion in Ruminants

Franklyn Garry • Craig McConnel

Definition and Etiology

Indigestion is a general term for a group of diseases characterized by dysfunction of the reticulorumen. Some texts have limited the use of the term to a single, poorly defined entity that includes inappetence, decreased reticuloruminal motility, and abnormal feces, with a nonspecific cause that involves intake of abnormal feed. The more generalized term applied here incorporates a pathophysiologic classification scheme of forestomach disturbances that was devised by workers in

VetBooks.ir

BOX 32.4

Classification of Ruminant Indigestion

Primary Indigestion

Reticuloruminal Motor Disorders or Diseases of the Rumen Wall

Traumatic reticuloperitonitis
Frothy bloat
Free gas bloat
Reticulitis/rumenitis
Ruminal parakeratosis
Obstructive (vagal) indigestion (failure of omasal transport, failure of pyloric outflow, and free gas bloat)
Obstruction of the cardia
Obstruction of the reticuloomasal orifice
Diaphragmatic hernia

Reticuloruminal Fermentative (Microbial and Biochemical) Disorders

Inactivity of rumen microbial flora (caused by poor-quality roughage that leads to rumen impaction)
Simple indigestion
Acute ruminal lactic acidosis
Subacute ruminal acidosis
Rumen alkalosis
Putrefaction of rumen ingesta

Secondary Indigestion (Secondary to Systemic Illness)

Secondary reticuloruminal motor inactivity
Secondary reticuloruminal microflora inactivity
Abomasal reflux

Germany.[43] An absolute division of the pathologic processes is impossible because the various forestomach functions are interdependent; that is, abnormal motor function affects microbial fermentation by altered mixing or passage of ruminal fluid out of the forestomach chambers, whereas abnormal fermentation products secondarily alter motor function. Nevertheless, this classification provides a clinically useful diagnostic framework by emphasizing the underlying pathophysiologic mechanisms of different forestomach disturbances.

The primary indigestions include diseases in which the reticulorumen is directly affected and responsible for the major clinical signs (Box 32.4). These problems can be divided into two categories:

1. Abnormal motor function of the reticulorumen, including disease of the reticuloruminal wall, its neuromuscular function, or impedance to the passage of ingesta
2. Abnormal contents of the reticulorumen, with dysfunction of microbial and biochemical fermentation

Secondary indigestions are the sequelae of systemic problems or disease in other organ systems. For example, problems such as endotoxemia, fever, or depression can produce anorexia, secondary ruminal hypomotility, and decreased microbial fermentative function. Primary abomasal disease can depress ruminal function, inhibit ruminal outflow, and cause reflux of abomasal contents back into the rumen.

With the exception of penetrating foreign bodies and sporadic infections of the forestomach wall (e.g., actinomycosis, mucormycosis), indigestions are due to abnormal physiologic function. In adult ruminants, one or more of the homeostatic processes of the fermentative environment are disturbed (e.g., an excessive carbohydrate intake generates an excessive amount of acid product; abnormal regulation of the ruminal motility pattern disturbs the mixing or aboral passage of ingesta). In young ruminants, the forestomachs are actively developing, and indigestions can result from disturbances of the developmental mechanisms. The forestomach diseases of young ruminants generally have received little attention, but they can be recognized and appropriately treated within a classification scheme similar to that for adult ruminants.[44]

Pathophysiology

Digestion of feedstuffs in the reticulorumen is accomplished by microbial fermentation. The mucosal epithelium absorbs and exchanges products of fermentation but performs essentially no secretory function. Appropriate forestomach fermentation depends on the coordination of processes that provide a fairly constant reticuloruminal environment. The requirements include addition of appropriate amounts and types of feed substrate and water by ingestion; buffering of substances from the saliva to counteract the acid nature of fermentation products; eructation of the gaseous products of fermentation; coordination of reticuloruminal motility to provide mixing; rumination and remastication; aborad passage of ingesta; temperature maintenance; and exchanges of electrolytes and VFAs across the ruminal wall. Because these functions are intimately interrelated, abnormalities in any one of them can lead to digestive disturbances.

CLINICAL SIGNS AND DIFFERENTIAL DIAGNOSIS OF INDIGESTION

General Signs. A general physical examination allows the practitioner to recognize signs of reticuloruminal problems (Table 32.14) and to assess whether a disease is present that could induce reticuloruminal dysfunction as a secondary phenomenon. General signs common to all forms of indigestion include a reduction in or absence of appetite, dullness or depression, and decreased animal productivity. The most common clinical signs of ruminal dysfunction are a decrease, absence, or abnormality of ruminal contraction sounds in the left paralumbar fossa or an abnormal left-sided abdominal contour. The left abdominal wall may show gauntness and decreased filling or display gross distention. It is often the failure to detect signs of another primary disease as the cause of ruminal dysfunction that directs attention to the forestomach as the possible primary site of disease. Indigestion in calves effectively produces a state of malnutrition, and additional signs in these growing animals include poor growth rate and long, rough hair coat. The acuteness of onset and the severity of these signs depend on the inciting cause of the indigestion. Specific abnormalities in the ruminal motility pattern are discussed in more detail, but most indigestions are marked by decreased or absent ruminations (regurgitation and cud chewing) and depressed ruminal contractions.[140] Only early cases of frothy bloat and some cases of obstructive (vagal) indigestion display increased ruminal motility.

Body temperature usually is within normal limits because the causes of indigestion are mainly physiologic abnormalities. Exceptions include TRP and occasional cases of rumenitis with significant inflammation. Disturbances of heart rate, respiratory rate, hematologic parameters, and body fluid vary tremendously among different forms of indigestion and different cases of any one form of indigestion. For example, an acute onset of severe ruminal bloat might produce a stress leukogram and severe disturbance of the cardiovascular and respiratory systems, whereas mild or chronic bloat may produce no remarkable change in these systems. Rapid accumulation of fluid in the forestomach chamber in severe ruminal acidosis with grain overload can induce severe dehydration with hemoconcentration, an inflammatory response, systemic acidosis, and increased heart and respiratory rates, whereas slow fluid sequestration in some cases of obstructive (vagal) indigestion may not induce marked changes in these parameters.

VetBooks.ir

TABLE 32.14

Clinical Signs Typically Associated With Primary Indigestion

Signs	Associated Problems
Fever	Traumatic reticuloperitonitis, reticuloruminitis
Decreased ruminal filling	Fermentative indigestion and secondary indigestion (especially with chronic anorexia) in which passage of material from the rumen is not impeded
Abdominal distention	See Fig. 32.119
Excessive fluid (or froth) in the rumen with loss of normal ingesta stratification	Acute ruminal acidosis, vagal indigestion, frothy bloat, anterior intestinal obstruction
Excessive firm, fibrous material in rumen	Ruminal inactivity caused by poor-quality roughage
Firm, doughy ingesta in ventral rumen with decreased ruminal filling	Prolonged ruminal stasis caused by chronic disease with anorexia
Ruminal hypermotility	Early cases of frothy bloat, some cases of vagal indigestion
Abdominal pain, either present or can be elicited	Traumatic reticuloperitonitis, abomasal ulceration, reticuloruminitis
Abnormal feces	Traumatic reticuloperitonitis, omasal transport failure, ruminal inactivity with poor-quality roughage; also dental disease and some abomasal disease
Decreased quantity, firm, dry, with increased fiber length	Acute or chronic ruminal acidosis
Feces with abnormal amounts of whole cereal grains	Pyloric outflow failure, abomasal displacement
Greasy consistency with very fine particle size	Acute ruminal acidosis
Foamy, fluid, yellowish color, acidic odor	Fermentative indigestion, enteritis
Pasty to fluid consistency with foul odor	Anorexia (various causes), acute indigestion before later development of abnormalities
Decreased quantity, dry, otherwise unremarkable	Ruminal overdistention with vagal indigestion, inflammation of reticulorumen, reticuloomasal orifice obstruction, diaphragmatic hernia, some intoxications (differentiate from esophageal disease)
Vomiting (rare)	

Most of the primary forestomach diseases do not induce remarkable changes in the serum biochemistry profile. In lactating or heavily pregnant animals, anorexia may induce a secondary form of ketosis, which is detected by the presence of urine or blood ketones. Affected animals must be carefully examined to differentiate ketosis with secondary anorexia and decreased ruminal activity from primary indigestion with secondary ketosis. Mild to moderate hypocalcemia and hypokalemia are commonly identified abnormalities in many cases of indigestion, especially when anorexia has been prolonged.

The history is important, especially with regard to the animal's feeding. Characteristics of the feed determine the type of fermentation pattern to be expected. Knowledge of the nutrient content thus allows an assessment of the biochemistry of microbial digestion. Consumption of a high-concentrate, low-fiber ration or legume pasture may lead to frothy bloat. A ration of poor-quality hay or straw may result in low microbial fermentative activity and accumulation of impacted indigestible roughage. Overeating of carbohydrates or sudden access to concentrate feeds without adequate adaptation time can induce chronic or acute ruminal acidosis. The feeding history should agree with the findings from inspection of the ruminal contents, or the history should be suspected to be inaccurate. The amount and consistency of the feces should also provide supportive evidence of the type and amount of feed intake.

Abdominal Contours and Animal Stance. Visual inspection of the abdominal contours allows assessment of the degree of forestomach filling (Fig. 32.128). Indigestions can be characterized by decreased, normal, or excessive filling of the reticulorumen. Most primary and secondary indigestions are associated with ruminal hypomotility and anorexia. Thus the rumen usually shows no obvious distention and may have less filling than normal, especially when the duration of the disease is prolonged. Forms of indigestion in which abnormal ingesta or abnormal ruminal motility prevents effective flow of ingesta (overfeeding of poor-quality roughage, obstructive indigestion) or in which fluid is actively sequestered in the reticulorumen (acute ruminal acidosis) typically cause some degree of forestomach distention (See Fig. 32.128).

A left-sided or bilateral ventral abdominal wall distention indicates ventral ruminal dilation, although advanced pregnancy and hydrops conditions must be considered. Distention of the dorsal left flank results from ruminal tympany with or without distention of the ventral rumen. Left abomasal displacement can produce mild distention of the dorsal left flank under the caudal ribs and extending into the paralumbar fossa, but the abdomen usually appears gaunt and empty when viewed from the side or the rear. Occasional cases of left displaced abomasum appear to inhibit eructation and produce gross ruminal tympany as the primary sign. Release of free ruminal gas through a stomach tube and reexamination for abdominal pings reveals this cause of secondary ruminal dysfunction. Frothy bloat in ruminants is discussed further in this chapter. Free gas accumulation is often secondary to the causes of ruminal motility inhibition and is an important sign of indigestion (Table 32.15). Right-sided abdominal distention suggests the various conditions of dilation, displacement, and obstruction or ileus of the intestines and abomasum. The diseases that cause obstruction and reflux of abomasal ingesta into the rumen may result in reticuloruminal distention. Prolonged cases of gastrointestinal obstruction at any site and generalized peritonitis can produce gross bilateral dorsal and ventral distention of the abdomen.

Affected animals should be studied for signs of pain. A pain-filled expression, reluctance to move, an abnormal stilted gait, an arched back with a tucked-up abdomen, and an extended neck are typical signs of anterior abdominal pain. These signs may indicate TRP, abomasal ulceration, or another source of pain. A similar stilted gait and reluctance to move are typical of laminitis, a common sequela of acute ruminal acidosis.

Palpable Findings. Deep palpation of the left side of the abdomen is used to determine the consistency of the ruminal contents and thus the nature and volume of the ingesta (see Fig. 32.128). In normal animals the organized contraction sequence produces a layering effect.[155] A fluid consistency can be palpated ventrally, whereas the consistency is firm and doughy dorsally. The doughy layer consists of the fibrous portion of the feed. In general, an animal fed a high-roughage diet has a more prominent layer of doughy ingesta. The ruminal contents of an animal fed concentrate feed are softer. In sheep and

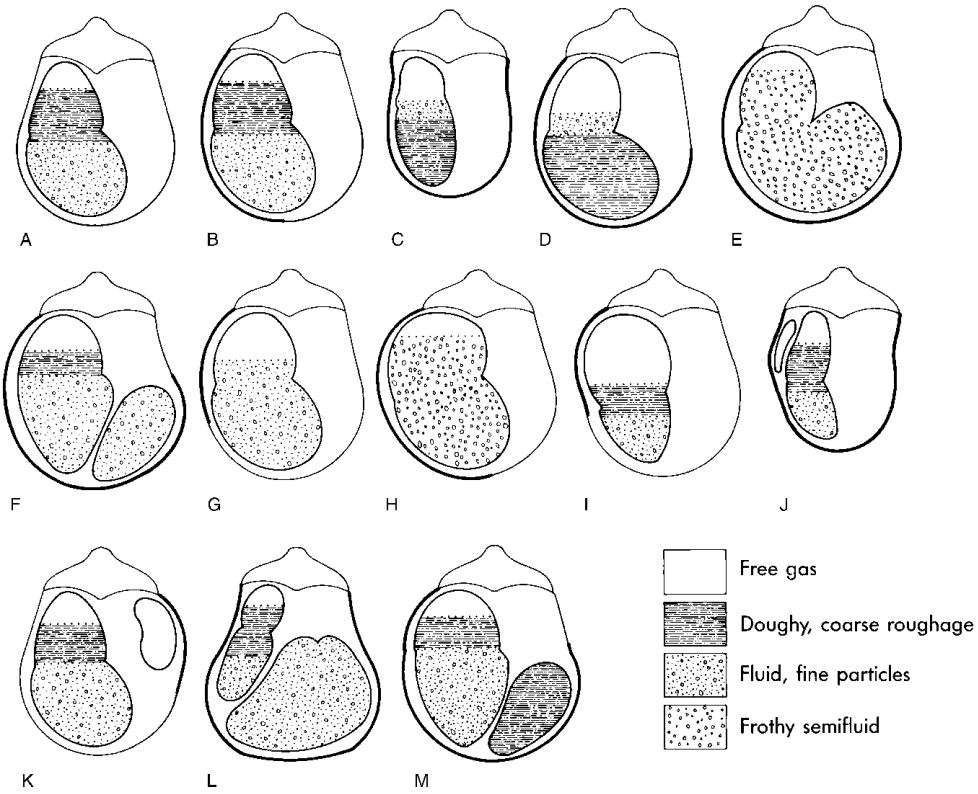

FIG. 32.128 Diagrams of abdominal contours (viewed from the rear) and abdominal palpation findings characteristic of cattle with various types of indigestion and other abdominal diseases. A *thin line* for the abdominal contour indicates the normal configuration. *Bold lines* indicate areas of the abdominal contour that typically deviate from normal in affected animals. **A,** Normal. **B,** Acute onset of rumen stasis with simple indigestion and traumatic reticuloperitonitis (findings: mild ruminal distention with normal layering of rumen content). **C,** Prolonged rumen stasis and anorexia: the most common results of subacute or chronic disorders such as microbial or fermentative indigestions, traumatic reticuloperitonitis, and secondary indigestions (findings: reduced rumen fill; "tucked-up abdomen"; firm, doughy contents that gravitate ventrally). **D,** Rumen inactivity with indigestible roughage (findings: rumen distended with firm, doughy contents that accumulate ventrally; recurrent free gas bloat often present). **E,** Omasal transport failure (findings: L-shaped rumen with gross accumulation of frothy ingesta; rumen hypermotility often present; free gas accumulation varies). **F,** Pyloric outflow failure (findings: fluid accumulation in abomasum; abomasal reflux to rumen common; doughy rumen content that usually accumulates dorsally until rumen stasis or anorexia is prolonged; abdominal contour similar to that for omasal transport failure). **G,** Acute rumen acidosis (findings: rumen distended with fluid; some free gas bloat common). **H,** Frothy bloat. **I,** Free gas bloat or chronic free gas bloat (findings: accumulation of gas in dorsal sac; layering or rumen contents usually normal; with chronicity, rumen fill often decreased; associated with some microbial or fermentative disorders and with esophageal and cardiac disorders). **J,** Left displaced abomasum (findings: gas-filled abomasum that often causes slight bulge of paralumbar fossa; rumen fill usually reduced). **K,** Right displaced abomasum, abomasal volvulus, cecal torsion (findings: distention of right flank with gas-filled viscus; rumen fill and consistency usually normal). **L,** Hydrops (findings: ventral abdomen distended with fluid-filled uterus: rumen fill usually decreased). **M,** Abomasal impaction (findings: abdominal contour similar to those in **E** and **F;** abomasum filled with firm ingesta).

TABLE 32.15

Differentiation of Types of Bloat Through Nasogastric Intubation

Results of Intubation	Probable Causes of Bloat
Tube does not pass.	Esophageal obstruction
Tube passes with resistance and releases ruminal gas.	Esophageal compression caused by thoracic inflammatory or neoplastic disease
Tube passes easily and releases ruminal gas.	Distortion of the cardia caused by inflammation, neoplasia, or abnormal anatomy such as abomasal displacement
	Ruminal stasis caused by reticuloruminal fermentative disorder, hypocalcemia
	Obstruction of cardia with ingesta (overfilling of rumen) or pedunculated mass
	Rumenitis (reticulitis)
	Weakened ruminal contraction caused by chronic overdistention with ingesta (vagal indigestion, indigestion with poorly digestible forage)
Tube passes easily but does not release gas or releases small amount of foamy ingesta.	Frothy bloat
	Frothy ruminal contents caused by abnormal motility in some forms of vagal indigestion

VetBooks.ir

goats, the normal dorsal rumen is softer than that of cattle no matter what the feed. In the normal condition, a small layer of free gas is present in the most dorsal region. Distention with gas or foamy feed produces a taut, elastic tension. With free gas bloat, the doughy layer can still be appreciated ventral to the gas accumulation, but in cases of frothy bloat, the doughy layer is much less prominent. Most cases of obstructive (vagal) indigestion and some cases of proximal intestinal obstruction cause gross dilation of the rumen with fluid or foamy contents that may fluctuate on ballottement.

Overfeeding of indigestible poor hay or straw with resultant inactivity of ruminal microbial fermentation leads to accumulation of more fibrous material than normal that barely yields to deep palpation. With prolonged or severe ruminal stasis, as may occur in TRP, the lack of ruminal motility leads to failure to maintain the normal layering of the contents. In some instances the ventral portion of the forestomach is firmer than the area above. During severe ruminal acidosis, fluid accumulates in the forestomach. This can lead to some degree of abdominal distention, and on palpation the ruminal contents are fluid and may even splash with ballottement.

The rumen should also be palpated rectally; a comparison of these findings with those obtained externally may be revealing. Moderate degrees of free gas accumulation are often more easily detectable on rectal palpation. Rectal palpation is also useful in distinguishing the presence of an L-shaped rumen, in which the ventral sac of the rumen is grossly distended and extends toward the right ventral quadrant. It is important to differentiate an L-shaped rumen from either abomasal distention or impaction, which can manifest in a similar external abdominal contour. It is also important to palpate for the size of the lymph nodes in the longitudinal groove of the rumen. These can enlarge to prominent size when rumenitis is present. The organs in the right half of the abdomen should be assessed as sources of abdominal problems.

Rectal examination is impossible in small ruminants and calves. External palpation with both hands can be valuable in these animals. In calves and goats, it is the best method for detecting bezoars or clotted clumps of milk in the rumen and for palpating intussusception, umbilical abscesses, or grossly abnormal kidneys.

Palpation of the left paralumbar fossa reveals the presence of ruminal contractions. In a normal animal, three contractions should occur over a 2-minute period. One of these contractions should be associated with an eructation of gas, which can be appreciated both visually and audibly. The rate of eructation increases or decreases in proportion to the fermentative production of gas. Most indigestions produce decreased ruminal motility or ruminal stasis. Early cases of frothy bloat and some forms of obstructive indigestion can result in prominent hypermotility. The motility pattern is characterized by changes in both frequency and strength, and weak contractions can also be detected by palpation. Some cases of secondary indigestion, in which the decrease in ruminal function is a result of inappetence rather than an inhibition of ruminal motility, manifest a normal contraction frequency but decreased contraction strength. The duration and strength of ruminal contractions are primarily determined by the nature of the forestomach contents, whereas the frequency relies on medullary gastric center control. Decreased ruminal fill, decreased fiber content of the ingesta, or overdistention of the ruminal wall musculature results in reduced strength and duration of the contraction sequence. These distinctions can be important in determining the cause of decreased ruminal motility.

Auscultable Findings. Auscultation of abdominal sounds is performed over several sites in the left flank and rib areas. Initial auscultation is used to assess the nature, frequency, and strength of ruminal sounds. This information can be compared with the information about ruminal motility gathered on palpation. The sounds represent the friction of fibrous ingesta rubbing against the ruminal wall as the ruminal sacs contract and mix their contents. In healthy cattle on a roughage diet, the normal rustling sound is prominent and prolonged with each contraction cycle. The ruminal contents of animals fed a high-concentrate diet produce less sound because very low fiber rations induce weaker contractions, and less fibrous material is in contact with the ruminal wall.

As with palpation, both the frequency and the nature of the sounds yield information about reticuloruminal motility. The ruminal motility pattern is disrupted in obstructive (vagal) indigestion. Although contractions are present and may be more frequent than normal, their lack of normal coordination can lead to a churning of the ingesta without the usual progression of transport. This disrupts the normal stratification of the contents and produces abnormal sounds that are heard as a rumbling, bubbling, or splashing. When stratification is disrupted because of a hypoactive rumen and more fluid is present in the dorsal area of the rumen, contractions produce splashing sounds. The accumulation of gas under these circumstances may produce ringing tones as the fluid moves, similar to the pings found with a displaced abomasum.

Some circumstances necessitate a distinction between primary and secondary contraction cycles, and they can be differentiated by auscultating for reticular contractions. Holding the stethoscope at the seventh intercostal space at the level of the costochondral junction, the examiner can detect a tinkling fluid sound as the reticulum contracts. A hand held in the paralumbar fossa can detect the tensed bulging of the dorsal sac as it contracts, allowing the examiner to determine whether the ruminal contraction is associated with a reticular contraction. Reticular contraction and motility can also be assessed by transabdominal ultrasonography.[15,17,19] Hyperactivity of primary cycles associated with feeding or the immediate postprandial period is normal. Mechanical stimulation of buccal sensory receptors can lead to an approximate doubling of the primary cycle rate. Hypermotility that results from excessive secondary contractions, without the normal mixing and propulsion of primary contractions, is abnormal and represents ruminal dysfunction.

Ruminal features related to the size and stratification of ingesta, echogenicity and thickness of the wall, size of the dorsal gas cap, and ruminal height at different intercostal spaces can be achieved with ultrasonography.[23] Combining ultrasonography and auscultation with percussion or ballottement allows assessment of gas or fluid accumulations. The sounds heard in the left flank should be compared with those in the left rib area and right side of the abdomen. High-pitched pings and fluid tinkling sounds suggest a viscus filled with gas and fluid. In the left flank this may represent a displaced abomasum, gas-forming abscess, pneumoperitoneum, or static rumen. Careful comparison of the sounds heard at different sites, combined with the results of rectal palpation, should enable localization of the source. In general, the rumen can be ruled out as the source of pings if palpation reveals normal doughy ruminal contents, no ruminal tympany is palpated rectally, and sounds of normal ruminal contractions are heard in the paralumbar fossa. Prolonged anorexia associated with infectious or inflammatory diseases such as pneumonia or mastitis can result in a static, underfilled rumen, and occasionally a prominent ping can be auscultated in the left flank, where a filled rumen normally would be found. This condition has been called "ruminal collapse," and careful evaluation is necessary to distinguish it from leftward displacement of the abomasum. Ballottement of the rumen may reveal splashing fluid sounds without a high pitch when the rumen has accumulated significant fluid. This occurs frequently in cases of severe ruminal acidosis. It may also occur in cases of marked inactivity of the ruminal flora with loss of the normal stratification of ruminal contents.

VetBooks.ir

Pain Elicitation. Tests of pain sensitivity in the anterior abdomen (percussion, deep palpation, withers pinch, xyphoid pressure) are performed to detect localized peritonitis caused by TRP or abomasal ulceration. The same procedures, especially percussion or application of pressure to a localized area in the ventral portion of the abdomen, can be used to localize pain associated with rumenitis or ruminal abscessation or perforating abosomal ulceration.[25]

Fecal Abnormalities. The rectal examination presents an opportunity to assess the volume and nature of the feces. The feces are abnormal in most cases of forestomach dysfunction. In adult cattle, passage of ingesta through the digestive tract requires 1½ to 4 days. Changes in the feces caused by acute diseases are thus often delayed by a day or longer beyond the first appearance of other clinical signs. Mature cattle typically pass a total of 30 to 50 kg of feces per day, divided into 10 to 24 defecations. The color and consistency of feces are influenced by the feed and should be assessed in view of the feeding history.

Diseases that reduce the flow of ingesta from the rumen to the lower gastrointestinal tract typically result in feces of reduced volume that are firm and dry. These findings are also present with reduced feed or water intake. If normal intestinal function is present, a decreased flow of ingesta from the forestomach allows longer retention in the bowel with greater resorption of water. In severe instances, the feces form into firm disks or balls with a dark, shiny mucus covering. These findings are typical of obstructive indigestion and forestomach diseases that produce ruminal stasis without a grossly abnormal fermentative pattern. Indigestions with abnormal fermentation may produce decreased quantities of dry feces initially but usually result in other fecal abnormalities as the abnormal ingesta passes into the lower tract. Intestinal obstructions also decrease fecal passage to the point of absence, but usually the material passed also has other gross abnormalities such as blood, melena, or discolored mucus.

The particle size of fecal material depends on the frequency and duration of rumination, the activity of the ruminal flora, and the function of the rumen in appropriately sorting out material for passage through the reticuloomasal orifice. Abnormalities of these digestive functions lead to passage of ingesta of inappropriate particle size. Plant fibers in normal bovine feces measure up to 0.5 cm. Particles with inadequate breakdown may measure 1 to 2 cm or longer. This long particle size may be seen in the feces of cattle with TRP, some cases of obstructive indigestion, and poor-quality roughage with insufficient microfloral activity.[18,125] Similar findings occur with tooth disease and some cases of abomasitis or cellulitis at the cardia or esophageal groove, in which rumination or activity of the reticuloomasal orifice is inhibited. Whole cereal grains (especially whole corn) may pass in the feces of normal cattle, but excessive amounts of grain should raise suspicion of excessive intake and acute ruminal acidosis. Feces with an abnormally fine particle size and greasy-pasty texture are associated with delayed passage from the forestomach. These are common findings in most cases of obstructive indigestion and abomasal displacement.

The odor of bovine feces is relatively inoffensive in healthy individuals. Foul odors are the result of abnormal fermentation or decomposition. Thus abnormal odor typically occurs when the ruminal fermentation pattern is altered, as in simple indigestion caused by abnormal feed, ruminal acidosis, ruminal alkalosis, or ruminal content putrefaction. A repugnant odor is also typical of enteritis when blood products, inflammatory products, or tissues decompose in the intestinal tract (e.g., *Salmonella* enteritis). Foamy, fluid feces with a yellow-brown color and acidic smell are typical of ruminal lactic acidosis in adult cattle. Abnormal ruminal fermentation not only produces feces with abnormal odor but also typically leads to a pasty or fluid consistency as well. Exceptions occur in acute cases, when ruminal stasis or the delay in the passage of ingesta from the forestomach can result in normal or firm feces during initial stages of the disease.

Heart Rate. Bradycardia of 40 to 60 beats/min is frequently associated with certain types of indigestion. This sign suggests reflex vagotonia to the heart and has been considered indicative of obstructive indigestion associated with vagal nerve damage. The bradycardia can be alleviated by subcutaneous administration of 30 mg of atropine, which differentiates increased vagal nerve tone from a primary cardiac conduction disturbance. The atropine test is not especially useful because only a minority of obstructive indigestion cases are caused by vagal nerve damage or show bradycardia.[18] Advanced cases with severe abdominal distention or fluid imbalances (or both) frequently manifest elevated heart rates (over 80 beats/min). In most cases the other physical signs are more reliable for establishing the diagnosis of obstructive indigestion. Moreover, bradycardia may be observed in other forms of indigestion when ruminal hypomotility is prominent and no significant fluid or electrolyte imbalances are present. Even in normal cattle, postfasting heart rates may drop below 50 beats/min.[106] Therefore bradycardia in association with other signs of ruminal dysfunction is probably most useful as evidence that tachycardic stimuli, such as inflammatory, infectious, or fluid balance disturbances, are not prominent factors in the individual disease occurrence.

Vomiting. Vomiting is uncommon in ruminants, but when it does occur, it generally reflects forestomach disease. Regurgitation from the abomasum frequently occurs with abomasal or intestinal disease. Abomasal reflux is not manifested externally and is discussed elsewhere because it is related to forestomach disease. Small volume regurgitation and remastication are routine and normal ruminant functions that do not result in expulsion of material from the mouth. Explosive vomiting of fluid ingesta in large quantity occurs when the reticulorumen is irritated and occasionally when it is overdistended. Vomiting may accompany diaphragmatic herniation of the reticulum, inflammation of the reticulorumen caused by actinobacillosis, obstructive indigestion, or obstruction of the reticuloomasal orifice. Animals are more prone than normal to vomiting around an orally passed stomach tube when they have almost any digestive disturbance. Vomiting also occurs with certain intoxications, most notably azalea, rhododendron, and sneezeweed toxicity and some organophosphate toxicities.

Disorders of Reticuloruminal Motor Function

NORMAL MOTOR ACTIVITY. The two reticuloruminal contraction sequences function independently. The primary cycle of contraction occurs approximately once a minute but more often during feeding and rumination. It consists of a biphasic contraction of the reticulum followed by a contraction that runs caudally across first the dorsal and then the ventral ruminal sacs. At the height of the second reticular contraction, the omasal orifice relaxes and fluid, mostly composed of reticular ingesta, passes into the omasum. This reticuloruminal motility pattern directly influences ruminal fermentation by mechanically mixing the ingesta to provide contact with the microbes and to macerate the particulate matter. The mixing function prevents local accumulations of substrate or end products of fermentation, distributes the buffering saliva for neutralization of acids, and provides increased contact of the fluid with the ruminal wall to promote VFA absorption. The coordinated sequence of contraction of various parts of the ruminal wall maintains a stratification of fluid and particulate matter that selectively sorts the ingesta by particle size. The sorting function serves to retain large particles for further digestive breakdown while promoting passage of small particles (smaller than 6 mm) into the omasum and lower gastrointestinal tract.[19,32,155]

TABLE 32.16

Factors Influencing Vagal Motor Discharge From the Gastric Centers of the Medulla[a]

Input	Location	Stimulus
Excitation of the Gastric Centers (Causes Increased Rumen Motility)		
Low-threshold tension receptors	Reticulum, medial wall	Mild distention; tension generated during contractions
Buccal receptors	Mouth	Feeding (only during chewing)
Acid receptors	Abomasum	Increased acidity as abomasum empties
Tension receptors[b]	Medial wall of cranial rumen sac	Increased rumen gas pressure
Inhibition of the Gastric Centers (Causes Decreased Rumen Motility)		
High-threshold tension receptors	Reticulum and cranial rumen sac	Bloat or other severe ruminal distention
Tension receptors	Abomasum	Abomasal distention
Chemical receptors	Reticulum, rumen	Increased concentration of undissociated volatile fatty acid with rumen acidosis; also locally activated by some toxins
Pain receptors in body increase sympathetic tone and adrenal secretory activity	Anywhere in body; can act directly and through medullary gastric centers	Pain, especially abdominal
Gastric centers	Medulla	Anesthesia, depressant drugs, toxins, endotoxins, fever, acidosis
Hypocalcemia	Reticuloruminal smooth muscle	Hypocalcemia

[a]There is no inherent reticuloruminal motility such as that found in the intestines.

[b]Secondary cycle activity; independent of primary cycle activity.

The secondary contraction cycle does not involve the reticulum. It begins in the caudal blind sacs, and a wave of contraction runs cranially across the dorsal rumen, pushing the gas cap into the cardia region. Eructation ensues, eliminating the gases generated by fermentation. Typically one secondary cycle contraction follows two primary cycles, so that three contractions occur every 2 minutes.[33] Two additional special contractions have been identified in sheep: primary-secondary contractions and prosecondary contractions.[9] These contractions appear when intraruminal pressure increases and allow ruminal gas to be evacuated. The primary-secondary and prosecondary contractions appear to help minimize free gas bloat when gas production is excessive.

Maintenance of the motility patterns requires well-coordinated neural control. The pathophysiologic mechanism of the first group of primary indigestions (i.e., diseases of the reticuloruminal motor function) involves disturbance of the mechanisms of normal ruminal motility, which secondarily affects ruminal fermentation.

The ruminal contraction sequences described rely almost completely on motor nerve activation arising from the medulla oblongata, in contrast to the intrinsic segmental and peristaltic movements of the intestine. Gastric centers in the medulla integrate sensory input and generate motor impulses, both of which are carried in the vagus nerves. The gastric centers have neither spontaneous activity nor an inherent rhythm. Generation of motor impulses relies on greater excitatory input than inhibitory input from the sensory nerves to determine the rate, magnitude, and duration of primary cycle contractions. During the quiescent period between the primary contractions, while the medulla collects the sensory information, there are no tonic vagal motor impulses.[94,153]

The splanchnic nerves also affect reticuloruminal motility by direct innervation and by neurohumoral effects of adrenal secretion. These nerves are not required for generation of normal contractions. The effect of splanchnic stimulation is inhibition of reticuloruminal motility. Splanchnic sensory nerves innervate sensory receptors in other areas of the gastrointestinal system, and some abnormalities such as intestinal distention or surgical manipulation produce reticuloruminal inhibition by means of reflex from splanchnic afferent activity.[153]

Primary Cycle Activity. A decrease in or absence of normal primary cycle activity (i.e., ruminal hypomotility or stasis) implies either a decrease of vagal motor discharges originating from the gastric centers or an ineffective motor response after motor impulse, as in cases of hypocalcemia. Causes of decreased motor discharges include the following:

1. Decreased excitatory input to the gastric centers
2. Increased inhibitory input to the gastric centers
3. Depression of the gastric centers
4. Defective vagal transmission of motor impulses
5. Other factors

Decreased Excitory Input. The three most important excitatory inputs to the gastric centers are from (1) low-threshold tension receptors in the reticulum, (2) buccal receptors in the mouth, and (3) acid receptors in the abomasum (Table 32.16). The tension receptors are located in the musculature of the medial wall of the reticulum. They are stimulated by mild distention during the resting phase and thereby influence contraction frequency. They are further stimulated by the tension generated during contraction and thus increase amplitude and duration of the primary cycle contraction. This mechanism is probably responsible for the increase in motility after feeding or during incipient bloat. Any cause of anorexia leading to decreased ruminal fill decreases this excitatory input, which results in ruminal hypomotility. Feeding mechanically stimulates buccal sensory receptors, providing a potent stimulus to both primary and secondary contraction cycles. This reflex can double the rate of primary contractions but is short-lived and declines as soon as chewing activity ceases. Thus anorexia effectively eliminates this potent excitatory input. Abomasal acidity increases as the abomasum empties, and this too provides excitatory input to the gastric centers. The resultant increased reticuloruminal motility leads to increased flow of ingesta to the abomasum, diluting the abomasal acid and maintaining normal filling of the abomasum. Certain types of abomasal disease such as abomasal distention associated with abomasal displacement or abomasal impaction diminish this stimulus to forestomach motility.[94,96,153]

Stimuli of reticuloruminal motility that are not as well defined include the physical and chemical characteristics of

VetBooks.ir

the ruminal ingesta. Fiber and water content, as well as the normal chemical products (i.e., VFAs) of fermentation, are important for normal ruminal contraction. The exact mechanisms through which these factors enhance ruminal motility have not yet been clearly defined,[81] but low levels of any of these ingesta characteristics impair normal function, causing decreases of both rumination and primary cycle activity. That these excitatory stimuli are decreased or absent in some feeding regimens and with some of the diseases attributable to abnormal fermentation may account for the impression of hypomotility observed clinically.[50]

Increased Inhibitory Input. Inhibitory inputs to the gastric center arise from (1) high-threshold tension receptors in the reticulum and cranial dorsal ruminal sac, (2) tension receptors in the abomasum, (3) epithelial receptors that detect high concentrations of nondissociated VFAs in the rumen, and (4) pain elicited at any site in the body (see Table 32.16). The high-threshold tension receptors are sensory nerve endings below the epithelial basement membrane of the reticulum and cranial dorsal ruminal sac. They respond to extreme distention of the wall and serve to modify the end stage of reticuloruminal contraction. With severe bloat or gross ruminal distention from other causes, such as overfilling with indigestible fibrous roughage, they can be continuously activated producing ruminal stasis. Abomasal distention can inhibit primary ruminal contraction cycles presumably through tension receptors in the abomasal wall.[78] In normal circumstances this activity serves to decrease the flow of ingesta to the abomasum when it is full. With abomasal displacement or impaction, this reflex may partly account for the observed ruminal hypomotility. Epithelial receptors in the reticulum and cranial dorsal ruminal sac are sensitive to increased concentrations of nondissociated VFAs. Inhibition of forestomach contractions occurs when conditions of excessive fermentation or acidosis increase the concentrations of these substances. Pain can reduce forestomach motility by increasing sympathetic nervous and adrenal secretory activity and by inhibiting the gastric centers. Although painful stimuli in the abdominal viscera are particularly potent, pain from anywhere in the body can inhibit or abolish reticuloruminal motility.[94,96,153]

Depression of the Gastric Centers. Depression of the gastric centers reduces vagal motor activation of forestomach motility and can be induced by central nervous system depressant drugs and anesthetics such as barbiturates, inhalant anesthetics and xylazine. Endotoxemia, fever, and possibly blood pH and electrolyte abnormalities can induce ruminal hypomotility or stasis through central effects on the gastric centers. These factors may also inhibit ruminal motility by increasing sympathetic nervous activity. In addition, some toxins or other abnormal fermentation products reduce ruminal motility. These substances may act locally at the ruminal epithelial receptors to generate inhibitory impulses, as do increased VFA concentrations, or they may act centrally after absorption into the blood. For the most part, the nature of the substances capable of chemically suppressing ruminal function is unknown, but abnormal fermentation end products are the likely cause of ruminal stasis in indigestion associated with abnormal ruminal contents.[50,94,95,155]

Defective Vagal Innervation. Failure of vagal nerve transmission of motor impulses has been implicated as the cause of a reticuloruminal contraction abnormality that leads to failure of aborad flow of ingesta (hence the often-used name *vagal indigestion*). The left and right vagi in the thorax divide into dorsal and ventral branches that unite to form dorsal and ventral vagi as the nerves enter the abdomen. The ventral vagus innervates the cranial and medial parts of the reticulum, the omasum, and the abomasum. The dorsal vagus innervates the rumen and parts of the other segments of the ruminant stomach. Sectioning of more than 50% of the vagal nerve trunks leads to impaired motility function, but in most naturally occurring cases of obstructive (vagal) indigestion, it is not possible to demonstrate nerve involvement. The importance of vagal nerve lesions in the pathogenesis of forestomach disease has been a subject of considerable debate and is discussed later in this chapter.[94]

Other Factors That Affect the Primary Cycles. Other influences on forestomach motility have been identified. Hypocalcemia inhibits motility by preventing contraction of the musculature after motor nerve discharge. This may explain the reduced ruminal motility seen in early cases of milk fever.[77] Low environmental temperatures[97,157] and milking[7] have been shown to increase ruminal motility mildly, whereas some drugs,[24,68,139] hyperglycemia,[149] and gastric hormones[66] are effective in decreasing reticuloruminal primary cycle contractions. These factors are not discussed further in this text.

Secondary Cycle Activity. The secondary cycle activity responsible for eructation is elicited independently of the primary cycles. An increase in ruminal gas pressure stimulates tension receptors in the medial wall of the cranial dorsal ruminal sac. This triggers relaxation of the cardia and eructation of the gas accumulated in the cardia region by the secondary contraction cycle. Receptors that apparently distinguish gas from fluid or solid matter inhibit opening of the cardia if it is covered by material other than gas. This reflex inhibition of cardia opening is responsible for bloat in cases in which abnormal ingesta cover the area, (as in recumbent animals), in frothy bloat, and when abnormal motility or overfilling of the rumen precludes clearing of the cardia. Under such circumstances and when ruminal distention is not yet extreme, both primary and secondary cycle contractions may increase in frequency. In other forms of bloat, hypomotility is a prominent feature, and the gas accumulates as a result of the poor motility function. This is the most probable cause of bloat in some of the disturbances of fermentative function.

Gross overdistention of the ruminal wall may inhibit motility by stretching the musculature beyond its ability to contract forcefully. If the process leading to the distention develops slowly, the high-tension receptor inhibition of motility appears to adapt, and complete inhibition of motor impulses does not seem to occur. Rather, in these cases motility is present but weak and relatively ineffective. This motility disturbance is likely to occur when poorly digestible roughage accumulates in the forestomach. Patients with this condition often have mild to moderate chronic free gas bloat, which may result from poor ability of the weakened rumen to clear the cardia and dispel the gas.[43]

RETICULITIS AND RUMENITIS. The most important inflammatory problem is reticuloperitonitis caused by sharp foreign body punctures (TRP, hardware disease).[108] This disease is discussed elsewhere in this chapter. The localized infection established by reticuloruminal perforation causes inflammation of the forestomach wall and adjacent peritoneal cavity and pain in the anterior abdomen, inhibiting forestomach motility, appetite, and aborad flow of ingesta. Other causes of ruminal wall inflammation can cause acute or chronic forestomach dysfunction. Neutrophilia and hyperfibrinogenemia are routine findings of TRP or rumentis and can aid in differentiating them from other forestomach diseases that do not generally feature hematologic abnormalities.

Most infections of the ruminal wall follow primary mechanical or chemical damage to the mucosa. The secondary invaders colonize the damaged areas and may gain access to the circulation and invade other tissues as well. The ruminal wall may be the niche for some of these microorganisms, and isolates from the ruminal wall have been matched with those isolated from liver abscesses.[113] Probably the most common cause of the initial mucosal injury is acute ruminal acidosis produced

VetBooks.ir

by grain engorgement (discussed later). Chemical damage resulting in ruminal ulcers also occurs in oak or acorn toxicosis and with ingestion of caustic chemicals. Common secondary ulcer invaders include *T. pyogenes*, *Fusobacterium necrophorum*, and several mycotic species.[113,151] Mycotic rumenitis can follow ruminal acidosis and septic diseases, especially after the use of oral antibiotics. It also can occur after feeding spoiled and moldy feeds and without apparent predisposing causes.[30,76] Diseases that cause anorexia and abomasal reflux of gastric acids may predispose an animal to mycotic rumenitis and omasitis. Mycotic rumenitis can be severe, with vascular thrombosis, infarction, mural necrosis and gangrene sufficient to cause death. Less frequently occurring, specific infections of the ruminal wall include atypical forms of actinobacillosis, actinomycosis, and tuberculosis. These infectious inflammatory diseases of the ruminal wall may be distributed widely throughout the forestomach, depending on the initial site of mucosal injury, but they tend to localize in the ventral regions of the reticulorumen. The granulomatous inflammatory lesions of actinobacillosis and actinomycosis are most commonly found in the cranial forestomach in the area of the esophageal groove.

Neoplastic growths in the rumen have also been identified. These uncommon lesions include papillomas, myxomas, fibromas, carcinomas, and lymphosarcoma.[62] These lesions are most commonly localized in the reticulum and cranial rumen near the cardia and esophageal groove.

The importance of these inflammatory reticuloruminal lesions depends on their extent and location. Acute and extensive lesions have been associated with signs similar to those of reticuloperitonitis caused by foreign body puncture, including pain, inappetence, impaired forestomach function, and in some cases death. The more chronic cases may cause forestomach motility disturbances and signs of obstructive indigestion. Pedunculated masses especially, but not exclusively, may obstruct the cardia or reticuloomasal orifice and lead to bloat or reticuloruminal outflow disturbance. Reticuloruminal inflammation can also result from certain generalized infections. These include BVD, FMD, MCF, and rinderpest. In these cases the forestomach problems are unlikely to be the most important clinical manifestation.

Diseases of the ruminal wall may be differentiated on the basis of the physical examination findings and results of a CBC, abdominocentesis, and ruminal fluid analysis. In many cases exploratory laparotomy is needed to confirm the diagnosis. Rumenitis or reticulitis may respond to antibiotic therapy, but the prognosis in these cases is guarded. Not only is the forestomach inflammation difficult to resolve, but also the hematogenous spread of infection to other organs often causes intractable disease in multiple organ systems.

RUMINAL PARAKERATOSIS. In parakeratosis the papillae are darkly colored, enlarged, thickened, and clumped together. Histologic changes of the epithelial cells include a thickened, cornified layer with abnormal retention of nuclei in the cornified cells. These morphologic changes appear to represent a reaction to persistently high concentrations of VFAs. The changes occur predominantly in animals on pelleted or very finely ground rations, especially when the ration contains a high amount of energy. These rations tend to increase the proportions of propionate and butyrate, reduce the proportion of acetate generated by microbial fermentation, and lower ruminal fluid pH. The growth of the ruminal papillae is promoted by contact with the VFAs, especially butyrate, and secondarily propionate.[155] It appears that a disproportion of the concentrations of these VFAs may be the cause of an excessive change in the epithelium of the papillae.[55,147,160] Initial changes in the epithelium under these conditions appear to increase the absorption of the VFAs, but in severe cases the absorption decreases. This disease of the ruminal wall is not usually diagnosed as a primary problem. Although it may lead to impaired performance of the animal, the disease signs that lead to its discovery are usually those of chronic ruminal acidosis, a disease with which it often coexists. Parakeratosis can predispose to other injuries of the ruminal wall because the abnormal papillae are more easily traumatized, which leads to chronic inflammatory disease of the wall, as discussed previously. In calves the problem is also associated with the development of hairballs (trichobezoars) because of the propensity of calves fed rations associated with parakeratosis to lick their hair coat.[147]

Parakeratosis is best treated by correcting the causal feeding error (reducing the amount of concentrate and increasing the feeding of long-stemmed forage). The ruminal papillae can grow or regress in a period as short as 3 weeks when the feed is changed from low- to high-concentrate content or vice versa. Exactly how long it takes for parakeratotic papillae to return to normal remains uncertain, but it probably depends on the degree of change of the diet. The prognosis of this problem is good if inflammation of the ruminal wall is not present.

OBSTRUCTIVE (VAGAL) INDIGESTION. Obstructive indigestion syndrome (vagal indigestion, Hoflund's syndrome) comprises a group of motor disturbances that hinder passage of ingesta out of the reticulorumen or abomasum or both. It is a syndrome, meaning a constellation of signs of disease, but with diverse potential causes. The disease signs are those that would occur if there were a physical obstruction of the reticuloomasal orifice or the pylorus. The author uses the term *obstructive indigestion* for this reason. Historically the term *vagal indigestion* has been used, but this has led to confusion because it implies that the vagal nerve is involved in the development of the syndrome, and this is true only in a minority of cases. Furthermore, damage to the vagal nerve can sometimes cause acute onset of free gas bloat as the most prominent disease sign, so some authors have felt obliged to develop a naming scheme for "vagal indigestion" that includes free gas bloat, even though this occurrence does not fit the syndrome that mimics obstruction of the reticuloomasal orifice or pylorus.

An animal with obstructive indigestion syndrome has progressive abdominal distention, characterized by distention both dorsally and ventrally in the left abdomen and ventrally in the right abdomen, and demonstrates overfilling and enlargement of the dorsal and ventral ruminal sacs with or without overfilling of the abomasum. Appetite gradually diminishes to complete anorexia. Body mass gradually decreases, and the animal may become weak and eventually unable to rise. Fecal output is scant, demonstrating little movement of ingesta through the gastrointestinal tract. In some cases free gas bloat occurs, adding to the abdominal distention. No single pathogenesis produces these signs of disease, and various investigations have yielded conflicting information.[18,20,42,72,124,125,129,146] It is the combination of all of these signs of disease that define the syndrome. Other disease conditions may cause some of these disease signs individually, but are distinguished from obstructive indigestion because the entire grouping of signs does not occur. For example, frothy bloat produces exactly the same abdominal distention, but it occurs rapidly, it does not lead to chronic loss of body condition, and feces are typically not scant. As an alternative example, free gas bloat can occur in a variety of circumstances but often is not accompanied by gross overfilling of the rumen and apparent obstruction of ingesta passage.

The term *vagal indigestion* was introduced by Hoflund, who hypothesized that the vagal nerve was damaged and experimentally produced motor defects and disease signs similar to those seen in clinical cases by transecting various branches of the abdominal vagal nerve.[72] On the basis of his experimental results, he defined the functional disturbance of stomach motor activity with obstruction of ingesta flow at two sites:

1. *Omasal transport failure* (anterior or proximal functional stenosis, reticuloomasal stenosis), which impairs flow of ingesta through the reticuloomasal orifice and occurs with atony of the reticulorumen (often associated with chronic recurrent bloat), or normal to increased ruminal motility.
2. *Pyloric outflow failure* (posterior or distal functional stenosis, pyloric stenosis), which impairs flow through the pylorus and occurs continuously, or in an intermittent, recurrent pattern (incompletely).

Hoflund's description of the syndrome is convenient for explaining the observed functional defects, but its presumed pathogenesis is not supported by the findings of later investigators..[53,146] Later, a classification scheme of four types of vagal indigestion was proposed in which type 1 is associated with a failure of eructation. Animals with type 2 present with bilateral distention of the abdomen as the result of a failure of rumen outflow and fluid accumulation in the rumen. Type 3 manifests similarly to type 2, but the distention is due to a failure of abomasal motility and outflow. Type 4 is a syndrome of partial pyloric obstruction or generalized ileus, not as well defined as the other types.[52,53] Unfortunately, this classification scheme is also flawed. Types 2 and 3 in this scheme align well with Hoflund's description, but type 1 can be construed to include all forms of gaseous bloat. Failure of eructation can result from vagal nerve involvement in inflammatory processes in the thorax, but there are numerous other causes of free gas and frothy bloat, most of which are not chronic or associated with animal tissue wasting, characteristic of this syndrome. Type 4 in this scheme is not described in a way that clearly distinguishes it from type 3. Therefore in this text the terms *omasal transport failure* and *pyloric outflow failure* are used because they encompass the problems described here as obstructive indigestion.

Similar to the use of *vagal indigestion* as a descriptor is the use of the term *stenosis*, which has also led to some confusion, although it was appropriate in its original context. "Functional stenosis" suggested that the defect was a functional one that mimicked a stenosis at the site of outflow. This paralysis or muscular dysfunction can be appreciated in some experimental and clinical cases.

Failure of Omasal Transport. Failure of omasal transport with hypermotility of the rumen is the most common naturally occurring form of the disease. Accumulation of ingesta in the reticulorumen leads to gradually progressive distention of the forestomachs, whereas the omasum and abomasum remain relatively empty. The animal's appetite diminishes as the rumen becomes overfilled, producing one of the most characteristic signs of the disease: inappetence with gross distention of the rumen in the left flank. Continued dilation of the rumen eventually leads to a marked and almost pathognomonic overfilling of the ventral ruminal sac. The rumen assumes an L shape because the ventral sac occupies both the right and left ventral quadrants of the abdomen. The resultant characteristic abdominal contour often is called a "papple" shape (see Fig. 32.128, *E*) because the left side of the abdomen is distended and assumes the appearance of an apple, whereas the right side assumes the contour of a pear. The reduced passage of ingesta results in low fecal volume. The normal ruminal process of selective retention of fibrous material is disturbed, which causes feces to have increased fiber length and a greasy or pasty consistency. In some cases, feces are firm with large particle size.[18,125] Affected animals often continue to drink water, but absorption from the rumen is poor, and the water accumulates in the forestomach while the animal becomes mildly dehydrated. Vigorous contractions of the rumen can be palpated in the left paralumbar fossa in most affected animals, although some display almost complete atony. The contraction pattern does not produce the typical stratification of material in the forestomach; rather, it churns the ruminal contents into a uniform frothy fluid.[124,125]

The signs just described, with abnormal flow of ingesta and normal or increased forestomach contractions, can be experimentally reproduced by sectioning of the ventral vagal trunk at the cardia and the dorsal trunk just distal to the branching of the ruminal nerves.[72] The forestomach distention, empty omasum and abomasum, and stasis of the forestomach with resultant free gas bloat can be reproduced by sectioning of both abdominal vagal trunks along the esophagus. The paralysis produced by vagal denervation can explain the failure of ingesta flow into the omasum by two mechanisms. First, the lower end of the esophageal groove is formed by two muscular lips. These overlap in a manner that allows a passive valve effect that blocks flow into the omasum when they are relaxed or paralyzed. Second, it appears that the flow of ingesta into the omasum is accomplished by an active pumping motion of the omasum that maintains a negative pressure gradient toward the omasum and draws fluid through the reticuloomasal orifice. Paralysis of the omasal musculature after denervation would eliminate the pressure gradient effect. Decreased reticular motility caused by paralysis may contribute to the changes in ruminal content and the alteration in particle passage.[124,125]

The most common predisposing cause of naturally occurring omasal transport failure is TRP. Other causes of omasal transport failure include abscesses, adhesions, and peritonitis around the reticulum (especially the right side of the reticulum) or reticuloomasal area without identification of an offending foreign body; hepatic abscesses; diffuse peritonitis; neoplasia of the ruminoreticular fold and esophageal groove; inflammatory disease of the reticular and ruminal walls; papilloma or other mass at the reticuloomasal orifice; herniation of the reticulum through a diaphragmatic defect; or chronic bronchopneumonia in calves. Foreign bodies that physically obstruct the reticuloomasal orifice cause this syndrome and can be identified in exploratory rumenotomy.[62] To reconcile the experimental findings with those from clinical cases, Hoflund hypothesized that the development of omasal transport failure resulted from involvement of the vagal trunks in the inflammatory process at the reticulum. Several findings make this an unlikely explanation in most clinical cases[94,146]:

1. Although sectioning the vagus nerves as described reproduces the syndrome, disturbance of only one of the two trunks still allows normal cyclic contractions in most cases. For a clinical lesion to produce disease development, the vagal nerves would have to be massively involved. In contrast, fewer than a third of examined cases reported show actual lesions in the nerve branches.
2. The ratio of sensory to motor nerve fibers in the abdominal vagi is approximately 9:1, which suggests the important sensory role of the nerve.
3. Inflammatory lesions of the reticuloruminal wall reported in clinical cases are predominantly in the area of important tension receptors that send afferent excitatory impulses to the gastric centers. Induration of the right (medial) wall of the reticulum and in the esophageal groove region may affect intramural nerves and ganglia and reduce the tension receptor activity and therefore the drive for primary cycle activity.

These considerations allow an explanation of some of the inconsistencies found in various cases. Omasal transport failure may occur with insufficient vagal sensory excitation, which in turn reduces excitatory input to the gastric centers, diminishes primary cycle motor drive, and results in paralysis of the omasum and reticuloomasal orifice. Alternatively, substantial reticular adhesions that develop after TRP could prevent normal delivery of small particle ingesta, with fluid consistency, to the reticuloomasal orifice.[124] Because this reduces or abolishes flow into

VetBooks.ir

the omasum, both the omasum and abomasum would remain relatively empty, a common finding in these cases. The hypermotility observed in these cases may be the result of secondary rather than primary cycle contractions.[20] Distention of the cranial ruminal sac would still be able to induce the secondary contractions if this region is not involved in the induration. Without normal primary cycle activity, the typical stratification of the ingesta would be disturbed, as is usually observed in clinical cases. The existence of hypermotile secondary contractions with absence or severe reduction of primary contractions can be detected clinically. In occasional cases, damage to the thoracic or abdominal vagi by inflammatory or neoplastic lesions may lead to both omasal transport failure and atony of the forestomachs, with resultant free gas bloat. This would be similar to the experimental sectioning of both vagal trunks.

Pyloric Outflow Failure. Failure of pyloric outflow (posterior or distal functional stenosis) causes accumulation of ingesta in the abomasum and omasum. Advanced stages of this form of the syndrome also display gross distention of the reticulorumen. In general, the motility of the forestomach is not markedly affected in the early stages, and normal stratification of ingesta is maintained. With severe distention, forestomach motility is reduced, and the ruminal contents become more fluid.[20]

Obstructive indigestion may cause no significant blood biochemical abnormalities or can result in severe disturbances of fluid and electrolyte homeostasis. Measurement of the serum electrolyte concentrations provides important clues about the site of obstruction of ingesta flow and is useful in adjusting fluid therapy. When the primary problem is a gradual failure of flow through the reticuloomasal orifice, the rumen fills and grossly distends with fluid but any dehydration tends to be mild, and significant abomasal reflux does not occur. The ruminal fluid maintains a normal chloride content, and affected patients generally show mild or no serum electrolyte abnormalities.[18,124] In contrast, overfilling of the forestomach as a result of pyloric outflow failure (internal vomiting) with reflux of high-chloride abomasal ingesta may result in marked dehydration, elevated ruminal chloride concentrations (normal is less than 30 mEq/L), and associated hypochloremic, hypokalemic metabolic alkalosis. In some instances these abnormalities can be dramatic. Prolonged or severe hypochloremia and hypokalemia may also result in paradoxic aciduria associated with avid renal sodium resorption in the presence of low concentrations of chloride and potassium.

Failure of pyloric outflow can be experimentally reproduced by sectioning the ventral vagus trunk at the cardia and the continuation of the dorsal trunk as it crosses the omasum.[72] This mimics the usual clinical form of the disease, which is characterized by complete inhibition of flow from the abomasum. Combinations of more distal resections of the nerves produce the syndrome of recurrent atony of the abomasum as it occurs in natural clinical cases. Again, the term *stenosis* is a misnomer because a true stenosis or spasm of the pylorus is not identified. Rather, the experimental vagal nerve resection and the naturally occurring cases cause a flaccid paralysis, and ingesta accumulates as a result of failure of propulsive activity. The dilation of the abomasum is in the fundus and body and not in the pyloric part.[72]

A common predisposing cause of pyloric outflow failure syndrome is abomasal volvulus. Other abomasal disturbances, including right and left displacements of the abomasum and abomasal ulceration, can cause the disease as well. After surgical correction of a volvulus, the abomasum remains atonic, and the disease may develop within several days. Clinical signs compatible with obstructive indigestion may arise from gross distention and twisting of the abomasum and lesser omentum, which result in potentially coexisting but distinct injury to the vagal nerves or structural damage to the gastric wall, with or without peritonitis. Although focally extensive vagal nerve lesions have been associated with concomitant vascular damage, which indicates that even with nerve regeneration there may not be a return to normal function, the damage appears reparable in some cases as a return to normal function has been observed.[129]

Inflammation and adhesions involving the abomasal fundus and reticulum have been associated with pyloric outflow failure in some studies.[124] Inflammation of the reticular wall may account for the reticular atony reported in some cases. This form of obstructive indigestion may be more frequently associated with true vagal nerve impairment than appears to be the case in omasal transport failure. Alternatively, reticular adhesions may prevent normal motility, alter the flow of ingesta to the omasum and abomasum, and lead to abnormal filling of the abomasum because of decreased fluidity of abomasal contents.[124]

Another predisposing cause of pyloric outflow failure is advanced pregnancy with a large fetus. An exact pathogenesis has not been clearly defined. Presumably the large, gravid uterus distorts the positioning of the abomasum or physically compresses and obstructs the anterior small bowel, preventing outflow of ingesta from the abomasum. In affected patients the gravid horn typically occupies most of the space in the omental sling. In support of these conclusions, the problem can be resolved by inducing delivery of the calf or performing a cesarean section. Supportive care may be required for severely affected cows, but the gastrointestinal system returns to normal function, which suggests that it was secondarily affected by the pregnancy. This problem is referred to as a form of obstructive indigestion because it appears as a pyloric outflow failure. Some patients have such severe obstruction of ingesta passage that they may be given the diagnosis of anterior bowel obstruction. This disease has been called *indigestion of late pregnancy*.

Animals affected with any form of obstructive indigestion for a prolonged time lose body condition because the failure to pass ingesta into the intestinal tract produces a state of malnutrion. The weight loss may be overlooked because of the impression of full body size produced by the abdominal distention, and in these instances a mild to moderate anemia may develop that may be attributable to micronutrient or macronutrient deficiencies.

Chronic Recurrent Bloat. Chronic recurrent bloat is commonly identified with obstructive indigestion in any of its forms. It is mild to moderate in severity, commonly waxes and wanes, and adds to the visual impression of gross abdominal distention. The pathogenesis of this ruminal tympany varies. Experimental resection of both abdominal vagal trunks stops eructation by causing complete forestomach stasis. In naturally occurring cases in which lesions of the vagal nerve truly inhibit motor impulse transmission, bloat may arise from this mechanism. When vagal nerve damage does not appear to be involved, other mechanisms may explain the bloat (see Table 32.17). Overfilling of the reticulorumen with frothy ingesta, a common finding, can inhibit the cardia dilation reflex that is a prerequisite of eructation. Gross distention of the forestomach can also weaken the contractile ability of the rumen, so that the contractions are not strong enough to clear the cardia before eructation.

Bradycardia is often identified in association with obstructive indigestion but can also occur with other forestomach diseases. The origin of the vagotonia is unclear. When vagal nerve lesions are present distal to the cardiac innervation, reflex excitatory discharges may cause bradycardia. Naturally occurring obstructive indigestion shows bradycardia as a feature in only a third or fewer of the cases.[18] These variations may exist because the experimental and natural cases have different causes or because the disease varies in duration. Once the forestomach

TABLE 32.17

Causes of Rumen Tympany (Bloat)

Mechanism	Cause	Disease Examples
Obstruction of eructations	Esophageal obstruction	Choke, tetanus, thoracic inflammation or neoplasia with swollen mediastinal lymph nodes
	Cardia obstruction	Papilloma, fibroma, actinobacillosis
	Failure to clear cardia of fluid or ingesta	Lateral recumbency, reticulorumen overfilled with ingesta (as in vagal indigestion, ruminal microbial inactivity with poorly digestible roughage, obstruction of the reticuloomasal orifice)
Ruminal motor dysfunction	Gas trapped in stable foam	Frothy bloat
	Failure of smooth muscle contraction	Hypocalcemia
	Weakened muscle contraction	Chronic ruminal distention with indigestible roughage, outflow obstruction, or vagal indigestion; hypokalemia
Chemical inhibition	Abomasal distention	Displaced abomasum (especially in calves)
	Vagus nerve damage	Thoracic inflammation (especially in calves and with neoplasia)
	Ruminal stasis	Rumen acidosis, rumen alkalosis, abnormal fermentation products with simple indigestion

has become severely distended, the heart rate tends to be elevated, probably as a result of pain and discomfort and deterioration of hydration and cardiovascular parameters.

Obstruction of the Cardia or Reticuloomasal Orifice. True mechanical obstruction of the forestomach is an uncommon occurrence. The obstruction can be either full or partial and occur at either the cardia or the reticuloomasal orifice. The inflammatory and neoplastic conditions described previously can appear to be obstructive indigestion when the tissues are sufficiently distorted and lesions involve one of these orifices. Papillomas are most prone to causing an obstruction when they become pedunculated. A variety of foreign bodies create obstruction. In calves, trichobezoars are most commonly the cause, occurring predominantly in animals on a low-roughage diet that consequently lick their hair coats vigorously. In adult cows, ingestion of the placenta occasionally results in an obstruction. Curious ruminants, especially goats, sometimes consume plastic bags or discarded rectal palpation sleeves. These and other nondegradable materials can lead to obstruction even after considerable time has passed.

Cardia obstruction leads to the signs typical of esophageal obstruction, with free gas bloat as a prominent, perhaps life-threatening development. Obstruction of the reticuloomasal orifice produces the classic syndrome of obstructive indigestion. Failure of ingesta flow beyond the rumen results in accumulation of fluid material in the forestomach and diminished or no passage of ingesta through the intestines. The degree and duration of obstruction determine the severity of associated problems such as dehydration, depression, elevated heart rate, forestomach stasis, colic, and muscular weakness. Only rumenotomy can effectively differentiate these obstructive diseases from other problems with similar signs.[69] Removal of pedunculated masses or foreign bodies at the reticuloomasal orifice can promptly correct such problems.

Diaphragmatic Hernia. Defects in the diaphragms of cattle are uncommon. Most cases involve a tear through which the reticulum can herniate. Other abdominal organs may also be involved if the rent is large. The diaphragmatic defect may be congenital or an acquired lesion caused by a local inflammatory process (TRP), sudden external trauma (fighting, hanging up on a fence), or internal pressure (parturition, acute tympany).[92] Entrapment of the reticulum may lead to acute changes in intrathoracic pressure and cause sudden dyspnea, tachycardia, and poor venous return to the heart. In general, however, this reticular problem causes the classical syndrome of obstructive indigestion with omasal transport failure.[43] Failure of flow through the reticuloomasal orifice may result from vagal nerve damage, or the anatomic distortion alone may explain the motility defect. Entrapment of the reticulum hinders normal reticular movements and distorts the esophageal groove and reticuloomasal orifice. Reticular ingesta can be heard moving inside the thorax, therefore complete reticular paralysis is unlikely to be the problem. Motility disturbance is reflected by hypermotility of the rumen, generation of frothy ingesta, persistent or recurrent moderate tympany, and overfilling of the rumen. Signs of pain may also be present, as in cases of TRP. Rumination usually is impaired, some affected animals develop a megaesophagus, and large volumes of ingesta may be vomited, especially after eating. Surgical correction of a diaphragmatic hernia involving the reticulum can be attempted but has usually proved unrewarding, especially if the lesion is chronic, involves a large defect, or is accompanied by inflammatory reaction.

Indigestion of Poor-Quality Roughage. Ruminants fed roughage of extremely low quality, without supplemental nutrition, may develop prolonged inactivity of the rumen microbial flora. Many such animals simply fail to thrive and develop protein energy malnutrition, and some may develop specific nutrient deficiencies. This feeding pattern induces a form of indigestion, described later as one of the disorders of fermentative function. However, it is mentioned here because the extreme cases, seen as "Haybelly," appear as obstructive indigestions. When the fibrous feed that is not adequately fermented accumulates in the forestomachs at an excessive level, affected animals show the typical signs of obstructive indigestion syndrome, including gradually progressive gross abdominal distention, body tissue loss, reduced fecal passage of abnormal feces, and sometimes chronic recurrent free gas bloat. This condition can be differentiated from other cases of obstructive indigestion by ruminal palpation that reveals very firm and uniform rumen contents, history or observation of the feeding regimen, and rumen fluid analysis described later.

Treatment of and Prognosis for Obstructive Indigestion. Obstructive indigestion is a chronic and insidious problem that generally warrants a guarded to poor prognosis. The syndrome of abdominal distention with an L-shaped rumen and possibly ruminal tympany has several different causes. Exploratory laparotomy and rumenotomy are essential for establishing an accurate assessment (see Fig. 32.128).[99] The two most common causes of obstructive indigestion syndrome are inflammatory lesions of the reticuloomasal region and abomasal diseases that involve gross distention, twisting, or vascular impairment of the organ. Obstructive indigestion caused by abomasal disease carries a poor prognosis, whereas the prognosis for cases with reticular involvement is more

BOX 32.5

Principles of Treatment of Obstructive (Vagal) Indigestion

1. Determine likely cause, often by means of exploratory laparotomy.
2. Administer specific therapy (e.g., give antibiotics or anti-inflammatory agents, remove foreign body or relief of obstruction, drain abscesses) for causative lesion.
3. Relieve forestomach distention; this often must be performed repetitively.
4. Limit feed and water intake; feed palatable, high-fiber rations.
5. Transfaunate.
6. Cannulate rumen if chronic bloat (free gas) is a problem.

variable. Animals in either category may respond favorably with appropriate therapy[124,129] (Box 32.5). Surgical exploration not only allows an assessment of the cause of the problem but may also allow repair. When abscesses are identified at the reticulum or liver, surgical drainage may help resolve the forestomach motor disturbance.[124] Identification of adhesions and active inflammation indicates that broad-spectrum antibiotic therapy may be beneficial, and as a preventive practice, some clinicians have advocated aggressive antimicrobial therapy before and after the surgical correction of a right-sided abomasal displacement or volvulus.[129] Gross abomasal distention, which indicates pyloric outflow failure, usually worsens the prognosis, as does the presence of granulomatous or neoplastic processes or generalized peritonitis and adhesion formation.[124] When the presence of a large gravid uterus appears to be the inciting cause of outflow failure, parturition or cesarean section usually resolves the problem completely.

The evaluation of animals with obstructive indigestion with a large fluid-filled rumen should include assessment of the fluid and electrolyte status. Abnormalities such as dehydration, hypocalcemia, hypochloremia, and hypokalemia should be addressed with supportive fluid therapy. Treatment should be administered parenterally because oral treatments are ineffective or deleterious. The forestomach should be emptied of the excessive ingesta accumulation either during surgery or with a large-bore stomach tube. This procedure may have to be repeated if the recovery period is prolonged. Relief of persistent forestomach distention is crucial for the reestablishment of normal motility. Limited feed and water should be offered to prevent repeated accumulations in the reticulorumen, and intravenous fluid therapy should be continued until reticulo-ruminal motility is reestablished and oral fluid intake can be allowed at normal levels. Once the ruminal distention has been alleviated, several liters of ruminal fluid transfaunate from a healthy donor should be administered.[122] The limited diet must be palatable and should consist primarily of long-stemmed hay or green feed for maximum stimulation of the normal forestomach motility pattern. A temporary rumenostomy may be indicated if tympany is a prominent sign.[26]

Response to treatment of obstructive indigestion usually is a slow process and may take several weeks. Favorable signs include a return of the normal primary and secondary contraction patterns, improvement in appetite, maintenance of normal forestomach dimensions, weight gain, and increased fecal production. Repeated development of forestomach distention, continued scant fecal output, poor ruminal motility, and recurrent bloat are indications that the animal is not responding to treatment, and the prognosis is grave.

FREE GAS BLOAT. Accumulation of free gas in the dorsal rumen should not be considered a primary disease entity but rather a sign of disease (see Table 32.17). However, because free gas bloat often is the most prominent sign and because it accompanies several different forms of indigestion, its pathogenesis is reviewed briefly here.

Ruminal microbial fermentation and neutralization of acids by salivary bicarbonate continually produce gas as an end product (primarily methane and carbon dioxide) in proportion to the rate of fermentation. Normally the ruminant can eructate volumes of gas that exceed the amount produced even at maximum rates of fermentation.[9] Thus an excessive production of gas is not the cause of bloat. Bloat develops either because the evacuation of gas is limited by a physical obstruction or because the mechanisms that expel the gas are inhibited.[28]

As in choke, physical obstruction of the esophagus by a foreign body can produce dramatic and peracute bloat. Other forms of esophageal occlusion (which may additionally involve inflammation of nerves or ruminal muscle malfunction) include muscular spasm (as in tetanus), swollen mediastinal lymph nodes (as in chronic pneumonia or thymic lymphosarcoma), and tumorous or inflammatory swellings of the cardia region (as in papilloma or actinomycosis). These problems tend to show that bloat has a progressive or chronic nature, although the degree of bloat may be marked.

Bloat is a common feature of indigestions caused by microbial fermentative disorders. When ruminal hypomotility occurs, the fermentative rate may decline, but weak ruminal contractions may be inadequate to move the gas layer and to clear the cardia preparatory to eructation. Thus dietary, microbial, or metabolic factors that affect the excitability of the gastric centers or the reticulorumen can result in bloat. Ruminal stasis can result in bloat because eructation occurs only with ruminal contraction. Bloat also accompanies indigestions that produce gross distention of the reticulorumen with fluid or solid ingesta (i.e., obstructive indigestion, ruminal acidosis, and microfloral inactivity caused by indigestible roughage). The cause of bloat in these cases may be a combination of ruminal stasis, weakening of the ruminal wall caused by the gross distention, and failure to clear the cardia.

As is the case in adult cattle, it appears that free gas bloat in calves has numerous causes, including fermentative indigestions, ruminal wall disturbances, and esophageal involvement in an intrathoracic inflammatory process.[45,86] Chronic bloat in calves has also been attributated to a form of vagal nerve damage resulting from mediastinal inflammation, often caused by lymphadenopathy as a consequence of pneumonia. Distinguishing between vagal nerve impairment and esophageal compression or inflammation as the cause of free gas bloat requires a thorough assessment of ruminal motor function.

When ruminal tympany is a prominent sign, it necessitates very critical assessment. Frothy bloat and free gas bloat can be differentiated by a thorough physical examination and knowledge of the feeding history. Passage of a stomach tube to help in this differentiation is very important and may alleviate the acute problem if free gas is present (see Table 32.15). Evidence of respiratory or cardiovascular distress indicates that the bloat is an acute, life-threatening problem that necessitates emergency treatment. With the exception of cardia or esophageal obstruction, the free gas bloat associated with indigestive disturbances is mild to moderate in severity and chronic or recurrent in nature. It does not represent a major threat to the animal and can be handled by treating the primary forestomach disturbance. Chronic free gas bloat does not respond to the antifermentatives or surfactants commonly used for frothy bloat. Only the restoration of physiologically normal reticuloruminal function corrects this type of bloat.

Inhibition of eructation caused by lesions of the cardia region can usually be confirmed only by exploratory rumenotomy. This approach also determines whether the lesion is surgically correctable. Inflammatory lesions may respond to long-term administration of broad-spectrum antibiotics. This is also the

VetBooks.ir

treatment of choice when chronic pneumonia appears to be the cause of the bloat. Failure to respond within approximately 3 weeks suggests that the treatment is not effective, and slaughter should be recommended after an appropriate withdrawal time. Detection of abnormal forestomach ingesta should direct treatment to the primary fermentative or feeding disorder.

The various causes of chronic or recurrent bloat usually necessitate chronic treatment for correction. It follows that the bloat also does not completely resolve until the underlying disturbance is corrected. Repeated relief of the bloat may be accomplished by passage of a stomach tube during the treatment regimen. In many cases this proves too tedious or too traumatic for the animal, and the most viable alternative often is the establishment of a temporary rumenostomy.[26] Several devices are manufactured for this purpose, or the rumenostomy can be created by suturing the rumen to the skin. Release of the fermentative gas in this manner is important for the reestablishment of normal forestomach motility, which is inhibited if distention is extreme. When free gas bloat is the result of an obstruction of eructation or another gastrointestinal tract disease such as abomasal displacement, surgical treatment of the primary problem may be necessary. The tympany responds rapidly in these cases, and rumenostomy and cannulation are not required.

Signs such as ruminal tympany, ruminal hypomotility or stasis, and forestomach distention can all result from a number of causes. Ruminal hypomotility, for example, is commonly a physiologic response to problems such as abnormal ruminal contents, a ruminal wall lesion, pain, or overdistention. In many cases the ruminal motility disturbance serves as a protective role for the animal. Former treatments that were directed at stimulating ruminal motility without addressing the causative disturbance included rumenatorics (i.e., nux vomica, ginger, tartar emetic) or parasympathomimetics (i.e., neostigmine, carbamylcholine). Such agents are not indicated under these circumstances. Likewise the treatment of indigestions with alkalinizing agents such as magnesium hydroxide is indicated only when the pH of ruminal contents is low.

Disorders of Reticuloruminal Fermentive Function

FORESTOMACH MICROBIAL POPULATION. The continuous culture system of the rumen involves an ongoing selection of microorganisms best adapted to grow in a variety of ecologic niches that are in a dynamic state. Numerous control mechanisms govern the environment and the resultant microbial population. Some of these mechanisms are related to the animal itself, such as salivation, mixing and rumination, removal of substances by absorption or diffusion, outflow through the reticuloomasal orifice, and eructation. Others are related to the diet, including nutrient quality of the substrate (feed), balance of required elements, solubility, particle size, presence of inhibitory substances, nutrient quantity, and rate of delivery to the rumen. Control of fermentation (see Box 32.4) also results from microbial interactions such as competition and symbiosis: cross-feeding between species, removal of inhibitory end products, and maintenance of the oxidation-reduction potential. The complexity of the system tends to promote an overall stability. Changes in the controlling factors create selective pressures that lead to population changes in the rumen.[100,155]

The rumen contains large numbers of bacteria, ciliated protozoa, anaerobic ruminal fungi, and bacteriophages.[100] Ruminal bacteria are predominantly anaerobes, with some coexisting facultative anaerobes. Although the facultative organisms are not important in normal ruminal function, they may be associated with some forms of ruminal dysfunction. Some microbes ferment the primary nutrients in the feed such as cellulose, hemicellulose, pectin, starch, and simple sugars. Other species ferment the products from the primary nutrient fermentation such as pentoses, glucose, lactate, succinate, and formate. Many species are very specialized and have numerous growth requirements that may be supplied by the general fermentation. Other microbes are important for their role in removing end products and cycling essential factors back to the other organisms.[71,101,155]

EFFECTS OF FEED CHARACTERISTICS. The concentrations and proportions of the microbial species vary with the composition of the diet (Table 32.18). An abundant supply of a certain substrate tends to favor a microbial population with a predilection or high capacity for utilizing that material. The most important factors in the rate of digestion are the properties of the carbohydrates and protein in the feed. High-protein diets favor proteolytic organisms, whereas high-starch, low-fiber

TABLE 32.18

Effects of Feed Characteristics on Ruminal Digestion and Health

Feed	Rumen Content	Effect on Health
Primary forage of high-quality, long fiber length, crude fiber > 18% of dry matter; with concentrate supplement at 20% to 50% of total intake, moderate protein level	pH, 5.5 to 7 VFA, 60 to 120 mmol/L Acetic acid level > propionic acid level > butyric acid level	Normal, healthy, productive
Excessive forage of low nutrient value (late cut) with little concentrate or protein supplementation	pH, 6.5 to 7 VFA, decreased Microbial activity, decreased	Poor production or growth, microfloral inactivity and rumen impaction, malnutrition caused by protein, energy, mineral, and vitamin deficiency
High level of concentrate feeding (>60%) with decreased forage or fiber length	pH, 5 to 6.5 VFA, increased Microbial activity, increased	High production, rapid growth; possible chronic rumen acidosis, milk fat depression, chronic laminitis, ketosis, ruminal parakeratosis, excessively fat condition
Extremely high level of concentrates (especially with sudden exposure to ration), low intake of forage	pH, 4 to 5.5 VFA, increased Lactic acid level, increased	Acute ruminal acidosis
Normal levels of forage intake, concentrate with very high protein or NPN supplementation	pH, 6.5 to 7.5 VFA, decreased Ammonia level, increased	Ruminal alkalosis, possible urea toxicity

NPN, Nonprotein nitrogen; *VFA*, volatile fatty acid.

VetBooks.ir

diets favor amylolytic bacteria.[111] Cellulolytic bacteria are prominent in a high-fiber diet, but their numbers also depend on the fiber size as this factor determines the rate of passage or retention in the forestomach. Cellulolytic species can be abundant with a high-concentrate diet if some long-stemmed roughage is included because the retention time of the fiber is prolonged. Diets with readily fermentable carbohydrates and low fiber favor species capable of rapid metabolism and tolerant of low pH. Acid production is rapid, and populations of microbes less tolerant of such changes decline.[85,101,144]

The microbial population is also influenced by the limits of supply of certain feed substrates.[154] High rates of fermentation and microbial growth on the abundant substrates depend on sufficient amounts of the more limited nutrients. Optimum carbohydrate use requires adequate sources of nitrogen, sulfur, and essential mineral nutrients.[46] When any essential nutrient is deficient, the rate of digestion and thus the digestibility of the feedstuff decrease. The presence of signs of nutrient deficiency or forestomach dysfunction with microbial and forestomach inactivity depends on the limiting nutrient and relative requirement of the host and bacteria for the nutrient. Substances and conditions that inhibit fermentation further reduce digestibility.

The feed material also affects ruminal fermentation by influencing the rate and extent of digestion and passage from the reticulorumen. Grains vary in average starch content; corn and sorghum contain the most starch (71 to 76%), followed by wheat (62 to 65%), barley (57 to 59%), and oats (44%).[117] Each grain also has unique features related to the protein matrix surrounding the starch, and the total quantity and rate at which starch molecules are converted to ruminal VFAs, lactate, and and gas are determined by the interaction of starch content, grain processing method, and degree of processing.[107] Fine grinding and pelleting of feed increase the rate of passage of the particulate matter from the reticulorumen. Very finely ground rations also reduce the stratification of fibrous material in the rumen. This affects the ability to sort material in the rumen selectively by particle size and density, so that larger particles less thoroughly fermented pass more readily into the lower bowel. Microbes associated with the feed particles are passed out of the rumen with the feed. Thus a faster rate of passage competes with the generation time of the organisms. Populations of slower growing microbes tend to be most influenced by changes in the retention or passage times. Slow-growing cellulolytic bacteria decline in numbers as the passage rate increases (retention time decreases). High passage rates usually produce faster digestion rates. Although these factors are primarily important to the feed efficiency of the animal, they also affect ruminal function and the adaptation of microbes to feeding changes.[155]

Adaptation of the microbial flora to dietary changes may require a week or longer.[51,65] The abruptness of a dietary change determines the degree of alteration of the ruminal microbial population and fermentation pattern and the potential for digestive disturbances. With abrupt and dramatic shifts to higher carbohydrate diets, the facultative species may overwhelm the more normal flora by producing excessive acid and lowering the pH. The importance of microbial adaptation to a particular diet is evidenced by the reduction in forestomach disturbances seen when the rumen is inoculated, before a feeding change, with fluid from animals already adapted to the new ration.[51,150]

The end products of microbial fermentation influence not only the microbial population but also ruminal function. High concentrations of nondissociated VFAs excite sensory epithelial receptors that reflexly inhibit ruminal motility. Ruminal stasis occurs if a sudden increase in concentrate feeding induces lactic acid fermentation. The ruminal pH suddenly declines, and a greater proportion of the VFAs shift to the nondissociated state with the degree of ionization governed by the rumen pH and the logarithmic acid dissociation constant (pKa) of each particular acid.[35,111] A consistently high level of concentrate feeding produces rapid fermentation, a high concentration of VFAs, and low pH, and the nondissociated VFA level may reach the threshold for stimulation of the inhibitory epithelial receptors. The ruminal stasis reduces the fermentation rate. Mild cases of ruminal acidosis may show spontaneous recovery of ruminal functions as the absorption of VFAs reduces the concentrations to a noninhibitory level. With more severe ruminal acidosis, the generation of acid continues despite the ruminal stasis, giving rise to more severe complications of the disease.

In some instances the effects of ruminal microbial metabolism and microbial end products extend beyond impacts on nutritional status and digestive system function. Several ruminant diseases are due to rumen-generated toxic effects. These have extremely variable manifestations and include toxicoses from ammonia, nitrate and nitrite, 3-methylindole, dimethylsulfide (*Brassica* spp., onion toxicity), and sulfur-associated polioencephalomalacia.[36,63,130,133]

In summary, excesses, deficiencies, or rapid changes of feed substrate can cause imbalance in the microbial population and the fluid milieu. The result can be bacterial overgrowth and overproduction of microbial end products or insufficient microbial growth and fermentation. The effects of these abnormalities on animals range from ruminal motility dysfunction to poor growth and performance and to outright toxicity and organic damage.

INACTIVITY OF RUMINAL MICROBIAL FLORA (CAUSED BY POOR-QUALITY ROUGHAGE, HAYBELLY, OR RUMINAL IMPACTION). When ruminal microbial flora inactivity occurs, the microbial populations and their metabolic and fermentative processes are diminished as a result of deficiencies of one or more nutrients. This occurs most commonly with poor-quality roughage deficient in protein and readily digestible carbohydrates (late cut, highly lignified hay or straw). Microfloral inactivity can also occur when specific mineral nutrients are deficient or when inhibitory substances such as antibiotics or some plant products are present in the feed.[155] Microfloral inactivity also occurs with prolonged anorexia, which abolishes the intake of all nutrients and is the primary pathogenesis of many cases of secondary indigestion.[21,41,79]

When microbial digestive processes decline, the breakdown of ingested feedstuffs is prolonged. Failure to reduce the particle size of the ingesta leads to a prolonged retention in the forestomach and gradual accumulation of the undigested feedstuff. Gradual distention of the reticulorumen is commonly observed (haybelly). In extreme cases, this produces the signs of obstructive indigestion. Forestomach distention can result in weak contractions and moderate recurrent tympany. Ruminal hypomotility alters the normal stratification of the ruminal contents, and the fibrous components are found mixed in the fluid or compacted ventrally on the ruminal floor. Abnormal passage of ingesta from the forestomach results in decreased fecal passage, and the feces usually are dried and contain undigested plant fibers. Other effects on animals are those of generalized or specific nutrient deficiencies (e.g., decreased growth or production, ketosis, emaciation, and a poor hair coat). When anorexia is the cause of the microbial inactivity, the ruminal fill decreases and the lack of normal distention also induces ruminal stasis.[43]

ACUTE SIMPLE INDIGESTION. Acute simple indigestion is the most common sequela of an abrupt change in the ration. Such feed changes present the ruminal microflora with nutrient substrates (1) to which they are not metabolically adapted, (2) to which they are adapted but in lesser quantities, or (3) that contain or produce substances that inhibit microbial growth

VetBooks.ir

and fermentation. The result is an imbalance in the microflora and its fermentation products. The difference between this problem and some of the other fermentation disorders is mostly a matter of degree. In general, this disease is relatively mild and self-limiting. Most affected animals show anorexia for 1 to 2 days, develop diarrhea in approximately 24 hours, and return to a normal appetite without treatment when the ruminal fermentation has stabilized and inhibitory substances have been eliminated. Ruminal motility is reduced but usually not absent, the filling of the rumen is not remarkably altered, and bloat, if it occurs, is mild. In some cases the ruminal fluid pH may change, but usually not dramatically. Mild acidosis or alkalosis of the ruminal fluid may develop, depending on the nature of the causative feedstuff and its resultant fermentative degradation. Signs of ruminal microfloral inactivity are common. Simple indigestion is an acute problem, in contrast to the microfloral inactivity discussed in the previous paragraphs, in which deficiencies produce microfloral inactivity over prolonged time.

Feeds commonly implicated as causes of simple indigestion include moldy or overheated feeds, frosted forages, and partly fermented, spoiled, or sour silages. This form of indigestion also occurs in animals fed high-quality feed, usually after an increase in the rate of feeding or after a change of one of the feed constituents. Thus these mild forms of indigestion can range from a mild acidosis to an excess of VFAs and to the generation of some bacterial inhibitory products. Because the rumen and its fermentative bacteria are very adaptable, the ways, if any, in which animals given a certain feed experience the problem vary considerably. It is not unusual to observe only one or several animals from a group on the ration may have signs.

ACUTE RUMINAL LACTIC ACIDOSIS (GRAIN OVERLOAD, TOXIC INDIGESTION). The various forms of indigestion may be manifested as acute, subacute, or chronic illness. In general they do not appear as critical emergencies with fulminating systemic signs and life-threatening conditions. The exceptions to this are frothy bloat and acute ruminal lactic acidosis. Acute ruminal acidosis is the most dramatic of the forms of ruminal microbial fermentative disorders and in some cases is lethal in less than 24 hours. It has also received the most research attention; therefore the events in its pathogenesis are more clearly defined than those of the other forestomach disorders. The condition has been known as *lactic acidosis*, *acute ruminal impaction*, *ruminal overload*, *acid indigestion*, *toxic indigestion*, *grain engorgement*, *grain overload*, and *D-lactic acidosis*.

Cattle examined a few hours after engorgement of grain may yet be alert but anorexic with a mildly distended rumen, weak ruminal contractions, and mild signs of colic. If the acidosis is mild, affected cattle show the signs of indigestion discussed previously and with or without treatment may recover their appetite within a few days. The severe form of this indigestion leads to severe systemic involvement, with depression, severe dehydration, weakness, recumbency, profuse diarrhea, and eventually death. The temperature usually is normal to subnormal. The heart rate elevates with the progression of dehydration and systemic acidosis; rates above 100 beats/min are usually associated with a poor prognosis. Respiration generally is increased (60 to 90 breaths/min) and shallow. The rumen accumulates fluid. Animals capable of rising may show a staggering gait and appear blind. The pupillary light reflex may be slower than normal. Recumbent animals usually lie quietly and may be stuporous. As the cardiovascular system becomes more severely affected with increasing dehydration and acidosis, the extremities become cool, and mucous membranes dry. Anuria may follow poor renal perfusion. Rapid progression of signs leading to recumbency bespeaks a poor prognosis, and affected animals may die within 24 to 72 hours. Therefore if the progression of signs is rapid, emergency therapeutic measures are mandatory.

Acute ruminal lactic acidosis is the result of excessive consumption of readily fermentable carbohydrates, which causes a rapid fermentation with production of lactic acid and a decrease in ruminal pH to physiologically inappropriate levels. This occurs when animals consume an excess of concentrate feeds (e.g., if animals are suddenly exposed to the feeds without prior adaptation; if animals already on such feeds suddenly consume an excessive quantity because of accidental access; or if animals that have been off feed return to feed and are offered unrestricted access to concentrates). The problem is more common when animals are grouped than when they are separate, probably because the psychological aspects of competition induce them to overconsume. In general the feeds involved include the cereal grains commonly used in high production rations and fruit and root crops (e.g., feed beets, sugar beets, potatoes) where they are available. Starch and soluble sugars promote an overgrowth of bacteria that produce glucose and organic acids. The acid end products increase ruminal acidity and osmolality, inhibit or destroy other ruminal microbes, and cause forestomach dysfunction and metabolic disturbances.[93,111,119,132]

Dramatic alterations of the blood biochemical characteristics may accompany severe ruminal acidosis. Usually the laboratory findings correlate with the degree of severity assessed on physical examination. Affected animals have metabolic acidosis with decreased blood pH and plasma bicarbonate. Blood lactate levels rise with the acidosis. The urine pH falls into the acidic range as the kidneys excrete some of the excess acid, but eventually severe dehydration results in renal failure and anuria, eliminating this route of acid excretion. Decreased renal function is reflected by elevated serum creatinine and urea nitrogen concentrations. Other findings commonly include increased serum phosphate concentration, possibly caused by massive cellular destruction, and mildly decreased serum calcium concentration, presumably the result of decreased gut absorption. Other serum electrolyte abnormalities, such as changes in the sodium and chloride concentrations, may reflect fluid balance changes in response to ruminal fluid hyperosmolality (a third space phenomenon).[132] Concentrations of serum enzymes of muscle and liver origin rise when acidosis and dehydration produce cardiovascular impairment with poor tissue perfusion, increased recumbency, and cellular destruction. Portal bacteria and toxins from the damaged ruminal mucosa contribute significantly to the increased serum liver enzymes: aspartate aminotransferase, sorbitol dehydrogenase, (orthinine carbomyltransferase), and γ-glutamyl transferase.

Specific characteristics of the feedstuffs contribute to acidification of the ruminal fluid. Cereal grains inherently possess less buffering capacity than do the fibrous forages. Low structured fiber content and decreased forage particle size induce less salivation during ingestion and less rumination subsequently; therefore salivary buffering declines when concentrate feeds are consumed. Some silages contain both high carbohydrate and lactic acid and thus introduce more acid at both ingestion and fermentation.[55,88,119]

Feeding regimens that include significant fibrous roughage limit carbohydrate availability and rates of microbial fermentation and growth. Carbohydrate fermentation efficiency relative to the amount of ATP derived from each sugar provides competitive survival value. Slower growing cellulolytic bacteria use substrate most efficiently. When starch or sugar is available in excess, the faster growing species such as *S. bovis* metabolize carbohydrate faster and produce more ATP per unit time, even though they are less efficient in ATP production per carbohydrate molecule. Under these conditions they can overgrow, and lactic acid is their end product.[119]

The severity of ruminal acidosis and disease signs vary considerably, depending on the amount and type of carbohydrate-rich

VetBooks.ir

feed consumed and the degree of prior ruminal microbial adaptation to the carbohydrate substrate. The disease can range from a mild form of indigestion to an overwhelming toxemia that may be difficult to distinguish from other acute toxic conditions or various diseases with endotoxemia.

If consumption of fermentable carbohydrate is only mildly excessive, *S. bovis* proliferation decreases when the carbohydrate has been fermented, pH rises toward normal, and the efficient fermenters reestablish dominance. If the carbohydrate source is abundant and its supply is not exhausted, the acidosis becomes more severe. Continued production of lactate by *S. bovis* reduces the fluid pH to the range of 5 to 5.5, and the ruminal fluid osmolality rises concurrently. Both these factors inhibit or kill the ruminal protozoa, which normally use starch and small sugars and help limit increasing lactic acid levels. There are also numerous species of lactate-using bacteria, of which *Megasphaera elsdenii* and *Selenomonas ruminantium* are the primary examples. These bacteria, which increase in numbers when animals slowly adapt to a high-concentrate diet, are eliminated by abrupt changes and generation of excessive acid; therefore lactate use decreases when the acid is generated too quickly.[51,119]

The lactobacilli are the major group of lactic acid producers in the rumen. The increasing acidity of the fluid enhances the growth of these organisms. Because the lactate-using bacteria are killed off before the lactobacilli overgrow, their diverse end products are unavailable as substrate for other bacteria. The lactobacilli are left as the predominant organisms to use the available carbohydrates. Even the *S. bovis* organisms that began the lactic acid production are inhibited below a pH of 4.5, leaving the lactobacilli, as the most acid-resistant species, to generate more lactic acid.[111,156]

The acidification of the fluid milieu enhances the lactic acid production by altering microbial metabolism.[119] The loss of the fluid bicarbonate buffer and the increase in available hydrogen ions block the conversion of lactate to propionate even before the lactate users die off. Also, when the pH is above 5 but declining, ruminal fluid amylase activity increases and liberates more free glucose from starch. However, glucose use is reduced, and ruminal glucose accumulates. Apparently the lactate-using bacteria such as *S. ruminantium* degrade less lactate to acetate in the presence of increased glucose concentrations.[14,119,137] Thus not only does the microbial population change but also the characteristics of the fluid accelerate the lactic acid production when the available carbohydrate is excessive.[119]

The effects on the animal from the ruminal fluid changes are numerous and detrimental. In the early stages of the acidic fermentation, the VFAs are produced in abundance. Although VFA production decreases as the microbes are increasingly inhibited, VFA concentrations remain elevated in advanced acidosis. The VFAs are much weaker acids than lactic acid; thus as pH drops, they accept hydrogen from lactic acid and serve as buffers in the fluid, so that a greater proportion of the VFAs exist in the nondissociated state. This form is more readily absorbable than free ions through the ruminal wall. During absorption some VFAs undergo metabolism by the ruminal wall epithelium, which results in the release of lactate and ketone bodies into the circulation. Excessive absorption of the VFAs leads to systemic acidosis, and circulating lactate and VFAs may also directly damage the liver. In addition, the high concentration of nondissociated VFAs at the ruminal epithelium provides a strong inhibitory effect on reticuloruminal motility and leads to ruminal stasis. This effect tends to protect the animal because it reduces the absorption of detrimental fermentation products from the rumen.[36,63,93,119,130,133]

The osmotic pressure of the ruminal fluid increases as lactic acidosis develops.[55,93,119] In a normal animal, ruminal osmolality remains relatively constant at approximately 280 mOsm/L, but osmolality may double in some cases of acute acidosis. Lactic acid accounts for a major fraction of the increase, but some of the components of this change remain unidentified. The increased osmolality inhibits and kills some of the microflora and draws fluid into the rumen, mostly from the extracellular compartment. This accounts for the increased ruminal fluid volume, ruminal distention, and severe dehydration observed clinically. The loss of circulating fluid volume leads to circulatory impairment, decreased renal blood flow and glomerular filtration, and in some cases leads to anuria. Poor peripheral circulation results in hypoxic metabolism and contributes to systemic acidosis.

Although it has been assumed that the systemic acidosis that develops with this disease is attributable to lactic acid absorption from the rumen, such absorption does not appear to occur readily.[119] Lactate is absorbed from the rumen at a much slower rate than are the VFAs because it is highly ionized at a pH near physiologic normal, which tends to inhibit absorption. At lower pH the rumen becomes static, thereby also inhibiting absorption. The hypertonicity of the ruminal fluid further limits absorption of lactate and other substances.[132] It appears that the peak entry of lactate into the circulation occurs in the early phases of the disease. Some lactate may be absorbed from the intestinal tract from fluid passed before the onset of complete stasis. Many experimental trials have not shown the development of severe systemic acidosis in the early phase of the disease. It may be that a large component of the later severe systemic acidosis is attributable to circulatory insufficiency rather than to absorption of lactic acid.

Some absorption of the lactic acid does occur, however, as evidenced by the appearance of D-lactic acid in the circulation. Microbes produce both the levorotational (L) and dextrorotational (D) forms of lactic acid, whereas animal tissues produce only L-lactic acid.[111] The animals' pathways for metabolism of D-lactic acid are not as efficient as those for L-lactic acid; therefore absorption of both forms leads to an accumulation of predominantly D-lactate in the animals' system.[98] The lactate is eliminated by oxidation, gluconeogenesis, and renal excretion. An animal's hydration status, liver and muscle metabolism, and renal function determine how rapidly it can eliminate excess lactate. Animals that survive ruminal acidosis often have metabolic alkalosis after the acidotic phase, as a result of lactate metabolism and production of bicarbonate.

Lactic acid is a strong corrosive agent that can destroy the ruminal epithelium, giving rise to the name *toxic rumenitis*. The increased ruminal fluid osmolality also damages the epithelium as extracellular water influx across the epithelium occurs in response to osmotic pressure imbalance and disturbed Na transport.[132] The effects of epithelial destruction can be far-reaching because the damage persists after resolution of the acute acidosis.[55,91] Some yeast and fungi that are resistant to the high acidity readily colonize the damaged sites, invade the vasculature, and cause thrombosis or spread to the liver and other organs.[30] Ruminal acidosis is considered one of the primary causes of mycotic rumenitis (discussed earlier in the Reticulitis and Rumenitis section) and mycotic omasitis, although other predisposing causes have been identified.[30,76] Bacterial rumenitis can also result from the chemical damage and may lead to abscess formation, diffuse cellulitis, or perforation and peritonitis. If the animal survives the acute acidosis, it may succumb to secondary ruminal damage.[30] Alternatively, the rumen may heal uneventfully, leaving scars in the ruminal wall, but bacterial access to the circulation through these chemical lesions can result in hepatic abscessation, a common problem of animals fed high-concentrate rations.[110,112]

In addition to lactic acid, several toxic factors have been implicated in acute ruminal acidosis.[111,119] The altered metabolism of the ruminal microflora has been shown to generate increased quantities of histamine, ethanol, methanol, tyramine,

VetBooks.ir

and tryptamine. Although conlusive evidence is lacking, these may play a role in the pathogenesis of the disease. For example, histamine been implicated as an agent in the development of laminitis that sometimes accompanies ruminal acidosis.[56] Histamine-producing microbes such as *Allisonella histaminiformans* thrive at low pH, and histamine can be absorbed through the rumen wall when the epithelium is damaged, as occurs in acidosis.[8] In addition, the destruction of ruminal Gram-negative bacteria has been suggested to release large quantities of endotoxin for absorption through damaged epithelial surfaces. Endotoxin would contribute to most of the signs of the disease such as ruminal stasis, poor tissue perfusion with cardiovascular deterioration, weakness, and depression. Increased ruminal and blood concentrations of endotoxin and increased blood arachidonic acid metabolites have been found in cattle with experimentally induced ruminal acidosis, but their importance in naturally occurring disease remains uncertain.[1,4-6] With liver impairment and ruminal wall damage, toxin absorption and clearance are likely to be altered. Premature delivery and retained placenta may occur in pregnant animals after acute ruminal acidosis, possibly as a result of from the effects of these circulatory toxins and metabolites.[123]

Severe grain overload requires prompt and aggressive treatment. Animals showing severe depression, an unresponsive condition, apparent blindness, and gross ruminal distention warrant a grave prognosis. Immediate slaughter should be considered for animals with similar signs but still able to stand. Emergency rumenotomy and removal of the acidic ruminal contents may be life-saving if the procedure can be performed before significant amounts of ingesta have passed into the lower gastrointestinal tract.[99] An alternative treatment in less severe cases is repeated flushing of the rumen with warm water through a large-bore stomach tube. Administration of magnesium hydroxide into the rumen and sodium bicarbonate solution (5%) intravenously is necessary to counter the acidosis. Intravenous fluid therapy should be continued until the animal has recovered to provide support against hypovolemic shock.[138] Other treatments that may be considered include NSAIDs. Additional therapeutic measures such as transfaunation and dietary adjustment should be continued during the recovery phase.

SUBACUTE RUMINAL ACIDOSIS. Like acute ruminal acidosis, subacute ruminal acidosis (SARA) is caused by feeding of excessive quantities of concentrate or low levels of well-structured fibrous roughage. However, SARA results from continued ingestion of these feeds over a prolonged period rather than sudden exposure without adequate adaptation. Beef feedlot cattle may be chronically exposed to a ruminal pH between 5.0 and 5.5 from the start of the intensive feeding period until slaughter. Dairy cattle are more probably limited to short periods of low ruminal pH, typically between calving and approximately 5 months post partum.[89,118] In early lactation, dairy cattle may be exposed to energy-dense rations too rapidly, whereas the high feed intake of cows in midlactation renders them particularly susceptible to sudden ration changes or faults in feed delivery or composition.[48] The ruminal microbial population adapts to a high grain ration, and large numbers of lactate-using and lactate-producing organisms are found. The proportion of cellulolytic bacteria decreases, whereas the starch- and glucose-fermenting species proliferate. The overall effect of the adaptation is development of a microbial population that rapidly ferments the ingested feedstuffs. Lactic acid does not accumulate because it is further metabolized by the bacteria. The increased rate of fermentation instead produces high concentrations of VFAs and results in moderately acidic ruminal fluid with pH values usually ranging from 5 to 5.5,[59] although pH values between 5.5 and 5.8 may suggest that cows are at risk for SARA.[48] Ruminal buffering of the increased acid load is impaired because the fine particle size of the high-energy rations induces less chewing and less saliva production.[40] As the name implies, the effects on the animal are chronic and insidious.

Along with the high concentration of VFAs and the low pH, a shift occurs in the proportions of the VFAs in the ruminal fluid. The proportions of butyric and propionic acids increase, and acetate decreases. Butyric and propionic acids stimulate dramatic structural changes and proliferation of the ruminal papillae epithelium within a few days of an acidotic insult. When this process is exaggerated it can progress to parakeratosis.[141] The ruminal papillae develop an excessively keratinized epithelium and clump. The parakeratotic changes are associated with decreased absorption of the VFAs and increased susceptibility to trauma and inflammation.[91] Epithelial damage and the acidic nature of the ingesta appear to be responsible for inflammation of the deeper tissues of the ruminal wall in some cases. The damage to the ruminal mucosa can lead to mycotic rumenitis or ruminal wall abscessation or can disseminate infection through the bloodstream to other organs, most notably the liver, which results in the formation of abscesses.[110] Liver abscesses usually have no pathognomonic signs. Affected animals tend to show poor productivity and may have signs of a chronic inflammatory response.[48,55,63,84,89,110]

The diagnosis of SARA is made on a herd level rather than on an individual cow basis. Cattle afflicted with SARA may demonstrate numerous clinical signs, including reduced appetite and ruminal hypomotility.[118] High ruminal VFA concentrations can inhibit ruminal motility by stimulating the inhibitory receptors in the epithelium. The finely ground ingesta also induces less active ruminal motility because it lacks the physical bulk of high-roughage diets that stimulate strong and sustained contractions. Although the bacterial population is metabolically very active, the number of species of bacteria is reduced,[73] with losses to both ruminal and epimural bacterial community diversity.[61,158] Likewise, the protozoal population is inhibited when the pH remains in the lower end of this range. The microfloral environment is less stable when fewer species are present and is thus more susceptible to sudden changes in the diet.

A continual high acid load may also reduce metabolic efficiency and overall animal performance. Cows may produce less milk, increase milk fat percentage, and demonstrate a positive deviation in the milk fat-to-lactose ratio.[83] High-concentrate diets also have been associated with poor use of dietary protein.[101] Other pathologic conditions have been attributed to SARA, including acute or chronic laminitis[114,134] and cerebrocortical necrosis. These conditions may be induced by some of the toxic by-products of acidic ruminal fermentation, such as endotoxins and hydrogen sulfide.[1,4-6,36,63,84]

FROTHY BLOAT. Frothy bloat results from the formation of stable foam in the rumen. Ruminal tympany is synonymous with bloat. The condition may be fatal if the distention is extreme enough to compromise ventilation by compressing the thoracic viscera. Cattle are more susceptible than sheep, but the disease does occur in small ruminants.

The degree of forestomach enlargement varies from that producing an even filling of the left paralumbar fossa to that causing a uniform, extreme abdominal enlargement when the animal is viewed from the rear. With intermediate degrees of distention, the left paralumbar fossa bulges beyond the contours of the last rib and the tuber coxae. Clinical signs of colic may be seen, including kicking at the abdomen, treading, frequent lying down and rising, and vocalizations. Some animals adopt a stretched stance with the rear feet placed far back. In sheep with heavy fleece, significant bloat may not be apparent because the changes in abdominal contour are not obvious. As the forestomach enlarges and compresses the diaphragm, breathing

VetBooks.ir

becomes more labored. Open-mouth breathing, cyanosis of mucous membranes, and collapse that leads to death may occur within a few minutes if the animal becomes frantic from the abdominal pain and respiratory distress. Other conditions to consider in the diagnosis of frothy bloat in ruminants include other causes of ruminal enlargement: free gas bloat and obstructive indigestion. Many systemic conditions influence the motility of the forestomach and thus may produce mild bloat coincidentally.

Clinical pathologic measurements are not necessary for the diagnosis and management of most cases of frothy bloat in ruminants. Evaluation of a sample of ruminal contents may provide useful information for prescribing treatment and prevention. The presence or absence of froth and the pH are critical features relating to the cause that influence the choice of therapy. The normal pH of the rumen varies with time after feeding but should be between 5.4 and 6.8.

Regardless of the cause of forestomach distention, the process may become self-perpetuating because of reflex inhibition of motility. Low-threshold stretch receptors in the ruminal wall augment cyclic forestomach contractions when stimulated. However, stimulation of high-threshold stretch receptors leads to inhibition of motility. Thus beyond a certain degree of stretching of the ruminal wall, further contractions that may relieve the distention through eructation are prevented.[126]

Frothy bloat is caused by the retention of gases of fermentation within the mass of ingesta that fail to rise and coalesce into a dorsal gaseous layer. This condition can arise from diets of lush legumes or winter wheat pasture or may be seen with high-concentrate finishing rations in the feedlot. In the case of legume-induced disease, bloat has occurred after grazing or feeding of fresh-cut forages or the feeding of alfalfa hay. The structure of stable froth in the affected ruminal contents is not true foam. The ingesta in the septa between adjacent bubbles form a complex structure that prevents coalescence. The viscosity of the fluid may prevent gravitational flow through the septa that would lead to the bubbles' rising and coalescing. Frothy ruminal fluid is higher in chloroplast membrane fragments, soluble protein, and very fine particles than is nonfrothy ruminal fluid.[74] The presence of the resulting frothy ingesta at neural receptors believed to be near the cardia prevents the reflex relaxation of the cardia during the secondary contractions of the forestomach that ordinarily lead to eructation.[67] In addition, the viscosity of the frothy ingesta is such that the cardia may become plugged during attempts to eructate.

Risk factors associated with the occurrence of frothy bloat can be categorized as animal risk factors, plant characteristics (species and maturity), and weather conditions.[74] Individual cattle have been classified as having either high or low susceptibility to legume bloat. Highly susceptible cattle have been shown to have larger ruminal volumes and specific salivary proteins in consistently different proportions in comparison with bloat-resistant cattle. There is a relationship between plant factors associated with bloat and the rapidity with which leaf structure is disrupted after ingestion.[74] Bloat-inducing plants are more readily macerated, which provides quicker bacterial access to the inner leaf cells. Less bloat-predisposing cultivars of the main bloat-causing species, such as alfalfa *(Medicago sativa)*, red clover *(Trifolium pratense)*, and white clover *(Trifolium repens)*, have a thicker leaf cuticle, smaller stomata, and a more fibrous leaf structure. Ionophore antibiotics such as monensin inhibit ruminal protozoa that normally ingest chloroplasts, which leads to a reduction in the bloat potential of some forages.[13,80]

Grain bloat occurs in a manner similar to that caused by legumes; a stable froth is produced from high-concentrate rations. Particle size and the rate of fermentation are thought to be the determining factors in the froth production. A mucoprotein slime composed of bacterial by-products stabilizes the froth.[13,128] This material tends to be stable at a lower pH than is found in non–grain-fed ruminants, so grain feeding promotes slime accumulation by lowering ruminal pH. Animals (such as dairy cattle) that are fed grain and then legumes may be particularly susceptible to frothy bloat because all the factors that lead to froth production and accumulation are present. Both legume bloat and grain bloat may resolve spontaneously if the animal stops consuming the bloat-producing feed and microbial digestion eliminates the froth-stabilizing factors.

Acute distress, often appearing as abdominal discomfort, is caused by overdistention of the forestomach that stimulates pain receptors in the ruminal wall. As the abdominal distention increases, an affected animal's ability to achieve normal respiratory movements of the diaphragm and rib cage is impaired. This exacerbates the animal's anxiety and distress. Death from asphyxia ultimately results as the lungs are compressed by the cranially expanding diaphragm, and venous return via the posterior or caudal vena cava is compromised.

Frothy bloat often occurs as an epidemic. Pasture bloat may occur wherever alfalfa, red clover, or white clover is grazed. Environmental conditions that produce rapid, early growth lead to a higher incidence of bloat. Frothy bloat also occurs when stocker cattle are grazed on winter wheat pastures in the southern Great Plains of the United States. Death rates at pasture range from 0.5% to 2.5% of cattle at risk on an annual basis. The incidence of feedlot bloat has been estimated at approximately 1%, with death rates of approximately 0.1%.[74]

The finding of tenacious froth in the rumen, along with other evidence of bloat, is grounds for a presumptive diagnosis of frothy bloat. The challenge for the diagnostician is to determine whether the bloat occurred before death; this may not be possible if the animal was not observed before death. The increase in intraabdominal pressure prevents venous return from the hindquarters and may lead to obvious edema in the intermuscular areas. Unfortunately, this is not a consistent finding; other evidence of impaired circulation or a differential degree of edema between fore and hind parts must be used to make a diagnosis.

Passage of a stomach tube is indicated to determine the cause of the ruminal distention and possibly initiate treatment. A sample of the ruminal contents for pH measurement should be obtained at this time. Care must be taken to exclude saliva from the tube by blowing into the rumen, flushing water through the tube, or using a ruminal sampling device that carries the tip of the stomach tube down into the liquid ingesta. If no gas can be released with a stomach tube, the tube should be withdrawn after suction has been applied and should be examined for the presence of froth. If the animal is not in respiratory distress or extremely colicky, surface-active agents should be administered by means of a stomach tube. Poloxalene or mineral oil can be given.

Some cattle are in violent pain with bloat but not in respiratory distress. Sedation with xylazine may be necessary for further examination and treatment. Animals with extreme distention of the forestomach and in respiratory distress require immediate surgical intervention. A trocar introduced through the left paralumbar fossa after local anesthesia relieves bloat caused by free gas accumulation but may not be adequate for frothy bloat. An emergency rumenotomy may be necessary to evacuate frothy contents.

Prevention of frothy pasture bloat relies on the general principle of decreasing the rate of rumen fermentation. To significantly modify the rate of rumen fermentation, grazing management strategies and controlling pasture yields and quality remain the most common methods applied to a population. Cattle could be fed other feeds before being turned out and could be allowed limited access to the problem forages. Accurately predicting when forages are safe has not been reliable. Strip grazing, another option, allows cattle a reduced amount of

VetBooks.ir

new forage every few days. The choice of forages and the stage of growth are also to be considered. Agronomists are selecting cultivars of the bloat-producing forages for slower rates of initial fermentation. These are likely to become more widely used in the regions in which bloat is a regular occurrence. When grazing strategies and pasture management are not enough, then as an alternative, cattle at risk have been treated with supplemental surface-active agents such as poloxalene or mineral oil. In Australia and New Zealand, oils and tallows have been drenched daily, sprayed on fields, and smeared on the flanks to be later licked off, to prevent pasture bloat. Although poloxalene has proved effective, it is more expensive than oils. It can be fed in molasses blocks or individually administered. Ionophore antibiotics such as Rumensin (monensin; 1 mg/kg daily) greatly reduced the incidence of legume bloat. Beginning treatment before exposure to the bloat-inducing feed was more effective than waiting until bloat occurred. Providing adequate fiber in feedlot rations and slowly introducing higher proportions of concentrates, particularly corn, barley, and soybean meal, enable ruminal adaptation that helps prevent bloat.

RUMINAL ALKALOSIS. An alkaline ruminal fluid pH occurs most commonly when microbial fermentation is reduced while the animal continues to ingest saliva. A ruminal fluid pH between 7 and 7.5 is found with prolonged anorexia, microfloral inactivity caused by poorly digestible roughage, and some cases of simple indigestion. The low rate of fermentation does not generate enough acid to neutralize the alkaline pH of the saliva. In addition, the absorption of VFAs through the ruminal epithelium proceeds with the generation of bicarbonate in the ruminal fluid. Acetate absorption is associated with greater generation of bicarbonate than is absorption of the other VFAs, and acetate is the predominant VFA produced during fermentation of roughage. Although the fermentation rate is low, the VFA absorption contributes to the ruminal alkalinity. Ruminal alkalosis occurring with these diseases is not the primary problem; therefore these entities are discussed separately.

Ruminal alkalosis can occur with the generation of excessive ammonia. Ammonia concentrations rise when high-protein diets are fermented. The pH usually does not increase above neutral because these diets also contain sufficient readily fermentable carbohydrate to maintain a slightly acidic pH.

More dramatic elevations in the ammonia concentration, with a ruminal fluid pH above 7.5, occur with overfeeding of nonprotein nitrogen sources such as urea, biuret, and ammonium phosphate (see Chapter 54). Accidental ingestion of some common fertilizers that contain ammonium salts can produce the same results. For the purpose of this discussion, it is important to realize that some of the signs of urea poisoning involve ruminal dysfunction. Severe cases of urea poisoning result in generalized signs such as muscle tremors, incoordination, weakness, tachypnea, and central nervous system excitation, and affected animals die quickly. Signs of forestomach dysfunction such as ruminal hypomotility, bloat, vomiting, and abdominal pain are also present. In milder cases, diminished appetite, ruminal hypomotility, recurrent tympany, and diarrhea may be the most prominent signs, along with muscular weakness and incoordination. Thus the disease may appear as a form of forestomach disease. The ruminal fluid shows an alkaline pH between 7.5 and 8.5 and has a strong odor of ammonia.[130]

PUTREFACTION OF RUMINAL INGESTA. Putrefaction of ruminal ingesta infrequently results from overgrowth of a microflora that decomposes feed material in a putrefactive manner. A high ruminal fluid pH, as exists with high-protein feeds, and repeated inoculation with abnormal bacteria allow the development of the putrefactive decomposition. Fermented feeds undergoing spoilage, feed and water contaminated with feces, and spoiling, contaminated concentrates supply the offending microflora, which includes the coliform group and *Proteus* spp.[43] This type of abnormal decomposition is ordinarily inhibited by the existence of an active physiologic microflora. Thus most cattle are remarkably resistant to aberrant digestive patterns even when spoiled feeds are ingested. This form of indigestion typically follows a chronic course. Ruminal motility declines, appetite is poor, and recurrent tympany develops, sometimes with the generation of frothy ruminal contents. The ruminal fluid characteristically has a blackish green color, a foul, putrefactive odor, poor protozoal and bacterial activity, and a pH in the neutral to alkaline range of 7 to 8.5. The cause of the forestomach hypomotility may be inhibitory products generated by the abnormal fermentation. In cases of prolonged duration, animals lose weight and display a poor hair coat, probably as a result of dietary deficiencies in the abnormal fermentation products.

Rumen Fluid Analysis. Evaluation of ruminal fluid characteristics is an essential procedure in establishing the cause of the indigestions of abnormal fermentation.[22,119] Several important determinations can be made at cowside in an ambulatory practice. Acquiring an appropriate sample is simplified with proper equipment. The advantages of various collection techniques and devices have been discussed.[57,116] Needle puncture of the ventral ruminal sac (ruminocentesis) may yield a satisfactory fluid sample, and studies demonstrate that rumenocentesis samples provide the most reliable evaluation of ruminal fluid pH for field evaluation of subacute ruminal acidosis.[49,57,116] Oral or nasal passage of a collection tube produces more fluid volume with no risk of peritoneal contamination but with an increased risk of saliva contamination. The ideal site for collection of rumen fluid for pH evaluation is the ventral rumen sac, where saliva is minimal, whereas investigators examining analytes such as VFAs and ammonia have suggested that sampling in the central rumen is appropriate.[135]

An adequate tube for aspiration of a ruminal fluid sample should be at least 2.3 m long to reach the ventral ruminal sac and should have an internal diameter of 1 cm or larger to reduce the incidence of plugging with ingesta. To adapt a plastic stomach tube for use in passing orally or nasally, multiple holes can be cut into the ruminal end of the tube. A digital examination glove can be placed over the end during passage to limit saliva contamination of the sample and then is forcefully blown off before sampling. The sample can then be withdrawn by a dose syringe. This technique is successful when ruminal fluid is accessible in the dorsal rumen, but the flexibility of the tube is disadvantageous when a prominent layer of fibrous feed is present. Several instruments with a flexible steel outer tube are commercially available (Dirksen Rumen Fluid Tube, Allschwil, Switzerland; Geishauser probe, Hamburg, Germany; Select-Collector, Hamberg, Germany) and have the advantage of enough stiffness and weight to penetrate the overlying firm layer of ingesta for collection of fluid from the ventral rumen.[143]

Ruminal fluid samples collected in an expeditious manner yield the most useful results. When the animal strongly resists sampling and a prolonged time is required from introduction of the tube until the fluid is obtained, saliva contamination of the sample increases. This contamination alters the pH and consistency of the sample. The specially designed ruminal fluid collection tubes reduce this problem. If the sample must be collected with a standard nasogastric tube, passing the tube nasally avoids the presence of a device in the mouth. This reduces the amount of struggling (once the tube has passed the pharynx) and thus reduces excessive salivation.

The sample should be evaluated as soon as possible after collection to minimize the effects of cooling and air exposure on protozoal activity and pH. Some chemical tests such as chloride, and ammonia concentrations can be delayed up to 9 hours on a room temperature sample and up to 24 hours on a refrigerated sample and still yield reliable results.[41] Ruminal

TABLE 32.19

Diagnostic Ruminal Fluid Analysis

Parameter	Normal
Color	Olive, brownish-green
Consistency	Slightly viscous
Odor	Aromatic, strong
pH	6 to 7 on roughage 5. to 6.5 on grain diet
Sedimentation/flotation	4 to 8 min
Redox potential (methylene blue reduction time)	3 to 6 min
Protozoal activity	Multiple forms, active motion
Gram stain	Predominant Gram-negative bacterial population
Chloride concentration	<30 mEq/L

fluid collected for therapeutic transfaunation also retains its beneficial activity for a similar duration.[109] Adding a 1-inch layer of mineral oil on the fluid may help preserve anaerobic microbial activity. The ruminal fluid parameters important in a clinical examination are listed in Table 32.19.

Color, Consistency, and Odor. The color, consistency, and odor of aspirated fluid are assessed immediately after collection. Normal color varies, depending on the nature of the feed. Ruminal fluid produced by animals fed a hay ration is olive to brownish-green; that produced by animals feeding on grass is a deeper green; and that produced by cattle fed grain or silage is yellowish-brown. Fluid from cattle with acidosis tends toward a milky gray. Ruminal fluid from animals with prolonged stasis or decomposition of the ruminal ingesta (or both) is a darker greenish-black, and fluid from calves with milk sequestered in the rumen as a result of abomasal reflux or esophageal groove failure is gray and may contain clots of milk.

Normal ruminal fluid has a slightly viscous consistency. The fluid becomes more watery when the microflora is inactive. Saliva contamination causes greater viscosity; therefore the results from a highly viscous sample should be evaluated with care, and it may be best to discard such samples. Ruminal fluid has a typical odor that has been called "aromatic." The odor is less prominent when the microflora are inactive. Abnormal odors include the acidic smell of lactic acidosis, the putrid, foul odor of protein decomposition or spoiled milk with putrefaction of ruminal ingesta, or the ammonia smell of urea poisoning.

Ruminal Fluid pH. The pH of ruminal fluid fluctuates within a broad range of normal values, varying considerably during the course of a day with shifts of 0.5 to 1.0 pH unit common during a 24 hour period.[89,115] The pH measured in a given fluid sample depends on the type of feed and fermentation pattern and the interval since the last feeding. Physiologic ruminal fluid pH typically ranges between 6 and 7 in animals on a mostly forage diet but is lower, at 5.5 to 6.5, in animals fed mostly grain.[57,89,93] The lower pH develops because the rate of amylolytic fermentation is faster than that of cellulolytic fermentation. Immediately after feeding, the pH tends toward the high end of normal with the addition of feedstuff and saliva, the production of which is determined by the duration an animal spends eating, ruminating, and resting.[102] Over a 2- to 4-hour period, the pH decreases to the lower range as the feed undergoes fermentation. With no further feed consumption, fermentation declines, and the pH rises with salivary buffering and acid end-product absorption. In animals held off feed, the ruminal pH rises above 7 within 12 hours after a hay meal and within 24 hours after a high-grain meal. Thus consideration of the most recent feed consumption is important in the interpretation of the ruminal fluid pH measurement.

Saliva contamination of the sample falsely elevates the measured pH value. Because it is impossible to exclude saliva completely from samples collected by tube, the pH is probably falsely elevated to a minor degree in all such examinations.[57] This elevation can be minimized by expedient collection of a large fluid volume (more than 100 to 200 mL). If the collected volume is small and the sample viscosity is high, the pH measurement will be inaccurate. Modest contamination (5% to 10%) raises the measured pH by approximately 0.1 to 0.2 pH units, whereas excessive contamination with approximately 50% saliva may increase pH by 1 pH unit. Ruminocentesis of the ventral ruminal sac below the left paralumbar fossa is preferred by some clinicians for preventing saliva contamination. This is particularly advantageous for samples collected to monitor ruminal pH for balancing rations and minimizing chronic ruminal acidosis. A sampling strategy that incorporates ruminocentesis and ruminal fluid pH measurement in groups of cows in a herd has been developed to optimally identify cow groups with feeding problems that lead to subacute ruminal acidosis.[57,116]

Ruminal pH values of 7 to 7.5 are common in animals with anorexia and in those that have ingested feed that is not suitable for fermentation (e.g., simple indigestion and inactivity of microflora caused by indigestible roughage). Even higher pH values may be measured with ruminal alkalosis caused by urea ingestion or putrefaction of ruminal ingesta. Low pH values result from engorgement with readily digestible carbohydrates and generation of ruminal lactic acidosis. In extreme cases, values occasionally decline to 4 to 4.5. Of importance is that prolonged anorexia and continued saliva ingestion result in rising pH values in these cases as well and that the ruminal pH of a cow with ruminal acidosis can be normal if a sufficient period of anorexia precedes the ruminal fluid analysis. Conversely, a ruminal pH of 5.5 to 6 is abnormal for a cow fed a roughage diet and may be indicative of unobserved access to grain and resultant lactic acidosis. Subacute or chronic ruminal acidosis usually is accompanied by a ruminal pH in the range of 5 to 5.5.[57,89,93,119] Abomasal reflux into the reticulorumen caused by abomasal disease, obstructive indigestion, or intestinal obstruction can cause mild decreases in ruminal pH because of the acidic nature of abomasal contents. However, ruminal pH measurement is a poor means of detecting abomasal reflux because the pH often remains within the wide range of normal values. Abomasal reflux is better assessed by measurement of reduced buffer capacity or the ruminal chloride concentration.

Sedimentation. The sedimentation time, or sedimentation/flotation test, provides a quick evaluation of microfloral activity. It must be conducted promptly after collection of the sample. The aspirated fluid is allowed to sit in a tube, and the time for completion of sedimentation and flotation of the solid particles is measured. Normally the finer particles settle to the bottom and the coarser particles float, buoyed by the gas bubbles of fermentation. Some of the finer particles sink and then rise again when the fermentation is very active. The normal time for completion of this activity is 4 to 8 min. Grossly inactive fluid shows very rapid sedimentation, and none of the material may float. This occurs with ruminal acidosis, prolonged anorexia, and microflora rendered inactive by indigestible roughage. When the ingesta is particularly frothy, as in cases of frothy bloat or some cases of obstructive indigestion, there may be no appreciable sedimentation or flotation. This test provides a crude evaluation of microfloral activity but does not differentiate well among the different forms of indigestion.

Redox Potential. The redox (reduction-oxidation) potential of ruminal fluid is a biochemical characteristic that reflects the anaerobic fermentative metabolism of the bacterial population.[155] A clinician can determine the redox potential indirectly

VetBooks.ir

by measuring the time required by ruminal fluid to decolorize methylene blue dye. A mixture of 1 mL of 0.03% methylene blue with 20 mL of ruminal fluid at normal body temperature is observed in a tube and compared for color with another unaltered tube of the ruminal fluid. With highly active microflora from an animal fed a hay and grain diet, the initial dark blue color of the mixture decolorizes within 3 minutes, leaving a narrow ring of blue color at the top of the decolorized sample. Fluid from a diet of hay alone requires 3 to 6 minutes to decolorize, and that from a mostly grain ration requires as little as 1 min. Reduction times up to 15 min and longer occur with diets of indigestible roughage, in anorexia of several days' duration, and after ruminal acidosis.[22] Thus the methylene blue reduction time provides an assessment of the degree of bacterial fermentative activity.

Microscopic Examination. Evaluation of the number and activity of protozoa in the ruminal fluid provides a sensitive indicator of the normality of the sample.[155] This is easily accomplished by microscopic examination of a drop of fresh, warm fluid. The examination requires only low magnification (×40 to ×100) and no special stains. In very active fluid samples, the largest protozoa can be seen with the naked eye. They are detectable in a tube as small gray specks of material in active motion in the fluid, and they tend to localize above the sedimented particulate matter. Both ciliate and flagellate forms of varying sizes and shapes can be observed microscopically, with ciliates usually outnumbering the flagellates. The protozoa are normal inhabitants of a healthy ruminant's ruminal fluid, although their specific function is not completely clear and their presence does not appear to be a prerequisite of normal digestive activity.[159] The importance of the protozoa from a clinical viewpoint is their sensitivity to abnormalities in the fluid milieu. Normal ruminal fluid should contain protozoa in a wide variety of sizes, in large numbers that are easy to see, and with active motility. Numbers of protozoa are reduced in inactive fluid samples. The larger species are more susceptible to abnormalities; thus a predominance of small protozoa would suggest a mild indigestive disturbance. All protozoa are killed off when the ruminal pH drops below 5. Thus a recent bout of acidosis results in lack of protozoal activity, even if the pH has subsequently risen back into the normal range. Fluid from such an animal should also show other abnormalities of color and consistency. Very recent disturbances of the fluid may result in the observation of a large number of dead protozoa.

Although elaborate isolation methods for evaluating ruminal bacterial growth are not clinically applicable, examination of an air-dried, Gram-stained smear of ruminal fluid can be useful in diagnosing ruminal acidosis. Normal ruminal fluid should contain a variety of morphologically distinguishable bacterial forms, with a predominance of Gram-negative organisms.[41] After the overconsumption of readily digestible carbohydrate (grain engorgement), a population of streptococci and lactobacilli proliferates as ruminal lactic acidosis develops. This shift in the bacterial population can be distinguished microscopically, and a predominance of Gram-positive cocci and rods are seen. The findings are best confirmed by comparing a smear from a herd mate.

Ruminal Fluid Chloride. The chloride concentration in ruminal fluid can be determined from the supernate from a centrifuged sample through the use of standard chloride titration devices. A delay in measurement does not appreciably affect the value. Saliva contains concentrations of chloride similar to those of normal ruminal fluid, so that saliva contamination has minimal effect on the results. The normal ruminal fluid chloride concentration is less than 30 mEq/L, with elevated values demonstrating reflux of abomasal ingesta into the rumen or administration of chloride in the feed or as therapy. Accurate assessment of measured values requires information about possible previous oral administration of electrolytes. In the clinical evaluation of forestomach dysfunction, an elevated level of ruminal chloride suggests secondary indigestion caused by abomasal disease or obstruction of intestinal flow. This test can be very helpful in differentiating abomasal reflux from ruminal lactic acidosis as the cause of low ruminal pH and abnormal fluid accumulation in the reticulorumen. With obstructive indigestion a high level of ruminal chloride suggests that the failure of aborad flow is posterior at the pylorus rather than anterior at the reticuloomasal orifice.[124] In general, cattle with elevated levels of ruminal chloride also have hypochloremia and metabolic alkalosis as a result of the chloride sequestration in the forestomach, although very slow development of the sequestration may allow the animal to maintain normal plasma levels by altering other excretion rates.

Numerous other tests of the ruminal fluid have been described for the evaluation of digestive activity of the ruminal microflora. These include cellulose digestion, glucose fermentation, nitrite reduction, and measurements of titratable acidity, VFAs, lactic acid, and ammonia concentration.[41] These procedures can more clearly define the nature of the ruminal fluid but are not generally used in a clinical setting.

TREATMENT, PROGNOSIS, AND PREVENTION OF FERMENTATIVE DISORDERS. With the exception of severe acute ruminal acidosis, the disturbances of reticuloruminal fermentation generally are not fatal unless the disease is undiagnosed for a prolonged period, which leads to extreme debility. Treatment of fermentation disorders centers around restoring a normal ruminal fluid environment that allows normal microbial metabolism. Identification of ruminal fluid parameters (see Table 32.19) and the nature of the forestomach ingesta directs the appropriate treatment (Box 32.6).

Feeding. The first and most important step in treatment of nutritionally related indigestions is correction of the specific causal feeding error. Because the imbalance may have gone on for weeks, especially in cases of calf indigestion, correction of the problem may also take some time. The evolutionary development of the ruminant has adapted it to be a grassland grazer. Economic pressures in the animal industry have caused managers to institute feeding practices that diverge widely from a pasture setting. Fresh green grass, however, remains one of the best means of stimulating normal forestomach digestion and motility. The second best type of diet includes a balance of palatable and digestible sources of energy, protein, fiber, and mineral nutrients. Fiber requirements should be determined by considering both the physical effectiveness of fiber and the production of fermentation acids.[2] The content of structured roughage should not fall below 10% of the ration dry matter, and a crude fiber component above 17% is desirable for any ration.

BOX 32.6

Principles of Treatment of Fermentative Indigestions

1. Determine and resolve initiating cause; adjust feed regimen.
2. Correct ruminal pH.
3. Correct systemic acid-base and electrolyte abnormalities through parenteral fluid therapy (especially Ca^{++} and K^{+}).
4. Remove grossly abnormal ruminal ingesta.
5. Correct ruminal fill (overdistention or emptiness).
6. Transfaunate repeatedly.
7. Resolve inspissation or impaction of ruminal contents that is present.
8. Provide oral and parenteral mineral and vitamin supplementation when indigestion or anorexia is chronic.

VetBooks.ir

Alteration of Ruminal Contents. When the viability or activity of the ruminal microflora is in question, as in the primary fermentative disorders and most cases of secondary indigestion, ruminal transfaunation is indicated.[39,122] The material should be obtained from a healthy individual that preferably is adapted to a ration similar to the one the patient is expected to consume. The fluid can be obtained from an animal with the rumen cannulated, by removal with a stomach tube, or from a local abattoir. After the large particulate matter has been strained from the fluid (cheesecloth or large stockinette can be used), it can be administered through a stomach tube. The transfer from donor to recipient is best accomplished immediately, but fluid that contains active and healthy microflora remains viable for up to 9 hours at room temperature or 24 hours under refrigeration.[109] Some clinicians add mineral oil to the fluid, which rises to the top and minimizes exposure to air in order to maintain anaerobic conditions. In calves, inoculation with 1 L is appropriate to reestablish microbial populations, whereas 3 L is minimal in an adult cow, and 10 to 16 L is more desirable. Similarly, transfaunation of sheep or goats with 1 to 4 L of fresh rumen fluid can reestablish normal microbial populations.[39]

Many animals with indigestion exhibit decreased ruminal fill. As discussed, one of the primary stimuli for active ruminal contraction is mild forestomach distention. In addition to the administration of ruminal transfaunate, it is usually beneficial in these cases to administer enough oral fluid to produce mild ruminal distention. This can be accomplished with water warmed to body temperature, and 20 to 30 L of fluid administered through a tube may be needed to achieve the desired effect. The addition of salt (sodium and potassium chloride) in amounts sufficient to produce an isotonic solution (≈2 teaspoons per liter) supplements deficiencies and promotes rapid turnover of the fluid from the rumen to the lower tract. Cathartic agents such as magnesium sulfate have been used but do not serve to supplement the common electrolyte deficiencies.

Correction of pH abnormalities to the normal range of 6 to 7 is important when ruminal acidosis or alkalosis is detected. Alkalinizing agents such as magnesium hydroxide and sodium bicarbonate are indicated for treatment of acidosis at an initial dose of 1 g/kg. Magnesium hydroxide is commonly used by some as a routine treatment for any animals in which ruminal hypomotility has been identified. This practice is not justifiable in most cases of ruminal hypomotility because the fluid pH is commonly at or near neutral. The use of magnesium hydroxide in such settings may induce a mild systemic alkalosis, and the agent is better reserved for true cases of acidosis. Ruminal alkalosis can be corrected with the infusion of acetic acid (vinegar, initial dose of 2 mL/kg, up to 12 L). These agents are best administered in several liters of warm water to ensure good distribution throughout the ruminal fluid.

Overdistention of the ruminal wall may be a primary inhibitor of forestomach motility in some cases of indigestion caused by abnormal fermentation. Treatment of free gas bloat has been discussed. When the distention is caused by accumulation of abnormal ingesta, normal contractions do not return, and the ruminal tympany is not resolved until the distention is relieved. This situation is best exemplified by cases of microfloral inactivity caused by poor-quality roughage and is the underlying problem in calves with haybelly. One approach to this problem is to restrict the animal to small quantities of readily digestible feed given several times a day. Between meals the animal can be kept in an unbedded stall or muzzled. This process is continued until the accumulated ingesta has passed out of the forestomach. Repeated transfaunations during this time help reestablish a more normal microflora. This approach relies on motility and microbial activity sufficient to break down the ingesta and pass it to the lower tract.

An alternative approach is to remove the accumulated ingesta by means of rumenotomy, after which the animal is transfaunated and allowed access to moderate amounts of feed until normal motility is restored. Emptying the rumen surgically is the treatment of choice when spoiled milk, putrefactive ruminal ingesta, or severe ruminal acidosis is detected. Prolonged cases of microbial inactivity or anorexia (or both) with ruminal hypomotility can result in loss of the normal stratification of forestomach ingesta. The fibrous, floating layer sinks to the ventral ruminal sac in these cases, forming a dense, firm mass. Return of normal forestomach motility is delayed unless the accumulation of material can be eliminated. This can be accomplished during the process of microfloral reestablishment by massaging of the mass through the lateral and ventral body wall. Dissolution and passage of the material can be enhanced by the administration of mineral oil (4 L), or dioctyl sodium sulfosuccinate (4 to 6 ounces in 2 to 3 L of water). Because dioctyl sodium sulfosuccinate kills ruminal protozoa when given in amounts greater than necessary to saturate the fibrous matter, at least one ruminal transfaunate should be given 1 to 2 days after the last application of this agent.

Animals with prolonged anorexia caused by a depressant or febrile disease that produced secondary indigestion may not return to feed or have normal ruminal motility even after the ruminal contents has been restored to normal. Chewing activity is one of the strongest stimulants for ruminal motility, and these animals sometimes benefit if palatable hay or grass is placed forcefully into the mouth by hand. An alternative is to give such animals access to pasture. In fact, during a bout of SARA, cows have been shown to self-regulate their dietary preference for physically effective higher fiber and slower starch fermentability.[104] Both the ruminant and its ruminal microflora have trace mineral requirements that are often not met by the type of diets that may induce microfloral inactivity. The ruminal microflora is also responsible for supplying animals with their vitamin B requirements. The stunted, poor body condition of calves affected by chronic indigestion may reflect these deficiencies, as well as protein energy malnutrition (see Chapter 9). Oral supplementation of minerals and parenteral supplementation of the B vitamins may be helpful until normal ruminal digestive function is established. Adult cattle, especially lactating animals with high metabolic demands, may also benefit from B vitamin supplementation when ruminal function is impaired.

Feeding changes and ruminal transfaunation are effective in inhibiting undesirable microbial populations, and inoculating the desirable population. When spoiled milk, putrefactive ingesta, or extremely acidic ruminal contents are found on ruminal fluid analysis, the desirable treatment is rumenotomy, removal of the contents, and flushing of the rumen.

Supportive Treatments. Indigestion often is accompanied by varying degrees of dehydration and electrolyte imbalance. When these abnormalities are only mild or moderate, the animal's fluid homeostasis may correct itself as the normal digestive processes are restored. More rapid recovery is achieved if these problems are addressed during the initial treatment, and animals must be treated if the imbalance is severe. Restoration of normal fluid balance improves attitude, appetite, and gastrointestinal motility.

When laboratory facilities are available and the specific electrolyte imbalances can be assessed, fluid therapy can be tailored to the individual case. Empirical treatment with a balanced electrolyte solution administered intravenously is sufficient in most cases because extreme disturbances of the body fluid electrolytes are uncommon in most indigestions. Exceptions include severe ruminal acidosis and obstructive indigestion with pyloric outflow failure and sequestration of abomasal chloride. These problems should be identified during the examination.

VetBooks.ir

Hypocalcemia and hypokalemia are routinely present in many cases of indigestion. Low serum concentrations of these elements can produce muscular weakness and impair gastrointestinal motility. Both calcium and potassium should be included in the administered fluids. As an alternative, calcium salts should be administered subcutaneously if intravenous fluid administration is not elected. Oral preparations of calcium salts are commercially available but seem less desirable as a means of treatment without normal rumen function. When anorexia has been prolonged, an additional oral dosage of potassium chloride (120 g/day) may be required even after adequate hydration has been achieved and fluid therapy has been discontinued.

Prevention. Some of the sporadically occurring diseases of the forestomach wall such as granulomatous infections, neoplastic invasions, and diaphragmatic herniation cannot be foreseen or prevented. The most common cause of vagal indigestion is inflammation of the perireticular area caused by TRP. Prevention of this disease by keeping metallic foreign bodies out of the feed, removing them from the feed through the use of a metal retriever or magnet, or prophylactic administration of a ruminal magnet is highly effective.

The microbial-fermentative forestomach disorders are best prevented by proper feeding management. A well-balanced diet of palatable feeds with an adequate amount of well-structured roughage (not finely ground or pelleted) prevents most problems. Dietary changes should be introduced slowly (over 2 to 3 weeks) to allow adaptation of the microbial flora to the new substrate. Calves undergoing ruminal development and cattle fed high-production diets or changing between production groups are at risk of oversights in proper feeding management.

Feed-grade buffers are used widely in both dairy and beef cattle production, in which high-concentrate diets are fed to maximize production. Dietary buffering is largely explained by dietary cation-anion difference; diets high in sodium and potassium in relative to chlorine and sulfur demonstrate a higher dietary cation-anion difference and promote higher ruminal pH.[75] These buffers stabilize the ruminal pH and alter the mechanics of ruminal fluid outflow, thus decreasing the chances of overgrowth of the lactate-producing organisms. Commonly used "buffers" include sodium bicarbonate, sodium sesquicarbonate, sodium bentonite, magnesium oxide, and calcium-magnesium carbonate, of which only the sodium carbonates are truly buffering agents in the chemical sense. The other agents do tend to stabilize ruminal pH, however, and all of these have shown some benefit in reducing the disease problems associated with heavy grain feeding and diets that are low or marginal in effective fiber.

The ionophore antibiotics (e.g., laidlomycin, lasalocid, monensin) and some other antibiotics (e.g., the sulfur-containing peptide antibiotic thiopeptin) have also proved effective in reducing lactate production in animals fed high-grain diets. The effect of these agents is to suppress the lactate-producing organisms while not appreciably affecting the lactate users. The ionophores are in common use in feedlot cattle and dairy heifer rations because the selective effects of these agents on the ruminal microbes alter the ruminal metabolism in a manner that promotes increased animal weight gain.[107] In 2004 the U.S. Food and Drug Administration approved the use of the ionophore monensin for lactating cattle in the United States. Although approval was based on increases in milk production efficiency, ionophore use may also reduce the risk of ruminal acidosis and ketosis.[47,60]

A number of other feed additives have proven effective in preventing the overgrowth of high acid–producing ruminal microflora and reducing the risk of disorders related to reticuloruminal fermentive function.[3,10,29,38,105] Research has increased the understanding of the importance of ruminal microbial diversity and the functional capacity of rumen microbial ecosystems under different dietary environments.[87] Molecular biological advances have been used to profile microbial communities with the use of techniques such as terminal restriction fragment length polymorphism analysis, 16S ribosomal DNA libraries, and metagenomic approaches.[90] The application of these tools in the evaluation of manipulators of ruminal fermentation can provide added value in optimizing feedstuff and minimizing digestive disorders.[105]

Forestomach Diseases of Calves

Normal forestomach development and diseases of the forestomachs of calves have been reviewed.[11,37] The newborn ruminant has the same anatomic division of the stomach into four compartments as the adult ruminant. The abomasum is functional as a secretory digestive organ, like the stomach of monogastrics, and has a capacity approximately twice that of the other compartments. The remaining stomach compartments are small and do not perform digestive functions in the first days of life. The reticulorumen may not develop an adult-type function until the age of 4 months or later and does not completely develop proportional dimensions similar to those of the adult until the ages of 9 to 12 months.[37,43,44,54,155]

Traditionally, preruminant calves have been viewed as functionally monogastric animals, and little importance has been attached to diseases of the forestomachs. Under most management conditions, however, the forestomachs have begun to develop their digestive function within the first week or two after birth. During the development process, a calf's forestomach is susceptible to problems different from those of adults. After the rumen has developed a functional status similar to that of the adult, a calf is susceptible to the diseases discussed previously. Typically the feeding management of maturing young stock includes pasture or a mainly forage diet and does not predispose to digestive disturbance.

ESOPHAGEAL (RETICULAR) GROOVE FUNCTION. Liquid feed bypasses the reticulorumen in the young ruminant, flowing directly into the abomasum through the esophageal groove. The groove consists of two lips that extend from the cardia to the reticuloomasal orifice. These lips close together, forming a tube to shunt liquid material to the abomasum when the soluble proteins and salts of milk stimulate a reflex through specific receptors in the oropharynx. Other salt solutions and even water can stimulate the reflex in very young animals, but the reflex weakens with age, especially after weaning. The response to stimuli varies among individuals, but generally milk produces the strongest response and plain water the weakest.[127,131,152] Both nipple and bucket feeding stimulate closure in very young calves, but beyond 12 weeks of age, closure is weak unless stimulated by nipple feeding. In older, weaned animals, the reflex can be stimulated weakly for short durations by orally administered strong solutions such as copper sulfate or sodium salts. Intravenous vasopressin can induce more profound closure of the groove and has been advocated to aid ruminal bypass of orally administered treatment.[131]

Milk replacers that contain nonmilk protein appear to stimulate a weaker closure of the esophageal groove than do whole milk or milk replacers containing real milk protein. Likewise, unpalatable fluids and spoiled milk do not seem to induce normal closure of the groove. Even in healthy calves that consume unspoiled whole milk, some overflow into the forestomach may occur. Failure of esophageal groove closure allows these fluids to pass into the rumen rather than bypassing it. Milk or other fluid administered through stomach tube or esophageal feeder does not contact the pharynx; therefore the reflex closure is not stimulated and the fluid deposits in the forestomachs. Under normal conditions fluid in the forestomach of neonatal calves younger than 2 weeks of age overflows into the abomasum when more than 400 mL has accumulated.[27]

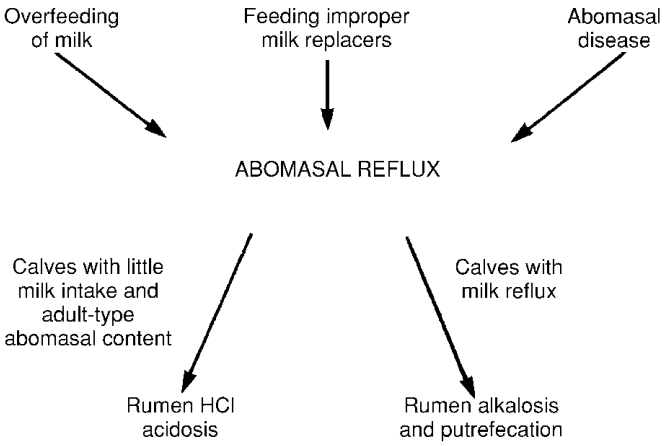

FIG. 32.129 Causes of abomasal reflux in calves. *HCl*, hydrochloride.

Reticuloruminal Milk Accumulation (Ruminal Drinking Syndrome). Milk can gain access to the reticulorumen by several means. Failure of esophageal groove closure, just discussed, is one possibility. In addition, if calves are maintained as preruminants for longer than 3 to 4 months, groove closure weakens and may allow greater escape of fluid to the reticulorumen. Fluid can also accumulate in the forestomach from abomasal reflux (Fig. 32.129). Overfeeding fluids beyond the capacity of the abomasum (≈2 L in the newborn, 35-kg calf) promotes backflow into the reticulorumen. Certain fluids affect abomasal motility and emptying times, prolonging their retention in the organ. These include acidic and hypertonic fluids and severely heat-treated skim milk powder. Nonmilk protein does not curd in the abomasum, as does casein, when it contacts the abomasal enzyme renin. Prolonged fluid retention and failure of curd formation in the abomasum may promote backflow into the rumen, especially when more fluid feed is consumed. Abomasal inflammation or ulceration may also inhibit normal emptying and promote abomasal reflux. In any case, ultrasonography may be useful for detecting milk in the reticulum and rumen of calves with ruminal drinking syndrome.[16]

Some amount of milk reflux from the abomasum appears to be a physiologically normal occurrence. In fact, this route supplies some of the inoculum for ruminal microfloral development and strongly influences the species distribution of the microbial population. But prolonged, repeated, or excessive retention of milk in the forestomach can lead to the development of abnormal fermentation patterns. Although amounts of fluid greater than 400 mL do not normally accumulate in the forestomach of neonates, more fluid can accumulate when the abomasum is already filled and when ruminal size has increased during the development process. In some cases, milk flow into the rumen accumulates significantly over prolonged periods.

The predominant organisms that constitute the forestomach microflora of 1- to 4-week-old ruminants are the coliforms and lactobacilli. These lactose-fermenting, facultative anaerobes tend to maintain the ruminal pH in the acidic range before the adult-type, anaerobic, cellulolytic flora becomes established. The high fat and protein content of milk in the rumen can predispose to a flora that decomposes these constituents and produces spoiled and rancid ruminal ingesta. Problems associated with ruminal milk accumulation are compounded when the milk or other fluid ingested is already contaminated or spoiled. The abnormal microflora established under these circumstances does not supply the young animal with the necessary digestive end products, and signs of dietary insufficiency develop. Affected animals fail to grow normally, show a poor hair coat potentially with widespread alopecia, and may have a depraved appetite. The stimuli for normal forestomach development are also deficient; affected animals have a potbellied appearance, and the rumen is distended with fluid and clots of milk. Ruminal motility is poor, and recurrent bloat is a common sequela. The ruminal fluid pH may be alkaline as a result of the proteolytic formation of ammonia, but in most cases the ruminal pH is acidic (<6) because of an accumulation of VFAs and lactic acid from bacterial fermentation, and the fluid has a putrid, foul odor.[121] An enteric imbalance also seems to occur, and the feces are commonly pasty or fluid in consistency. Ruminal "drinking" appears to compound problems in calves with infectious enteritis and diarrhea, and affected calves frequently develop systemic acid-base and fluid balance disturbances.[58,145]

Problems in Ruminal Development. The age at which a calf has reticuloruminal digestion depends largely on its diet. A plentiful supply of milk delays the time until the calf consumes significant quantities of dry feed. Neonatal ruminants maintained solely on milk during the first months of life show limited ruminal development with regard to rumen weight, capacity, papillary growth, keratinization, pigmentation, and musculature development.[11] The nervous reflexes that drive ruminal motility, eructation, and regurgitation are already functional before birth, awaiting only the drive of normal stimuli to begin operating. Dry feeds pass into the rumen, and bacterial inoculation from the environment or from abomasal reflux stimulates fermentation to begin. This process can be initiated as early as 1 week of age, when calves are encouraged to consume dry feeds.[34]

The increase in the size of the forestomach results from the ingestion of bulky, fibrous feeds.[70,82] Mild distention stimulates ruminal motility and the development of the muscular wall. Mucosal development is regulated through variable gene networks influenced by the presence of VFAs in the ruminal fluid that result from microbial fermentation.[31] Butyrate and propionate are most effective in this regard, whereas acetate is less stimulatory. The thickness of the mucosa increases with proliferation of the ruminal epithelium and elongation of the papillae.[160] These changes serve to increase the ability of the mucosa to absorb the VFAs. These metabolites act in concert with the resident microbiota and the microbes provided in feed to influence the gastrointestinal barrier function.[12,142] Dietary excesses or deficiencies affect the developing rumen by altering the balance of these stimuli.

Calves fed concentrate diets to the exclusion of forages or mixed diets with the hay pelleted or finely ground may experience ruminal parakeratosis as a result of a lack of feed abrasion[64,148] and the excessive production of the stimulatory VFAs: butyrate and propionate.[160] These calves can have a form of chronic ruminal acidosis that results in a reduced growth rate and poor body condition. Ruminal contents in such calves are typically fluid with an acidic pH, ruminal hypomotility occurs, and recurrent free gas bloat is common. Affected calves often display a craving for fibrous materials. Hair coat licking is common in these calves, and hairball formation in the reticulorumen is a common sequela. The hairballs may not be deleterious, but occasionally they cause obstructive disease or abrade the parakeratotic papillae or the abomasal mucosa, predisposing the animals to ulcers and inflammatory lesions.[44] Acute ruminal acidosis is not typically recognized in young, developing ruminants, probably because feed consumption is limited and because the predisposing adult-type ruminal microflora have not yet developed.

An opposite extreme can occur when the young calf is fed dry forage to the exclusion of more readily digestible carbohydrates. Concentrates and grass contain soluble carbohydrates and are well digested by the developing ruminant. Hays contain much less soluble carbohydrate and an abundance of the structured, slowly digestible forms. These substances are not

VetBooks.ir

as well digested by calves because the appropriate cellulolytic microflora are not fully developed. With moderate hay intake and the supply of other sources of nutrition, problems are rarely encountered. When dry roughage is the only available feed, and particularly when the hay is of poor quality, adequate breakdown of the fiber is prolonged. The low availability of nutrient substrate that results from delayed digestion of the structured carbohydrates decreases microbial proliferation and fermentation. Inadequate fermentation of the feedstuff deprives animals of required nutrients as well and results in poor performance and growth. When the only available feed source is the hay ration, calves continues to consume while the long undigested fiber accumulates in the rumen. The rumen continues to expand as a result of the increased filling, eventually becoming grossly distended. Recurrent bloat is common in these animals because of the overfilling and poor ruminal contractility. This phenomenon is a frequent occurrence under some management conditions and has commonly been called "haybelly." Affected animals display a typical abdominal contour, with gross distention of the abdominal wall that is more prominent on the left side. The ruminal contents are very firm, the fluid has a pH around neutral and shows little microbial activity or odor, ruminal motility is poor, and, despite the full abdomen, the animal is thin. This form of microfloral inactivity is more common in calves than in adults because the young ruminant is less able to ferment fibrous roughage.[43,44]

Recurrent Bloat (Ruminal Tympany). Moderate gas distention of the rumen is a common sign of disease in calves, usually as a result of free gas accumulation, whereas frothy fermentation is very uncommon in young ruminants. The pathogenesis of free gas bloat has been discussed, and the same principles hold for young ruminants. The differences between free gas bloat in adults and in young calves are more a matter of chronicity and frequency of occurrence than cause. Digestive disturbances of the adult rumen tend to develop more rapidly and are more readily identified than those of the calf rumen. Because of the involvement of ruminal developmental processes in the pathogenesis of calf indigestion, in young ruminants the diseases are often more chronic than acute in nature. In most cases the calf continues to consume feed, and the abnormal ruminal function and development may be easily overlooked.

Ruminal tympany seems to accompany indigestion in calves more often than in adult cattle and also assumes a more prominent appearance in calves than in adults. These factors may be reflections of the juvenile anatomy and the incomplete development of adult function. For instance, left-sided abomasal displacement, although uncommon in young calves, almost invariably is accompanied by marked ruminal tympany. In contrast, in adults the disease is common, but ruminal tympany is an infrequent sign of the disease.

Purulent lung infections appear to be a common cause of bloat in calves, probably as a result of intrathoracic compression or irritation of the esophagus or possibly the vagal nerves.[45] However, other causes of bloat that are associated with abnormal ruminal function are also common in calves with indigestion. They include overdistention of the rumen, insufficient clearing of the cardia, and inhibition of motility by abnormal fermentation products. Thus a thorough examination is necessary to determine the underlying cause of the individual case.

Abomasal dilation and tympany in calves (acute bloat syndrome) is often associated with forestomach distention as well. Although the exact pathogenesis is unknown and appears multifactorial, large amounts of fermentable carbohydrate in the abomasum along with fermentative enzymes probably lead to gas production and bloat.[103,120,136] This syndrome is discussed in detail elsewhere (see Chapter 20). One presumed cause of bloat in calves that is not a cause of adult bloat is sudden filling of the abomasum by milk feeding during weaning. Calves not yet completely converted to a diet of solid feed still consume milk eagerly. In some cases, acute free gas bloat occurs immediately after the milk feeding. Because the esophageal groove directs the milk into the abomasum but the abomasum is already partly filled by ingesta from the developing rumen, acute overdistention of the organ can occur and reflexly inhibit forestomach motility. Feeding smaller milk meals or discontinuing the milk feeding resolves the problem in these cases, which is evidence of the presumed cause.

Peritonitis in Ruminants

Gilles Fecteau

Despite the frequency with which peritonitis is suspected, it remains a frustrating disease for all food animal clinicians. A presumptive diagnosis is often based on clinical signs and history and rarely confirmed by ancillary tests. If response to therapy is satisfactory, the clinician may never confirm the diagnosis or the precise cause.

Review of the Peritoneal Cavity

HISTOLOGY. The peritoneal cavity is lined by a serous membrane composed of two layers called the *peritoneum*. The deeper layer (subserosa) is composed of loose connective tissue containing collagen, fat and, reticular cells, and macrophages. Covering that layer is a single-surface layer of mesothelial squamous cells (serosa). On the surface of the diaphragm, special lymphatic collecting vessels are located under the mesothelial basement membrane. Small stomata are found between mesothelial cells. They act as channels for lymphatic drainage from the peritoneal cavity to the thoracic duct.

NORMAL PERITONEAL FLUID. The peritoneum acts as a bidirectional semipermeable barrier to the diffusion of water and low-molecular-weight solutes between the blood and the peritoneal fluid. Peritoneal dialysis is based on this principle. Normal peritoneal fluid provides lubrication for the movement of abdominal organs and apposed peritoneal surfaces. It is formed and resorbed constantly. Normal fluid movement is achieved by movement of the viscera and contraction of the diaphragm during respiration. A normal animal has no more than 1 mL of peritoneal fluid per kilogram of body weight.[1] In acute severe peritonitis, the inflammatory process may induce a net flow of liters of proteinaceous fluid (80 mL/kg/day in humans), which leads to hypoproteinemia, hypovolemic shock, or both.[2]

Several authors have described normal peritoneal fluid values.[3-10] Each study should be appraised for its strengths and weaknesses and conclusions drawn accordingly. Later, in the diagnostic section, the author shares his personal experience with interpretation of peritoneal fluid in cattle.

Pathophysiologic Mechanism of Diseases in the Peritoneal Cavity in Response to Injury

HEALING. Peritoneal regeneration and healing can occur by reperitonealization or creation of an adhesion with an adjacent nearby mesothelial surface. This adherent type of healing occurs more frequently if the inflammation is severe, with presence of bacteria, foreign material, or both.

HOST DEFENSES AGAINST PERITONEAL INFECTION. The first mechanism of defense is physical removal of the bacteria. The second mechanism relates to the response to noxious stimuli. This intense acute inflammatory response includes degranulation of peritoneal mast cells with release of vasoactive substances. This creates a net influx of fluid rich in complement and serum opsonins that can bind to the bacteria. Third, the omentum contributes to the defense mechanism by adhering to an area that is infected or damaged, or both, to wall off the

problem site. Finally, the rapid movement of neutrophils and later, of macrophages is also an important mechanism of control of infection.

ADHESIONS. Adhesions are fibrinous or fibrous bands that create an abnormal attachment of two or more surfaces that should be moving freely against each other. Formation of adhesions is part of the healing process and should be interpreted as an effort to control an injury. The omentum is often involved in adhesions and acts as a natural sealing device to control the acute phase of inflammation. Whole blood potentiates adhesion formation by providing more fibrinogen. Adhesion may or may not be reversible, depending on the amount of organization that takes place in the process. Adhesions that are cut or broken usually rapidly re-form. As the fibrin deposition process is replaced by capillaries and fibroblasts, the adhesion becomes solid fibrous tissue. The three major elements responsible for dissolution of the fibrinous adhesions are (1) adequate oxygen and nutrient supply for the mesothelium, (2) liberation of plasminogen-activating substance by mesothelial and submesothelial cells, and (3) control of the inflammatory process.[2] Mechanical obstruction to the normal flow of ingesta and subsequent development of bowel obstruction are major undesirable side effects of adhesions.

Peritonitis

Definition and Etiology

Peritonitis is an inflammatory process involving the peritoneal cavity and its serosal surface, the peritoneum. Peritonitis is not truly synonymous with intraabdominal infection because the latter is defined as an inflammatory response of the peritoneum to microorganisms and their toxins that results in purulent exudates in the abdominal cavity. Peritonitis should be considered as the localized equivalent of SIRS, whereas intraabdominal infection is the localized equivalent of sepsis. Intraabdominal abscess is an intraabdominal infection confined within the abdominal cavity. Because most often in farm animals peritonitis is caused by bacteria, the two terms are often used as synonyms. The peritoneal inflammation may result from trauma, surgery, or vascular damage associated with an intestinal obstruction or an accident or from gastrointestinal ulceration (Box 32.7). Peritonitis is a serious and complex process that is often accompanied by various degrees of abdominal pain, changes in gastrointestinal motility, progressive signs of hypovolemia and septicemia, and endotoxemia.

BOX 32.7

Causes and Examples of Peritonitis in Approximate Order of Frequency

Traumatic Perforation

Traumatic reticuloperitonitis
Septic abdominal surgery
Vaginal perforation during coitus
Penetrating wound

Visceral Rupture

Perforation of abomasal ulcer
Perforation of ulcer in other part of gastrointestinal tract (oak toxicity of other cause)
Abomasal rupture after torsion
Small intestinal rupture after volvulus, strangulated hernia, or intussusception
Bladder rupture secondary to urolithiasis
Spontaneous uterine rupture during gestation or dystocia

Abscess Formation and Possible Intraabdominal Rupture

Reticuloperitonitis, localized
Liver
Umbilicus
Perimetritis
Pyelonephritis

Iatrogenic

Intraperitoneal injection of irritant solution or contaminated solution
Uterine rupture during dystocia
Perforation of the uterine wall with a pipette
Rectal tear secondary to palpation

Miscellaneous

Hematogenous with systemic infection: tuberculosis, septicemia
Fat necrosis

Classification Peritonitis may be classified according to the clinical presentation, the cause, or both. Clinically relevant classifications include acute versus chronic, septic versus chemical, localized versus generalized, and primary versus secondary. Although classifying types of peritonitis is useful, it is imperative to recognize that it is a dynamic process. An apparently localized nonseptic peritonitis can evolve into a more diffuse septic process if the primary cause is not resolved.

Pathophysiology After peritoneal injury or contamination, mesothelial cells initiate an inflammatory response, modifying the permeability of the peritoneum and its vascular supply. Then several blood constituents move into the peritoneal cavity. Macrophages and polymorphonuclear cells, humoral opsonins, natural antibodies, serum complement, and a protein-rich fluid are the most important. The inflamed peritoneum also becomes more permeable to toxins, allowing them to be absorbed into the bloodstream. Although this initial response is beneficial to the organism, it induces several systemic abnormalities that the clinician must recognize and treat adequately.

Hypovolemia, hypoproteinemia, bacteremia or septicemia, and toxemia are commonly observed in acute diffuse septic peritonitis. The major adverse effects of peritoneal contamination are (1) rapid clearance of bacteria, which leads to the development of endotoxemia, bacteremia, or both; (2) rapid influx of fluid rich in protein, which leads to hypovolemia and hypoproteinemia; (3) deposition of fibrin, which occludes lymphatic drainage and thus contributes to abdominal distention and enhances the chance of abscess formation; (4) ileus; and (5) adhesion formation, which may lead to obstruction.

Clinical Signs and Diagnosis Clinical signs are often nonspecific but suggestive of gastrointestinal dysfunction. Severity of clinical signs ranges from mild recurrent discomfort caused by a localized abscess to an acute severe onset of toxemia and hypovolemia that lead rapidly to death after the sudden rupture of a viscus. Cattle suffering from acute peritonitis tend to show more characteristic signs. As the condition becomes less acute, the ability of the bovine to seal the infection will attenuate the clinical signs. Chronic but active peritonitis remains to this day a very difficult diagnosis to make without ancillary tests. Abdominal rigidity and tenderness, abdominal distention, scleral injection, fever, anorexia, and sudden reduction in milk production are classic findings but not pathognomonic of acute peritonitis. In the acute stage, abdominal pain and the release of catecholamines often lead to a complete gastrointestinal stasis and ileus. The rumen is then completely atonic. Feces are abnormal in quantity and quality. In the acute stage, feces are present in small amounts and often dry. In more chronic cases, feces are present with a tendency to be diarrheic.

VetBooks.ir

VetBooks.ir

Pain, decreased plasma volume, and endotoxemia often result in persistent tachycardia. Anterior abdominal pain, evaluated by the withers pinch test, may be difficult to interpret. The withers pinch test is based on the normal reflex of the bovine to drop its back when the withers and back are pinched (ventroflexion). Cattle with anterior abdominal pain may be reluctant to ventroflex on withers pinch. The sensitivity of this test can be increased by simultaneous auscultation of the trachea during the manipulation. Production of an expiratory grunt during ventroflexion is considered a sign of pain. Cranial ventral pressure with the fist, knee, or some other external force (transverse pole under the abdomen) just behind the xyphoid process can help identify the presence of pain (expiratory grunt) and even localize it in some cases. The author believes that one of the most reliable clinical signs of abdominal discomfort in cattle is reluctance to move. Scleral injection, fever, tachycardia, gastrointestinal stasis, and distention are the clinical signs that should be monitored to evaluate peritonitis.

■ ***Ancillary Tests*** Hematologic findings associated with peritonitis range from completely normal hemogram results to severe leukopenia with degenerative left shift and presence of toxic neutrophils, depending on the severity of the peritoneal contamination. In severe cases, variations observed reflect the degree of sepsis and toxemia. PCV tends to increase as plasma/proteins decrease. In less severe cases, neutrophilic leukocytosis and hyperfibrinogenemia are often present. Hematologic analysis has been a useful tool for monitoring response to therapy. Plasma fibrinogen concentration is also evaluated to monitor the progress of a particular case.

The blood chemistry profile is rarely altered by peritonitis in a way that is diagnostically useful. Chronic inflammation causes a marked increase in serum proteins, particularly the globulin portion. In acute severe cases, secondary findings may include increased serum urea nitrogen and creatinine levels, mildly increased liver enzyme levels, reduction in total CO_2, and strong ion difference and reduction in serum albumin level. Ileus and upper gastrointestinal stasis may result in marked hypochloremia and alkalosis.

In the author's experience, abdominocentesis followed by cytologic examination of the peritoneal fluid is a useful aid in making a definitive diagnosis of peritonitis. The technique is simple and safe. The right side just cranial to the udder is the preferred site (to avoid stomach and omentum; Fig. 32.130). A needle, a blunt teat canula, or a bitch catheter and scalpel blade may be used with success (Fig. 32.131). Because of bulls' heavy fascia, a needle is preferable. Failure to secure fluid is common and should be interpreted with caution (because fibrinous peritonitis with fluid loculation is common). More than one site should be attempted if no fluid is secured on the first attempt.

Interpretation of values and what is considered normal appears difficult when the entire literature is searched.[3-5,11] Some authors have tried to establish better reference values for cattle.[10] Unfortunately, the range seems extremely wide even in the normal cattle population. The authors have been using certain criteria over the years on the basis of some older literature and personal experience: Normal fluid is clear and often in small quantity. Ease in collecting a large amount of fluid should arouse suspicion. A sanguineous fluid leads to suspicion of a compromised bowel problem (e.g., intussusception). A cloudy fluid is more indicative of peritonitis. Any foul smell is enough to conclude that septic peritonitis is occurring. Cytologically, the total number of cells is not as important as the differential. More than 50% neutrophils is suggestive of a septic process. The protein concentration should be less than 30 g/L (publications have moved the cutoff value higher than this number). No bacteria should be visualized. After exploratory celiotomy and omentopexy on normal cattle, peritoneal fluid has increased specific gravity, total protein, and WBCs for at least 6 days, even without any peritonitis.[12] Because of the bovine's ability to deposit fibrin and seal areas of the peritoneal cavity, the interpretation of peritoneal fluid analysis applies only to the immediate area that was sampled. Results of a caudal tap can mislead the clinician into concluding that a nonseptic process is occurring, when in fact a septic process has already been sealed by the fibrin deposition in the cranial abdomen.

Abdominal radiographs obtained with a high-power unit are extremely useful in cases in which TRP is suspected. They have limited value in other causes of peritonitis. Ultrasound examination is useful for assessing the size and anatomic relationships of lesions, particularly when considering drainage, aspiration, or surgical exploration of a mass surrounding vital structures (see Ultrasonography of the Ruminant Abdomen

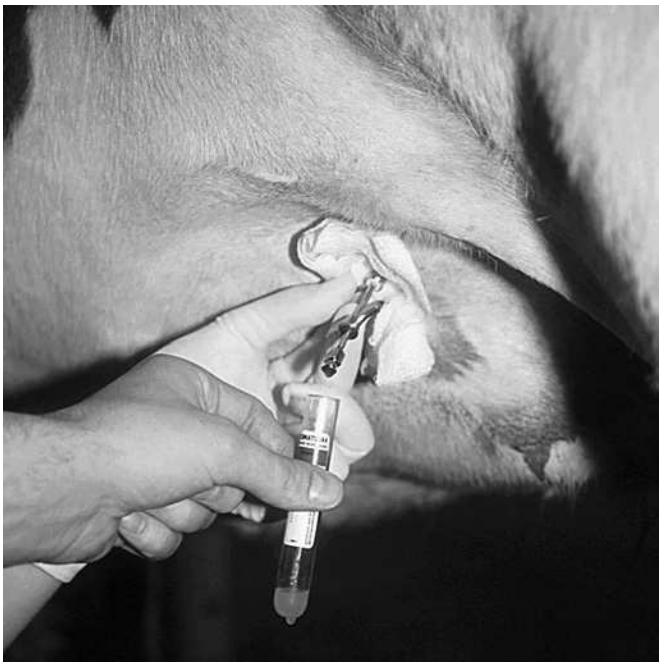

FIG. 32.130 Site of caudal abdominocentesis.

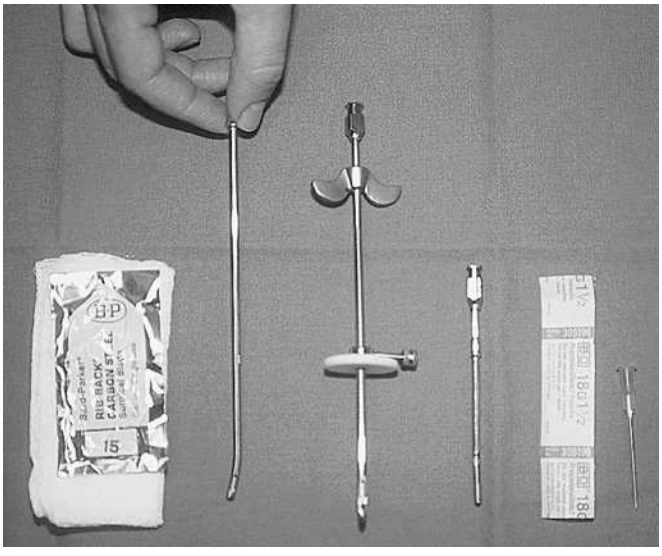

FIG. 32.131 Material used to perform abdominocentesis of bovines.

VetBooks.ir

section). Knowledge of the underlying anatomy is important to prevent misinterpretation. Recognition of free abdominal fluid is easily accomplished by ultrasound examination, and it is also useful for guiding a peritoneal tap. Areas that should be scanned include the caudal lower flank area (right and left), right perirenal area, liver, abomasum and pylorus, and right paramedian area. During exploratory surgery, ultrasonography can be used to image an internal mass or a viscera that appears abnormal. Intraoperative ultrasonography is performed by placing the probe in a sterile sleeve filled with ultrasound gel.

Surgical exploration is often used to confirm or rule out an intraabdominal problem. Information obtained from physical examination and laboratory data is often indicative of a diagnosis but does not provide a specific cause. Cattle are particularly amenable to exploratory surgery, as the procedure is performed when they are standing and is not often associated with complications. Advances in minimally invasive surgical technique in cattle are promising. Laparoscopy can be used to diagnose acute and chronic peritonitis, which is otherwise difficult to identify with ultrasonography or abdominocentesis. It is easier to evaluate the extent of the lesions with the organs in situ.

Treatment The basic elements of therapy are support, antibiotics, and surgery.

SUPPORTIVE THERAPY. Depending on the severity of the process, the patient may be in shock. Large volumes of isotonic intravenous fluids and correction of any acid-base deficit are indicated. Electrolyte abnormalities (hypokalemia and hypocalcemia) should be identified and corrected. If the animal is hypoproteinemic, plasma or whole blood transfusions may be beneficial. NSAIDs or steroidal antiinflammatory drugs, or both, may be of importance to prevent the synthesis of more inflammatory mediators. Pain control is also important. Transfaunation with normal rumen fluid may be beneficial in cases of prolonged anorexia.

ANTIBIOTIC THERAPY. Systemic antibiotic therapy should be instituted as soon as a decision to treat is made. Until results of culture and antimicrobial susceptibility become available, a broad-spectrum antibiotic should be used. The choice should take into consideration the following: cost of treatment, permitted use and withdrawal periods in food animals, spectrum of activity, and treatment regimen (frequency and route). Tetracycline or a β-lactam antibiotic (third-generation cephalosporin or a synthetic penicillin) appears to be a good choice. Diffusion into the peritoneal cavity is not a major limiting factor because the permeability of the peritoneum is always increased in peritonitis. However, when fibrin becomes organized and forms multiple small pockets of infected peritoneal fluid, diffusion becomes more problematic. Duration of therapy is empirical in bovines. The author and colleagues normally recommend at least 1 week of intravenous therapy, followed by another week of intramuscular therapy. Some clients elect to have their animals undergo the 2 weeks of therapy in the author's hospital, and the animals are maintained on intravenous antimicrobials.

SURGICAL THERAPY. Surgical control of peritonitis includes peritoneal débridement, irrigation, and drainage. With ultrasound guidance, it is possible to safely establish drainage from the abdominal cavity. A thoracic chest trocar can be used temporarily until all fluid has been removed.

The concept of abdominal lavage during surgery was adopted by human surgeons at the beginning of the twentieth century, and it has been accepted as a part of the treatment of peritonitis since then with fluctuating support.[13] Although the principle of removal of any gross contamination is not in question, the level of aggression with which clinicians should institute abdominal lavage during surgery is still open to debate in human and veterinary literature. There is evidence of a negative effect of lavage on the mesothelial cells, the peritoneal defense mechanisms, and the risk of spreading the infection.[13] The solution used to irrigate is also under debate. There is no significant advantage to adding antibiotics to the lavage solution, and controversy exists regarding the possible advantages of adding an antiseptic.[13] In bovines, large amounts of fibrin may be deposited in a short period of time; in combination with the omentum, this makes drains plug and become rapidly ineffective.

Prognosis The ultimate outcome of a bacterial peritonitis episode is determined by many factors, some of which are controlled by the clinician. The early decision on treatment (medical and surgical), correct choice of antimicrobials, and adequate supportive therapy contribute to the success or failure of a therapy. The owner's delay in seeking therapy, the primary cause of peritonitis, and the patient's age are important factors beyond the clinician's control. When aggressive therapy is economically possible, survival rates are good, but long-term sequelae may compromise a complete recovery.

MISCELLANEOUS PERITONEAL CONDITIONS

Ascites. Ascites is a collection of serous fluid in the peritoneal cavity. It must be considered a secondary sign rather than a primary diagnosis. In that regard the primary cause must be identified in order to treat the patient adequately. Common causes of ascites in ruminants include severe liver disease and congestive right-sided heart failure. Young cattle with mesothelioma have remarkable ascites. Ascites remains an uncommon condition that needs to be differentiated from septic causes of peritonitis and from urine accumulation with ruptured bladder.

Pneumoperitoneum. Pneumoperitoneum is commonly observed postsurgically in the bovine. Presence of air in the abdomen can be recognized by simultaneous percussion and auscultation. A low-pitch resonance can be auscultated in the upper flank on both sides of the abdomen. Presence of pneumoperitoneum normally resolves in the week after surgery. No clinical signs seem associated with the presence of pneumoperitoneum, although some clinicians describe abdominal pain associated with no cause other than the presence of air in the peritoneal cavity. Pneumoperitoneum not associated with surgery is indicative of bacterial peritonitis and the presence of gas-producing bacteria (see Box 32.7).

Retroperitoneal Abscess. Retroperitoneal abscess is a particular condition occurring in cattle after a flank laparotomy. It develops in many affected animals several days after surgery. They are mildly febrile, not performing adequately, and showing clinical signs compatible with peritonitis. The skin wound is often unremarkable, but some pain may be elicited while the flank area is palpated. A substantial mass may be palpated rectally, localized in the upper quadrant of the side of the previous surgical approach. The mass is firm, smooth, unmovable, and close to the previous flank incision and may have adhesions attached to it. Transabdominal or rectal ultrasound examination reveals a large amount of fluid located between the peritoneum and the rectus abdominis or the internal oblique of the abdomen. More superficial abscesses can also occur. A needle aspiration allows visual inspection of a thick, opaque, foul-smelling fluid. Treatment is aimed at establishing drainage and systemic antimicrobial therapy. A large volume of purulent and fibrinous material (up to 40 L) can be removed from the abscess. Rapid decompression may provoke hypovolemic shock, and intravenous fluids should be administered before a large abscess is drained. Prognosis is good, but the recovery phase is extremely long because of the large cavity left after drainage. Early closure of the drain is often observed, necessitating

reopening. Some clinicians effectively use Penrose drains as they close a contaminated flank wound, to prevent serum accumulation in the wound, and stave off the development of an abscess.

Traumatic Reticuloperitonitis (Hardware Disease, Traumatic Reticulitis)

David Francoz

Definition and Epidemiology

TRP, or hardware disease, is a frequent disease of cattle but it is rarely diagnosed in small ruminants. It is considered the most common cause of anterior abdominal pain in cattle. The ingestive behavior of cattle allows sharp nonfood items to be prehended and swallowed. Ingestion of such items by sheep or goats is rare. The disease affects confined cattle where mechanical processing of forages or construction activities increases the chances that piece of wire or nails will be included in the feed.

Few data available are on the frequency of TRP in cattle. In one study in Denmark, data were collected on 222,490 cows from 5979 herds. TRP was presumptively diagnosed by veterinarian in 1621 (0.7%) cows in the year before slaughter and in 1521 (0.7%) cows at slaughter. However, in only 48 of these 1521 cows had TRP been diagnosed by a veterinarian premortem.[1] Gröhn and Bruss[2] reported a similar prevalence (0.6%) of TRP veterinary diagnosis in live dairy cattle in 1990. Data from England and Wales indicated that 141 of 2709 adult cattle carcasses submitted to the Veterinary Laboratories Agency from January 2004 to May 2008 had a diagnosis of TRP.[3] In western Canada, TRP was the most frequent postmortem findings (8%) in beef cows and replacement heifers.[4] Most cases are sporadic, but outbreaks have occurred when such things as multistranded cable have been chopped up by a forage harvester and ensiled or when cattle have chewed nails containing charcoal from burned buildings.

Etiology and Pathophysiology

The ingestive behavior of cattle predisposes them to the accidental swallowing of metal foreign objects. Ingestion of a foreign body may also be associated with diseases that cause pica, such as phosphorus deficiency.[5] Foreign bodies of high specific gravity initially settle to the bottom of the ventral sac of the rumen. Subsequent contraction cycles of the forestomach move those objects from the rumen into the reticulum. Subsequently, depending on the presence of a magnet, four things can happen to a sharp foreign body[6]: (1) It may attach to the magnet without any clinical disease; (2) it can penetrate the reticular wall only with intramural inflammation; (3) it can perforate the reticulum wall, penetrate into the peritoneal cavity, and create a localized septic peritonitis; or (4) it can migrate into the peritoneal and thoracic/pericardium cavities. The diaphragm, pericardium, and heart muscle are located just cranial to the reticulum, with the liver positioned medially and dorsally and the spleen laterally and dorsally. These organs are sometimes penetrated by foreign bodies and become involved in the inflammatory and infectious process. The pain and inflammation associated with the trauma and infection lead to decreased appetite and ruminal hypomotility or stasis. Agalactia is abrupt because of the acute anorexia and subsequent failure to absorb precursors for milk synthesis.

Rehage and colleagues[7] suggested that the motility disturbances of ingesta through the forestomachs and the abomasum in cows affected with TRP develop in three phases. The first one, characterized by poorly comminuted feces, occurs after reduce or arrest of the reticulum contractions caused by pain and inflammatory adhesions. With extension of the adhesions, additional impairment of reticulum motility develops. In this second phase, stratification of the food particles in the reticulorumen is lost, volume of these two forestomachs is increased, and ruminal outflow is reduced. In the third phase, the consistency of ruminal contents is changed and becomes pasty with high viscosity. Increase in viscosity of ruminal content leads to inhibition of the transpyloric outflow. Abomasal volume increases and internal vomiting occurs.

Clinical Signs and Differential Diagnosis

TRP in the most severe, acute form is characterized by fever, anorexia, decrease in or absence of ruminal contractions, and evidence of cranial abdominal pain. Pinching of the withers or upward pressure on the xyphoid region may elicit a grunt on expiration. Affected cattle may stand with an arched back and resist ventral flexion of the back when pinched over the withers (normal cattle flex ventrally). Some cattle grunt spontaneously when forced to move or when defecating or urinating. Lactating cows show a sudden decrease in milk production. Some cows regurgitate ruminal fluid, especially if the oropharynx is mechanically stimulated. Tachycardia, reluctance to move or lie down, mild bloat, constipation, or abducted elbows may also be observed. These typical signs often abate within the first day or two, making diagnosis more difficult as the disease progress. Sudden death has occurred as a result of the laceration of a coronary blood vessel or puncture of the heart by the foreign body.

Less severe or more long-standing cases show clinical signs that are more subtle and less specific. Cows in early lactation may have ketosis; however, a distinguishing feature of TRP is the abrupt onset of anorexia and hypogalactia. Fever may be absent or very mild. Weight loss, rough hair coat, diarrhea, or generalized lameness, along with cranial abdominal pain that is difficult to localize, may be the only clinical signs.

If the pericardial sac has been seeded with bacteria, pericarditis usually develops. Clinical signs of pericarditis are discussed in detail in Chapter 30. In addition to the clinical signs previously described for TRP (decreased appetite, fever, tachycardia, pain), muffled heart sounds, jugular vein distention, and edema of the submandibular region, brisket, and ventral abdomen are typically observed.[8]

The foreign body may penetrate the liver or spleen, which leads to abscess formation. These abscesses, as well as reticular adhesions, may be responsible for reticuloomasal outflow problems and may lead to chronic indigestion.[7] TRP is a leading cause of chronic indigestion, more specifically of type 2 chronic indigestion (i.e., failure of omasal transport).

Agreement between premortem and postmortem diagnosis of TRP has been reported to be low, which can be explained by the low specificity of the clinical signs associated with TRP.[1] TRP must be differentiated from other causes of cranial abdominal pain. They include localized peritonitis associated with abomasal ulcers or liver abscesses, pleuritis, and pericarditis. In one study, cows with a premortem diagnosis of TRP not confirmed during postmortem examination were more likely to have one of the previously listed diseases detected post mortem.[1] More information regarding the differential diagnosis of abdominal pain is presented in the section on acute abdomen in cattle. When thoracic structures are involved, TRP must be differentiated from pneumonia or pleuritis, diaphragmatic hernia, and heart diseases such as endocarditis, lymphosarcoma of the heart, and cor pulmonale. Finally, TRP must be differentiated from others causes of ruminal distention and chronic indigestion.

Ancillary Tests

COMPLETE BLOOD CELL COUNT. The WBC count and differential may indicate an acute or chronic inflammatory process depending on the stage of the TRP. Neutropenia and

a left shift are expected in acute cases. However, in more chronic cases, changes are less pronounced, and both the WBC count and differential may return to normal,[6] but modification associated with chronic inflammatory diseases such as erythrocytopenia, thrombocytopenia, and hypohemoglobinemia may also be noted.[9,10] Gokce and colleagues[9] also reported longer activated partial thromboplastin time, prothrombin time, and thrombin time in cattle affected by TRP than in a control group of healthy cattle.

PLASMA PROTEINS AND ACUTE-PHASE PROTEINS. High total plasma proteins, primarily reflecting high globulin levels, are expected in chronic cases of TRP.[9,11] Higher concentrations of total plasma proteins has been observed in cases of TRP than in other abdominal disorders.[12,13] Plasma proteins concentration of 87 g/L[12] and 100 g/L[13] have been proposed for the differentiation between TRP and other abdominal disorders.

Elevated fibrinogen concentration may be observed in acute (2 to 3 days after the beginning of the disease) and chronic cases. A significant increase in fibrinogen concentration has been reported in comparison to healthy control cows.[14] In addition, studies in referral centers have demonstrated highest plasma fibrinogen concentration compared with other abdominal disorders.[12,13,15] Cutoff points have also been reported in these studies for the differentiation between TRP and other abdominal disorders. Jafarzadeh and colleagues[13] proposed a value of 6.91 g/L (with a sensitivity and specificity of 81% and 72%, respectively), whereas Nazifi and colleagues[15] suggested a value of 5.7 g/L (with a sensitivity and specificity of 32% and 100%, respectively).

Serum amyloid A and haptoglobin concentrations have also been reported to be elevated in case of TRP.[12,14-16] Cutoff points for the differentiation between TRP and other gastrointestinal disorders of 0.67 g/L[12] and 0.74 g/L[15] for haptoglobin and 68 µg/mL[15] for serum amyloid A have been reported. These two parameters seem to be more accurate than plasma fibrinogen or protein concentrations for the differentiation between TRP and other gastrointestinal disorders.[12,15] However, in one study, a nonsignificant increase of serum amyloid A was observed in cases of TRP in comparison to healthy control cows.[14] Of importance is that other inflammatory disorders can induce the same modifications, and absence of these abnormalities does not rule out TRP. Other diagnostic tests thus must be performed to confirm the diagnosis

SERUM BIOCHEMISTRY PROFILES AND BLOOD GAS ANALYSIS. Serum biochemistry profiles and findings of blood gas analysis are usually within normal range but may reflect anomalies associated with ileus and chronic indigestion, such as hypochloremic metabolic alkalosis, hypokalemia, and hypocalcemia.[10,11] Other abnormalities reported include increases in specific and nonspecific indicators of liver damage (such as aspartate aminotransferase, ALP, lactate dehydrogenase, and bilirubin),[6,9,10] and increases in specific and nonspecific indicators of skeletal or cardiac muscles (such as CK [CK-MB], lactate dehydrogenase, aspartate aminotransferase, and cardiac troponin).[9-11]

DIAGNOSTIC IMAGING. Ultrasonography and radiography are complementary methods that provide different and useful information for the diagnosis and management of TRP. Radiography of the reticulum is available only in centers where powerful equipment is available. Different techniques have been described for radiography of the reticulum. They can be performed on recumbent or standing animals; lateral radiographic views of the reticulum on standing animals are the recommended methods. Radiographs allow the detection of a metallic foreign body and the determination of its location in or outside the reticulum. They can also be useful in order to assess the success of magnet administration. Different parameters criteria may be evaluated on radiographs for the diagnosis of TPR. They include presence or absence of a foreign body, position of the foreign body, presence of focal gas shadows or gas-fluid interface near the reticulum, and the shape, size, and location of the reticulum (Fig. 32.132).[17-19] Of these parameters, location of the foreign body is the most reliable indicator for the diagnosis of TRP.[12,14]

Ultrasonography of the reticulum is presented elsewhere in the Diagnositic Imaging subsection of the Acute Abdomen section in this chapter. Ultrasonography provides information about the localization and extension of peritoneal effusion,

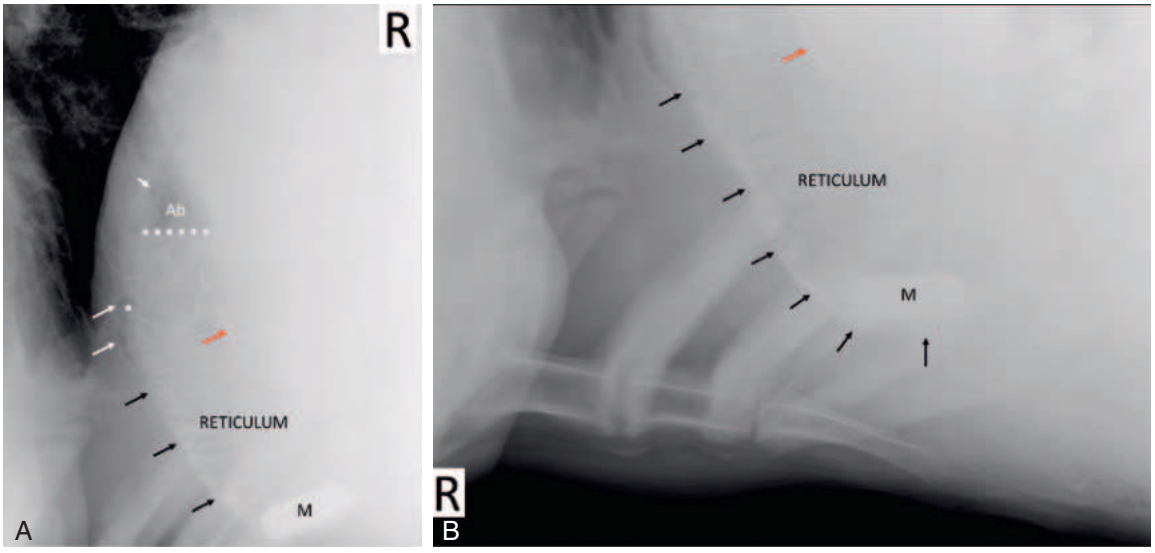

FIG. 32.132 Radiographs of the reticulum of a cow with traumatic reticuloperitonitis. Two lateral views were obtained: a craniodorsal view **(A)** and a caudoventral view **(B).** The reticulum is displaced dorsally and cranially. Its contour *(black arrows)* is irregular. Multiple gas bubbles *(white arrows)* are observed, and fluid lines *(white asterisks)* are also visible. Those observations are compatible with septic peritonitis and possible abscesses formation (*Ab*, large abscess). A linear foreign body *(red arrow)* is visible in the two views but most easily evaluated on the craniodorsal view. This foreign body is not attached to the magnet (M). *(Courtesy Centre Hospitalier Universitaire Vétérinaire de l'Université de Montréal.)*

the presence of perireticular abcesses, and the contraction of the reticulum.[20] Ultrasonography is also the most useful complementary examination for the diagnosis of pericardial effusion.[7]

ABDOMINOCENTESIS. Abdominocentesis and pericardiocentesis may be performed blindly or with ultrasound guidance. Abdominal fluid analysis and its limitations in cattle are discussed in the Peritonitis in Ruminants section. Pericardiocentesis may be performed at the level of the point of the elbow in the left fifth intercostal space. Aseptic preparation of the skin and local anesthesia of the region to be punctured are required; pulling the left forelimb forward may be helpful. A 5- to 10-cm spinal needle or intravenous catheter can be used; the length required depends on the size of the animal and the amount of subcutaneous fat. Previous ultrasonographic examination is helpful for the choice of the needle. Caution is advised for advancing the needle to prevent laceration of the myocardium or of a coronary vessel. Ultrasonographic guidance helps prevent trauma to the myocardium. Visual inspection of the fluid obtained is usually adequate to confirm the diagnosis of pericarditis; in case of septic traumatic pericarditis it is cloudy and foul smelling. The fluid may be examined bacteriologically and cytologically.

Treatment

Conservative medical treatment is generally attempted first. It is based on the administration of a magnet for attachment of the foreign body, parenteral antibiotic therapy for the control of infection, administration of NSAIDs for the control of pain and inflammation, and the correction of dehydration and electrolytes imbalances when present. Different drugs have been used to enhance the chance of the magnet to enter the reticulum cavity. The effects of premedication with atropine, scopolamine, or xylazine and the practice of standing the cow with its forelimbs 30 cm lower than its hindlimbs on successful administration of a magnet (i.e., adequately located in the reticulum cavity) have been evaluated in healthy cows.[21] Adequate location of the magnet was controlled radiographically 1.5 hours after the administration of the magnet. None of the procedures increased the chance of the magnet's being successfully located in the reticulum. In all groups (treatment groups and control groups), only 57% of the magnets were adequately located in the reticulum.[21] In one study, Braun and coworkers evaluated radiographically the efficacy of magnet administration for the treatment of TRP.[22] They demonstrated that foreign bodies that have already penetrated the reticulum wall or that have clearly perforated the reticulum before magnet administration had approximately a 54% and 32% chance, respectively, of becoming attached to the magnet.

Treatment of peritonitis requires systemic antibiotic therapy and possibly drainage of the affected area; surgical correction of the inciting cause is discussed in the Peritonitis section in this chapter. Forestomach bacteria are involved the in acute phases, and *T. pyogenes* and anaerobic bacteria in chronic cases when perireticular abscesses are present. NSAIDs are the drugs of choice for the control of inflammation and pain. However, the risks associated with their side effects, abomasal ulcerations and renal toxicity, should be evaluated in case of anorexic and dehydrated animals. Multimodal approaches such as the combination of NSAIDs and opioids or continuous infusion of analgesics should also be considered for pain management.[23] Institution of fluid therapy is necessary in cases of diffuse peritonitis and associated hypovolemic shock, as well as for the correction of electrolytes imbalances associated with ileus or indigestion. Physiologic salines (0.9%) containing potassium and calcium are the solutions of choice.

Many cattle recover after such a course of medical therapy with resumption of forestomach motility and appetite within 1 to 3 days. Appetite and rumination activity monitoring is also useful for an objective assessment of the response to treatment. These parameters have been reported to normalize within 3 to 5 days after the initiation of medical treatment or rumenotomy.[24] Animals that have not significantly improved by the third day may require a rumenotomy to remove the foreign object. Ideally, radiography combined with ultrasonography is recommended at this time to verify the diagnosis and objectively assess the response to treatment,[22] but ultrasonography is more feasible in most practices. During rumenotomy, abscesses that adhere tightly to the reticulum may be drained into the lumen of the reticulum. In some instances, reticular abscesses may also be drained through an ultrasonography-guided transcutaneous incision,[25] ultrasonography-guided insertion of a chest trocar, or insertion of a trocar during ventral laparotomy.[6]

Prognosis

The prognosis of TRP depends mainly on the location of the foreign body and the other organs affected. The prognosis is fair to good when TRP is associated with localized peritonitis and when only the spleen or the liver is also affected. The prognosis is poor to guarded in TRP associated with pericarditis, pleuritis, or diffuse inflammatory adhesions in the abdomen.[6,7,26] In most cases, as inflammation diminishes, the reticular function can return to normal.[26] In a multicenter retrospective study on rumenotomy and rumenostomy, data on long-term outcome (5 months to 5 years after the procedure) were available for 23 bovines that underwent rumenotomy for TRP: Six bovines (26%) were still in the herd and productive, 9 (39%) were removed from the herd, and 8 (35%) died or were euthanized.[27]

Necropsy Findings

Cattle that die peracutely may have a lacerated myocardium with resulting hemorrhage or cardiac tamponade. Diffuse peritonitis characterized by copious, foul-smelling peritoneal fluid with an obvious reticular defect may be present in acute cases. More chronically affected animals may have extensive pericardial effusion with a thick epicardial layer of fibrin if the pericardium was penetrated. Localized peritonitis with adhesions alone is unlikely to kill the animal. The penetrating foreign body generally is still present in the wall of the reticulum or pericardium.

Prevention and Control

Eliminating sources of sharp foreign objects in the feed supply prevents TRP. Installation of large magnets on feed handling equipment and prophylactic administration of forestomach magnets to all animals at 15 to 16 months of age prevent almost all cases caused by magnetizable objects.

Abomasal Displacement and Volvulus

Gilles Fecteau • Charles L. Guard

Etiology Although the precise cause of displacement of the abomasum remains unknown, general agreement exists in veterinary literature that it is a multifactorial syndrome and that abomasal hypomotility is an absolute prerequisite. Abomasal motility can be decreased in many ways. Numerous common disorders of postpartum dairy cattle have been incriminated as possible triggering events to abomasal dilation and displacement. Among the most important, ketosis, low serum calcium levels, hyperinsulinemia, and reduced insulin sensitivity have been studied.

Prevalence and Incidence Abomasal displacement occurs either to the right or to the left side of the abdomen when gas accumulates within this viscus. Left-displaced abomasum (LDA) is the more common, accounting for most of the cases. The incidence is highest by far in adult dairy

VetBooks.ir

cattle in the early postpartum period, but cases have been seen in all other classes of cattle. LDA is probably a worldwide problem. The prevalence among dairy herds is variable, depending on multiple factors such as geographic location, climate, management practices (confinement versus pasture), and feeding practices.

Pathophysiology After abomasal atony, distention with gas produced by microbial fermentation occurs and probably precipitates the displacement. It has been hypothesized that the displacement is oriented (left or right) according to the size of the rumen. If the rumen is small and empty (as in the early postpartum period), the abomasum can move to the left, and LDA can occur (Fig. 32.133). If the rumen is large and filled, the left displacement is less likely, and the abomasum dilates and in some cases twists to the right (Figs. 32.134 and 32.135).

Surgical Therapy Numerous surgical techniques exist with advantages and disadvantages.[7] All techniques have a common objective to create a permanent attachment, usually by suturing either the abomasum or the greater omentum to the abdominal wall. This prevents recurrence. The techniques may be classified into three different broad categories: blind technique, surgical (open) technique, and laparoscopic technique. Another way to consider the different options is to classify the techniques as performed on an animal standing or in recumbency. Multiple factors influence the technique used or recommended for a particular case. Cost and preference of the surgeon are very important. Laparoscopic technique has also been described and studied.[8-11]

All techniques have been successful when performed adequately. The less invasive techniques have been studied to evaluate the possible advantages over the more invasive open techniques. The advantages are time to perform the surgery, less frequent use of antimicrobials, a shorter interval from calving to first service, and a faster abomasal emptying.[12-15] Understanding the limitations of each technique allows the clinician to best serve the patient and client in all situations. Success rates and possible economic advantages of having the procedure performed by herd personnel have been discussed in the literature.[16,17]

Left Displacement of the Abomasum

Clinical Signs and Differential Diagnosis

Cattle with simple LDA have a reduced appetite (complete anorexia, reduced consumption of concentrates, or alternating periods of normal appetite and anorexia). Milk production is reduced. Ketosis is usually present, either as a predisposing factor or as a consequence. Feces are often normal to softer than normal but reduced in volume. Rectal temperature is normal, unless a concurrent infectious problem is present (metritis, mastitis). Pulse and respiration rates are normal or slightly above normal, unless a concurrent or secondary problem is present. Ruminal contractions are decreased to absent and difficult to hear because the abomasum interferes with transmission of the sound. It is not unusual to observe the animal ruminating despite the displaced abomasum. The last one or two ribs on the left are sprung, but the abdomen is sunken in the paralumbar fossa. Gurgling or tinkling rather than normal scratching sounds may be heard on auscultation in the left paralumbar fossa. Simultaneous auscultation and percussion reveal a ping over the gas-filled portion of the abomasum. With LDA the area of ping may be anywhere from the lower third of the abdomen in the eighth intercostal space to the paralumbar fossa (see Chapter 1, Physical Examination section). Attention should also be given to the cranial and lower aspect

of the flank because in some cases the ping will be audible only in this area. On rare occasions, during rectal examination the clinician may be able to palpate the abomasum to the left of the caudodorsal blind sac of the rumen or at least perceive that the rumen is displaced medially.

Ruminal tympany, pneumoperitoneum, and collapsed rumen may all produce pings on the left side of the cow. Physometra (air in the uterus) and dilation and displacement of the cecum to the left of the rumen (which is rare) may also produce left-sided pings. Having an assistant blow on the stomach tube passed into the rumen while auscultating over the left side helps the clinician differentiate the rumen from other structures. Percutaneous needle aspiration of fluid or gas from the suspected abomasum aids in correct identification. A pH of less than 4.5 as determined with wide-range pH paper or the odor of abomasal gas (slightly acrid or of burned almonds) confirms the presence of LDA. Ultrasound examination could also be helpful in determining the position of the pylorus and to compare the position with the actual normal variation.[18]

Clinical Pathology The most important abnormalities detected by clinical chemical evaluation usually involve the serum electrolyte levels, acid-base levels, and liver metabolism and integrity. Sequestration of the hydrochloric acid secreted into the abomasum or by means of reflux in the ruminoreticulum may occur and lead to metabolic alkalosis. The blood pH and bicarbonate concentration are slightly elevated, with a concomitant small decrease in the blood chloride concentration. Ketosis is common, and liver enzyme levels are often elevated, reflecting a degree of hepatic lipidosis.[6,19,20] The serum calcium level may be below normal as a result of decreased intake and absorption. Hypokalemia may develop as a consequence of both the metabolic alkalosis and reduced intake and absorption. Cattle with LDA tend to be hypophosphatemic.[21]

CBC analysis may reveal a mild dehydration and a stress leukogram. If LDA is combined with bleeding abomasal ulcers, it may produce severe anemia. The presence of a concurrent disease may lead to specific changes (e.g., left shift with acute coliform mastitis). The peritoneal fluid of cows with abomasal displacement reveals changes compatible with ischemia and inflammation.[22]

Epidemiology Cows in early lactation (particularly the first month) are at greatest risk of developing LDA. The overall incidence is highly variable among herds and related to nutrition program and associated problems. Retained placenta, metritis, and increased serum concentration of β-hydroxybutyrate were associated with a greater risk for LDA.[3] Cows identified with subclinical ketosis early in lactation (3 to 5 days in milk) were 6.1 times more likely to develop an abomasal displacement than were cows affected later in lactation.[1] A serum β-hydroxybutyrate concentration above 1200 μmol/L in the first week after calving were associated with an increased risks of subsequent abomasal displacement (odds ratio, 2.6).[2] On a herd basis, in one study in Sweden, large herd size, high maximum daily milk yield, keeping dry cows in one group, and not cleaning the feeding platform daily appear to be risk factors associated with a high incidence of abomasal displacement or clinical ketosis.[23] The same research group also demonstrated that high-incidence herds have a lower metabolic index and a higher incidence of ketosis than do low-incidence herds.[5] The metabolic index used was the revised Quantitative Insulin Sensitivity Check Index (RQUICKI). Genetic factors may also play a role in the predisposition to LDA. Fox suggested that body depth had increased in dairy cattle since 1945 and that this may provide more room for the relatively empty abdominal viscera to move more freely at parturition.[24] More recently, cows selected for large body size had significantly greater health costs, related mostly to the greater incidence of LDA.[25] Also, the depth of the abdomen and the vertical distance between the ventral abdomen and the descending duodenum were greater in cows with a previous history of LDA than in the controls.[26] Some evidence exists to support a genetic basis for predisposition to LDA, and perhaps this is mediated through body size or conformation.

Treatment and Prognosis Treatment of LDA involves returning the abomasum to its normal anatomic location and preventing recurrence (abomasopexy); treating the electrolyte and acid-base abnormalities and the energy metabolism problems (ketosis and hepatic lipidosis); and providing therapy for concurrent diseases. The prognosis for animals with LDA is good but is influenced by the severity of the concurrent disease. Cattle with severe hepatic lipidosis and LDA should be given a guarded prognosis because their recovery is often slow and incomplete. Also, some cattle develop LDA as a consequence of gastrointestinal malfunction. As an example, LDA could be diagnosed in an animal suffering chronic indigestion. The prognosis of this group of cattle is poor because the primary disease is often more serious than the LDA per se.

Prevention and Control The incidence of LDA has been reduced in problem herds by dietary manipulation that reduces the likelihood of forestomach and abomasal atony caused by high-concentrate rations. This includes slow introduction of concentrates after calving, prepartum introduction of ensiled and concentrate feeds, and increase in the particle size of the forage. Maintaining serum calcium concentration at the time of parturition and reducing subclinical ketosis early in lactation are of particular importance. Dietary cation-anion difference is a reliable guideline for controlling hypocalcemia in dairy cows (see Chapter 41).

Right Displacement of the Abomasum

Simple right displacement of the abomasum (RDA) occurs at approximately 10% to 15% the frequency of LDA.

Clinical Signs and Differential Diagnosis The general systemic state of cows with a simple RDA is the same as that of cows with LDA. On the other hand, as simple RDA evolves toward the volvulus, the systemic changes observed in cattle with abomasal volvulus progressively appear. An area of tympanitic resonance is heard on the right side with simultaneous auscultation and percussion. The ping usually is confined to an area under the last five ribs in the upper half of the abdomen. The condition must be differentiated from other causes of right-sided pings, such as cecal distention (with or without volvulus), gas in the spiral colon, pneumorectum after rectal examination, pneumoperitoneum, physometra (gas in the uterus), signoid flexure volvulus, and abomasal volvulus. Cecal and rectal pings usually are detectable in a linear pattern just below the transverse processes of the lumbar vertebrae extending to the tuber coxae (see Chapter 1, Physical Examination section). Rectal examination identifies the gas-filled structure. Pings heard with gas in the spiral colon typically have a variable pitch, depending on the location over the cranial paralumbar fossa and last three or four ribs. In general, the spiral colon may be palpated rectally as a laterally flattened, mildly distended viscus adjacent to the right body wall. Gas in the uterus can be detected on rectal palpation. Pneumoperitoneum creates a ping that is distributed all along the dorsal portion of the abdominal cavity and is usually heard on both sides.

Abomasal volvulus is the condition most difficult to differentiate from RDA. Determination of the difference by physical diagnosis in an early case of abomasal volvulus is probably impossible. With time affected cows become progressively more dehydrated and more severely ill with volvulus

VetBooks.ir

than is usual with RDA. Rapid heart rate (>100 beats/min), total absence of ruminal motility, and almost no fecal output are clinical signs in favor of a diagnosis of abomasal volvulus. Advanced cases of volvulus also produce a ping that reflects an arched dorsal border and a horizontal ventral border caused by the fluid level in the abomasum. This fluid is auscultable on succussion of the abomasum. Even with ultrasonography in one study to determine positions of the liver, omasum, and small and large intestines, the two conditions could not be distinguished from one another.[27]

Treatment and Prognosis Surgical treatment is necessary to correct RDA. Because of the difficulty of differentiating RDA from early volvulus, intervention should be as prompt as possible. The prognosis for a successful recovery after surgery is comparable with that for LDA if no other concurrent disease is present.

Abomasal Volvulus

Abomasal volvulus, or right torsion of the abomasum, leads to complete obstruction of the flow of ingesta into the duodenum and is therefore a surgical emergency. The condition occurs in all classes of cattle. Although RDA is thought to precede its development, unknown factors lead to abomasal volvulus.

Clinical Signs and Differential Diagnosis The systemic effects of the gastrointestinal obstruction that results from abomasal volvulus progress to a much more severe degree than in LDA or RDA. Sunken eyes and loss of skin turgor accompany the dehydration that develops. The heart rate increases above 100 beats/min, and the pulse is weak and thready. Abdominal distention is marked bilaterally. Complete ruminal stasis develops, which leads to bloat, and the abomasum greatly enlarges on the right. Despite the severe degree of gastric distention, colic rarely develops in cattle with abomasal volvulus; it is much more likely to occur with cecal distention. The skin is cool to the touch. Feces are absent or watery but scant. A large area of tympanitic resonance with uniform pitch throughout is detectable on the right, extending from the eighth rib to the middle of the paralumbar fossa. The ventral border of the ping is a horizontal line reflecting the fluid level in the greatly distended abomasum. Borborygmi is absent. Splashing fluid sounds can be heard when the abomasum is ballotted (succussed) behind the last rib.

Other causes of proximal intestinal obstruction and torsion of the intestinal mass around the root of the mesentery must be differentiated from abomasal volvulus. On rectal examination the abomasum can usually be palpated with abomasal volvulus. With intestinal obstruction or intestinal volvulus, distended loops of small intestine can be palpated. Pings caused by gas in the intestines have a variable pitch over the areas involved. Cecal distention with rotation can produce a similar degree of abdominal distention high on the right, but the abdomen usually is less filled cranioventrally on the right. A ping extends to the tuber coxae, and the cecum can be palpated rectally. Diffuse peritonitis leads to complete atony of the gastrointestinal tract, and the abdomen may become distended with gas in all parts of the tract; there is no discrete ping extending over a large area of the right side. As abomasal volvulus progresses, cattle become recumbent and depressed. Death occurs within hours in this stage, which occurs 1 to 3 days after the development of the volvulus.

Clinical Pathology The serum biochemistry profile shows much more dramatic changes with abomasal volvulus than with RDA or LDA. Clinicopathologic consequences include hypovolemia, dehydration, hemoconcentration, metabolic alkalosis, hypochloremia, hypokalemia, and paradoxic aciduria. Hyperglycemia, hypocalcemia, and hyponatremia may also be observed. Later in the condition a superimposed metabolic acidosis is also present. Anion gap gradually increases with the severity of the disease. Systemic shock eventually causes fatality. Reduced fluid intake and sequestration of large quantities of chloride-rich fluid in the stomachs (third space problem) leads to dehydration and hypovolemia. Hyperphosphatemia was also observed, possibly as a consequence of decreased renal blood flow.[21]

Under the influence of carbonic anhydrase, hydrogen ions are normally pumped into the abomasal lumen. A chloride ion follows into the lumen, whereas bicarbonate and sodium remain in the blood. Under normal circumstances, the hydrochloric acid leaves the pylorus, where the hydrogen ions are neutralized by pancreatic and intestinal secretions and the chloride is resorbed. When abomasal volvulus occurs, the hydrochloric acid is sequestered in the abomasum and regurgitated into the omasum and rumen (internal vomiting). Ruminal chlorides increase. The animal becomes alkalotic and hypochloremic. Because of shifts between intracellular and extracellular compartments, potassium moves intracellularly as hydrogen ions move extracellularly in response to the metabolic alkalosis. This, plus the total anorexia, leads to severe hypokalemia. The hallmarks of abomasal volvulus are metabolic alkalosis, hypochloremia, and hypokalemia.

Paradoxic aciduria occurs in the presence of metabolic alkalosis, when a cow should be retaining hydrogen ions. The overwhelming renal physiologic drive appears to be sodium retention. Dehydration and reduced cardiac output result in falling blood pressure. The animal must respond by volume expansion; thus sodium is resorbed in the renal tubules. Chloride is also resorbed. Because there is hypochloremia, the electrical gradient that must be corrected is high; if 140 mEq/L of sodium is resorbed and only 60 mEq/L of chloride is available, there is a net of 80 mEq/L (140 – 60) of cations that must be secreted back into the tubules. This is normally accomplished by secretion of potassium. Because hypokalemia is severe, hydrogen ions are paradoxically secreted to retain electrical neutrality so that blood pressure can be maintained by means of maximum sodium resorption.

Peritoneal fluid of cattle with abomasal volvulus has been studied.[22] In comparison with cows with a diagnosis of LDA, cows suffering from abomasal volvulus had significant changes in their peritoneal fluid parameters. Total protein, albumin, L-lactate, CPK, ALP, lactate dehydrogenase, and D-dimer levels were increased, whereas fibrinogen level was decreased. Also, a higher percentage of apoptotic and necrotic neutrophils was detected despite the fact that total leukocyte count was not significantly different. At least in one study, evidence of abnormal coagulation profile reflecting possible disseminated intravascular coagulation was present in a small proportion of cattle studied (3 of 10). Hemostatic dysfunction could be present in advanced stages of the disease.[28]

Pathophysiology At least some of the factors predisposing to LDA or RDA probably contribute to the development of abomasal volvulus. Whether true RDA precedes abomasal volvulus is not known. Dissection of naturally occurring cases of abomasal volvulus demonstrated that the structures involved in rotation can vary from the reticulum to the omasum at the orad end. The rotation probably occurs most frequently at the reticuloomasal junction. The duodenum is looped around the omasum, regardless of the degree of volvulus. The ensuing displacement leads to a counterclockwise rotation of the abomasum and omasum as viewed from the right side and the rear. The duodenum is pulled medial to the body of the omasum and wraps around the neck of the omasum in the final configuration. The continued hydrochloric acid secretion of the abomasum and the gas produced in the omasum and abomasum

VetBooks.ir

further stretch and occlude the duodenum. The abomasal blood vessels and the ventral vagal trunk are compromised near the site at which the duodenum wraps around the omasum in long-standing cases. Thrombosis of vessels may occur.

The acid-base and electrolyte abnormalities of early abomasal volvulus are the same as those of LDA. In cases of severe distention of the abomasum and omasum with vascular compromise, systemic cardiovascular insufficiency develops. Reduced perfusion of peripheral tissues may lead to metabolic acidosis terminally. Hemoconcentration develops, although bleeding into the abomasum may occur from devitalized mucosa, which lowers the hematocrit. These changes are compounded by the developing necrosis of the abomasum. The abomasum may physically leak contents through a weakened, overstretched wall. Endogenous inflammatory mediators and bacterial toxins may diffuse from the abomasum to viable surrounding tissues, where absorption occurs. In either case, the viability of the abomasum is lost, and death follows shortly. At least in a sheep model of abomasal volvulus, ischemia and reperfusion injury occur.[29]

Treatment Immediate surgical intervention usually is necessary to save the animal's life. At the same time, fluid, electrolyte, and acid-base abnormalities must be corrected. For early cases of hypokalemic, hypochloremic alkalosis and dehydration, intravenous fluids consisting of 20 to 80 L of 0.9% sodium chloride with 25 to 100 mEq/L potassium chloride added are administered. Intravenous potassium should not be given at a rate greater than 1 mEq/kg/h to prevent cardiotoxicity. If the serum potassium level is unknown, it is best to stay with an IV rate of less than 0.5 mEq/kg/h. For advanced cases with metabolic acidosis, balanced electrolyte solutions such as Ringer's solution are indicated. Broad-spectrum antibiotics are appropriate if the integrity of the abomasal mucosa is questionable. NSAIDs are indicated to control pain, inflammation, and shock. Both standing right-sided and recumbent right paramedian approaches have been successful for correcting abomasal volvulus. There may be less cardiopulmonary compromise if the animal remains standing, especially if reperfusion injury is suspected.

Prognosis Establishing an accurate prognosis before surgery would be optimal because at that time salvage remains a possibility and little expense has been incurred. It is not a simple task. A second critical time is shortly after surgery in cows suspected of not fully recovering. The decision will be whether to continue to treat (cost) or salvage, if that still is an option.

Preoperative assessment is difficult. In the author's experience, assessment cannot be based on a single clinical observation or serum biochemistry value. In the best published studies, investigators examined two different classifications of outcome: death versus survival and productivity versus nonproductivity. A logistic regression model of heart rate, base excess, and serum chloride level was developed as a preoperative predictor of death or survival.[30] Constable and colleagues found that four presurgical variables (hydration, heart rate, duration of inappetence, and pelvic alignment level) could be used to best predict cattle as productive or nonproductive after surgery.[31]

Assessment of outcome after surgery has been investigated. The overall success rate of surgery varies between 61.5% and 86.3%.[32-35] The number of forestomachs involved in the twist has been found to adversely affect survival and productivity. Wallace found only 20% success in cattle with reticuloomasal-abomasal volvulus.[35] Another study demonstrated success in 55% of cattle with omasal-abomasal volvulus and 87% success in cattle with only an abomasal volvulus.[31] Edema of the abomasum carries a guarded to poor prognosis.[35-37] Edema around the proximal duodenum was associated with a poor outcome in Pearson's study, but Fubini and coworkers found no association with outcome.[36,38] Purple discoloration of the abomasal serosa tends to bode poorly for long-term outcome, as does severe distention of this organ, abomasal necrosis, and thrombosis of the gastric veins.[30,35] The measurement of intraluminal pressures of greater than 16 cm Hg also carries a poor prognosis because of mucosal damage.[31] A logistic regression model of some of the surgical findings did not predict outcome any better than did the preoperative model.[30]

After surgical correction, cattle with abomasal volvulus often have diarrhea for 24 hours. Feces then firm up to normal consistency. Postoperative clinical signs associated with a poor prognosis include melena, anorexia, persistent tachycardia, and dehydration.[33,37,39] In the author's experience, even if appetite and general attitude are initially good (24 to 48 hours after surgery), persistence of a loose low-volume stool 72 hours after surgery may indicate complications.[40] Among animals in which clinical signs compatible with chronic indigestion develop, the survival rate is only 11.5% to 20%.[35,41] Prolonged treatment seems irrelevant. Prokinetics and their possible benefit in postoperative care have been studied and reviewed.[42,43] Erythromycin (10 mg/kg) IM given preoperatively improves abomasal motility in cattle suffering from abomasal volvulus.

Necropsy Findings Cattle that die of abomasal volvulus are grossly dehydrated, and the abomasum is severly distended or ruptured. The omasum often is also distended when torsion occurs at the reticuloomasal junction. Affected cattle that die or are euthanized after developing postoperative complications have one or more of the following postmortem lesions: gastric compartment dilation, peritonitis, abomasal wall necrosis or ulcer, vascular thrombosis, or vagal nerve lesions.[40]

Prevention and Control Because factors predisposing to atony of the forestomach and abomasum probably are important in the genesis of abomasal volvulus, prevention should be similar to that outlined for LDA.

Abomasal Ulcers

David Francoz • Charles L. Guard

Definition and Classification Smith and colleagues[1] classified abomasal ulcers into four types: (1) nonperforating, (2) nonperforating with severe blood loss, (3) perforating with local peritonitis, and (4) perforating with diffuse peritonitis (Table 32.20). Braun and associates subdivided type 1 abomasal ulcers (nonperforating ulcers) into four subtype on the basis of their structure.[2] In some case, abomasal ulcers rupture into the bursa omentalis and lead to omental bursitis. This type of ulcer has been classified as type 5 abomasal ulcers.[3] These classifications are useful for describing the various clinical scenarios that may be observed in examination of an animal with abomasal ulceration.

Epidemiology Abomasal ulceration occurs in cattle of all ages. Veal calves appear the most frequently affected. At slaughter, healthy veal calves are found to have clinically inapparent abomasal erosions and ulcers, with reported prevalence ranging from 67% to 87%.[4,5] In beef calves that died between the fourth day after birth and weaning, abomasal ulcers were observed in 3.9% on gross postmortem examination reported by a private veterinarians and in 18.9% on histologic examination or confirmation results by a veterinary pathologist.[6] In clinically affected calves, perforation with peritonitis (rather than hemorrhage) usually develops. In clinically normal cows, 20.5% had type 1 ulcers in a slaughter study.[2] In adult cattle with abomasal ulcers causing illness, approximately one third of clinical cases in a referral population had significant

VetBooks.ir

TABLE 32.20

Abomasal Ulcers

Type	Lesions	Clinical Signs
1. Nonperforating	1a. Erosion with minimal mucosal defects sometimes distinguished from the surrounding tissue by mucosal discoloration (often reddish-violet or green-brown) 1b. Deeper erosions with focal mucosal hemorrhage, sharply demarcated with a depression in its center 1c. Craters with coating of detritus or fibrin, depression in its center, and bulging margins 1d. Radial wrinkles with a central point, affecting gastric folds only	Partial anorexia; decreased ruminal motility; positive fecal occult blood
2. Nonperforating with severe blood loss (bleeding)	Penetration of mucosa and submucosal blood vessel; hemorrhage into abomasum	Partial anorexia; decreased ruminal motility; anemia; pale mucous membranes; melena; tachycardia; cool extremities
3. Perforating with local peritonitis	Penetration from mucosa to serosa; leakage of abomasal contents; localized peritoneal reaction with adhesion formation	Total anorexia; low-grade fever; ruminal motility decreased or absent; localized abdominal pain; very similar to traumatic reticuloperitonitis
4. Perforating with diffuse peritonitis	Penetration from mucosa to serosa; widespread contamination of the peritoneal cavity with abomasal contents; significant exudate in peritoneal cavity; fibrin deposition of all serosal surfaces	Total anorexia; fever early, then hypothermia; ileus of entire gastrointestinal tract; tachycardia; shock; terminal recumbency with grunt on respiration

hemorrhage.[7] Of these, half had lymphosarcoma and, for the most part, were older than 6 years of age. The age of the cattle with nontumor-associated bleeding ulcers was generally younger. In the remaining two-thirds of the cattle, ulcers had perforated, with approximately half having diffused and half having localized peritonitis.[8] Most adult cattle with abomasal ulcer are in the first month of lactation after calving and have a concurrent disease. Several cows have been discovered to suffer of an abomasal ulcer during surgery to correct displaced abomasum. Metritis, mastitis, and ketosis are the other diseases commonly seen with abomasal ulcers.

Few data are available in small ruminants. However, the prevalence of abomasal ulcers at slaughter has been reported to be 61% among goats in one old slaughter study from Iran.[9] The incidence of abomasal ulcers was reported to be highest in goats severely affected with nematodes.[9] In two slaughter studies from the Middle East, the prevalence of abomasal ulcers in healthy sheep ranged from 18%[10] to 75%[11]; almost all of these abomasal ulcers were type 1 ulcers.

Etiology and Pathophysiology

The specific events leading to erosion and ulceration of the abomasal mucosal epithelium are unknown. Cytoprotective mechanisms include a mucous barrier, cloudy mucus containing bicarbonate ions to neutralize back-diffusing hydrogen ions, and high submucosal rates of blood flow to remove back-diffusing hydrogen ions. When these mechanisms are disturbed, gastric (abomasal) ulcers may occur.

The exact cause of abomasal ulcers is still obscure and may be multifactorial. Hund and Wittek[12] reviewed the different suspected causes of abomasal ulcers in cattle and small ruminants. In calves, development of abomasal ulcers was proposed to be associated with mineral deficiencies (mainly copper), stressful management practices, feeding practices (type of milk and frequence of feeding), concomitant diseases, proliferation of microorganisms (*C. perfringens* type A or D, *Escherichia coli*, *Sarcina*-like spp., fungi, or others), and abrasion of the abomasal mucosa by roughage, geosediments, or trichobezoars. However, all explored hypotheses have failed to demonstrate involvement of any of these alone in the development of abomasal ulcers. In adult cattle, the disease is associated with stressful events such as recent parturition, peak milk production, presence of concurrent diseases (mainly those of the peripartum period), feeding practices such as diets high in starch, and presence of lymphosarcoma. Finally, abomasal ulcers are an adverse effect of antiinflammatory drug administration.

Clinical Signs and Differential Diagnosis

Loss of gastric epithelium may range from no clinical signs to hemorrhage and subsequent melena, to peritonitis if the erosive processes penetrate all layers of the abomasum (see Table 32.20).

The mildest form (type 1) is caused by nonperforating ulcers that do not result in extensive hemorrhage. Affected animals may have mild or no clinical sign. Mild abdominal pain, shown by partial anorexia, decreased ruminal motility, and mild ruminal tympany are the possible clinical signs if present. There is usually no fever. Feces may be normal or reduced in amount and stale because of prolonged transit. In some cases, abdominal pain may be evident on manual pressure on the right ventral abdomen. TRP or indigestion may be suspected. In one study, approximately two-thirds of affected cows produced a positive result of a fecal occult blood test measured with the use of an ortholidine-based tablet.[13]

In cattle with ulcers that erode into major gastric blood vessels (type 2), blood loss can be sufficient to cause signs of anemia and hemorrhagic shock. These animals have dark blood clots in their feces or tarry, black feces with the characteristic smell of partly digested blood. The mucous membranes may be pale, tachycardia and a pounding heart may be pronounced. Respiratory rate may be elevated. Total anorexia and rumen stasis usually are present. The rumen may have a fluid consistency, and if the animal is able to stand, abdominal pain sometimes is evident. There are other possible sources of proximal gastrointestinal hemorrhage in cattle, but abomasal ulcers are by far the most common cause. Among them, bleeding abomasal ulcers must be differentiated from melena sometimes seen with intussusception or hemorrhagic bowel syndrome (hemorrhagic bowel syndrome; see Diseases Caused by *Clostridium perfringens* Toxins [Yellow Lamb Disease, Lamb Dysentery, Necrotic Enteritis, Enterotoxemia] section). In these cases, feces are usually more the color of blackberry or strawberry jam. The PCV usually is increased with intussusception,[14] normal or increased in hemorrhagic bowel syndrome,[15-17] and decreased with a bleeding ulcer.[18]

VetBooks.ir

Abomasal ulcers that perforate the serosal surface may lead to localized peritonitis (type 3) from contamination with abomasal contents. If the lesion is small or the local inflammatory reaction sufficiently swift, localized peritonitis results. This condition mimics the presentation of TRP. The animal may have a moderate fever and partly or totally anorexic. Milk production may decrease acutely. There is evidence of abdominal pain, usually localized to the right ventral quadrant (positive withers pinch test). Ruminal motility is reduced, and mild bloat may be present. As with TRP, the signs usually abate over the course of a few days if the infection is successfully contained. In some cases the infection is confined to the omental bursa, where extensive contaminated fluid (pus) may accumulate. The course of omental bursitis is much more prolonged than that of simple localized peritonitis and usually results in a guarded prognosis.

Major leakage from a perforating ulcer leads to acute diffuse peritonitis (type 4). The course of the disease usually is rapid, with signs of septic shock developing within 24 hours of the onset. Total anorexia and ruminal stasis are accompanied by tachycardia with a weak, thready pulse and a heart rate of more than 100 beats/min. Pain may be evidenced by grinding of the teeth or groaning. The extremities are cool, and affected animals usually become recumbent. Abdominal enlargement may be evident as a result of both ruminal tympany and the accumulation of peritoneal fluid. Dehydration is detectable by skin pinch or by observation of the position of the eye in the orbit. Septic shock from other causes may be difficult to distinguish. Diffuse peritonitis from uterine, cecal, or intestinal ruptures have the same final course. Abomasal volvulus of more than a day's duration has similar characteristics but can be differentiated by the right-sided ping and fluid in the abomasum.

Ancillary Tests

Antemortem diagnosis of abomasal ulcers may be challenging, particularly in cases of nonperforating and nonseverely bleeding ulcers.

COMPLETE BLOOD CELL COUNT. If peritonitis is present, leukocytosis usually is present, with neutrophilia predominating in many cases. The plasma fibrinogen is increased (>700 mg/dL) in most cattle with peritonitis. The hematocrit is normal or elevated with peritonitis, but plasma protein levels may be decreased as a result of protein accumulation in the peritoneal cavity or increased if dehydration is severe. If blood loss is severe, the PCV is decreased.

SERUM BIOCHEMISTRY PROFILES AND BLOOD GAS ANALYSIS. Results of a serum biochemistry profile or blood gas analysis are nonspecific. In most cases, they reflect a digestive stasis (hypochloremic metabolic alkalosis), but in animals in shock a metabolic acidosis may be observed. BUN level may be increased. This can be a result of blood degradation in the intestine or hypovolemia and prerenal azotemia. The utility of BUN in the diagnosis of abomasal ulcers by identifying digestive hemorrhage remains to be determined.

OTHER BLOOD TESTS. Serum pepsinogen concentration has been reported to be increased in one study in cases of severe abomasal ulceration.[19] Because serum pepsinogen concentration can also be elevated in other abomasal diseases such as nematode infection, this finding is not specific.[19,20] Serum gastrin concentration has also been reported to be increased in cases of type 2 ulcers in comparison with healthy cows.[21] However, the sensitivity and specificity of this test are not known.

Cattle older than 5 years of age with a bleeding abomasal ulcer should be tested for bovine leukosis virus.

ABDOMINOCENTESIS. Abdominocentesis confirms diffuse peritonitis (a large quantity of abdominal fluid is obtainable); centesis fluid may contain leukocytes with phagocytosed or free bacteria and even feed particles. In localized peritonitis, the results of abdominocentesis may be normal (see Peritonitis in Ruminants section for more details).

FECAL OCCULT BLOOD TEST. Fecal occult blood tests may be helpful for detection of type 1 ulcers. The tests are inexpensive and can be performed during the physical examination. Testing multiple samples may increase its sensitivity.[22] However, these test did not provide any information about which part of the gastrointestinal tract is involved in the bleeding. One study have reported a sensitivity of 77% and a specificity of 97% for ulcers confirmed at surgery or necropsy.[13] However, the reagent used in this study is not commercially available anymore. Researchers have since evaluated a guaiac test and a urinary test strip for the diagnosis of type 1 ulcers. They reported low sensitivity, low specificity, or both and concluded that these tests are not suitable for the detection of type 1 ulcers.[23]

DIAGNOSTIC IMAGING. Because of forestomach anatomy, oral endoscopy of the abomasum is not possible in ruminants. Because ultrasonographic assessment of the abomasal mucosa integrity is difficult, ultrasonography is of limited value for the diagnosis of abomasal ulcers. However, images compatible with focal mucosal or omental edema and abdominal effusion associated with abomasal ulcers may be observed and lead to the suspicion of ulcers (Fig. 32.136). Ultrasonographic images of lymphomatous infiltration of the abomasal mucosa has been described in cows with lymphoma.[24] Abdominal ultrasonography is also useful for the diagnosis and the evaluation of peritonitis associated with type 3 and 4 abomasal ulcers (see Normal and and Main Abnormal Ultrasonographic Aspects of Abdominal Organs in Calves and Cows section). Braun and colleagues reported that percutaneous ultrasonography-guided abomasocentesis can be safely performed for the evaluation of abomasal fluid.[25] According to the investigators, the presence of blood or hemoglobin is principally associated with abomasal ulcers.

EXPLORATORY LAPAROTOMY. Exploratory laparotomy may also be an alternative in the diagnosis abomasal ulcers by palpation of a thickening of the abomasal wall, roughing of the abomasum serosa, adhesion of the abomasum, or directly

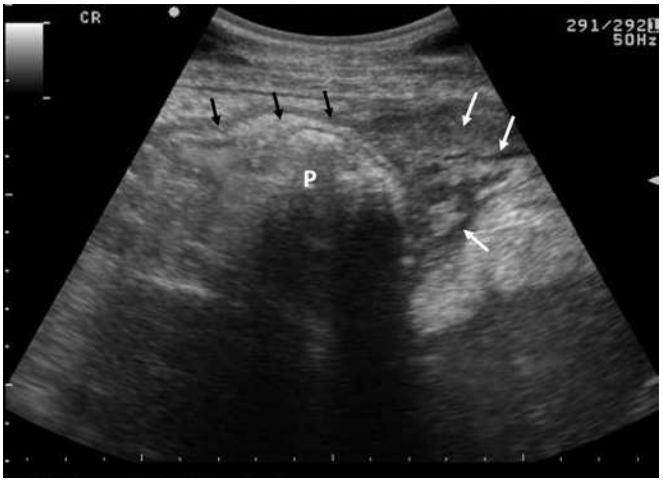

FIG. 32.136 Ultrasonography of the right cranial abdomen of a cow diagnosed with abomasal ulcers. The pylorus *(P)* is visualized *(black arrows)*. The surrounding images are compatible with inflammatory changes (*white arrows*, indicating hypoechogenic pocket with structures of various echogenic appearance). *(Courtesy Centre Hospitalier Universitaire Vétérinaire de l'Université de Montréal)*

a perforation in the abomasal wall. However, potential aggravation after the exploratory procedures should be considered.

Treatment

Treatment is aimed at correcting dietary problems, reducing stress, treating concurrent diseases, and initiating specific therapy to address the consequence of the ulcers.

SUPPORTIVE TREATMENTS. Removal of high-energy feedstuffs and replacement with good-quality hay combined to confinement in a stall are beneficial.[26] The buffer effect of food is very important in controlling the abomasal pH. Consequently, recovering a normal appetite is the main goal of the treatment of abomasal ulcers.[27]

Blood transfusions may be necessary for cattle that have lost enough blood to lower the hematocrit to 14% or below. Usually 4 to 6 L given once is adequate, but repeated transfusions may be necessary. Crossmatching is usually not necessary in cattle unless repeat transfusions are performed over more than 3 days.

Broad-spectrum antibiotics are administered when peritonitis is suspected. Principles and details regarding the treatment of peritonitis are described in the Peritonitis in Ruminants section. Intravenous or oral fluids may be necessary to treat dehydration and metabolic or acid-base disturbances. Animals with diffuse peritonitis must be given intravenous fluids with caution because of the risk of pulmonary edema associated with the low plasma oncotic pressure.

DRUGS THAT INCREASE THE ABOMASAL PH: ANTIACIDS. Numerous studies have been performed to evaluate the effect of different therapeutic agents on abomasal pH of healthy calves. Results of these studies have been summarized by Constable and colleagues.[27] The therapeutic agents studied in normal calves included oral administration of an antacid agent containing aluminum hydroxide and magnesium hydroxide (25 mL and 50 mL, tid), oral administration of specific H_2 antagonists (cimetidine, 100 mg/kg and 50 mg/kg, tid; and ranitidine, 10 mg/kg and 50 mg/kg, tid), and oral administration of the proton pump inhibitor omeprazole (4 mg/kg q24h). All these extralabel treatment regimens induce an increase in the mean 24-hour abomasal luminal pH. Oral administrations of aluminum hydroxide agent induced a dose-dependent increase in luminal pH and were more efficacious when administered postprandially. Because some deleterious effects (diarrhea, hypomagnesemia, metabolic alkalosis) were observed when this antacid was administered at the dose of 50 mL tid, this should be considered the maximal dosage in calves. Frequent (every 8h) oral administration of 25 mL of aluminum hydroxide is reported to be the most effective treatment.[27] Cimetidine (100 mg/kg tid) was the most effective. However, ranitidine (50 mg/kg tid) was the most cost-effective in these studies. Interestingly, the effect of omeprazole on abomasal pH decreased over time (reduced effect observed after five daily treatments).[28] Results of these studies may or may not apply to ill calves. In adults, oral administration of these therapeutic agents is of doubtful benefit because of dilution in the rumen and slow release into the abomasum. Oral medications administered after stimuli that induce esophageal groove closure would be more likely to have the desired effect. Traditional stimuli have included copper sulfate solutions and 10% sodium bicarbonate solution. Vasopressin (0.25 IU/kg IV) was shown to induce reliable abomasal deposition of materials given by drench to adult goats.[29]

Intravenous administration of H_2 antagonists at lower doses may be efficacious, but their use by this route is cost-prohibitive ($100 to $200 per day) or reserved for valuable animals. In the authors' clinic, ranitidine 1 to 1.5 mg/kg IV tid is used; the clinical impression is that this is effective. Intravenous administration of ranitidine (1 and 2 mg/kg) in healthy sheep has shown an increase in the abomasal pH for up to 150 min, and authors conclude that administration of ranitidine at a dosage of 1 mg/kg tid or 2 mg/kg bid IV could be the most effective treatment protocols.[30] Intravenous administration of famotidine at 0.4 mg/kg once or tid has also been reported to increase abomasal outflow pH, but the effect decrease with time.[31] Injectable proton pump inhibitors (omeprazole, pantoprazole) are also available in some countries, but their efficacy in cattle and small ruminants is unknown.

SURGERY. Surgery may be an option in cases of perforated ulcers or when abomasal adhesion secondary to a localized peritonitis lead to abomasal dysfunction. Right paralumbar fossa, right paracostal, or right paramedian approaches can be used to access the abomasum (see abomasal impaction) and allow ulcer resection. However, prognosis associated with these surgeries is guard. In calves, 40% of 10 calves survived the corrected surgery in one study[32] whereas none survived in another (8 calves, one of which had a nonperforated ulcer).[33] In another study in cattle with concurrent abomasal displacement and perforating ulceration, the short- and long-term survival rates were 38% and 14%, respectively.[34]

Prognosis

The prognosis is good for ulcers that are neither bleeding nor perforated. For animals that stop bleeding and those with localized peritonitis, survival and eventual return to normal function are possible. Many dairy cattle stop lactating during the acute course of the illness and do not return to milk until the next lactation. Because abomasal ulcers generally occur within the first month after calving, most of these animals are used for slaughter. Most cattle with diffuse peritonitis (type 4 ulcers) die despite aggressive specific therapy. Cattle with ulcers that occur secondary to lymphosarcoma should be euthanized.

Necropsy Findings

Cattle with bleeding abomasal ulcers resulting in death are very pale and may have blood or bloody fluid throughout the distal gastrointestinal tract. The lesion in the abomasum is typically small and involves an abomasal blood vessel in the submucosa. Most bleeding and perforating ulcers were found in the fundic portion of the abomasum in the region of the proper gastric glands. The most ventral portion of the abomasum in its normal position is frequently affected.[18] Most affected animals have a single bleeding ulcer, but approximately 60% have one or more additional ulcers or erosions.[18] Cattle with diffuse peritonitis have many liters of foul-smelling fluid in the peritoneal cavity. Fibrin usually covers the serosal surface of all abdominal organs. The defect in the serosal surface of the abomasum is usually nearly round and 3 to 6 cm in diameter. Abomasal fluid freely enters the peritoneal cavity. Omental bursitis may be present, with the omental recess filled with purulent to fibrinous fluid. In these cases, the remainder of the abdomen may not be grossly affected. Asymptomatic abomasal ulcers (often 50 to 200) may be found coincidentally in cattle that die of septic metritis or mastitis. These ulcers generally produce no signs of hemorrhage and go undetected until necropsy.

Prevention and Control

Because the exact cause of development of abomasal ulcers is unknown, prevention is difficult. Dietary management that reduces other abomasal diseases likewise reduces the incidence of abomasal ulcers. Avoiding abrupt changes in rations and including adequate fiber sources of sufficient particle size to facilitate normal ruminal function also promote normal abomasal function. Minimizing stress caused by overcrowding, excessive competition, and adverse environmental conditions and minimizing mastitis and metritis should also reduce problems with abomasal ulcers. Removal of animals infected with the bovine leukosis virus from the herd eliminates lymphosarcoma as a cause of

abomasal ulcers. Judicious use of corticosteroids and NSAIDs is also important.

Abomasal Dilation and Emptying Defect of Suffolk Sheep

David Francoz

Definition and Epidemiology

Failure of abomasal transport and abomasal dilation has been described in adult sheep.[1] The disease has been reported mainly in Suffolk breed and has occurred mostly in winter months in association with lambing and feeding of concentrates. A similar syndrome has been described in two Hampshire,[2] one Dorset,[3] and one Texel sheep.[4] An abomasal emptying defect syndrome has also been reported in Toggenburg goats, which could suggest that this syndrome may therefore occur in goats.[5]

Animals described in reports from several teaching hospitals were adults of both sexes.[1,6] Most cases are sporadic, but at least two outbreaks have been reported.[1,6] The incidence in one report was 13 of 92 mature ewes affected in the flock during one winter.[6] In the other report, 5 ewes of a flock of 200 ewes were submitted for necropsy in the same day.[1] In both studies, pedigree analysis of affected sheep showed no hereditary pattern. One report from a diagnostic laboratory in England described abomasal impaction in a Texel ewe and in a Suffolk ram that were simultaneously diagnosed as having scrapie.[4] It remains to be seen whether any causative connection exists between the two diseases. In one study, six sheep were immunohistochemically tested for scrapie; five results were negative and one was positive, and the affected sheep had equivocal microscopic lesions.[1]

Pathophysiology

The mechanisms underlying the dilation of the abomasum and the failure to transport ingesta to the intestines are unknown. None of the problems commonly associated with abomasal impaction and dilation in cattle have been identified in affected Suffolk sheep. It has been advanced that abomasal emptying defect of Suffolk sheep may be an acquired form of dysautonomia.[1]

Clinical Signs and Differential Diagnosis

The disease is manifested primarily by anorexia and weight loss. Most patients eventually die. The following clinical signs have been reported in affected animals but are not always present: watery green diarrhea; ruminal tympany; pear-shaped abdominal distention; increase or decrease in or absence of ruminal contractions; a palpable (by ballottement) firm mass in the right lower abdomen; mild abdominal pain; tachycardia; duration of observed signs from days to months; partial to total anorexia; dullness and depression; marked to undetectable weight loss; and ketonuria.

This syndrome should be differentiated from other wasting diseases of sheep such as malnutrition, parasitism, dental problems, Johne's disease, caseous lymphadenitis, other chronic infections, and neoplasia. Abomasal emptying defect is distinguishable by the palpable abomasum in advanced cases and the exclusion of other possible problems. Other causes of abomasal enlargement or impaction resembling those reported in cattle must also be considered. However, when a mature Suffolk sheep from a well-nourished flock shows weight loss and a palpable abomasum, this syndrome must be considered highly likely. Confirmation may require necropsy or exploratory surgery.

Ancillary Tests

Reports on cases diagnosed in North America have found CBC and systolic blood pressure to be of little benefit in the diagnosis.[6] The hypochloremic metabolic alkalosis common in cattle with abomasal problems may be present[2,7] but is not consistently observed in affected sheep.[3,6,8,9] Increased liver enzyme levels are frequently reported in affected sheep and goats and were associated with hepatic congestion and ischemia secondary to abomasal distention.[3,5,6,7] Mild hypocalcemia was observed in all cases in one report.[5] Because of internal vomiting, elevated ruminal chloride ion values (34 to 130 mEq/L; normal, 8 to 15 mEq/L) are also frequently reported in published reports.[2,3,6,7,9]

Treatment and Prognosis

Medical therapy alone with cathartics and laxatives has been of limited benefit. Mineral oil, dioctyl sodium sulfosuccinate, and magnesium sulfate have all been used. Neostigmine and calcium gluconate were not useful.[8] Abomasotomy has led to death from complications in many affected sheep,[6,8] but those that survived more than 2 days manifested recrudescence of clinical signs within 12 weeks.[8] Ewes treated with metoclopramide (dosage not reported) have shown varying degrees of recovery; some of them survived for 12 weeks but continued losing weight.[6] Experimental studies in cattle and sheep have failed to demonstrate any beneficial effect of metoclopramide on abomasal emptying.[10,11] On the other hand, erythromycin has been shown to increase abomasal emptying rate in lambs.[12] However, in a context of judicious use of antimicrobial drugs, the administration of erythromycin for its prokinetic properties is questionable and is not recommended. Despite these successes, most affected sheep die of cachexia. Because of the expense, poor response, and risks associated with abomasotomy, this treatment is reserved for valuable breeding stock.

Necropsy Findings

The abomasum is greatly distended in sheep that die of this condition. The contents are either dry or liquid but most often have resembled normal ventral ruminal sac contents. Investigators always reported a patent pylorus. Normal ingesta have been observed throughout the remainder of the intestinal tract. Incidental findings have included aspiration of ruminal contents and subsequent pneumonia, abomasal ulcer with local peritonitis, passive congestion of the liver, megaesophagus, and esophageal ulcers. Reports of histopathologic findings include no lesions other than thinning of the abomasal muscle layers (presumably as a result of stretching),[6] mononuclear cell infiltration of the main muscle layers of the abomasum,[8] and, in one case, myxomatous changes in the abomasal branches of the vagus nerve.[9] Chromatolytic and necrotic neurons without signs of inflammation within the celiacomesenteric ganglia were found in all six affected sheep examined in one study.[1]

Prevention and Control

Until more is known about the pathogenesis of this specific defect in abomasal function in Suffolk sheep, no useful recommendations for prevention can be made.

Abomasal Impaction

David Francoz

Definition and Classification

Abomasal impaction is the accumulation of firm ingesta in the abomasum with failure of aboral transport associated with an increased volume of the abomasum. The impaction involves the body and the pyloric antrum of the abomasum. However, impaction of the pyloric antrum only is also described in dairy cattle.[1] Abomasal impaction can be classified as primary when no underlying cause can be identified and as secondary when impaction is secondary to another condition. *Dietary abomasal*

impaction refers to abomasal impaction secondary to ingestion of abnormal diet.

Etiology and Pathophysiology

Primary abomasal impaction is considered idiopathic and has been described mainly in dairy cows in the early postpartum period.[1] Dietary abomasal impaction is the result of feeding poor-quality, coarse roughage as the sole feed. Abomasal impaction can also be secondary to consumption of nonfood material such as sand or gravel or secondary to abnormal alimentary behavior or ingestion of feed mixed with sand.[2-5] Secondary abomasal distention may also occur with normal diets after correction of abomasal volvulus, as a result of reticuloperitonitis, or as a result of the development of adhesions between the abomasum and the rumen or the abdomen wall (or both). Lymphoma involving the abomasum or other space-occupying lesions adjacent to the pylorus may lead to abomasal distention. These conditions are referred to as *chronic indigestion* and are discussed elsewhere in this chapter. Abomasal emptying defects of Suffolk sheep are addressed in the previous section.

The pathophysiologic mechanism of abomasal impaction is not known. In dietary abomasal impaction, animals fed roughage that is poorly digestible and incapable of meeting their energy requirements consume as much as the rumen will physically allow. The flow of ingesta from the forestomachs to the abomasum normally contains only small, finely digested particles of forage material. With chronic engorgement of highly lignified, poorly digestible forage, larger particles escape the forestomach and accumulate in the abomasum. Once a mass of fiber forms in the abomasum, further accumulation of particulate material is enhanced. Accumulation of dry materials modifies the abomasal content viscosity and consequently, the abomasal emptying rate decrease.[1] Additional ingesta distends the abomasum to several times normal size, which leads to a severe abomasal distention that prevents any return to normal motility. Also, abomasal secretion may be inhibited by the cachexia and chronic distention of the organ.

Clinical Signs and Differential Diagnosis

Adult dairy cows with primary abomasal impaction have a consistently decreased appetite, but other signs are inconsistent.[1] Primary abomasal impaction should be considered in the differential diagnosis of nonspecific clinical signs of decreased milk production and appetite in dairy cows.[1] Conditions that cause dehydration and bilateral abdominal distention with absence of feces must be considered in the differential diagnosis. In many of these cases, exploratory celiotomy is necessary to arrive at a definitive diagnosis.

Dietary abomasal impaction has mainly been described in beef cows, but dairy cows exposed to similar feeding and environmental conditions may also be affected. Several animals in a herd may be affected over a short period. Beef cows with abomasal impaction develop abomasal and ruminal distention over a period of days to weeks. Close monitoring of animals reveals reduced feed intake and a reduced volume of firmer than normal feces. The animal may have right ventral abdominal enlargement. Ruminal contractions are of normal or increased frequency but are often reduced in amplitude. In the later stages of the disease, ruminal motility is often absent. Cattle with advanced abomasal impaction may be recumbent and groan with each respiration. The consistency of the ruminal ingesta, as judged by ballottement, may be more fluid than expected on the basis of the coarse diet. Other animals have a uniformly firm and distended rumen. The pulse and respiration are usually normal until the animal is near death, at which time tachycardia develops. The abomasum may be palpable as a firm mass behind the right coastal arch. Rectal examination reveals a distended rumen; often the ventral sac extends to the right body wall (L-shaped rumen). The pyloric part of the distended abomasum may be palpable in the right ventral quadrant. Wintering beef cows usually are pregnant, and therefore the uterus may prevent palpation of the abomasum. Feces are absent or very scant and dry. Mucus may be all that clings to the clinician's sleeve after rectal examination. The body condition of affected animals is invariably poor because negative energy balance precedes and is amplified by the impaction. If the abomasum ruptures, signs of generalized peritonitis occur. Death usually follows within hours of rupture.

Ancillary Tests

The hypochloremic, metabolic alkalosis typical of upper gastrointestinal obstruction in ruminants does not always develop in abomasal impaction.[1] Initially some fluid ingesta may pass through the abomasum, preventing chloride sequestration. However, some cattle have metabolic alkalosis, with chloride accumulating in the rumen to a level greater than 30 mEq/L (internal vomiting). In terminal stages, a mixed acid-base imbalance with both a metabolic alkalosis and a metabolic acidosis can result in a normal overall pH. Anemia and leukopenia can accompany the cachexia of chronic abomasal impaction in poorly fed animals. If abomasal rupture has occurred, profound hemoconcentration and leukopenia are present. Abdominocentesis generally is not useful in diagnosing abomasal impaction because peritoneal fluid is abnormal only after abomasal rupture.

Treatment

Medical management includes correction of fluid and electrolyte abnormalities. Early cases may be resolved with easily digestible feeds, aggressive fluid therapy, and oral administration of laxatives such as mineral oil (4 L daily). The use of prokinetic drugs may be indicated in order to increase abomasal emptying rate and the passage of ingesta through the pylorus. However, no data on the efficacy of the administration of prokinetic drugs in the specific treatment of abomasal impaction are available. Constable and colleagues[3] published a comprehensive review on the data available for the recommendation of the use of prokinetic drugs in abomasal disorders. They concluded that (1) erythromycin (8.8 to 10 mg/kg IM bid) is the most effective drug to increase abomasal emptying rate; (2) according to in vitro studies, bethanechol (0.07 mg/kg SC tid) is potentially effective, but no controlled clinical trials have actually demonstrated its effectiveness; and (3) metoclopramide is ineffective in promoting abomasal emptying rate in cattle and cannot be recommended. However, prudent use guidelines from many countries indicate that the use of an antibiotic such as erythromycin for its prokinetic activities is controversial and should not be recommended. Pregnancy may be terminated by induction of parturition with corticosteroids or prostaglandin, or both, which improves comfort.

Different approaches have been proposed for a surgical treatment of abomasal impaction. Rumenotomy, followed by installation of a nasogastric tube inserted into the abomasum through the omasum, can be performed. Through the indwelling tube, laxatives and emulsifiers may be given during the postoperative days to aid in softening and removing the abomasal contents. Mineral oil (8 mL/kg/day), dioctyl sodium sulfosuccinate (50 mg/kg/day), magnesium hydroxide (1 g/kg/day), and magnesium sulfate (2.5 g/kg/day) have each been recommended. However, none of these treatments has been evaluated, and detrimental effects have been reported with some of them (see discussion of magnesium hydroxide in the Acute Abdomen in Ruminants section). Right paralumbar fossa, right paracostal, or right paramedial approaches can also be used to gain direct access to the abomasum. The authors prefer the right paracostal approach, with the animal in left lateral

VetBooks.ir

recumbency, for abomasotomy and removal of abomasum contents. However, even with this approach, complete exteriorization of the abomasum and exploration of the oral portion of the abomasum and omasum is often not possible, particularly in large animals. Even if the prognosis for restoring the abomasal function is poor, the authors have had some positive outcome, depending on the cause of impaction and the extent of abomasal lesions. External massage may help break up the contents of the abomasum. Intraluminal administration of 5% dioctyl sulfosuccinate solution or saline can also be performed during surgery.[1]

Prognosis

Because most cases of abomasal impaction are quite advanced when brought to the attention of the veterinarian, treatment is usually unrewarding. In dairy cows the short-term prognosis was reported to be good (93%) for impaction that affected only the pyloric antrum and guarded (50%) for impaction involving the entire abomasum.[1] The clinician must weigh the severity of the metabolic disturbances and the likelihood of recovery. Salvage by slaughter is often the most economic recommendation. If therapeutic measures do not resolve the impaction, death usually occurs within a few days of the onset of severe signs.

Necropsy Findings

Emaciation and a firm, grossly enlarged abomasum are consistent with primary or dietary abomasal impactions that involve the entire abomasum. The abomasal contents resemble normal, dry ruminal contents. The rumen is also enlarged but either filled with homogeneous, watery ingesta that lack normal stratification or impacted with dry ingesta, like the abomasum. Accumulation of sand or gravel is evident.

Prevention and Control

Prevention of dietary abomasal impaction requires proper dietary management of cattle in cold weather. Because animals outside without shelter have substantially increased maintenance energy requirements in cold, windy weather, straw or corn stover (stalks) is not adequate as the sole feed. Concentrates and better-quality forage prevent abomasal impaction. Monitoring body condition during winter weather alerts the good manager that supplemental feed is needed before abomasal impaction occurs.

Obstructive Intestinal Diseases

David Francoz • Charles L. Guard

Definition and Etiology

Several conditions may lead to obstruction of the flow of ingesta through the intestinal tract. These conditions can be divided into functional or mechanical obstructions. Functional obstructions (pseudoobstruction or ileus) are the consequence of neuromuscular perturbations of the gastrointestinal tract. Mechanical obstructions are the consequence of a physical obstruction of the intestinal tract secondary to digestive tract lesions (intussusception, volvulus, or congenital lesions) or extradigestive lesions (mesenteric fat necrosis, fibrous adhesions, or hernia). Each of the specific diseases is discussed in the following paragraphs and summarized in Table 32.21.

Clinical Signs and Differential Diagnosis

Acute manifestations of obstructive diseases include a reduced amount of feces or failure to pass feces, progressive abdominal enlargement with areas of tympanic resonance on the right side of the abdomen, and sometimes colic. If pain is severe, forestomach atony may occur. Mechanical obstructions may lead to circulatory shock and collapse. Electrolyte abnormalities depend on the site of the obstruction; obstructions in the jejunum or near the duodenum or pylorus lead to sequestration of abomasal secretions and result in hypochloremic, hypokalemic metabolic alkalosis, whereas those in the cecum, colon, or rectum may lead to dehydration without alkalosis. If bowel necrosis or rupture occurs, acidosis may result from the circulatory collapse that accompanies peritonitis and the absorption of toxins.

Volvulus of the Duodenal Sigmoid Flexure

A syndrome affecting the duodenal sigmoid flexure was reported in Holstein cattle by Vogel and colleagues.[1] The etiologic and pathophysiologic features of this condition are not known, but the authors advanced a potential role of duodenal ulcers or previous omentopexy (years to months before development of volvulus of the duodenal flexure). Clinical presentation resembles abomasal volvulus with anorexia, decreased milk production, scant feces, tachycardia, moderate dehydration, tympanic resonance in the tenth to twelfth right intercostal spaces, and succussion of fluid in this area.[1] Serum biochemistry panels

TABLE 32.21

Causes of Intestinal Obstruction in Ruminants

Disease	Animals Most Commonly Affected	Signs
Intestinal atresia or stenosis	Neonates	No feces; abdominal distention
Intestinal volvulus around mesenteric root	All ruminants; more common in neonates	Colic; rapid abdominal distention; collapse; shock
Intussusception	All ruminants; large or small intestine of neonates; small intestine of adults	Colic early, then chronic low-grade pain; dehydration; mucus plus blood in dark red feces; slow abdominal distention; decreased fecal output; mass palpated rectally; distended loops of intestine palpated rectally
Cecal dilation and volvulus	Adult dairy cattle in early lactation	Mild to severe colic; distended abdomen, especially upper right; ping in right paralumbar fossa; distended cecum palpated rectally
Intestinal tumors	Sheep, rare in cattle	Progressive weight loss; in cattle, mass may be palpable rectally; in sheep, mass identified by celiotomy or necropsy
Mesenteric fat necrosis	Cattle, especially Channel Island breeds	Masses possibly discovered on routine examination; progressive weight loss; scant or no feces; dilated loops of bowel palpated rectally
Intestinal incarceration	All ruminants	Same as for intussusception
Ileus	All ruminants	Scant or no feces; right-sided ping; succussable fluid on right; often associated with peritonitis

VetBooks.ir

revealed a severe hypokalemic and hypochloremic metabolic alkalosis, as well as hyperbilirubinemia and increased liver enzyme levels. Interestingly, those modifications were more pronounced than those observed in cases of abomasal volvulus. Confirmation of the diagnosis is made by palpation of a counterclockwise duodenal sigmoid flexure volvulus during right flank exploratory laparotomy. Treatment consists of manual reduction of the volvulus, massage of the duodenum, and fluid therapy to correct electrolytic disorders. Prognosis of the condition is reported to be fair; 22 of 29 animals were treated successfully.

Intestinal Atresia or Stenosis

Intestinal atresia or stenosis is a congenital anomaly reported in calves and lambs. Clinical signs usually become evident within a few days after birth. Animals with anal or distal rectal atresia usually have the slowest onset of signs, whereas proximal obstructions lead to more rapid onset of signs. Malformations of the anus and rectum are believed to be hereditary,[2] and breeding of surgically corrected survivors should be discouraged. Jejunal atresia in Jersey cows is reportedly inherited as an autosomal recessive trait. The etiopathogenesis of atresia coli in calves is not well understood, but autosomal recessive inheritance has been reported,[3] and Holstein calves seem to be predisposed to its development.[4] Rectal palpation of the amniotic vesicle for diagnosis in early pregnancy (<42 days of gestation) is also suggested to be a cofactor for the development of atresia coli.[4,5] If the anus or distal rectum is atretic, animals strain or pump their tails in an attempt to defecate. A fistulous connection may exist between the rectum and the urogenital tract (e.g., either the vagina or the pelvic urethra). Visual and digital exploration of the perineum reveals the absence of feces and may permit definition of the specific defect.

Stenosis or atresia of the intestinal tract may occur to any degree and can be differentiated in four types according to humans classification: narrowing, a membranous diaphragm with a perforation, or an imperforate membrane (type 1); a cordlike remnant of the intestine (type 2); a unique blind-ended dilation with complete separation of the intestine (type 3, the most frequent); and multiple sites of atresia (type 4).[6] All have been described in cattle. Affected neonates show depression and mild colic and progress to cardiovascular collapse after the intestine proximal to the obstruction becomes distended with fluid and gas. Tympany may be easily detected by percussion. If the anus and rectum are normal, a digital examination usually reveals only mucus or blood (or both). Because the rectal and descending colon walls are thin in cases of atresia coli, retrograde tubes or catheters should be used with extreme caution to prevent rupture of the bowel or should be avoided completely.[6] Complete intestinal volvulus must be considered in the differential diagnosis, but the histories in the two conditions are often different.

Surgical repair is indicated if the animal is of high value. However, the prognosis for normal and productive life is guarded. Many affected neonates develop severe complications in the immediate postoperative period. Pneumonia, sepsis, and peritonitis are among the most frequent complications, and the development of bowel stasis or ileus is common. A prognosis of a rate of 39 to 44% short-term survival has been reported.[6-8] When registered animals are involved, a letter should be sent to the appropriate breed registry stating that the defect has been corrected.

Volvulus of the Large and Small Intestine Around the Mesenteric Root

Volvulus of the large and small intestines around the mesenteric root leads to severe colic and relatively rapid abdominal enlargement. Circulatory shock develops rapidly. Ruminants of any age are susceptible, but most cases are seen in preruminant neonates. Severe colic is seen, including kicking and vocalization. Affected animals rapidly become recumbent, and hypovolemic shock develops. The heart and respiratory rates increase drastically as shock develops. Variable-pitched resonant sounds may be heard bilaterally over the abdomen with the use of simultaneous percussion and auscultation. In affected adult cattle, the tympany is restricted to the right side. Succussion reveals splashing sounds, particularly on the right side. Rectal examination reveals distended loops of gut. Surgical correction is the only successful treatment option.[9] The prognosis depends on the degree of devitalization of bowel. Animals that undergo surgical correction during the early stages respond better.

Volvulus of smaller portions of the intestinal tract leads to signs similar to those of complete intestinal volvulus around the root of the mesentery, but often the onset is more progressive. Colic with accompanying tachycardia, ruminal stasis, and anorexia is present to varying degrees. The abdomen is moderately distended on the right, as viewed from the rear. Simultaneous auscultation and percussion on the right side reveal multiple-pitched, resonant pings from the gas accumulated proximal to the obstruction. Rectal examination may reveal scant feces, mucus, or blood. The affected bowel usually is palpable as grossly distended with gas and some fluid. Because of their relatively long mesentery, the spiral colon (or part of it), the distal jejunum, and the proximal ileum may develop an obstructive volvulus. Therapy requires correction of acid-base and electrolyte abnormalities and rapid surgical manipulation by means of celiotomy.

Intussusception

In the development of an intussusception, the oral portion of gut (intussusceptum) usually is engulfed and propelled distally by peristaltic action of the enveloping portion (intussuscipiens). Constable and colleagues reported that the prevalence is increased among calves younger than 2 months of age in comparison with adults and in Brown Swiss cows in comparison with Holstein cows.[10] The condition has also been reported in goats[11] and in sheep.[12,13] Intussusception may occur in either the large or the small intestine of calves but is much more frequent in the jejunum.[10] Clinical signs include colic caused by the tension on the mesentery on the invaginating portion of the intestine. With time, ischemia of this portion leads to pain and eventually loss of sensation. Distention of the intestine with fluid and gas proximal to the obstruction leads to abdominal pain. Therefore an affected cow may show violent behavior or kicking at the abdomen in the first few hours that is eventually succeeded by treading and repeated lying and standing. Over the course of several days, the intussusceptum may become totally devitalized and slough. This is accompanied by focal peritonitis, and in the event of bowel rupture, diffuse peritonitis and toxic shock develop. The exact cause of intussusception remains unknown. Intramural or luminal mass or lesions, viral enteritis, intestinal parasitism, abrupt dietary changes, administration of intestinal motility modifier drugs, and foreign body or prior surgery have all been reported to be potential predisposing factors, but in most cases, intussusception is idiopathic.[10]

Dehydration develops as gastrointestinal secretions accumulate in the gut lumen. In adults, hypochloremic, hypokalemic metabolic alkalosis develops gradually. The rumen becomes distended with fluid as its contents become more finely digested and abomasal reflux accumulates. The right side of the abdomen (or both sides) also enlarges as a result of the distention of the small intestine. Simultaneous auscultation and percussion of the right side of the abdomen reveal areas of variable-pitched resonance. Rectal examination reveals distended loops of small intestine. The intussusception may be palpable as a firm mass, painful when palpated. Feces may eventually be absent. The examiner may find mucus and blood in the descending colon.

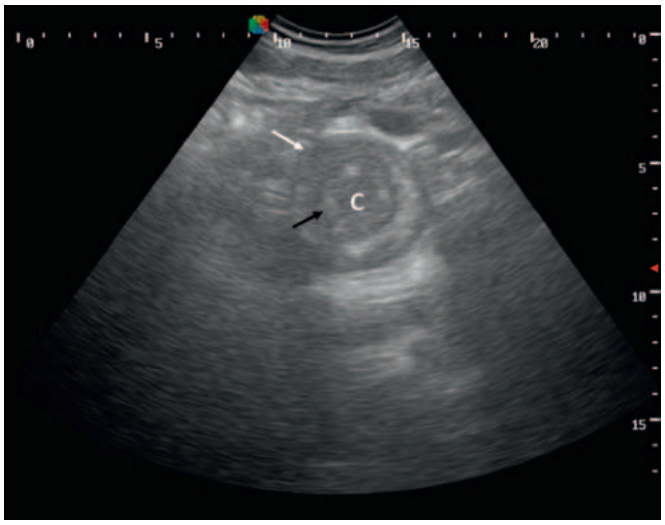

FIG. 32.137 Right abdominal ultrasonography of a cow with an intussusception: intussuscipiens *(white arrow)*, intussusceptum *(black arrow)*, and core *(C)*. *(Courtesy Centre Hospitalier Unversitaire Vétérinaire de l'Université de Montréal).*

In long-standing cases the scant feces are very dark red and must be distinguished from the black feces (melena) associated with abomasal bleeding. Fluid obtained by abdominocentesis reveals an elevation in erythrocytes and leukocytes counts and an elevated protein concentration. If the condition is long-standing and bowel rupture has occurred, bacteria may be present. CBC may reveal neutrophilia and an elevated plasma fibrinogen level.

In neonates with enteritis, fecal output decreases and appetite is lost when the intussusception develops. A fever may develop as peritonitis occurs. Affected calves and other neonates may not exhibit obvious signs of colic. Percutaneous abdominal palpation with both hands in an attempt to detect a mass is often successful in delineating an intussusception in a neonate. When neutrophilia, hyperfibrinogenemia, and loss of appetite develop after enteritis, intussusception should be suspected.

Findings compatible with an intestinal obstruction are seen on transabdominal ultrasonography (distended intestinal loops, decreased or absent peristalsis). In some cases, the affected intestinal segment may be visualized. At that time, ultrasonographic appearances described as "target-like" or "bull's eye" lesions or as multiple-layered, onion ring–type masses with a "sandwich configuration" are observed in transversal and longitudinal views of the intestine, respectively (Fig. 32.137).[14]

Treatment requires both surgical correction of the obstruction and parenteral restoration of fluid and electrolyte balance. Because of the losses of chloride and potassium and the development of alkalosis, 0.9% sodium chloride solution with 30 mEq/L or more of added potassium chloride is recommended. Intravenous potassium should not be given more rapidly than 1 mEq/kg/h (conservative rate is 0.5 mEq/kg/h). Once intestinal patency has been restored, oral fluid and electrolyte supplementation usually allows the patient to achieve normal status.

The prognosis is usually good if surgery is performed early in the course of disease. Complications such as peritonitis can occur and need to be treated appropriately to maintain the chance of success. A retrospective study of 336 cases of intussusception demonstrated a postoperative survival rate of 43% and an overall survival rate of 35%.[10]

Intestinal Incarceration

Intestinal obstruction may occur in ruminants as a result of accidental entrapment of intestinal loops, usually of jejunum, around remnants of embryonic structures or through an acquired defects in mesentery, a ligaments or the abdominal wall. Remnants of the urachus, the omphalomesenteric duct, the left umbilical vein, and the ductus deferens have been described as responsible for incarceration of the jejunum. The authors of one report indicated that 26% of cows examined had a persistent round ligament of the liver and falciform ligament.[15] Thus tears in the falciform ligament that lead to intestinal entrapment may be among the most common causes of the relatively rare problem of intestinal incarceration in cattle. Duodenal obstruction caused by malposition of the gallbladder was also reported in a heifer.[16] Intestinal adhesions caused by intraperitoneal injections of irritating substances may also lead to intestinal obstruction. Initial signs of colic followed by depression, anorexia, progressive abdominal distention, and absence of feces usually develop. Distended loops of small intestine usually are palpable rectally. Treatment of intestinal incarceration requires surgical intervention.

Cecum Dislocation

Cecum distention may be classified in three ways: (1) In cecal dilation, the cecum is distended only by gas, and the apex of the cecum is displaced toward the rectum and may be palpable transrectally; (2) in cecal retroflexion (which can cause vascular damage and ischemia; i.e., volvulus,: the cecum is distended, displaced, and folded dorsally or ventrally, the apex of the cecum is consequently oriented cranially and is usually not palpable rectally; and (3) in cecal torsion, the cecum is distended and rotated along its long axis, and the apex of the cecum is displaced toward the rectum and can be palpated transrectally.[17] In a large study of 461 cases of cecal dilation, the preoperative clinical diagnoses based on rectal palpation were cecal dilation alone in 291 animals (63.2%), cecal dilation and retroflexion in 94 animals (20.4%), and cecal dilation and torsion in 20 animals (4.3%); in the remaining 56 animals, no diagnosis of cecal dilation could be made preoperatively.[18] In adult cattle, cecal dilation generally is believed to precede retroflexion or torsion.

The etiologic and pathophysiologic features of cecal dilation and retroflexion or torsion remain unknown. Different feeding or management practices may predispose animals to cecal disease.[18] Increased luminal concentration of VFAs was classically believed to play a major role in the etiopathogenesis of cecal disorders. However, results of studies on the effect of VFAs on cecal motility have been contradictory. In one study, increased concentration of VFA had only minimal effect on large intestine motility and was unlikely to play an important role in the development of cecal disorders.[19] Factors that affect cecal motility, as described for displaced abomasum, are probably similar.

Cecal dilation produces a more gradual onset of illness than that noted with cecal retroflexion or torsion. The time required for dilation to develop into retroflexion or torsion is unknown. With simple dilation, feed intake and milk production decrease. Mild abdominal pain may be observed. Feces are usually still produced, but the consistency may be loose and the amount reduced. Rumen motility is decreased. Distention of the right paralumbar fossa without the ribs being sprung is frequently observed in the authors' clinic and has been mentioned in different reports. However, Braun and colleagues[18] reported that the abdominal shape was modified in only 51 animals of the 461 cattle affected with cecal dilation, retroflexion, or torsion. Of those animals, 22 had a slight distention of the right flank, 20 a bilateral abdominal distention, and 7 a pear-shaped abdomen. The most important clinical findings for the diagnosis of cecal dilation are (1) the presence of a large area of resonance (ping), auscultable from the tuber coxae to a variable distance cranially (see Chapter 1), which may or may not be associated with a positive succussion of the right flank[18];

VetBooks.ir

and (2) the transrectal palpation in the pelvic canal or nearby of the apex of the gas-filled cecum. Cattle with cecal retroflexion or torsion have more severe clinical signs. They show an abrupt onset of anorexia, agalactia, and severe abdominal pain. Tachycardia and forestomach stasis are also present. Feces are scant or absent. The abdominal distention is usually more severe than in simple cecal dilation. The area of resonance in the right paralumbar fossa is larger, and fluid usually can be detected in the cecum and proximal colon by succussion. In cases of retroflexion, the apex of the cecum is usually not palpable rectally; rather, the distended body of the cecum or proximal colon impinges on the pelvic canal because the apex is directed cranially. In cases of cecal torsion, the apex of the cecum can be palpated rectally as well as a tense ileocecocolic ligament that spirals around the cecum.[17] Distention of the small intestine may be palpated with either dilation or retroflexion or torsion.

Although some cows with simple dilation have no acid-base abnormalities, most cases of cecal retroflexion are accompanied by some degree of metabolic alkalosis with hypochloremia and hypokalemia. Hypocalcemia is reported to be observed in approximately 85% of cases of cecal dilation, retroflexion, or torsion.[18]

Medical management of cecal dilation is usually successful with fluid therapy to restore normal hydration status and correction of electrolyte abnormalities, including hypocalcemia. Administration of NSAIDs to control abdominal pain is also important. Laxatives have also been recommended for the medical treatment of cecal dilation. However, Braun and coworkers[20] reported that the use of laxatives (liquid paraffin) for the treatment of cecal disorders delayed the time to first defecation. Moreover, magnesium hydroxide may be responsible for detrimental effects such as metabolic alkalosis,[21] increased ruminal pH,[22] and decreased ruminal microbial activity.[22] Prokinetic drugs that can be used in the management of cecal disorders are presented in the section on the acute abdomen in cattle. Affected animals should be fed a high-fiber diet.

Braun and colleagues[18] reported that 122 of 461 animals with cecal dilation, retroflexion, or torsion were first managed medically. Of these 122 animals, 42 eventually required surgery. Considerations for medical versus surgical treatments are presented in the Acute Abdomen in Ruminants section. Cattle with cecal retroflexion or torsion require immediate surgical intervention, IV fluid, and pain management (NSAIDs). The prognosis for surgical patients depends on the degree of ischemic injury to the cecum and other structures involved in the obstruction. The recurrence rates after surgery range from 10% to 13.8% within a year of the first incident.[18] In cattle with recurrence of cecal dilation or with devitalized portion of the cecum wall, amputation of the cecum is recommended.

Intestinal Tumors

Intestinal tumors are rare in cattle. The most commonly reported intestinal tumors in cattle are adenocarcinomas. However, lymphosarcoma, adenoma, adenomatous polyps, carcinoid, leiomyoma, leiomyosarcoma, and fibrosarcoma have also been described.[23] The incidence of adenocarcinoma in sheep is relatively high in some areas of the world, such as New Zealand.[24] The predisposing factors for adenocarcinomas are not known, but different environmental carcinogens have been suspected.[24,25] In sheep, no association with infectious agents (herpesviruses, *Helicobacter* spp., or *Mycobacterium avium* subsp. *paratuberculosis*) was found.[24] Genetic predisposition is suspected,[25] but no significant genetic defects were found in one study.[24]

Affected cattle or sheep may have a protracted course of weight loss with no other observable signs until near death. Alternatively, there are reports of acute gastrointestinal disturbances manifested by colic, abdominal distention, and auscultable right-sided pings.[26] Although these cases are rare, they must be differentiated from other causes of acute obstruction in cattle such as cecal volvulus, intussusception, or abomasal volvulus. In cattle in which rectal examination is possible, the lesion may be detected on routine examination as an intramural mass or annular constriction of the jejunum or ileum. In sheep, the diagnosis is usually made at necropsy. Clinical signs in affected animals might include diarrhea, abdominal distention caused by the accumulation of gas and ingesta proximal to the obstruction, or ascites. The well-characterized lesions in sheep involve local spread of the tumor through the lymphatic system and intraperitoneally. Ultimately, cellular deposits occur on all visceral and parietal peritoneal surfaces, severely impairing lymphatic drainage from the abdomen.

Mesenteric Fat Necrosis

Mesenteric fat necrosis affects cattle of all breeds, but more commonly Aberdeen Angus and Jersey cattle.[27] It has also been reported in a pigmy goat.[28] The cause remains unknown but dietary factors have been implicated, such as consumption of feed containing long-chain, saturated fatty acids; trace element deficiency; trauma; hormonal disturbance; and ingestion of endophyte-infected fescue.[27,28] The lesions develop as an inflammatory response around degenerating adipose cells. The triglycerides in these cells are thought to undergo hydrolysis to glycerol and fatty acids. Fatty acids with longer carbon skeleton have greater degree of saturation and are more resistant to removal by normal cellular mechanisms. Remaining clumps or crystals of fatty acids serve as inflammatory foci for the subsequent necrotic masses.[27] Affected cattle have subnormal serum levels of free cholesterol and elevated serum levels of free fatty acids.[29] Cattle with fat necrosis may eventually develop an intestinal obstruction. The clinical signs resemble those of progressive intestinal obstruction from other causes. Weight loss, anorexia, diarrhea, bloody stool, abdominal enlargement, and right-sided ping are all possible signs. Fever, tachycardia, and signs of discomfort such as tenesmus, treading, and teeth grinding may be seen as the obstruction becomes more severe. Many affected cattle have no clinical signs, and the condition is discovered during rectal examination for other reasons. Rectal examination may be impossible because of stricture of the rectum, or dystocia may occur as a result of the necrotic fat masses in the pelvic canal. Fat necrosis usually affects mature cattle,[27] but there is a report of a 6-month course of illness attributed to fat necrosis in a 13-month-old Black Angus heifer.[30] Ultrasonographic appearance of abdominal fat necrosis has been described and appears to be a useful diagnostic tool, combined (or not) with ultrasonography-guided mass biopsy.[31]

Animals with fat necrosis that becomes clinical usually are not treated. Different treatments have been attempted over the years, but none was considered effective. Experimental therapy of subclinical fat necrosis with a compound that alters lipid metabolism in fungi was successful in one study.[29] The fungicide isoprothiolane was given at a dosage of 20 g/day PO for 8 weeks. Approximately half of the treated cows had a 50% reduction in necrotic masses by 12 weeks; at follow-up evaluation in 1 year, the masses were not detectable in half the surviving cows. Cows given such unapproved drugs should not be used for food.

Hemorrhagic Bowel Syndrome (Jejunal Hemorrhage Syndrome)

Hemorrhagic bowel syndrome, also called *jejunal hemorrhage syndrome*, is an acute enteric disease of cattle characterized by segmental intraluminal hemorrhage with subsequent obstruction of the small intestine. The disease seems to have been described for the first time in 1991[32] and is now reported in different countries. Hemorrhagic bowel syndrome affects mainly dairy cows, but it is also reported in beef cows and bulls.[33,34] It is

principally a sporadic disease, but outbreaks in dairy herds have been reported.[35,36]

The pathogenesis, causes, and clinical presentation of hemorrhagic bowel syndrome is presented in the Diseases Caused by *Clostridium perfringens* Toxins (Yellow Lamb Disease, Lamb Dysentery, Necrotic Enteritis, Enterotoxemia) section.

The prognosis for animals with hemorrhagic bowel syndrome is guarded. Mortality rates of 100%[33] and 77%[37] have been described. However, prognosis of 55% (20 of 36)[34] and 58% (18 of 31)[38] have been reported from two referral centers. In the first study, two animals of five that were treated medically and 18 animals of 30 treated surgically survived.[34] In the other study, all dairy cows underwent surgery; among the 18 animals that survived, 6 had a recurrence within the following 12 months and 13 were still alive after 12 months. In this study, short-term prognosis was reported to be significantly improved when the blood clot could be dislodged by massage.[38]

Functional Ileus (Pseudoobstruction)

Failure to pass feces usually is a sign of intestinal obstruction. However, in adult lactating dairy cattle, a condition of functional ileus (or pseudoobstruction) of the intestinal tract that mimics complete intestinal obstruction is commonly observed. The condition resolves with medical treatment (fluids, calcium, and pain management); in rare instances, surgical decompression of the affected bowel is required. Affected cows are most often in early lactation, and treatment is sought for partial anorexia. Colic sometimes is the presenting sign. Clinical examination reveals a normal temperature, a normal to elevated heart rate, and normal respiratory rate. Ruminal motility is decreased. Slight right-sided abdominal enlargement may be seen early and may progress to extreme distention of the abdomen on the right. No borborygmi is heard on the right side, but fluid tinkling sounds may be audible. Simultaneous auscultation and percussion reveal areas of variable-pitched resonance. Succussion produces sloshing sounds. On transrectal examination a distended spiral colon, cecum, or small intestine may be palpated. Early in the course of the disease, the distention is mild, and compression easily flattens the affected bowel. If abdominal distention is severe, introducing the arm into the abdominal cavity may be difficult because of the pressure of distended bowel at the pelvic inlet. No feces are passed, but the examiner's arm may be coated with sticky mucus and feces with a stale odor. Serum electrolytes and acid-base status are usually normal or toward a mild metabolica alkalosis. Serum calcium may be decreased. Differential diagnoses to consider include intussusception, intestinal incarceration, intestinal volvulus, and cecal dilation. There is no blood in the feces, and no masses are palpable rectally with functional ileus.

Because most obstructive lesions of the intestine in cattle are not immediately life-threatening, symptomatic therapy combined with close observation may be elected for 24 hours. If surgery is necessary in the absence of an obstructive lesion, the bowel may be decompressed and drained. This is a laborious procedure that requires multiple punctures unless the distention is restricted to the cecum and spiral colon. Despite the lack of correction of a specific underlying defect, many affected cows pass feces soon after an exploratory celiotomy. Manipulation of the intestinal tract alone seems to have beneficial effects. This response is difficult to differentiate from the spontaneous recovery that may occur without surgery in cows. Moreover, medical treatment (IV fluids and pain control medication) is commonly provided during surgery, which makes it difficult to assess the effect of surgery alone. Relief of distention of portions of the intestinal tract may remove reflex inhibition of motility that can occur in response to extreme stretching of mural tension and pain receptors. The cause of functional ileus of the intestine is unknown, and little pathophysiologic information has been elucidated. Medical management is described in detail in the Acute Abdomen in Ruminants section. It mainly includes administration of fluids, calcium, and NSAIDs. Numerous practitioners also administer oral laxatives, but as mentioned earlier, the practice of using magnesium salts may be questionable and could have deleterious effects.

Diseases Caused by *Clostridium perfringens* Toxins (Yellow Lamb Disease, Lamb Dysentery, Necrotic Enteritis, Enterotoxemia)*

Francisco A. Uzal • Bradford P. Smith

Definition and Etiology

C. perfringens is a gram positive, toxin-producing, anaerobic, spore-forming rod that causes a variety of diseases in human beings and animals. Some biotypes are normal inhabitants of soil, and some are commensal intestinal organisms of humans and animals. Clinical isolates have historically been assigned to one of five types (A through E) on the basis of possession of the genes encoding four so-called major toxins (alpha-, beta-, epsilon-, and iota-toxins).This nomenclature has, however, been revised, and two additional toxinotypes, F and G, have been added on the basis of production of enterotoxin (that of *C. perfringens*) and necrotic enteritis B–like toxin, respectively (Table 32.22).[1]

In addition to these six typing toxins, individual strains of *C. perfringens* may produce any of several other nontyped toxins, which may or may not contribute to the virulence of this microorganism, such as perfringolysin O and beta-2–toxin.[2]

C. perfringens enterotoxin is mainly responsible for the second most prevalent type of food poisoning in humans in the United States and also for a less prevalent antibiotic-associated diarrhea; its role in animal disease remains poorly determined.[2] Because the full name of this toxin is *C. perfringens* enterotoxin, the latter should be avoided to refer to other clostridial toxins produced in the intestine.

The different toxinotypes of *C. perfringens* cause diseases that are almost exclusively mediated by their powerful toxin arsenal.[2] Several diseases in many animal species have been ascribed to *C. perfringens*, but the ubiquitous nature of the organism and the fact that it rapidly overgrows into tissues after death makes the significance of its isolation questionable. This is particularly true for type A, which is the toxinotype most commonly found in the intestine of clinically healthy animals and in the environment.[3]

One additional potentially confusing bit of nomenclature concerns the term *enterotoxemia*. Although this term is widely

*The authors gratefully acknowledge contributions to this section in previous editions by Paul G.H. Michelsen.

applied to various diseases caused by *C. perfringens*, it is strictly appropriate only for diseases in which the major signs are caused by systemic spread of a toxin produced in the intestine through the blood. Whereas some *C. perfringens* diseases present as true enterotoxemias (e.g., type D enterotoxemia of sheep), others are characterized by the effects of the toxin only in the intestinal tract (e.g., colitis associated with the chronic form of type D disease in goats) and a third group may show a combination of both forms (e.g., type C infection in multiple species).[4]

Diseases produced by the major types of *C. perfringens* in livestock are discussed in the following paragraphs. Type E is only occasionally isolated from livestock, and its role in animal disease has not been confirmed. Likewise, the newly defined types F and G are not considered to have a significant role in diseases of livestock.[1] These three types are therefore not discussed here.

General Considerations on Diagnosis of Disease Caused by *Clostridium perfringens*

Meaningful diagnosis of *C. perfringens* as the cause of death or disease in an animal requires an integrative, open-minded approach. Type A is routinely isolated from soil and intestine of clinically normal animals. Types C and D are only rarely isolated from soil but can occasionally be isolated from asymptomatic animals. The isolation of *C. perfringens* from a necropsy specimen is therefore not by itself sufficient basis for the diagnosis. However, if some of its toxin is also demonstrated in gut contents and the history and lesions are compatible, a diagnosis of death from *C. perfringens* intoxication can be made. This probably does not apply to alpha-toxin, as this toxin is produced by all types of *C. perfringens* and it is very frequently found in the intestine of clinically normal animals.[3]

Typing of *C. perfringens* is mostly achieved by a multiplex PCR technique that detects the genes for toxin production in a clinical isolate.[1,5] In addition, alpha-, beta-, and epsilon-toxins can be detected with commercially available assays. Meaningful samples for bacterial isolation come from freshly dead animals. Samples of gut contents should be collected into sterile containers and cooled or frozen. Whereas alpha- and epsilon-toxins are very robust and can be detected in samples of intestinal contents many hours or even days after a sample is collected, beta-toxin is very sensitive to the action of trypsin and other proteases and breaks down very soon after production, which causes results to be false negative; freezing or rapid submission of samples to the laboratory for beta-toxin investigation is paramount.[6]

Clostridium perfringens Type A (Yellow Lamb Disease)

C. perfringens type A can be found in many soils and is a normal inhabitant of the gut in many species. Although all seven types of *C. perfringens* produce alpha-toxin, some type A strains may produce more than other types. The toxin is a phospholipase and causes lysis of RBCs, platelets, and leukocytes (equine and caprine RBCs are resistant to the hemolyzing effects of the toxin).[7]

The only type A disease on which there seems to be general agreement among several authors is the so-called yellow lamb disease (so named because of the icteric nature of necropsy specimens from such lambs). This is an uncommon disease characterized by widespread hemolysis, which leads to anemia, weakness, hemoglobinuria, and icterus. Affected animals have a high temperature and usually die within 6 to 12 hours of onset. Differential diagnoses for yellow lamb disease include other causes of hemolytic disease, such as leptospirosis and copper toxicosis. As with other type A infections, the diagnosis is always questionable because of the commensal nature of the organism and its rapid invasion after death. The finding of predominantly large Gram-positive rods in impression smears from intestinal mucosa and high counts (>10^6 colony-forming units/g) of *C. perfringens* type A, lend support to the diagnosis.[7]

Although type A isolates have been suggested to be implicated in enteritis, abomasitis and enterotoxemia of cattle,[8] definitive proof of the role *C. perfringens* in these syndromes is lacking.[2] Type A isolates were also thought to be associated with the so-called hemorrhagic bowel syndrome of cattle,[9] but this does not seem to be the case, and the cause of this syndrome remains undetermined.[3]

Clostridium perfringens Type B (Lamb Dysentery)

DEFINITION AND ETIOLOGY. Lamb dysentery is a disease of young lambs that has been described in Britain, South Africa, and the Middle East. Type B disease has not been reported in the American continent. Its clinical course and presentation are similar to those of necrotic enteritis caused by *C. perfringens* type C.[4,10] *C. perfringens* type B has been postulated, although not proved, to be involved in the pathogenesis of multiple sclerosis in humans.[11,12]

CLINICAL SIGNS AND DIFFERENTIAL DIAGNOSIS. Affected lambs younger than 1 week of age become depressed and die. A yellowish diarrhea becomes brown from blood as the disease progresses. Morbidity rates may be high, and the mortality rate approaches 100%. The disease must be differentiated from types C and D enterotoxemia in lambs.[10]

PATHOPHYSIOLOGY. The pathogenesis of type B infections is not fully understood. On the basis of experimental infections, it was postulated that intestinal lesions are produced by beta-toxin, whereas lesions in the brain are produced by epsilon-toxin.[13] Because epsilon-toxin requires trypsin for activation, whereas beta-toxin is degraded very quickly in the presence of trypsin and other proteases, it is thought that, depending on which of these toxins exerts its major action in a given case, clinical signs and lesions could be different.[13]

Gross and Microscopic Findings. Necropsy findings include necrotizing enteritis and ulcers (rarely perforating) in the small intestines and dehydration of the carcass and tissues. Focal symmetrical encephalomalacia is occationally observed.[10]

DIAGNOSIS. A presumptive diagnosis of type B infection can be made on the basis of clinical signs and lesions, including diarrhea, neurological signs, necrotizing enteritis and, occasionally, focal symmetric encephalomalacia. Confirmation of the diagnosis should be based on detection of epsilon- and beta-toxins in the intestinal content. Isolation of *C. perfringens* type B from intestine adds certainty to the diagnosis, but it is not confirmatory as this type may be occasionally found in the intestine of clinically normal animals.[10]

TREATMENT, PREVENTION, AND CONTROL. Sanitation and the use of type B vaccine aid in prevention and control. Types B, C, and D toxoids cross-protect because of the overlap in toxin types. Treatment is usually unsuccessful because of the acute nature of the disease.[10]

Clostridium perfringens Type C (Necrotic Enteritis, Neonatal Hemorrhagic Enterotoxemia, Struck)

DEFINITION AND ETIOLOGY. *C. perfringens* type C elaborates the alpha-toxins, common to all types, and the beta-toxins. Beta-toxin is the main virulence of *C. perfringens* type C, and it is required for type C isolates to produce disease. The amount of this toxin produced varies greatly among isolates and determines the virulence of a type C strain.[14]

VetBooks.ir

Necrotic enteritis is primarily a disease of neonates and occurs mainly in calves, lambs, foals, and piglets. A similar disease in adult sheep, known as *struck*, has a very limited geographic range in Great Britain.[15,16]

CLINICAL SIGNS AND DIFFERENTIAL DIAGNOSIS. Affected animals may die acutely without diarrhea, but this is rare. The diarrhea may be yellow or, in more hemorrhagic cases, brownish. Gray-red streaks of fibrin and blood which look much like necrotic mucosa may be present in the stools. Foals with type C disease at first show acute abdominal pain, then explosive yellow diarrhea that becomes brown and hemorrhagic. Affected animals become dehydrated, anemic, weak and moribund, despite intensive therapy. Neurologic signs due to epsilon-toxin may be observed in lambs, foals and calves with type C disease. Morbidity and mortality rates are high, but the disease is quite sporadic in occurrence. Salmonellosis and coccidiosis should be considered in the differential diagnosis of ruminants. In foals, the disease must be mainly differentiated from salmonellosis and enteritis produced by *C. difficile* infection.[15,16] Co-infection by *C. perfringens* type C and *C. difficile* may also occur in foals.[17]

PATHOPHYSIOLOGY. The causative beta-toxin is readily destroyed by proteolytic enzymes such as trypsin present in the intestine. Neonates are especially predisposed to beta-toxin attack by the trypsin inhibitor effect of the colostrum, the function of which is to prevent proteolytic degradation of immunoglobulins. The scattered cases of necrotic enteritis in adult animals may be the result of diets containing trypsin inhibitors such a soy bean (high content), beans, peas, peanuts, or sweet potatoes and others. Type C disease has been reproduced experimentally in lambs and goats by administration of type C cultures with soybean flour or other trypsin inhibitors.[18,14]

In humans, type C infection is known as *enteritis necroticans*, *darmbrand*, or *pigbel*, and it occurs sporadically in several Southeast Asian countries and occasionally in other parts of the world. Enteritis necroticans was highly prevalent in the 1960s in Papua New Guinea, where most cases were observed in malnourished children thought to be trypsin deficient.[15,19,20,21]

Ingestion of a protein-rich diet into a protease deficient intestinal tract allows rapid growth of *C. perfringens* organisms, which produce large amounts of beta-toxin that is not destroyed by proteases. Beta-toxin results in necrosis and invasion of deeper intestinal layers. Death results from the direct effects of the severe diarrhea or may be caused by secondary bacteremia or toxemia from the compromised gut barrier.[16]

EPIDEMIOLOGY. Neonates that ingest type C organisms during the first few days of colostrum feeding are at risk. They pick up the organism from an environment contaminated by a symptomatic or asymptomatic shedder, or from contaminated feed. Type C may be isolated from asymptomatic individuals on occasion but it is not usually considered a normal commensal as is type A. Once established on a premise, the disease may become endemic. In foals the disease is significantly associated with housing in a stall or dry-lot during the first few days of life, previous presence of livestock on the farm, low amounts of grass hay fed postpartum, being born on dirt, and having stock horse parentage (e.g., Quarter Horse, Paint).[22]

GROSS AND MICROSCOPIC FINDINGS. Necrosis of the mucosa of the small intestine, especially the jejunum, is the consistent finding in all species. The large intestine may be similarly affected in horses, whereas in other species it may be normal except for intraluminal blood. The peritoneal cavity often contains excessive fluid, which clots when exposed to air because of a high content in protein. The mesenteric lymph nodes may be hemorrhagic. Microscopic study of affected gut shows necrosis and hemorrhage throughout the mucosa and submucosa, as well as mucosal and submucosal thrombosis. The tips of the necrotic villi and the surface of the colonic mucosa are covered with numerous large Gram-positive rods.[15,16]

DIAGNOSIS. Although a presumptive diagnosis may be established on the basis of epidemiologic study and gross and microscopic pathologic study, coupled with isolation of *C. perfringens* type C from feces or intestinal content, confirmation of the diagnosis is based on demonstrating the beta-toxin in these specimens. Because this toxin is so sensitive to the action of proteases, failure to detect beta-toxin does not preclude a diagnosis of *C. perfringens* type C infection.[15,16]

TREATMENT, PREVENTION, AND CONTROL. Once a case becomes clinically apparent, treatment generally is unsuccessful because of the fulminant nature of the disease. Foals can be treated with supportive intravenous broad-spectrum antibiotics (to cover Gram-negative and Gram-positive bacteremia caused by loss of gut integrity), oral metronidazole, fluids, plasma (intravenous and oral), withdrawal of milk for 24 hours, and intravenous *C. perfringens* type C antitoxin. Metronidazole (10 mg/kg PO or IV given twice daily) can be given to at-risk foals during an outbreak, beginning at 8 to 12 hours of age and continuing for 5 days. Toxoid has been administered to horses to control the disease on an apparently endemic property, with good results. Experimental oral treatment with trypsin has been used with apparent promising results. Vaccination is not routinely practiced, but it has proved to be effective in problem herds (J. Glenn Songer, personal communication). *C. perfringens* type C is a common component of multivalent vaccines. Because most cases of type C infection affect neonates, vaccination should be practiced on the dams. The primary vaccination series consists of two injections, approximately 1 month apart, with the final dose given roughly 2 weeks before parturition, and a yearly booster thereafter. Neonates should be vaccinated at 8 and 12 weeks of age on problem farms.[4] Also see Chapter 48, *Clostridium perfringens* toxoids.

Clostridium perfringens Type D (Enterotoxemia, Overeating Disease, Pulpy Kidney Disease)

DEFINITION AND ETIOLOGY. Enterotoxemia caused by *C. perfringens* type D is a disease of major importance in sheep and goats, and of lesser importance in cattle. This type is not a common soil organism, as is type A, but it may be isolated from the feces of a relatively small percentage of apparently normal sheep and goats, and less often, cattle. Most clinical disease occurs in animals fed a highly nutritious diet, especially grain-fed livestock. The disease occurs most frequently in animals older than 2 weeks, but rare cases have been seen in lambs as young as 1 day of age.[23,4]

Clinical Signs and Epidemiology

Sheep. The sudden death of a well-fed, rapidly growing animal is the most common presentation of the acute form of enterotoxemia. The disease may run its course in 30 to 90 minutes, with affected lambs showing ataxia, trembling, stiff limbs, opisthotonos, respiratory difficulty, convulsions, coma, and death. Diarrhea is rarely observed. At the onset of clinical signs, the animal may be hyperglycemic, and at death it may be glycosuric. The differential diagnoses should include other causes of neurologic signs such as listeriosis, enterotoxigenic *E. coli* infection, septicemia, polioencephalomalacia, acidosis, tetanus, and botulism, as well as causes of sudden death such as anthrax and black disease.[4]

Subacute and chronic cases may result in focal symmetric encephalomalacia (see Chapter 35) which causes affected lambs to be dull and unresponsive to normal environmental

stimulation, and show respiratory difficulty. The major differential diagnosis is polioencephalomalacia.[4]

Morbidity rates are usually low, but the nature of the disease may be insidious with cases occurring over several days or weeks. Most affected animals die.[4]

Goats. The disease in goats may be acute, subacute or chronic; the acute form is very similar to the acute form described in sheep, whereas the chronic form is confined to the intestinal tract, mainly the colon, diarrhea being the main clinical sign. The subacute form of type D enterotoxemia in goats includes a combination of the neurologic and respiratory signs observed in the acute form of the disease and the diarrhea characteristic of the chronic form.[4]

As in sheep, morbidity rates are usually low, although outbreaks affecting a significant number of dairy goats have been reported. Lethality rates are also close to 100%.[4]

Cattle. Type D disease occurs rarely in cattle, and information about clinical signs and epidemiologic features in this species is scant. Experimental intravenous injection of type D epsilon-toxin and intraduodenal infusion of culture supernatant of *C. perfringens* type D in calves produced neurologic and respiratory signs similar to those described in the acute and subacute forms of the disease in sheep and goats.[24,25,26]

PATHOPHYSIOLOGY. Some factor of overnutrition, often sudden access to heavy grain feeding or very rich pasture, provides substrate for rapid proliferation of the type D organism, which leads to elaboration of the epsilon-prototoxin. In vitro, production of epsilon-toxin by *C. perfringens* type D is enhanced in the absence of glucose. This seems similar to what occurs in vivo, when an animal is suddenly provided with excessive quantities of starch-rich food but adaptation of the ruminal flora is delayed. As a consequence of this, undigested starch reaches the intestine, and *C. perfringens* type D is likely to take advantage of it. The lack of digestion of starch would also be responsible for the absence of glucose in the small intestine, which enhances epsilon-toxin production.[27,4]

Other factors that alter the intestinal environment (i.e., heavy parasite infestation) may also predispose sheep to type D enterotoxemia.[27,4] Although it has long been assumed that the same factors also predispose goats to type D enterotoxemia, little information is available in this regard, and cases of enterotoxemia have been reported in goats fed hay diets for several months.[4]

In the intestine, cleavage of the relatively inactive epsilon-prototoxin by proteases yields the fully active toxin. Epsilon-toxin thus increases intestinal permeability, facilitating its own absorption into the blood. Once in circulation, epsilon-toxin causes vascular damage with increased vascular permeability, which leads to edema in a variety of organs, notably the lungs and brain, and fluid accumulation in body cavities.[28,29] When affected animals survive 24 hours or more, the edema in the brain leads to parenchymal necrosis, the so-called focal symmetric encephalomalacia.[30] Epsilon-toxin crosses the blood-brain barrier and has also a direct effect on neurons and oligodendrocytes.[29]

GROSS AND MICROSCOPIC FINDINGS

Sheep. In sheep that die of acute enterotoxemia, the carcass is usually in very good nutritional condition. Evidence of diarrhea around the rump may be observed, but this is rare. There is frequently an excess of yellowish pericardial, thoracic and abdominal fluid, which may contain fibrin strands; this fluid clots on exposure to air. Pulmonary congestion and edema and subserosal hemorrhages are evident. Usually there is no visible inflammation throughout the gastrointestinal tract, although the small and large intestine may be hyperemic and moderately distended with gas and liquid content. Softening of the renal parenchyma, so-called "pulpy kidney" may be present in a small number of cases, but it is of little, if any, diagnostic significance, inasmuch as it is probably consequence of accelerated autolysis and this change is never observed in freshly-dead carcasses.[27,3]

In the subacute and chronic cases, the gross lesions are similar to those in the acute form, but herniation of the cerebellar vermis or focal symmetrical encephalomalacia, or both, may be seen in the brain.[27,3]

Microscopic changes in the brain of sheep with type D enterotoxemia are observed in approximately 90% of acute and subacute cases and consist of intramural proteinaceous edema that is perivascular, vascular, or both. Microscopic lesions of focal symmetrical encephalomalacia can be observed in subacute and chronic cases.[27,3]

Goats. Gross lesions in the acute form of the disease are similar to those in sheep, with the exception that brain lesions are very rare. In subacute cases, there is also mesocolonic edema and necrohemorrhagic colitis, which in some cases may extend to the small intestine. Chronic cases show colitis or enterocolitis with usually no involvement of organs outside the gastrointestinal tract.[27,3]

Microscopic changes are usually not seen in acute cases, except for very rare occasions in which perivascular edema of the brain similar to that described for sheep is seen. In the subacute and chronic forms, the main microscopic lesions consist of fibrinonecrotizing colitis, and, less frequently, enterocolitis.[27,3]

Cattle. Type D enterotoxemia occurs very rarely in cattle, and the few cases documented share most clinical and pathological characteristics with the disease in sheep.[27,3]

DIAGNOSIS. In sheep, a presumptive diagnosis of type D enterotoxemia can be based on clinical history, including sudden access to a diet high in carbohydrates, clinical signs, and gross postmortem lesions. Hyperglycemia and glycosuria can be diagnostically useful when present, although this is neither pathognomonic nor consistent. In freshly dead animals, large numbers of Gram-positive rods found in smears of intestinal mucosa support a diagnosis of enterotoxemia. Isolation of *C. perfringens* type D from small or large intestinal content is also supportive of this diagnosis; however, because this microorganism can be found in a relatively small percentage of clinically normal animals, isolation alone is not diagnostic.Confirmation of the diagnosis should be based on one or more of the following: (1) perivascular or mural vascular edema in the brain; (2) focal symmetrical encephalomalacia; and (3) demonstration of epsilon-toxin in intestinal content.

In goats with acute and subacutely disease, the same criteria mentioned for sheep apply, although perivascular edema in the brain is rarely seen. Necrotizing colitis and, less frequently, enterocolitis seen in some acute and subacute cases supports but does not confirm a diagnosis. Confirmation of any of the forms of the disease should be based on detection of epsilon-toxin in intestinal content. In the rare cases in which perivascular edema is seen in the brain, this is considered a diagnostic finding. The diagnostic criteria for cattle have not been established, although it is usually assumed that they are probably similar to those reported for sheep.[27,3]

TREATMENT, PREVENTION, AND CONTROL. If initiated at the first suspicion of overeating disease, type D antitoxin and oral antibiotics (sulfa) may have dramatic results.Vaccination is also recommended in an outbreak, but owners should be cautioned that antibody titers take between 12 and 14 days to appear, so deaths are expected to continue occurring for a while. The use of antitoxin provides passive immunity while active immunity from vaccination has time to occur.

The diet should be adjusted downward (more grass hay, less grain and legumes) in outbreaks to try to minimize the

VetBooks.ir

substrate, especially starch, that reaches the bacteria. Lambs on rich pasture should be moved to poorer pasture or corralled and fed hay until several days after they have been vaccinated twice.

Sheep and goats brought into a feedlot should be vaccinated before arrival, and should have the concentrate ration increased slowly to minimize microfloral disruptions.

Vaccination with type D toxoid is effective in preventing disease. Two doses should be given 4 to 6 weeks apart, to lambs and kids of approximately 2 to 3 months of age, which is when colostral antibody titers fall below protective levels. This should be followed with an annual booster to sheep and revaccination of goats every 3 to 4 months. The annual booster is recommended a week or two before heavy grain feeding or exposure to rich pasture begins or, in dams, 2 to 3 weeks before delivery. The aluminum hydroxide adjuvanted vaccines may cause raised subcutaneous lumps (most noticeable on goats) that may go on to abscess.[27,3]

Oak (Acorn) Toxicosis in Ruminants and Horses

Bradford P. Smith

Definition and Etiology

Toxic signs can appear in ruminants,[1,2] and occasionally in horses,[3] that ingest large quantities of oak buds, oak leaves (green or dried), or acorns. Most species of oak (*Quercus* spp.) cause similar signs when ingested, although there are marked differences in the amount of toxin among the 75 oak species.[4] The metabolites of oak tannins and volatile phenols present in the buds, leaves, twigs, and acorns are responsible for causing toxicosis. The mouth, esophagus, gastrointestinal tract, and kidneys (renal tubular nephrosis) are the organs most affected. Because they are less selective in what they ingest, cattle seem to be the most frequently affected species. Signs begin shortly after ingestion of 50% or more of the diet as oak, and young cattle (weighing less than 300 kg) often appear to be more severely affected than adult cattle. Acorns tend to be relatively low in crude protein (2% to 7%) but high in starch, with variable levels of tannins.[4]

Factors leading to toxicosis include the presence of large acorn crops when forage is scarce, wind or hail that causes large numbers of acorns to drop suddenly, or the sudden presentation of oak buds and young leaves to hungry cattle, as in spring windstorms or snowstorms that cover the grass and break branches. In the southwestern United States, range cattle regularly consume some oak species, which are apparently highly palatable and nutritious.[5] The condition has been described wherever oak grows, including most of the United States, France, Great Britain, Germany, Sweden, Australia, China, and South Africa.

Acorn calf syndrome is completely different from the oak toxicosis described in this section. Acorn calves are congenitally malformed calves born to dams that ingest large numbers of acorns under poor forage conditions during the second trimester of pregnancy. The cause appears to be a combination of poor nutrition and exposure to acorns. The calves have very short leg bones and may have abnormal hoof development and a short or long narrow head (Fig. 32.138). In badly affected herds, as many as 15% of calves are affected. The disease has been reproduced experimentally. Supplementation of the herd with adequate protein and energy eliminates the disease.

Clinical Signs and Differential Diagnosis

The course of oak toxicosis usually is 1 to 12 days, but some cattle have a protracted, debilitating disease.[1,2] In an outbreak in England, the first death from renal failure occurred 21 days after the animals had been removed from exposure and housed.[6]

FIG. 32.138 Acorn calf, a congenital defect from dam which consumed many acorns and low quality forage during gestation. The calf has short legs, abnormal head shape and deformed hooves. This syndrome is different from acute oak/acorn toxicity.

FIG. 32.139 Perirectal and vulvar edema in a 3-month-old calf with acute oak bud toxicity. Acute acorn or oak poisoning causes similar lesions.

In the peracute stages, cattle are recumbent, weak, anorexic, and listless.[1] The rectal temperature is normal or below normal, and the heart and respiratory rates are elevated. Marked edema is present in the perineum and vulva (Fig. 32.139), and edema is obvious in the submandibular area, brisket, and ventral abdomen. Due to the edema, determination of hydration status is difficult, but anuria is present. Firm, dark, mucus-covered feces usually are produced. Evidence of hydrothorax, hydropericardium, and ascites may be noted on physical examination. Some affected cattle may simply be found dead.

A day or two after ingestion, affected animals appear anorexic and listless and have decreased ruminal motility. Many affected calves have hemorrhagic diarrhea or dark diarrhea that tests positive for fecal occult blood. The feces may have a smell of phenol. Dehydration occurs rapidly, but vital signs may be remarkably normal until hypovolemia develops. As uremia progresses, scleral vessels become dark and engorged, and the breath may take on the smell of ammonia. The major differential diagnoses are other causes of renal failure and other toxins and clostridial diseases; viral diseases that cause ulceration of the alimentary tract should also be considered. Protracted cases most often result from renal failure and uremia, although some animals have chronic oral, esophageal, or gastrointestinal ulceration or perforation with abscessation.

VetBooks.ir

In horses, signs usually are peracute or acute; they include sudden death or colic, tenesmus, and hemorrhagic diarrhea.[3] Acorn husks and shells may be noted in the feces. As with most colics, tachycardia, hyperpnea, and injected oral mucous membranes are seen. Abdominal borborygmi often is increased, and hemoglobinuria may occur. Determination of serum or urinary phenolic (hydrolyzed tannin) content, on the basis of a gallic acid standard, may be used in acute cases.[3]

Clinical Pathology

In cattle with peracute and acute signs, the serum urea nitrogen and creatinine levels are elevated, whereas other laboratory values may show considerable variation.[2,3] Initially, hyponatremia, hyperkalemia, hypochloremia, hyperphosphatemia, marked hypocalcemia (5.1 to 6.8 mg/dL) and a mild metabolic acidosis with a very high anion gap (29 to 32) are found.[1] Neutrophilia with mild hyperfibrinogenemia may be present. Although sorbitol dehydrogenase and GGT may be elevated, biopsy does not indicate that significant hepatic disease occurs with oak toxicosis. Affected animals may be anuric. If urine is being produced, often isosthenuria, proteinuria, and glucosuria occur. The urinary fractional excretion of sodium was elevated in one steer.[5]

In protracted cases, the major findings are elevated serum levels of urea nitrogen and creatinine and elevated anion gap, with variable hyponatremia, hypokalemia (as opposed to hyperkalemia in acute stages), hypochloremia, and hyperphosphatemia. A mild metabolic alkalosis may be present. Hyperfibrinogenemia and an increase in total plasma proteins also are variable. An elevated WBC count most often reflects chronic ulceration or abscessation (neutrophilia or monocytosis or both). Liver enzyme levels usually are normal in protracted cases. Urinalysis results are similar to those in acute cases; in addition, hematuria often is present. By 6 weeks after exposure, a normocytic, normochromic anemia may develop as a result of chronic inflammation and uremia, and hypoalbuminemia may result from chronic renal and gastrointestinal losses. By 8 weeks after exposure, surviving cattle have largely returned to normal renal function as determined by normal serum urea nitrogen and creatinine concentrations and by the ability to concentrate urine after a 24-hour water deprivation test.[1]

Laboratory findings in horses are similar to those in ruminants, except that during the acute stages, rapid hemoconcentration and marked increases in PCV occur.[3] Although protein, occult blood, and hemoglobin casts have been reported to be present in the urine, the urine specific gravity was 1.052.

PATHOPHYSIOLOGY. The toxicity of oak is attributed to its high concentration of tannins, which are hydrolyzed in the rumen to gallic acid, pyrogallol, and other compounds. The tannins themselves may contribute to oral, esophageal, and gastrointestinal damage by binding to proteins, including those in epithelial cells. This results in oral, esophageal, and ruminal ulcers or perforations. Protein-bound tannins are liberated in the acidic abomasum, making them available once again to damage intestinal epithelium. Some hydrolyzed tannins are absorbed and bound to plasma proteins and endothelial proteins, which results in hemorrhage and fluid loss from the vascular compartment into body cavities and tissues; this results in edema. The gallic acid and pyrogallols are extremely toxic to renal tubules, causing acute tubular necrosis, anuria, electrolyte abnormalities, and uremia. Ruminants are more susceptible than horses because of the hydrolysis of the gallotannins in the rumen.

EPIDEMIOLOGY. Young cattle weighingh 100 to 300 kg seem to be particularly susceptible. In the southwestern United States, oak toxicosis accounts for considerable economic loss in cattle.[5] The disease is seen sporadically in other ruminants and in horses. Adult cattle fed 10 kg of fresh oak leaves preceded by feed restriction experienced a critical reduction in rumen fermentation along with acute oak toxicity. Adult cattle that were not feed restricted did not develop oak toxicity.[7] The morbidity rate in cattle varies considerably, with several to many calves in a pasture usually affected, and case fatality rates frequently exceed 80%.[2]

The disease is most often associated with ingestion of acorns in the fall and buds or young leaves in the spring. Cattle turned onto a pasture with oak trees under which acorns have accumulated may have toxicosis even when adequate forage is available.[2] In other cases windstorms have dropped numerous acorns or branches in a pasture to which cattle were already accustomed. In the early spring, a heavy, unseasonable snowstorm may cover the grass, bend young trees, and break branches so that oak buds and young leaves are accessible.[1] Young leaves and acorns are more palatable than older leaves and also contain more tannins (up to 10% dry matter in acorns). The seedlings, buds, and acorns of small scrub oak may be important forages for cattle in parts of the United States.[5]

Necropsy Findings

In peracute and acute cases, prominent edema is often the most striking lesion. Ascites, hydrothorax, hydropericardium, perirenal edema, and subcutaneous edema are found. The kidneys are normal in size with multiple diffuse hemorrhages on the surface and extending into the cortex. The liver is slightly swollen and pale or mottled. Digestive tract lesions vary from congestion to hemorrhage and deep ulceration or perforation with necrotizing inflammation. Mucosal ulceration is found in the pharynx, esophagus, rumen, abomasum, small intestine, cecum, and colon. Free blood or melena may frequently be observed.

Diffuse renal tubular damage is present. The changes include coagulation necrosis of cortical tubular epithelium and dilated tubules devoid of epithelium but with intact basement membranes. Many medullary tubules contain hyaline, granular, or cellular casts. The principal renal lesion is necrosis of the proximal convoluted tubules, but glomerular degeneration and fluid in Bowman capsules are also seen.

By 3 to 6 weeks after exposure, the lesions include gastrointestinal ulceration, often with secondary infection; some healed ulcers; secondary bacterial bronchopneumonia; and slightly swollen, pale brown kidneys. Histologically, atrophy of the cortical tubular epithelium with a marked interstitial fibrosis and mononuclear infiltrate is seen. Evidence of tubular epithelial regeneration may be present. The liver appears normal.

Treatment and Prognosis

In acute stages, intravenous fluid therapy aimed at promoting diuresis and correcting acid-base and electrolyte abnormalities is indicated. Calcium, sodium, and chloride deficits should be replaced, and sodium bicarbonate should be given if needed to correct metabolic acidosis. In anuric animals, furosemide (1 mg/kg given IV) can be administered every 12 hours, along with adequate fluid therapy. Corticosteroids and NSAIDs are not likely to have a measurable effect on the course of the disease because they are unlikely to alter the direct toxic effects of the metabolites. The prognosis is guarded and must be considered poor in animals that remain anuric despite therapy. The case fatality rate undoubtedly depends more on the amount of toxic material ingested than on therapy. Antibiotics, given to prevent secondary pneumonia and abscessation, ruminal transfaunation, and readily accessible grass hay and water, are recommended components of nursing care.

If the animal survives the acute stage and begins to eat voluntarily, the prognosis for recovery is good unless secondary pneumonia or gastrointestinal abscessation after perforation occurs. Renal function can return to normal by 5 to 10 weeks,

VetBooks.ir

and weight gains as high as 1.76 kg/day have been recorded in recovered cattle.[1]

Colicky horses can be treated as usual for colic (intravenous fluids, analgesics, oral laxatives). Particular attention should be paid to diuresis, acid-base balance, and maintenance of serum calcium levels.

Prevention and Control

No specific antidote exists for oak toxicosis, but supplementation with calcium hydroxide (hydrated lime) immediately before anticipated exposure to oak has been effective under experimental conditions.[8] Feed containing 10% or less calcium hydroxide is palatable. Consumption of 0.9 kg/head/day of cubed or pelleted supplement containing 10% hydrated lime is effective in preventing toxic manifestations.

Supplementation of cattle suddenly exposed to oak with any feed reduces death losses, apparently by allowing hungry cattle to consume the supplemental forage preferentially.[1,8] In an outbreak in California caused by spring snows in which 2700 cattle died of oak toxicosis, ranches where hay was immediately supplemented had fewer losses than did ranches where feed supplementation was not offered.[1]

Winter Dysentery in Cattle (Bovine Coronavirus)

Gilles Fecteau • Charles L. Guard

Definition and Etiology

Winter dysentery is an acute, contagious diarrheal disease of cattle (especially dairy) that occurs in epizootic manner in a herd, usually during the colder months of the year (November to April). It is usually recognized by the clinical syndrome that occurs in herds and by exclusion of other causes of contagious diarrhea.[1] In the United States the disease is more common in the northern states; it has also been reported in Australia, Sweden, the United Kingdom, Israel, France, Belgium, Japan, and Canada. The period of illness in an individual is brief (a few days to a week), and within a herd the outbreak usually lasts less than 2 weeks. Recovery is spontaneous in most individuals, but in some cases, supportive therapy is necessary. The morbidity rate is usually high (from 30% after a few days to almost 100% after 1 week to 10 days). Mortality, however, is usually rare.

The cause of winter dysentery is a bovine coronavirus that may be related (antigenic differences are reported) to the coronavirus that causes diarrhea in neonatal calves.[2-7] By immune electron microscopy, antigenic cross-reaction has been demonstrated between the original Nebraska calf coronavirus diarrhea agent and coronavirus isolated from field outbreaks of winter dysentery.[4,6]

Clinical Signs and Differential Diagnosis

Winter dysentery is an explosive diarrheal disease accompanied by some degree of anorexia and depression. In lactating cows, milk production is severely reduced. If the diarrhea is severe or persists longer than one or 2 days, dehydration may develop. Loss of body condition is apparent. Rumen motility usually is reduced, but intestinal borborygmi may be increased. Thirst often is increased, and polydipsia follows the diarrhea. Rectal examination may reveal dilated intestinal loops. The feces vary from light tan to dark brown; bubbles commonly form in the puddles that are deposited several feet behind the cow. Blood may be present in the feces of several animals in a group, typically in the first-lactation cows. The amount of blood may range from just visible to large clots, or it may be uniformly mixed into the feces. Some animals may have thick mucus in the feces. The odor in a barn during an outbreak of winter dysentery has been described as musty, fetid, and sweet and nasty.[8]

Fever usually is not present during the diarrheal phase of the disease but has been reported to precede it[1] or have no consistent relationship.[9] Mild respiratory signs consisting of serous nasolacrimal discharge and a soft cough have been inconsistently observed before diarrhea. Diarrhea caused by BVDV, coccidiosis, and salmonellosis must be considered in the differential diagnosis of winter dysentery. With winter dysentery, no mucosal lesions are visible on physical examination. The absence of coccidial oocysts or parasite ova in the feces helps exclude these agents as responsible for the diarrhea. The rapid occurrence of multiple cases within a herd, and often within several herds in a locality, suggests winter dysentery. Fecal culture for *Salmonella* yields negative results in uncomplicated cases of winter dysentery.

Clinical Pathology

No consistent hematologic changes that would be of diagnostic benefit have been observed. If significant dysentery persists for longer than a day, signs of anemia may develop.

Pathophysiology

Epithelial cells of colonic crypts are destroyed by viral action, which leads to necrosis and hemorrhage. Even though histologic changes have been observed only in the colonic mucosa, blood was observed from the distal duodenum aborally in cattle that died of winter dysentery.[7] Loss of intestinal mucosal epithelium from colonic crypts leads to transudation of extracellular fluid and blood.

Epidemiology

The incubation period is thought to be 2 to 8 days. The most susceptible animals are first and most severely affected. In a small, housed herd, the typical incidence of diarrhea during an outbreak begins with the explosive appearance of signs in 10 to 15% of animals on the first day. The second day, another 20 to 40% are affected. On subsequent days, similar proportions become ill. By the end of a week, the first affected animals are completely recovered, and only a few new cases occur. Typically within 2 weeks of the onset of diarrhea, all animals have recovered. This period is marked by significant reduction in milk production. In large herds the outbreak may be prolonged for 6 to 8 weeks. This scenario is typical of a herd that had not experienced an epizootic of winter dysentery during the preceding few years. In some herds, milder outbreaks occur annually, with fewer animals showing diarrhea and with less severe clinical signs.

Treatment and Prognosis

Most animals with winter dysentery recover spontaneously in a few days without specific treatment. Many palliative treatments have been recommended and used over the years. On the basis of 30 years of observations, Roberts[10] considered none of these treatments to alter the course of the disease. Provision of adequate fresh water, palatable feed, and free-choice salt is the most useful nonspecific therapy. The occasional animal with prolonged or severe dysentery may need a transfusion of 4 to 8 L of whole blood.

Salmonellosis in Ruminants

Bradford P. Smith

Definition and Etiology Salmonellosis is one of the few diseases that appear to be increasing in prevalence, especially in dairy cattle. In addition, more than one million human cases of nontyphoidal salmonellosis occur yearly in the United States (90 million worldwide), and so this is an important public health concern. *Salmonella* serovar Dublin was isolated from the bloodstream of 60% of 228 human patients suffering from

VetBooks.ir

Salmonella serovar Dublin infection in the United States; 74.9% required hospitalization and 3.7% died, and so it is considered the most severe nontyphoidal *Salmonella* infection in humans. Twenty eight per cent of isolates were resistant to sulfas, tetracycline, ampicillin, chloramphenicol, amoxicillin-clavulanic acid, and ceftriaxone.[1]

Large dairy farms are more likely to be infected with *Salmonella* than are small dairy farms.[2] Milk yield decreased significantly in affected herds, and the reduction was detectable several months after the increase in bulk tank milk *Salmonella* antibodies. It took more than 1 year for milk yield to return to preinfection levels.[3] According to one study, 75% of dairies sampled in California had evidence of *Salmonella* infection.[4] A multistate study demonstrated that 56% of dairies sampled contained cows shedding *Salmonella* in feces.[5] *Salmonella* of concern for livestock belong mainly to one species, *Salmonella enterica* subsp. *enterica*, with numerous serovars or serotypes, such as *S. enterica* subsp. *enterica* serovar Typhimurium, with the words *serotypes* and *serovars* used interchangeably.[6] (In this text, the terms are shortened it to, for example, *Salmonella* Typhimurium by convention.) More than 2500 *Salmonella* serotypes (serovars) have been identified, and many are potential animal and human pathogens. Multidrug-resistant *Salmonella* Typhimurium DT104 (serogroup B) and *Salmonella* Newport (C2) are particularly virulent in animals and human beings. New variants occur; a variant of *Salmonella* Typhimurium designated I 4,[5],12:i:– lacking one H antigen has been a cause of clinical disease in cattle in the USA (Table 32.23; personal communication from Brenda R. Morningstar-Shaw, National Veterinary Services Laboratory, USDA, 2018). The presence of identical strains of *Salmonella* Newport among bovine and human isolates indicates that zoonotic transmission is likely to occur.[7] Fortunately, only 10 serotypes of *Salmonella* in serogroups B, C, D, E, and K are responsible for most disease in cattle; therefore control programs can be aimed at these.

Table 32.23 lists the serotypes most commonly isolated from ill cattle in 2016 in the United States. Group K, not long ago considered an exotic serogroup, has become prevalent (number 2).[8] *Salmonella* organisms are Gram-negative enteric bacteria that are facultative intracellular parasites. Most serotypes are non–host-specific, but a few are host-adapted. *Salmonella* Dublin is host-adapted to cattle, *Salmonella abortus ovis* and *Salmonella* Arizonae to sheep, and *S. abortus equi* to horses. Host-adapted serotypes are found most often in their host species, where true long-term carriers exist.[9] In contrast, non–host-adapted serotypes rarely achieve carrier status and usually infect an animal for a period of 3 to 16 weeks before infection is cleared,[9] although one cow with multidrug-resistant *Salmonella* Newport excreted the organisms for 190 days.[7] Infection with either host-adapted or non–host-adapted serotypes can be symptomatic or asymptomatic, depending on the dose, the virulence of the serotype, and the host's immune status. There appears to be an association between an increased incidence of *Salmonella* infections and intensive management practices such as large farms, crowded conditions, and high-protein diets. In the absence of carriers, chain infections and persistence of *Salmonella* in the environment are responsible for long-term persistence of a given strain on a given dairy.[7]

Salmonella are grouped into serogroups (A to Z and 51 to 65), depending on their cell wall antigens (somatic antigens that comprise specific oligosaccharides, often called *O antigens*, *LPSs*, or *endotoxin*). Thus for example, local and regional laboratories often report that an isolate is a group D *Salmonella*. The most common group D isolate of cattle is *Salmonella* Dublin, although nonmotile isolates that do not express flagella at that time also can be found. The author and colleagues found that these would express motility and be typed as *Salmonella* Dublin if the isolate were inoculated into semisolid media where it had to move to get nutrition (Smith BP, personal observation). Final confirmation that the *Salmonella* isolated is indeed *Salmonella* Dublin comes from the National Veterinary Services Laboratory in Ames, Iowa, or from some other laboratory in which antisera and facilities exist for identification of all 2500 serotypes on the basis of flagellar (H) antigens and somatic (O) antigens. Some serotypes also express capsular (Vi) antigens composed of mucopolysaccharide under some conditions. Identification of the serotype is important in planning control strategies. In addition to the serotypes listed, lambs may be infected with *Salmonella* Arizonae, which comes from several different serogroups. *Salmonella* organisms are relatively easy to culture from the feces or tissues of infected animals, with the use of common enteric agar such as Hektoen Enteric, XLT4 or brilliant green agar, with tetrathionate and selenite as selective enrichment media.

TABLE 32.23

Most Frequently Isolated *Salmonella* Serovars or Serotypes From Ill Cattle in the United States in 2016[a]

Order of Frequency	Serovar or Serotype (Serogroup)	Total	Percentage
1	Dublin (D1)	332	23.5%
2	Cerro (K)	275	19.5%
3	Typhimurium (B)	142	10%
4	Montevideo (C1)	110	8%
5	Heidelberg (B)	101	7%
6	Newport (C2)	67	5%
7	I 4,[5],12:i:-* (B)	54	4%
8	Anatum (E1)	33	2%
9	Kentucky (C3)	26	2%
10	Muenster/ Meleagridis (E1)	22 each	1.5% each
All others		226	16%
Grand Total		1414	100%

[a]Variant of Typhimurium.

Data supplied by Brenda R. Morningstar-Shaw, National Veterinary Services Laboratories, United States Department of Agriculture, Ames, IA, 2018.

Clinical Signs and Differential Diagnosis

Salmonella infection can cause a variety of clinical signs. The most common signs are fever and diarrhea[10] after an incubation period of 1 to 4 days after exposure or a recrudescence from the carrier state. Ruminants of all ages may be affected, but serious illness is observed most frequently in very young animals and parturient dairy cattle.

The character of the diarrheic feces varies from watery to mucoid with fibrin and blood. Sheets of fibrin may look like sloughing mucosa. The feces often have a putrid, foul odor because of the presence of plasma proteins associated with severe inflammatory bowel disease. Salmonellosis causes an acute protein-losing enteropathy. The systemic effects of endotoxins (and other toxic material) absorbed through the damaged bowel mucosa may be severe (fever, anorexia, depressed attitude, and shock).

Bacteremia may occur rapidly, especially in neonates infected with *Salmonella* Dublin, Typhimurium, or Newport. Peracute to acute septicemia in calves may produce lesions in many organ systems. Affected calves usually are younger than 2 months of age (the range is 1 day to 6 months). Dyspnea, respiratory symptoms, sudden death, and occasionally diarrhea are the principal signs of *Salmonella* Dublin infection, the incidence of which usually peaks in 6-week-old calves. Blood

VetBooks.ir

culture results frequently are positive. Pure cultures of *Salmonella* Dublin often can be grown from specimens from the lungs of 4- to 8-week-old calves with pneumonic (septicemic) salmonellosis. Calves infected with *Salmonella* Typhimurium are only 14 days of age on average (the range is 1 to 35 days) and have mainly enteric lesions, including enlarged mesenteric lymph nodes, abomasitis, fibrinonecrotic plaques in the ileum, and hemorrhage of Peyer's patches.[11]

Dry gangrene of the extremities may occur in calves after *Salmonella* infection, particularly with *Salmonella* Dublin. Legs, ears, and tails are most commonly affected, and cold agglutinins are suspected to be involved.[12]

A strain of *Salmonella* Saint Paul was implicated in an outbreak of encephalopathy (without encephalitis) in stressed Holstein calves.[13] Calves exhibited diarrhea, head tilt, ataxia, auditory hyper-responsiveness, and partial blindness. The β-lactam antibiotics ceftiofur and ampicillin protected against the neurological effects by increasing glutamate export from the brain despite resistance of the *Salmonella* St. Paul isolate to both drugs.[14]

In adult cattle, diarrhea or abortion may occur.[9] Abortion may occur by two mechanisms because both culture-positive and culture-negative fetuses and placentae may be found in an outbreak. In the former, bacteremia in the dam results in infection of the placenta or fetus, with resulting fetal death and expulsion. Bacteremia, endotoxemia, and fever associated with diarrhea and damaged gut mucosa in cattle may result in release of prostaglandin $F_{2\alpha}$ and subsequent lysis of the corpus luteum. Abortion follows in 2 to 3 days, and the fetus and placenta yield culture-negative findings. When the fetus has a culture-negative finding, many other causes of abortion must be considered. Many infectious agents that infect only the dam can act similarly to cause luteolysis and abortion.

Differential diagnoses for the enteric form of salmonellosis in neonates include all the common enteropathogens of neonates: *Escherichia coli*, rotaviruses and coronaviruses, clostridia, cryptosporidia, and other forms of coccidia. Concurrent infection with these agents is common. In older animals outbreaks should be differentiated from those caused by BVD, winter dysentery, and feed-induced indigestion. Pneumonic and bacteremic salmonellosis in 4- to 8-week-old calves must be differentiated by culture from pneumonic pasteurellosis; in goats, from mycoplasmal infection; and in lambs, from septicemic pasteurellosis.

Clinical Pathology

Salmonella enteritis often results in changes in the hemogram,[15] as effects of endotoxin manifest.[16] Plasma fibrinogen frequently is elevated because of the inflammatory nature of the disease, and either neutrophilia or neutropenia may be seen. In severe cases a left shift may be present. Initial dehydration may result in an elevated PCV and plasma protein level. The plasma protein level often drops over a period of days as protein is lost into the bowel lumen. Many other nonspecific abnormalities in clinical chemistry values are often seen, including elevated liver enzymes, decreased plasma calcium, and indications of prerenal azotemia if dehydration occurs.

Definitive diagnosis of salmonellosis requires culture of the organism from feces, blood, or tissues. PCR is also available. Culture was most sensitive and specific in comparison with ELISA and PCR.[17] Pooled fecal cultures from five cows provide a sensitivity of 62.5%, in comparison with individual samples from culled dairy cows.[18]

Pathophysiology

Salmonellae are invasive organisms that may penetrate ocular, nasal, oral, or intestinal mucous membranes. Once eaten, salmonellae attach to mucosal cells, probably by means of a nonfimbrial adhesion.[19] Attachment is increased if gastrointestinal stasis is present or the normal competitive flora has been disturbed or is not yet established, as in neonates. Salmonellae cause degeneration of nearby cells and penetrate both through microvilli and through tight junctions between cells.[20] The *Salmonella* type III secretion system translocates five *Salmonella* effector proteins (SipA, SopA, SopB, SopD, and SopE2) into enterocytes, and is required for induction of diarrhea by inducing intestinal fluid secretion and recruiting neutrophils to the infection site. [21] The bacteria also pass through the enterocytes to the lamina propria, where they stimulate an inflammatory response and are engulfed by macrophages and neutrophils.[22] Intracellular bacteria reach regional mesenteric lymph nodes or beyond. The organism has a predilection for lymphoid tissues and is found in highest numbers in Peyer's patches and mesenteric lymph nodes.[23] This is one reson why culturing mesenteric, iliac and other lymph nodes is useful. Thrombi form in vessels, and tissue damage can be severe. Virulent salmonellae are capable of surviving in host tissues and multiplying, often as facultative intracellular parasites in macrophages and reticuloendothelial cells.[24] In the case of carrier animals, salmonellae survive in cells in the presence of high titers of specific extracellular serum immunoglobulins. This is the basis for using ELISA serologic testing to detect *Salmonella* Dublin carriers. Intracellular salmonellae can also avoid many antimicrobial drugs and complement. Stress may cause a latent infection to recrudesce, which results in fecal or mammary gland shedding or clinical disease.

The cell wall of all Gram-negative bacteria contains LPS as a component. LPSs are also called *endotoxins*, and they are extremely biologically active, setting off an immunologic cascade of events that can lead to leukopenia, fever, anorexia, and eventually shock and death.[16]

Epidemiology and Control

Salmonella infection is most often transmitted by fecal-oral contamination from livestock or rodents, or by feeding of contaminated protein source animal by-products (e.g., fish meal, meat meal, bone meal, or feather meal, many of which are contaminated) or contaminated forages or plant proteins such as soybean or cottonseed. Of cattle feed tested for *Salmonella* in 2010, approximately 6.1% was positive, according to U.S. Food and Drug Administration surveillance data. Even if small numbers of organisms are initially present, they multiply rapidly in moist warm conditions.

Salmonella Dublin is an endemic herd problem and is shed by lower numbers of animals compared with *Salmonella* Typhimurium, which tends to be epidemic and shed in higher numbers by many more animals at a time.[25] In 2009 in the northeast United States, in 11% of 831 herds with suspected clinical cases of salmonellosis, the leading isolates were *Salmonella* serovars Newport and Typhimurium.[26] A study of calves in California found that 18% of 1-day-old calves shed some serotype of *Salmonella*, but this percentage declined rapidly over the first 11 weeks of life. Perhaps even more alarming, a fetus may be infected with *Salmonella* in utero and thus vertical transmission occurs as well.[27] *Salmonella* Typhimurium, Muenchen, Cerro, and Kentucky were isolated from mesenteric, subiliac, and prescapular lymph nodes and calves at parturition.[27] Farms that received calves from other sources were 35 times more likely to have calves that were shedding *Salmonella* in feces than were closed herds.[28] *Salmonella* Dublin, Newport, and Typhimurium can also be tranmitted via colostrum and milk.[29]

Infection with host-adapted *Salmonella* serotypes may occur as a cyclic endemic disease, especially in calves when *Salmonella* Dublin is involved. *Salmonella* Dublin infections on a farm are maintained by carrier animals shedding *Salmonella* Dublin in the feces[9] or milk,[30] chain infections in infected calves and cows, rodents, and environmental contamination. *Salmonella* carriers infected with a host-adapted serotype such as *Salmonella*

Dublin may shed constantly or intermittently. Cattle with the highest risk of becoming *Salmonella* Dublin carriers are heifers infected between 1 year of age and first calving and cows infected in the parturient period,[31] but calves surviving *Salmonella* Dublin infection and illness may also become carriers (BPS personal observation). Infected carriers that are not shedding are called latent carriers; stress may cause shedding in feces or milk to recrudesce. A single infected, asymptomatic fecal shedder may produce over one billion *Salmonella* Dublin organisms per day to contaminate the environment (one million organisms per gram of feces). Unlike most other serotypes, *Salmonella* Dublin may be carried as a chronic gut and mesenteric lymph node infection and passed in feces or carried as an intramammary infection and passed in contaminated milk.

Calving areas must be constantly cleaned and disinfected between calvings. Raw milk feeding to calves may be a source of *Salmonella* (100 to 100,000 organisms per milliliter of milk).[30] Raw milk must not be allowed to sit unchilled, as this allows *Salmonella* and other pathogens to multiply (numbers can double every 20 minutes at 100 F (37C). Acidification of milk to a pH lower than 4 for 2 hours can effectively eliminate most pathogens, including *Salmonella* spp. and *M. bovis* from milk; acceptance of taste by calves may be an issue with some acidification techniques.[32] Infected calves constantly amplify the number of organisms in the environment, causing exposure of other calves. Calves with clinical signs may shed billions of *Salmonella* into the environment daily. See Chapters 19 and 20 for more on calves.

Environmental contamination can be difficult to eliminate because salmonellae survive for months in moist areas out of direct sunlight and in lagoons and drainage areas. Cows shed more *Salmonella* on a commercial dairy in hot weather by a factor of 4.5X for every 5C rise in ambient temperature.[33] *Salmonella* Dublin was recovered from feces dried for 41 months.[34] Freezing feces at –20°C (–4°F) kills 85% of salmonellae in 2 days and more than 95% by 1 month.[35] Direct sunlight and drying in hot weather are effective at eliminating salmonellae. Using composted manure for bedding can be effective: *Salmonella* Newport survived less than 24 hours in composted manure reaching 69°C (115°F) but survived for more than 4 months in the lagoon and more than 9 months in soil.[36]

Research has documented contaminated irrigation water as an important source of *Salmonella* organisms. In some cases municipal sewage treatment plant effluents had contaminated water.[37] On one dairy farm, river water used to sprinkler irrigate green chop contaminated the green chop, which was fed to cows.[38] On another farm, *Salmonella*-contaminated river water was used to irrigate cotton. When the cottonseed from that gin was used as feed, cattle became infected.[38] On a third dairy farm, contaminated irrigation water resulted in haylage containing *Salmonella* organisms.[38]

Feedlot cattle colonized by *Salmonella* organisms could pose a public health risk when meat is contaminated at slaughter. In a study by National Animal Health Monitoring System, 7.5% of cattle on feed the longest shed salmonellae, whereas 3.5% of cattle that had recently entered the feedlot were shedding salmonellae in the feces.[39] A study of 68 feedlots in 12 states found that 9.1% of 5050 fecal samples were positive for *Salmonella* and 64.7% of feedlots had at least 1 positive sample, and that fewer than 10% of isolates were resistant to antimicrobials other than sulfas and tetracyclines.[40] Contamination of the animals before entry can cause the entering cattle to have a higher rate of shedding than was found in cattle that had been in the feedlot for several months.[41] A major difference in the incidence of *Salmonella*-positive lymph nodes was found between two different feedlots and in time on feed, with cattle on feed more than 120 days having 94% (17/18) *Salmonella*-positive lymph nodes.[42] These lymph nodes are believed to be a major source of contamination for beef.

Standing water contaminated with feces is frequently highly contaminated with *Salmonella;* culture of temporary shallow lakes (called *playas* in the southwestern United States) yielded numerous *Salmonella* serotypes.[43] An unusual outbreak of *Salmonella* Newport in cows and calves on a beef farm resulted in a cow mortality rate of 7.9% (32 of 407) and a calf mortality rate of 14.4% (52 of 361). BVD virus was also diagnosed in the group, and it was suspected of playing an immunosuppressive role.[44]

Control of *Salmonella* infection requires an integrated herd approach.[45,46] Pens of sick animals were found to be 7.4 times more likely to yield *Salmonella* than were pens of preweaned calves.[47] Management interventions that were found effective in helping control *Salmonella* on dairy farms include separation of sick and parturient cattle into hospital and maternity pens, respectively (considered the most important and effective intervention), switching from a phenolic disinfectant to a peroxygen biocide such as Virkon S (DuPont, Sudbury, U.K.) for equipment disinfection, use of separate footwear or footbaths for personnel in the hospital and maternity pen sections, strict protocols for disinfection of hands and equipment between handling each sick or periparturient cow, strict separation of feeds used in the hospital and maternity pens, and use of clean bedding in the hospital and maternity pens.[7] Having one person manage the calves, good colostrum management, and not purchasing cattle from an infected premise had beneficial effects in reducing infection.[48]

To detect herds infected with *Salmonella* Typhimurium or Dublin, a herd serologic profile based on ELISA can be used.[49] The commercial test available in the United States is the PrioCHECK *Salmonella* Ab bovine ELISA (Prionics, Switzerland). One laboratory that runs such tests on milk or serum is the Animal Health Diagnostic Center at the College of Veterinary Medicine, Cornell University. Rectal swab sampling and culture of culled dairy cows was found not to be a satisfactory method of detecting *Salmonella*-infected herds.[50] To control *Salmonella* Dublin, carrier cows and calves older than 6 months of age are identified by serologic testing (ELISA) for anti-*Salmonella* antibody.[30,51-53] Suspect animals are culled or tested further by serologic means or by multiple fecal cultures and milk cultures (five samples at weekly intervals). Strongly positive results of serum ELISA tests over an 8-month period are considered to indicate carrier status.[54] Animals with positive test results are culled. In infected herds, *Salmonella* Dublin carriers (fecal or mammary) usually make up 0.4% to 3% of a dairy herd. A Danish study[55] showed that only 14 of 31 persistently seropositive animals were culture positive for *Salmonella* Dublin at postmortem examination, and one seronegative animal was culture positive. One study found that ELISA serologic testing had a good negative predictive value for cattle 100 to 300 days of age, whereas fecal culture had a poor predictive value.[56]

To control all non–host-adapted and host-adapted serotypes of *Salmonella*, calves and cows are promptly treated when signs of illness occur, and strict procedures to prevent the spread of infection are instituted. A study of 14 farms infected with *Salmonella* Typhimurium DT104 showed that clinical disease ceased by 4 months, but widespread infection and contamination continued. Over time the number of infected farms gradually declined, and vaccination correlated positively with a herd remaining free of clinical illness from DT104.[57] Control measures include the use of separate feeding utensils for each calf, washing of boots and hands by calf raisers between calves, isolation of ill calves to noncontact pens, and thorough disinfection of pens between calves. Decontamination of pens is most effectively accomplished if an all-in, all-out system is used. Pens are divided into four groups, with each group of pens used for calves born during a given week. When 3- to 4-week-old calves leave their pens as a group, these pens are cleaned

VetBooks.ir

and disinfected with a chlorine product such as bleach, a peroxygen product such as Virkon S, or a phenylphenolic disinfectant (also see Chapter 46 for more on disinfection). This helps prevent continuous recycling of bacteria to each group of new calves. Environmental monitoring by frequent swab cultures of pens is the best way to check the effectiveness of the sanitation and disinfection program.

Infection with *Salmonella* Typhimurium and other non–host-adapted serotypes most often occurs as an epidemic after the organisms enter the farm by means of feedstuffs, purchased cattle, rodents,[58] or rendering trucks. Even *Salmonella* Dublin may be maintained on a farm by mice.[59] A case control study of farms infected with *Salmonella* Typhimurium DT104 found that the most effective interventions included purchasing cattle directly rather than through a sales yard, quarantining purchased cattle for 4 weeks, housing sick cattle in dedicated isolation areas, and preventing wild bird access to feed storage areas.[60] Feeds may be contaminated by irrigation water,[38] in manufacturing when by-product ingredients contain *Salmonella* organisms, on the farm, or in shipment by birds or rodents or contaminated trucks. When an epidemic involving a common or exotic serotype occurs, feedstuffs should be examined as a likely source. Exotic serotypes are *Salmonella* from serogroups other than B, C, D1, E1, and K; that is, all those groups not listed in Table 32.23. High-protein supplements, rumen bypass protein, or calcium-phosphorus supplements of animal origin are sources of epidemics of various *Salmonella* serotypes in livestock. Many animal by-product feedstuffs in the United States are contaminated with *Salmonella* organisms. Once a *Salmonella* serotype enters a herd, the bacteria are rapidly spread among livestock and into the environment, where they may cause a prolonged course of herd illness and can be difficult to eliminate. Such appeared to be the case with *Salmonella* Newport and *Salmonella* Montevideo in dairy cattle in California in the past (Table 32.24). These and other group C *Salmonella* spp. tend to become endemic and persist for years on a dairy farm once it has become infected. By 2016, *Salmonella* Montevideo was the fourth and *Salmonella* Newport the sixth most prevalent serotypes from ill cattle in the United States (see Table 32.23; National Veterinary Services Laboratory data). Culture of feeds before use on a farm currently is the only means of preventing the introduction of new *Salmonella* serotypes via feedstuffs because national and international feed quality controls currently appear to be inadequate.

TABLE 32.24

Changing Incidence of *Salmonella* Serotypes (Serogroup) From Ill Calves on California Dairy Farms, 1985 to 1988

Serotype	Percentage *(n)* of Farms From Which Each Serotype Was Isolated	
	1985–1986	1987–1988
Dublin (D1)	78 (29)	53 (49)
Newport (C2)	19 (7)	36 (33)
Typhimurium (B)	3 (1)	7.6 (7)
Montevideo (C1)	0	6.5 (6)
Infantis (C1)	0	2.2 (2)
Anatum (E1)	0	1.1 (1)
Muenster (E1)[a]	0	1.1 (1)

[a]Formerly called "S Arkansas."

From Blanchard P, Anderson M. Unpublished data based on calves brought for necropsy to the laboratories of the University of California, Davis, Veterinary Medicine Teaching & Research Center and the California Animal Health & Food Safety (CAHFS), Tulare, Calif., from Tulare area farms, 1988.

VACCINATION. Control by vaccination of dams with killed bacterins may be somewhat beneficial in protecting neonates under 3 weeks of age through colostral and milk immunoglobulin. Because most dairy calves are taken from their dam and fed milk replacer after day 1 to day 3 of age, the potential benefit of intraluminal milk antibody from the dam is lost. This may account in part for the fact that vaccination of cows by itself often is insufficient to protect dairy calves from salmonellosis. In neonates over 3 weeks of age, colostral immunity appears to play only a small role in protecting against salmonellosis. Because both humoral and cell-mediated immunity are important in protecting against salmonellosis,[60-62] active immunity is superior to passive. Modified live-virus, genetically altered vaccines that stimulate humoral and cell-mediated immunity offer better protection for calves than do killed whole cell vaccines.[62,63]

The role of increased nonspecific immunity to Gram-negative core antigens (through immunization with rough mutants of *E. coli* and salmonellae lacking complete cell walls) has been investigated. Some studies have been able to demonstrate an increased survival rate for salmonellosis after vaccination with a mutant strain of *E. coli* (J5),[64] designed to produce antibodies to the common core antigens of Gram-negative bacteria. Two such products available in 2012 are Enviracor J-5 (Zoetis, Florham Park, N.J.) and J-Vac (Merial, Duluth, Ga.). Endovac-bovi (Re mutant *Salmonella* Typhimurium bacterin-toxoid produced by Immvac Inc., Columbia, Mo.) is marketed with the same goal.

Available commercial *Salmonella* vaccines are killed whole-cell bacterins for use in cattle and a genetically altered modified live *Salmonella* Dublin vaccine for calves (EnterVene-D [Boehringer Ingelheim Vetmedica, St Joseph, MO]. Although the vaccine is to be given subcutanously, some practitioners report that they have used the live vaccine orally and found it to be effective but with fewer adverse reactions than when used parenterally. EnterVene-D was used in dry cows without any observed adverse reactions, and produced an increase in colostral antibody against *Salmonella* Dublin, but no natural or experimental challenge was given to assess its effectiveness.[65] The only products that are solely *Salmonella* vaccines contain (1) *Salmonella* Typhimurium, (2) *Salmonella* serovars Typhimurium and Dublin, (3) live *Salmonella* Dublin organisms, or (4) siderophore receptor protein (SRP) *Salmonella* Newport subunits (also see Chapter 48). Autogenous bacterins can be made for serotypes not commercially available when they are isolated from animals on a farm and believed to be the causative agent of disease. A subunit SRP vaccine called *Salmonella* Newport Bacterial Extract vaccine is being marketed by Zoetis for vaccination of cattle against *Salmonella* and other Gram-negative bacteria.

Siderophores (SRPs) are iron chelating proteins produced by all *Salmonella*, so producing antibodies against SRPs from *Salmonella* Newport should theoretically be effective for all serotypes of *Salmonella*, and because they are a subunit, they should be less toxic. The initial vaccination requires 2 doses at 2- to 4-week intervals, followed by a yearly booster. The SRP vaccine did not decrease fecal shedding in feedlot cattle (which were mainly shedding *Salmonella* Montevideo [C1] and *Salmonella* Anatum [E1] and not *Salmonella* Newport [C2]).[66] To the author's knowledge, no peer reviewed controlled studies documenting the effectiveness of this SRP vaccine at controlling salmonellosis have been published as of early 2018. A major problem associated with *Salmonella* bacterins and modified live *Salmonella* vaccines is adverse reactions. Adverse reactions vary from fever, depression, and anorexia to collapse and death after vaccination. Affected animals may have severe reactions after the first, second, or third dose. The apparent cause of these severe reactions is a high degree of sensitivity to the presence of Gram-negative endotoxin, which results in a rapid immune cascade that leads to shock.[16] This sensitivity is genetically

VetBooks.ir

controlled, possibly accounting for the high frequency of adverse reactions in one herd and their absence in a neighboring herd. High ambient temperatures also increase sensitivity to the adverse effects of endotoxin. Adverse reactions usually can be averted or reversed with epinephrine (1 mL of 1:1000 [1 mg/mL] for every 50 kg of body weight given IM or IV) as soon as evidence of polypnea, dyspnea, or weakness appears.

Lack of efficacy of killed *Salmonella* bacterins in calves is evident in experimental studies. Commercial bacterin vaccines in aluminum hydroxide administered directly to calves at 2 and 4 weeks of age failed to protect the calves when they were orally challenged at 6 weeks of age.[64] Other research has demonstrated protection in older vaccinated calves that were challenged intravenously.[67] Calves younger than 12 weeks of age do not serologically respond with anti-LPS antibodies after vaccination with two or three doses of killed bacterins in aluminum hydroxide.[68] On the other hand, calves older than 12 weeks of age and cows do respond serologically to two doses of the same vaccine.[69] The ELISA titer in cows is short-lived (2 to 4 weeks); therefore the timing of vaccination before parturition is critical if the aim is to increase the anti-*Salmonella* colostral immunoglobulin G titer.[69] Under experimental conditions, calves fed colostrum from vaccinated dams were not protected against oral challenge at 3 weeks of age.[15] One report suggests that vaccination with killed *Salmonella* Typhimurium vaccine prevented reinfection and recrudescence of clinical signs after an outbreak of DT104 and helped in eliminating the organism from the farm.[59] As mentioned previously, these differences may in part be explained by whether a calf continues to receive milk from its dam and thus has or does not have intraluminal antibodies. Other live vaccines have been found effective in calves and capable of cross-protection against other serotypes, including a DNA adenine methylase–deficient *Salmonella* Typhimurium[70] and an avirulent live *Salmonella* Choleraesuis strain 54,[71] but neither was licensed for cattle in the United States as of 2018.

Necropsy Findings

ENTERIC FORM. Many affected calves are emaciated and have serous atrophy of fat. Especially with *Salmonella* Typhimurium, the ileal, cecal, or colonic mucosae may be thickened and hemorrhagic with adherent fibrinonecrotic plaques. Fibrin may be found in sheets, especially pronounced in the areas of Peyer patches. The abomasum, duodenum, and jejunum are often involved but less severely. The abomasum usually contains brown, fetid liquid. Bowel contents often are watery and may contain fibrin, blood, or both.[11] The mesenteric lymph nodes frequently are enlarged and dark. Chronically affected cows or calves may have discrete areas of necrosis in the cecum or colon that may involve the entire thickness of the wall.[11]

SEPTICEMIC FORM. Gross lesions of bacteremic *Salmonella* infection are acute and usually subtle. *Salmonella* Dublin is often septicemic in calves. Serosal and subcutaneous petechiae are widespread. The spleen usually is enlarged. The lungs are edematous and fail to collapse and have random foci of hemorrhage or congestion.[11] The wall of the gallbladder is thickened and may contain hemorrhages. The bile frequently is inspissated into a firm coagulum.[11] Less common lesions include jaundice, cystitis, meningitis, osteomyelitis, arthritis, and dry gangrene of ears, tail, or feet. Gastrointestinal lesions may or may not be present. Histopathologic study of *Salmonella* Dublin in calves younger than 6 months old demonstrates pulmonary alveolar capillary neutrophilia with or without hepatocellular necrosis and paratyphoid granulomas, splenitis and lymphadenitis.[72]

Treatment

The keys to successful treatment of bacteremia caused by Gram-negative bacteria are (1) antimicrobial drugs, (2) fluids and electrolytes, and (3) NSAIDs. *Salmonella* Typhimurium antiserum is available commercially. Adverse reactions by cattle to horse serum are common; care should be taken.

Early in the course of disease in calves, appropriate antimicrobial therapy often increases the survival rate markedly because bacteremia frequently occurs. Appropriate antimicrobial therapy depends on culture and antimicrobial sensitivity patterns. Many of the most virulent *Salmonella* types are now multidrug-resistant, but isolates of relatively nonpathogenic *Salmonella* on dairies and feedlots found on surveys are usually sensitive to most antimicrobials, or resistant only to tetracyclines and sulfas.[28,73] In general, most pathogenic *Salmonella* isolates are sensitive to florphenicol, ceftiofur (and other third-generation cephalosporins), trimethoprim-sulfonamide, gentamicin, amikacin, and fluoroquinolones such as enrofloxacin.[24,28] Higher than label doses of ceftiofur used in calves with experimentally induced *Salmonella* Typhimurium infections did not alter mortality rates but did reduce fecal shedding and promote more rapid clearance.[74]

Sulfas and fluoroquinolones may not be used extralabel in food animals in the United States. Aminoglycosides such as neomycin, gentamicin, and amikacin produce long-term tissue residues and should be avoided in animals intended for use as food. Susceptibility to ampicillin, amoxicillin, sulfas, and tetracycline varies considerably, whereas resistance to penicillin, streptomycin, erythromycin, and tylosin is anticipated. Trimethoprim-sulfonamide combinations are relatively inexpensive, especially when given orally, but oral trimethoprim-sulfonamide should be used only in calves younger than 3 weeks of age. In calves older than 3 weeks of age, trimethoprim should be given intravenously because it is destroyed in the rumen and not absorbed. Antimicrobial drugs such as fluoroquinolones, florfenicol, or trimethoprim-sulfonamide that achieve good intracellular levels and have a large volume of distribution appear to be more effective than those that do not achieve good intracellular levels (e.g., gentamicin and amikacin). Florfenicol or cephalosporins such as ceftiofur may be good choices for therapy against many *Salmonella* isolates depending on susceptibility testing results. *Salmonella* strains resistant to fluoroquinolones and ceftiofur are also being discovered.[75] In a Minnesota study, researchers examined *Salmonella* from clinically ill cattle (2006 to 2015) and found that *Salmonella* Dublin, Montevideo, and Cerro became more frequent during those years, and none of the isolates were resistant to enrofloxicin or gentamicin, but 11% were resistant to trimethoprim-sulfonamide, 27% to neomycin, 37% to ceftiofur, 43% to florfenicol, 47% to ampicillin, 52% to oxytetracycline, and 83% to sulfadimethoxine.[76] A similar study in Wisconsin also demonstrated no isolates resistant to enrofloxacin.[77] Only 1 in 380 *Salmonella* organisms randomly collected from fecal floor samples in feedlots was resistant to fluoroquinolones despite the fact that a fluoroquinolone was used as the primary therapeutic antimicrobial to treat bovine respiratory disease in these feedlots.[78]

Antimicrobial drugs may not be effective at altering the clinical course of strictly enteric infections without bacteremia, but because bacteremia frequently accompanies salmonellosis, systemic antimicrobial therapy often is chosen. A very large precise genotyping and phylogenetic study comparing cattle and human isolates of *Salmonella* serovars Dublin and Typhimurium suggests that antimicrobial resistance genes are associated primarily with a particular host species with little overlap.[79] Another whole genome analysis concluded that the animal and human isolates of *Salmonella* Typhimurium DT104 were different, with only a small amount of spillover in each direction.[80]

In the United States, FARAD's VetGRAM must be consulted to ensure correct drug route, frequency, dose, withdrawal time, and legality.

VetBooks.ir

The effects of endotoxins can be partially dampened or controlled by the judicious use of NSAIDs. The cascade of events caused by bacterial endotoxin (LPS from the cell wall) must be brought under control early and rapidly, by the use of drugs such as flunixin (Banamine) at a dose of 1.1 to 2.2 mg/kg IV every 12 hours. Once the animal is stabilized, NSAIDs should be discontinued, as continued administration can lead to adverse side effects such as abomasal ulceration.

Intravenous fluid therapy to maintain blood volume and pressure and correct acid-base or electrolyte abnormalities is important in any animal that is dehydrated or in shock (see Chapter 20, Neonatal Diarrhea section; this chapter, Fluid Therapy section, for adult equine; and Chapter 44, Critical Care section). Measurement of blood gases and electrolyte values assists in fluid therapy formulations. Balanced fluids containing sodium, with supplementation of glucose, should be administered intravenously as needed. Metabolic acidosis with mixed water and electrolyte losses is most often seen. Oral fluids and electrolytes may also be effective supplements. The prognosis is good if animals are treated aggressively and early in the course of illness.

Control of Infectious Disease in a Veterinary Hospital

Veterinarians must also be aware of preventing the spread of *Salmonella* and other nosocomial diseases within an animal hospital and should have an effective written infectious disease control program in place.[81] See Chapter 46 for more details. In one study, 1.4% of cattle, mostly from dairy farms, shed salmonellae when in a veterinary clinic,[82] whereas the author has found an average of 7% of cattle (mainly dairy cows) ill with a variety of disorders in the author's large animal clinic were shedding *Salmonella*.

Clusters of cases occurred mainly in August and September in one northeast U.S. veterinary hospital, with 15 different serotypes involved; the most common were Typhimurium (33%), Newport (23%), and Agona (12%).[83]

Paratuberculosis (Johne's Disease)

Raymond W. Sweeney

Paratuberculosis is a chronic enteric disease of ruminants caused by infection with *Mycobacterium avium* subsp. *paratuberculosis (MAP)*. Cattle, goats, sheep, deer, and camelids are most commonly affected, but the disease is also reported in wild ruminants and other species. In the United States, at least 68% of dairy herds have *MAP*-infected animals, with a much lower prevalence among beef herds (7.9% in one study).[1,2]

The causative organism, *MAP*, is a hearty organism that survives for prolonged periods in the environment, including soil and water. However, it has fastidious growth requirements in vitro, and culture on solid media may require 8 to 16 weeks. Results of studies indicate that *MAP* is also able to assume a spore-like bioform that is resistant to heat treatment in vitro, which may account for the organism's ability to survive pasteurization.[3] In vivo, the organism is an intracellular pathogen with the ability to survive within macrophages by preventing the maturation and acidification of the phagocytic vacuole. The term *Johne's disease* is often used to refer to the clinical syndrome of diarrhea and weight loss that results from *MAP* infection.

Transmission and Susceptibility

Paratuberculosis is most commonly transmitted by the fecal-oral route. The organism is shed in the feces of infected animals (usually adults) and ingested by susceptible (usually young) animals. Critical points for potential exposure include maternity pen surfaces, cows' udders, contaminated feed or feeding implements, and calf housing areas. Small amounts of manure from heavy-shedding animals can result in vast contamination and exposure of susceptible young stock. Results of studies have also shown that *MAP* may be aerosolized and spread with dust barns with infected animals, which raises the possibility of exposure through inhalation, or oral ingestion of organisms where contaminated dust has settled on feeding utensils and other objects.[4,5] The organism can also be shed directly into colostrum and milk of infected cows, or these products can be contaminated by organisms on the skin, at the time of collection if insufficient sanitation is practiced. Transplacental transmission has been demonstrated and becomes more likely to occur (40% of fetuses from cows with clinical signs) as the infection progresses to advanced stages.[6,7]

Resistance to infection with *MAP* in calves increases with the age of the animal, with neonates considered particularly susceptible. Most studies indicate that calves older than 6 months of age are less susceptible, and by the age of 1 year, susceptibility is equivalent to that of an adult animal.[8,9] Although adult animals are more resistant to infection than juveniles, natural resistance in adult animals can be overcome by exposure to high doses of *MAP* organism. Furthermore, if infection with *MAP* occurs in an adult animal, the animal may be culled during the prolonged incubation period for other reasons before clinical manifestations of paratuberculosis are recognized. In addition to age, the exposure dose influences not only whether an animal becomes infected but also the rate of progression of the disease. Exposure to higher doses of *MAP* is thought to lead to more rapid progression of the infection and manifestation of clinical disease at a younger age.[9] Finally, there is growing evidence that genetic factors may play a role in susceptibility. Evidence gleaned from studies of breed differences, sire line differences, and DNA markers or candidate genes have indicated a clear genetic influence on susceptibility to *MAP*.[10] In the near future it may be possible to identify sires and dams with decreased susceptibility to *MAP* for breeding purposes.

Pathogenesis and Stages of Infection

Although tonsillar invasion by *MAP* after oral ingestion in calves has been demonstrated experimentally, most evidence suggests that the intestinal epithelium, particularly the ileum, is the usual portal of entry. The Peyer's patches are populated by specialized intestinal epithelial cells (M cells) that deliver the *MAP* organisms to macrophages in the submucosa of the intestine.[11] The progression of infection from this point is determined by a balance of the host's innate and adaptive immune response against the ability of the *MAP* organisms to evade destruction. In the early phases of infection, macrophages activated by T-helper type 1 (Th1) cytokines, such as interferon-gamma (IFN-γ), are able to limit proliferation of *MAP* and expansion of the infection.[12,13] Some animals might even eliminate the infection at this stage.[14] In those animals that do not clear the infection, the *MAP* infection is kept in check by the immune system, with limited slow progression initially. However, this comes at a cost to the host, and the persistent presence of *MAP* antigen in the intestinal and gut-associated lymphoid tissue incites a chronic inflammatory response. Inflammatory cells are recruited to the area, which results in granuloma formation with *MAP*-laden macrophages, epithelioid cells, lymphocytes, and multinucleate giant cells.[12] This period of insidious, slow proliferation is associated with a clinically silent "eclipse" phase, during which there is neither detectable fecal shedding of *MAP* nor detectable serum antibody production. Tests of specific cell-mediated immunity, such as detection of IFN-γ production in vitro after peripheral blood lymphocyte proliferation, might yield positive results during this eclipse phase, but are not available on a practical basis at this time.

Eventually, the host cell-mediated immune response is no longer able to contain the infection. The previously effective

VetBooks.ir

Th1-type response is replaced by development of a T-helper type 2 (Th2)–type response with elaboration of cytokines such as IL-4 and IL-10, which are associated with antibody production and waning of cell-mediated immunity.[16] Although there are no outward signs of clinical disease, and production is not yet affected, detectable fecal shedding (at a low level) begins at this stage, followed by development of detectable antibodies.[17,18] The asymptomatic fecal shedder has the potential to spread the disease within herds or between herds without arousing suspicion, as it appears clinically healthy.

As the infection progresses, *MAP* organisms begin to spread to extraintestinal sites, either via blood or through the lymphatic system. This can result in transplacental infection, and direct shedding in milk and colostrum, as noted earlier. Fecal shedding of *MAP* also increases, so that high levels of fecal shedding may be detected before clinical signs are observed. In this subclinical phase of infection, effects on production parameters in dairy cattle are variably affected. A 16% reduction in milk production during the lactation preceding culling has been reported, with little (4%) or no reduction in the penultimate lactation.[19,20] Studies on the effect of *MAP* infection on parameters of reproduction efficiency (days open, pregnancy rates) and udder health (somatic cell count) have had conflicting results.[20,21] In one study, days open was greater in infected cows[21] yet another showed a greater number of days open in infected cows.[20] Results also vary depending on the diagnostic method used to identify cases. Most studies show no deleterious effect on somatic cell count.[20] Because the effect of *MAP* infection on these production parameters is usually not evident, producers are often reluctant to cull asymptomatic infected cows, as the animals remain apparently productive members of the herd.

Ultimately, the *MAP* infection, and accompanying inflammatory response, progressively leads to severe granulomatous infiltration of the bowel, causing thickening of the intestinal lining, with clubbing of villi and marked lymphangiectasia. The resulting maldigestion and protein-losing enteropathy result in the clinical syndrome recognized as Johne's disease.

Clinical Johne's Disease

The hallmark clinical sign of Johne's disease in cattle is watery (pipe-stream or projectile) dark green diarrhea. The diarrhea is not associated with tenesmus, blood or mucus is not typically present, and the animal does not exhibit fever, dehydration, or inappetance, but rather maintains a good appetite and possibly increased water consumption. Rapid weight loss usually accompanies the diarrhea, and edema due to hypoproteinemia develops in the submandibular and brisket areas (Figs. 32.140 and 32.141). Clinical laboratory tests will reveal hypoproteinemia, hypoalbuminemia, and possibly anemia of chronic disease. In this stage of the infection, *MAP* organisms are shed in the feces in massive quantities and these animals can serve as an important source of environmental contamination. Differential diagnosis might include severe parasitism, renal amyloidosis, or copper deficiency. If the animal is not culled at this point, progression to end-stage Johne's disease, with inappetance, cachexia, and death, ensues. Postmortem examination reveals grossly visible thickening and increased corrugation of the lining of the epithelium, and potentially enlargement of the mesenteric lymph nodes in the ileocecal region. Histopathologic examination reveals the aforementioned granulomatous inflammation in gut and associated lymphoid tissue, with macrophages laden with acid-fast staining bacilli.

In sheep, goats, and camelids, diarrhea may not be a prominent feature of clinical Johne's disease as it is in cattle. Although watery feces may sometimes be found, more often, feces may be normal or lose their pelleted form and take the form of dog stool. Weight loss is prominent, and the hypoproteinemia with submandibular edema is a frequent finding.

FIG. 32.140 A Guernsey cow exhibiting clinical signs of Johne's disease, including thin body condition and fecal staining on hind end. *(Courtesy Dr. Robert H. Whitlock, Kennett Square, Pa.)*

FIG. 32.141 Holstein cow exhibiting submandibular edema associated with clinical Johne's disease, hypoproteinemia, and protein-losing enteropathy. *(Courtesy Dr. Robert H. Whitlock, Kennett Square, Pa.)*

Goats, in particular, may become quite anemic, more than might typically be expected with anemia of chronic disease. Of course anemia, hypoproteinemia, and weight loss may be exacerbated by concurrent intestinal parasitism, which may initially obscure the diagnosis of Johne's disease. Johne's disease in farmed deer may differ in that there may be a shorter incubation period with rapid progression to clinical disease with diarrhea and emaciation. Also, postmortem examination of deer with Johne's disease may reveal caseation or calcification, or both, of mesenteric lymph nodes.[22]

Diagnosis

The available diagnostic tests are divided into two broad categories: (1) immune-based diagnostic tests that detect the host's antibody or cell-mediated immune response to *MAP* infection, and (2) organism detection tests that detect *MAP* organisms or *MAP* bacterial DNA in fecal or tissue samples.

IMMUNE-BASED TESTS. Tests of cell-mediated immunity include the intradermal Johnin test, which is similar to a tuberculin test, and in vitro lymphocyte stimulation with *MAP* antigens with detection of IFN-γ production. The intradermal Johnin test is generally regarded as unreliable because of both

VetBooks.ir

false-positive and false-negative reactions. Stimulation in vitro of peripheral blood lymphocytes with antigens of *MAP*, followed by detection of IFN-γ in cell culture supernatant, has shown the ability in a research setting to detect animals early in the course of *MAP* infection, in the eclipse phase before antibody production and fecal shedding are detectable. However, the tests are not available in a practical commercially available setting.

The most commonly applied immune tests are those that detect antibodies in serum or milk. These include the complement fixation test, the agar gel immunodiffusion test, and ELISA. The ELISAs have superior performance to the complement fixation or agar gel immunodiffusion tests when applied to serum from cattle, but some nations still list complement fixation or agar gel immunodiffusion testing as an import requirement. The ELISA is the most specific and sensitive of the commercially available antibody tests. It may be applied to serum or milk, and studies have shown comparable results when ELISA is applied to both matrices. The ELISAs are attractive because of their relatively low cost and amenability to automation, which makes testing of large numbers of samples practical and cost-effective. Many Dairy Herd Improvement Association services now offer the option to include Johne's ELISA testing on milk samples, adding to the convenience of testing. Preservatives added to Dairy Herd Improvement Association milk samples do not interfere with milk ELISA testing.

Antibody detection tests are hindered only by the natural biological features of the disease, in that infected cattle do not ordinarily produce detectable antibodies until after fecal shedding has begun. Thus the sensitivity to detect asymptomatic cattle that are "low fecal shedders" may be as low as 15%, whereas 90% of clinically affected, "heavy shedding" cattle are positive. The ELISAs generally have high specificity (98% to 100%).[23,24]

ORGANISM DETECTION TESTS. Organism detection tests on fecal samples include both culture and PCR detection methods. They have the advantage over antibody-based tests in that they (1) generally allow detection earlier in the course of infection because fecal shedding usually precedes antibody detection; (2) allow quantification of the degree of fecal shedding to assess the biosecurity effect of individual animals; and (3) definitively identify *MAP* in a herd at the time of first diagnosis. They have the disadvantage of being more expensive than ELISA and, in the case of culture, requiring a long incubation period to obtain results. Cultures performed on solid Herrold's Egg Yolk Medium may require up to 16 weeks for incubation. Many laboratories now employ a liquid culture system that can shorten the culture time to 1 to 2 months. Commercially available real-time PCR tests for fecal samples also permit quantification of *MAP* shedding and have sensitivity comparable to or better than culture. The specificity of culture and PCR methods is generally regarded as 100%, but it should be remembered that when *MAP*-contaminated feed is consumed by uninfected cattle, the *MAP* organisms may pass through the gastrointestinal tract and cause a transient positive result on fecal PCR or culture. A list of USDA-approved or accredited laboratories for Johne's disease testing is available at the USDA Animal and Plant Inspection Service (USDA-APHIS) website (https://www.aphis.usda.gov/aphis/ourfocus/animalhealth/lab-info-services/sa_approved_labs/ct_approved_labs).

TESTING SCENARIOS. Diagnostic tests should be selected on a case-by-case basis, depending on the clinical scenario, the objectives of the producer, and the inherent advantages and disadvantages of each test. For example, to confirm the diagnosis of Johne's disease in an adult cow with weight loss and diarrhea, a clinician will not have the luxury of waiting for fecal culture results before making a culling or treatment decision. Thus a test with rapid turnaround time is indicated, and both ELISA and fecal PCR would provide rapid results with a high predictive value positive (or negative). If the case in question is the index case in a herd, then organism detection would be more appropriate than ELISA, to provide a definitive confirmation that *MAP* is the etiologic agent because the implications of a diagnosis for the herd may be great. Postmortem demonstration of typical lesions and identification of *MAP* by culture of mesenteric lymph node or ileum can also be used to confirm a diagnosis.

An alternative objective might be to identify infected asymptomatic cattle in a herd that is known to be infected with *MAP*, for purposes of culling in an eradication program, or segregation for calving pen or colostrum management. In higher prevalence herds, serum or milk ELISA can be used if the magnitude of the ELISA result is used to interpret the results (i.e., as opposed to just "positive" or "negative"). Animals with a negative ELISA result, even if infected, are probably not shedding *MAP* in feces, milk, or colostrum at a significant level. Animals with "low positive results" are more probably shedding *MAP* in feces and might remain in the herd if production is good, but their status should be kept in mind when managing calving pens and colostrum. "High positive" ELISA results suggest heavy fecal shedding and a potential significant source of farm contamination; affected cows should be culled as soon as possible. Although more expensive, fecal culture or PCR can similarly be used to identify asymptomatic infected cattle with greater sensitivity than ELISA. Where management/control is the objective, a low positive result will warrant appropriate calving pen and colostrum management but not necessarily culling, whereas a high positive result may warrant sooner culling. In an aggressive eradication program, any fecal culture positive result might result in a decision to cull, either immediately or at the end of the lactation. Testing can be performed on an annual, whole-herd basis, or in some systems, cows can be tested at the time of drying off. With this method, if ELISA, fecal culture with liquid medium, or fecal PCR is employed, the results will be available before calving to guide management decisions.

A third scenario is to determine whether a herd has *MAP* infection or to document test-negative or low-prevalence status for certification programs. One of the more cost-effective methods for this purpose, on dairy farms, is to perform fecal culture or PCR on environmental fecal samples collected from areas with high cow traffic and from the manure pit or storage lagoon. Culturing from 5 to 6 such sites has been shown to detect at least 70% of herds with infected animals.[25]

The USDA-APHIS Uniform Program Standards for Voluntary Bovine Johne's Disease Control Programs (VJDCP) provide testing guidelines for establishing herd infection status. Although individual states' programs may vary, the current standard establishes six classification levels. Levels 1 to 3 identify herds with low test-positive prevalence, or herds with 1 year of all-negative test results, whereas levels 4 to 6 identify herds with 2 or more years of test-negative results, with level 6 having the highest certainty of infection-free status. Herds establish classification status by whole herd (or statistically determined subset for large herds) ELISA or organism detection testing (individual samples or pooled). The reader is referred to the VJDCP Program Standards for more information about more detailed testing requirements (https://www.aphis.usda.gov/animal_health/animal_diseases/johnes/downloads/johnes-ups.pdf).

Finally, testing may be desired to screen animals purchased as herd replacements or for use as embryo transfer recipients. Unfortunately, currently available tests are not useful for detecting infection in these animals, which are often of a young age (<3 years) and in the "eclipse" phase of infection. Greater

VetBooks.ir

assurance of likelihood of infection-free status in young stock can be obtained through testing of adult animals in the herd of origin. Purchasing animals from herds that have achieved VJDCP classification level 4 or above will give the greatest assurance that the animals are not infected. If the seller does not participate in a VJDCP, results of comparable testing on adult cattle older than 3 years of age in the herd should be requested. If such results are not available, purchase is extremely risky and should be avoided. A potential but less desirable recommendation is to screen potential replacements by ELISA and fecal PCR, recognizing that if the animal is in the eclipse phase, false-negative results are possible, and continued monitoring on an annual or semi-annual basis after addition to the herd is warranted.

NONBOVIDS. In goats, serum ELISA and fecal culture and PCR have similar accuracy to that found in cattle. However, serum testing for antibodies in sheep is less reliable, and organism detection tests on feces are recommended. The sheep strain of *MAP* is more difficult to grow in vitro than the cattle strain that affects dairy cattle, beef cattle, goats, and camelids in the United States. Development of specialized liquid media for culture of *MAP* from sheep feces has improved sensitivity, but best results will probably be achieved by employing fecal PCR testing. In camelids, PCR and culture in liquid media have similar sensitivity to detect *MAP* in feces.

Treatment

In most production situations, treatment for *MAP* infection is not attempted. However, in some cases treatment may be desirable to allow for preservation of genetics (e.g., through embryo transfer or in vitro fertilization), or for sentimental reasons, especially those animals viewed as pets. Before undertaking treatment, the owner must be made aware that treatment may result in remission of clinical signs and reduction of fecal shedding, but the infection is rarely eliminated, and daily treatment will probably be required for the life of the animal, with relapse likely to occur when treatment is discontinued. Treatment of a clinically affected pregnant cow to salvage her fetus is not recommended because of the high likelihood of transplacental infection of the fetus. In addition, any chemotherapeutic program will involve extralabel use of antimicrobials, which in the United States must be performed in accordance with the regulations set forth in the Animal Medicinal Drug Use Clarification Act. As reliable withdrawal times are not established for many of the antimicrobials employed in treatment of Johne's disease, owners should be informed that once treatment begins, the animal or its products should never enter the human food supply chain.

The therapeutic agents most often employed include those used to treat mycobacterial infections in humans (isoniazid, rifampin, clofazimine), monensin, and aminoglycosides, and combination therapy is often recommended, at least to induce remission.[26] Clofazimine, an antileprosy drug, has been used successfully by the author at a dose of 2 mg/kg q24h, alone or in combination with other agents. Improvement in fecal consistency and plasma total protein occurred within 7 to 14 days of starting treatment. However, this drug has not been available in the United States, prompting use of other combinations. Thus a typical currently employed treatment protocol, if clofazimine is not available, for cattle, goats, sheep, and camelids includes rifampin (10 mg/kg PO q24h) and isoniazid (10 to 20 mg/kg PO q24h). Again, because of its potential carcinogenicity, rifampin is not appropriate for extra-label use in animals intended for food and should thus only be used in pet animals or animals that will never enter the human food chain. Gentamicin (6.6 to 8.0 mg/kg IV q24h) for the first 5 to 10 days of treatment may hasten onset of remission, provided renal function is normal and can be monitored for signs of nephrotoxicosis. For cattle, monensin should also be recommended. Approved for its effect as a coccidiostat and for its effect on rumen microflora and digestion efficiency, momensin has also been shown to inhibit *MAP* growth in vitro and improve the signs and lesions of disease in experimentally and naturally infected cattle.[27,28] Use of monensin as a feed additive also has the potential to play a chemoprophylactic role in prevention of *MAP* infections in susceptible cattle. However, monensin as a feed additive cannot be used in an extra-label fashion in the United States, so the intended animal must have a label indication for use of monensin, not solely treatment of *MAP*.

Prevention and Control

For herds not currently infected with *MAP*, prevention relies primarily on establishing a closed herd. If herd replacements must be purchased, the herd of origin should be screened as indicated earlier, and ideally have achieved level 4 or higher status in the VJDCP.

For herds that are infected, clear objectives should be established. For large production herds with high turnover, no steps may be economically warranted. For other herds, management to reduce transmission and ameliorate the economic effect of the disease may be desirable, and in other herds eradication may be the goal. Regardless of the goal, a test-and-cull strategy employed without other management changes to reduce transmission will not be successful.

Whether the goal is eradication or managing the disease to minimize losses, a risk assessment should be performed to identify potential areas of *MAP* transmission, especially to susceptible young stock, and a management plan developed. A plan must be individually tailored to a specific facility, but in general key control points are calving pens, calf feeding (colostrum and milk) management, and calf housing, especially as they pertain to potential exposure of calves to feces of adult infected cows, or to fecal-contaminated surfaces. Handbooks for veterinarians to assist them in performing risk assessments and management plans for both dairy and beef cattle, designed by the Johne's Disease Committee of the U.S. Animal Health Association, are available at http://www.johnesdisease.org/. On most dairy farms, control strategies focus on calving pen hygiene, early removal of calves from the calving pen after birth, providing an uncontaminated source of colostrum and milk or colostrum replacer and milk replacer, and calf housing free of contamination by feces from adult cattle. Testing in some form to identify and remove or segregate highly infectious adult cattle is usually warranted. In beef cow-calf operations, preventing transmission to calves again must focus on manure contamination of calving areas, manure contamination of cows that are nursing calves, and other possible sources of calf exposure to feces from potentially infected adult cattle. Recommendations can be adapted as appropriate for use with small ruminants and camelids, again to focus on prevention of transmission to susceptible young stock.

Vaccination has been employed with mixed results in cattle and small ruminants. In the United States, vaccination of cattle is permitted in some states, on approval by the State Veterinarian. The only licensed vaccine (Mycopar [Boehringer Ingelheim Vetmedica, St. Joseph, Mo.]) is a killed oil suspension of *M. avium*. The vaccine is generally regarded to reduce the incidence of clinical disease, and in some instances also reduce the level of fecal shedding, yet in other studies prevalence of fecal shedding was not affected. Vaccination should be considered as a useful adjunct, particularly in herds of high prevalence with significant losses due to clinical Johne's disease. Vaccination alone, without implementation of management changes to reduce exposure of calves to *MAP*, is often unsuccessful as any resistance achieved by vaccination may be overcome by heavy *MAP* exposure.

VetBooks.ir

ZOONOTIC POTENTIAL. Traditionally, *MAP* was not regarded as a pathogen of humans. However, because of some similarities between Crohn's disease in humans and Johne's disease in ruminants, the possible connection between *MAP* and Crohn's disease has undergone further scrutiny. These studies, especially those that employ PCR methods to identify *MAP* in tissue samples from people with Crohn's disease, have definitively shown an association between presence of *MAP* in intestinal tissue and Crohn's disease.[29] However, what is more difficult to determine is whether this association is causal or secondary. Crohn's disease is thought to involve an overly florid immune response to antigens in the gastrointestinal tract. Proponents of the hypothesis that *MAP* causes Crohn's disease believe that *MAP* antigens are responsible for that response, whereas skeptics believe that *MAP* may be present secondarily to damaged mucosa with diminished resistance to *MAP* colonization. Improved clinical signs in patients with Crohn's disease in response to antimicrobial therapy directed against *MAP* might constitute further evidence for the role of *MAP* in the disease. However, results of clinical trials of antimycobacterial therapy have had mixed results with differences in opinion regarding their interpretation.[30] Undoubtedly, Crohn's disease is a multifactorial disease influenced by a complex interaction of genetics, environment, cigarette smoking, and potentially infectious agents. Human exposure to *MAP* occurs potentially via survival of *MAP* in pasteurized milk or drinking water contaminated by fecal runoff from infected farms. Increasingly, regulatory agencies around the world are treating paratuberculosis as a food safety issue. More recently, an association with immune-mediated disorders such as diabetes mellitus Type 1, multiple sclerosis, and thyroiditis through molecular mimicry and dysregulation of the immune system.[31] It may be difficult to scientifically establish an etiologic connection between *MAP* and Crohn's disease or these other disorders; however, in the author's opinion, even the potential for a role of *MAP* in Crohn's disease or other human conditions should motivate producers and veterinarians to control the disease in food-producing animals.

Copper Deficiency in Ruminants

John Maas • Bradford P. Smith

Definition and Etiology

Copper deficiency occurs when the diet contains an abnormally low amount of copper (primary copper deficiency) or when copper absorption or metabolism is adversely affected (secondary copper deficiency). If inadequate amounts of copper are available to tissues in the form of essential metalloenzymes, the signs of copper deficiency (hypocuprosis) may occur. Clinical signs in ruminants can include diarrhea, decreased weight gain, unthrifty appearance, anemia, changes in coat color (achromotrichia) or wool quality, anemia, spontaneous fractures, lameness (epiphysitis), and demyelinization (enzootic ataxia of sheep and goats, or swayback). One of these syndromes usually predominates in a given herd. The reason or reasons that one or another syndrome predominates are unknown. For example, a report from New Zealand concluded that protein-calorie malnutrition with periods of copper deficiency resulted in spontaneous fractures in dairy heifers.[1]

The minimum recommended dietary copper concentration (dry matter basis) is 4 to 10 ppm (mg/kg) for cattle,[2,3] 5 ppm for sheep,[4] and 7 ppm for merino sheep.[4] Young animals and fetuses are more susceptible to copper deficiency than are mature animals, and cattle are more susceptible than are sheep. Secondary copper deficiency is associated with high dietary levels of molybdenum, sulfates, zinc, iron, or other compounds. Secondary copper deficiency often presents with clinical signs of diarrhea and weight loss or unthriftiness. It has been called *teart*, *peat scours*, *renguerra*, *pine*, and *salt lick disease*.[5] Salt sickness in Florida appears to be the result of combined copper and Co deficiencies. The cause of copper deficiency in clinical cases is often multifactorial and can be difficult to quantify. In addition, unknown factors cause clinical expression of copper deficiency in ruminants to be manifested as a variety of syndromes.

Clinical Syndromes and Differential Diagnosis

Profuse watery diarrhea with poor weight gains or weight loss is a common syndrome seen in ruminants with copper deficiency.[5] When it occurs on boggy pastures that contain high concentrations of molybdenum, it has been referred to as *teart*.[5] Decreased weight gains or weight loss as a herd problem can have many other causes, including parasitism, trace mineral deficiencies (selenium, cobalt), protein calorie malnutrition, and Johne's disease. A syndrome characterized by epiphyseal enlargement, stiffness, and unthriftiness is seen in young ruminants and is the result of copper deficiency[6] and is sometimes called *pine*.[5] Copper deficiency can cause spontaneous fractures in ruminants and can be associated with phosphorus deficiency or protein-calorie malnutrition.[1] Enzootic neonatal ataxia (swayback) of lambs and kids is characterized by progressive incoordination and recumbency that begins with the hind limbs and progresses to the front-limbs. It has also been reported in deer and pigs. Inadequate keratinization of wool and achromotrichia is the result of imperfect oxidation of free thiol groups during hair growth and keratinization. Subsequently, the wool fibers do not crimp normally, and they appear to be "stringy" or "kinky." A copper-containing enzyme, tyrosinase (polyphenol oxidase), is needed to convert L-tyrosine to melanin. With copper deficiency, this conversion is slow and hair is lighter in color than normal (achromotrichia). Loss of wool crimp and pigmentation changes in sheep or cattle, respectively, occur late in the course of copper deficiency. In addition to the previously listed clinical syndromes that may occur alone or jointly, copper deficiency may be associated with anemia[7] (altered iron metabolism) or infertility.[8] Infertility probably has multifactorial causes and may not respond to an increase in copper intake alone. Copper deficiency also seems to result in decreased immune function in ruminants.[9,10]

Pathogenesis

A frank dietary deficiency of copper results in hypocuprosis and eventual clinical signs. Also, a variety of conditions can decrease copper absorption from the gastrointestinal tract (large intestine in sheep and small intestine in cattle). The interactions between dietary copper, molybdenum, and sulfates (or sulfur) are important (Fig. 32.142). Excess dietary molybdenum can lead to the formation of sparingly soluble cupric molybdates in the rumen that are not absorbed from the intestine. The addition of excess sulfur or sulfates in the diet or water can result in the formation of insoluble copper thiomolybdates in the rumen. The interactions among these three elements are complex.[11] The infertility seen with secondary copper deficiency may be caused by excess circulating oxythiomolybdates, which interfere with the release of luteinizing hormone.[12] However, the feeding of dried distillers grain, with a high sulfur content, at 0.75% body weight as fed did not result in differences in average daily gain, body weight, plasma copper, or plasma zinc concentrations in comparison to control cattle.[13] This study concluded that high sulfur, dried distillers grain fed at 0.75% body weight did not result in copper antagonism; however, liver copper concentrations were not measured.[13]

Of importance is that at low sulfur concentrations in the diet, excess molybdenum has a minimum effect on decreasing copper absorption. Even when no dietary molybdenum or sulfates are present, only approximately 5% of ingested copper is ordinarily absorbed. Excessive calcium in the diet, particularly

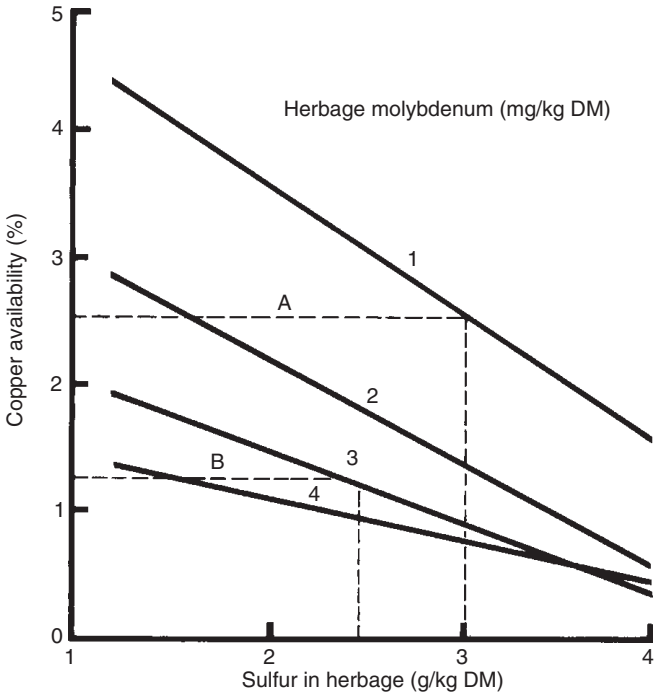

FIG. 32.142 Estimating the availability of copper in herbage from its molybdenum and sulfur concentrations: the difference of 3 mg of molybdenum and 0.5 g of sulfur per kilogram of dry matter *(DM)* between two pastures (*A* and *B*) is sufficient to reduce availability from 2.6% to 1.3%, thereby doubling a grazing animal's requirement of copper from the pasture. *(From Suttle NF. 1986. Copper deficiency in ruminants: recent developments.* Vet Rec *119:519.)*

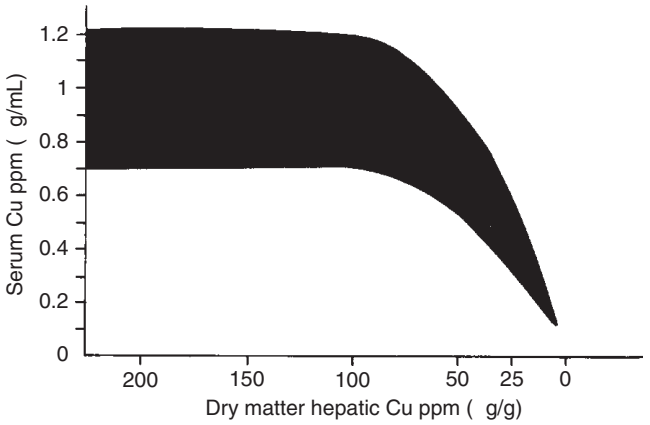

FIG. 32.143 Relationship between serum and hepatic copper concentration in ruminants.

in the form of limestone, decreases copper absorption. Excessive iron, 30 mg/kg of body weight or 1200 ppm in the diet of calves, reduces copper absorption.[14] Overgrazing, with the subsequent ingestion of excess soil, also decreases copper absorption. In addition, excess cadmium (3 to 7 ppm) or excess zinc (100 to 400 ppm) reduces hepatic copper concentration, probably through the combined effects of decreased absorption and competition with copper for hepatic metallothionein.[15,16] It had been suggested that excess dietary selenium might interfere with copper absorption, utilization, or both, but this has been shown not to occur.[17] Copper is an essential component of a number of mammalian enzymes. Some of the medically important copper-containing enzymes are (1) the cytosol form of superoxide dismutase (copper and zinc), (2) cytochrome oxidase (c and aa_3), (3) lysyl oxidase, (4) ascorbic acid oxidase, and (5) ceruloplasmin.[18] In addition, normal copper nutrition appears essential for iron absorption and transportation of iron to the liver and reticuloendothelial system and is thus necessary for normal hemoglobin formation. The precise pathophysiologic mechanism of most of the copper deficiency syndromes is not known. However, the central role of copper in preventing cellular oxidative damage and its role in iron and sulfur metabolism are probably important.

Epidemiology

Copper deficiency can occur when diets are inadequate in copper or contain excess amounts of interfering substances, particularly molybdenum and sulfates. This occurs in many parts of North America. Forages and water can be sources of molybdenum, sulfur, and sulfate. To avoid primary copper deficiency, pasture (dry matter) should contain over 5 ppm of copper, with 3 to 5 ppm considered marginal and less than 3 ppm deficient. Soil copper concentrations are generally slightly lower than those of the harvested forage. Molybdenum adversely affects plant uptake of copper. Forage molybdenum concentrations greater than the copper concentrations often lead to secondary copper deficiency, even when forage copper is adequate. Because copper content in grasses and legumes can be different, forage samples must be selected to reflect dietary intake. Forage copper concentrations as high as 12 to 27 ppm have been associated with copper deficiency when molybdenum levels are high.[5] The critical ratio of copper to molybdenum in feeds is 2:1, with 5:1 recommended for sheep and 5:1 to 10:1 for grazing cattle.

Clinical Pathology and Diagnosis

The primary site of copper reserves is the liver and the copper concentration in the hepatic tissue is the best indicator of copper status (Fig. 32.143). The reference range for hepatic copper concentrations in cattle is approximately 90 to 200 µg/g (ppm) and in sheep 90 to 250 µg/g on a dry weight basis (dry matter basis [DMB]).[5,19,20] Hepatic copper concentrations as high as 250 µg/g DMB are not unusual in supplemented ruminants (even over 350 µg/g DMB in sheep). Blood (serum or plasma) copper concentrations can be maintained near normal until hepatic copper concentration falls to 35 ppm DMB or less, at which time the serum copper concentration invariably begins to decrease.[21] When blood samples are used for copper level determination, serum or plasma are normally preferred. Plasma copper concentration is usually approximately 5% greater than an identical serum copper concentration.[22] Normal serum copper is 0.7 to 1.2 ppm (µg/mL).[5,18] Serum or plasma copper concentrations of 0.4 ppm or less are considered as evidence of frank deficiency. Values of 0.4 to 0.7 ppm are marginal and it is difficult to estimate the actual liver copper concentration on the basis of these serum copper concentration ranges. Approximately 50% to 90% of the copper in serum or plasma is present in ceruloplasmin. The remainder is bound to albumin or amino acids. The correlation between serum copper and serum ceruloplasmin was found to be weak (0.50)[22]; thus ceruloplasmin is not commonly used to aid in diagnosing copper deficiency. In addition, serum ceruloplasmin increases with inflammatory conditions and can result in falsely higher values. Hepatic copper concentration is the preferred diagnostic sample and is easily secured at necropsy. Hepatic copper values less than 35 ppm DMB are considered deficient.[5,19-21] However, surgical biopsy is necessary for live patients, and, because laboratories generally require 100 mg or more of tissue, a biopsy instrument with an internal diameter of 3 to 5 mm is necessary.[23] The biopsy procedure in cattle is performed by locating the tenth intercostal space on the right side of the animal along a line from the tuber coxae (point of the hip) to

the point of the shoulder.[23] This site is surgically prepared and blocked with lidocaine (12 mL of 2% lidocaine) and a stab incision is made. The biopsy instrument is directed slightly ventrad and craniad and advanced through the intercostal space and the diaphragm to enter the liver where the biopsy sample is obtained.[23] The liver biopsy can place the patient at increased risk for black disease or bacillary hemoglobinuria in some areas. This risk should be decreased by prior vaccination and a single dose of procaine penicillin G (4 million IU SC) administered at the time of biopsy. This technique has been shown to be safe and effective.[23] The tissues of young animals (neonates) contain variable amounts of copper compared with adults of the same species. In sheep, serum and liver copper concentrations are the same for lambs (1 week of age) and adults.[24] The plasma copper levels in lambs are low at birth but rise to adult values by 1 to 7 days of age. Plasma copper levels in the bovine neonate are lower than in mature cattle.[25] In the bovine neonate hepatic copper concentration changes little from birth to maturity; however, copper distribution in the liver is quite variable in neonates.[20,25] Because of these differences, interpretation of neonatal serum copper concentrations is difficult. Milk is a poor source of copper, containing only 0.2 to 0.6 ppm in normal ewes and 0.01 to 0.02 ppm in severely copper-deficient ewes or cows. Milk copper concentration in cattle is 0.05 to 0.2 ppm. To make matters worse, molybdenum is concentrated in milk.[26] Research has allowed for the estimation of true wet weight (fresh) or dry weight of hepatic samples by concurrently measuring potassium in the specimen.[27] This allows for much more accurate estimation of hepatic copper concentration in samples that have become dehydrated before reaching the diagnostic laboratory. This technique allows the laboratory to accurately estimate the original wet weight or to calculate the dry weight without time-consuming drying of the specimen.[27]

Treatment and Control

Treatment of copper-deficient animals is usually possible, and the prognosis is guarded to good, depending on the severity of the deficiency and the associated syndrome or syndromes. When excess molybdenum, sulfate, and other factors leading to secondary deficiency are present, they can be overcome to some extent by increasing dietary copper or by injecting copper glycinate. Copper glycinate must be prescribed by the attending veterinarian and dispensed by a compounding pharmacy as no commercial over-the-counter products are currently available. There are currently very few compounding pharmacies manufacturing injectable copper glycinate. Injectable copper glycinate (30% copper by weight) is given to adult cattle at the rate of 400 mg (120 mg copper) subcutaneously. Calves are given 100 to 200 mg of copper glycinate (30 to 60 mg of copper), depending on their age. One injection may be effective as a treatment/supplement for up to 4 to 6 months in cases of primary copper deficiency. However, in cases of excess molybdenum, sulfates, or sulfur, repeat injections may be necessary. Injections of copper glycinate frequently result in large swellings, granulomas, or abscesses and may be cosmetic considerations for some cattle. These reactions can be minimized with sterile technique and the use of the subcutaneous tissue of the brisket as the injection site. Acute deaths can occur in calves after the use of copper glycinate injections. In some countries copper disodium edetate solutions are used as injectable copper supplements. The dosage of copper is usually the same as that recommended for copper glycinate solutions. Also, acute deaths can occur after copper disodium edetate use in cattle.[28] Copper can be supplemented to cattle in salt-mineral mixes in situations in which adequate consumption (1 to 2 oz [28 to 56 g]/cow/day) of the salt-mineral mix occurs. These mixes are usually 0.2 to 0.6% copper. Feed grade copper sulfate ($CuSO_4$-5 H_2O) is 25% copper on an as-fed basis (40% copper on dry matter basis). Feed-grade copper oxide is usually 50% copper as fed (80% copper on a 100% dry matter basis). To make a 0.4% copper salt mixture, 7.2 g of $CuSO_4$ or 3.6 g of CuO is added to each 454 g (1 pound) of salt. For large batches, 14.52 Kg (32 pounds) of $CuSO_4$ or 7.26 Kg (16 pounds) of CuO is added to each ton of salt. Salt mixtures for copper-deficient sheep should usually contain only 0.0625% to 0.13% copper (0.25% to 0.5% copper sulfate). Copper supplements can be added to a total mixed ration easily in the form of trace mineral–vitamin premixes or premix-containing pellets. Copper sulfate can be added to molasses or other sweet feed at 0.363 g/head/day for mature cattle and correspondingly less for calves. This would supply approximately 91 mg of copper to a 450-kg (1000-pound) cow per day or 10 ppm of the total diet (20 pounds [9.1 kg] of dry matter). The copper in $CuSO_4$ is more available than that in CuO.

Another method of copper supplementation involves the oral administration of copper oxide needles (fine rods, 1 to 10 mm long) placed in gelatin capsules that dissolve in the reticulorumen and liberate the CuO wires. These wires reside in the reticulum and abomasum and slowly release copper for absorption. These boluses are currently available in the United States (Copasure, Animax, Bury St. Edmunds, Suffolk, U.K.]) and contain either 25 g or 12.5 g per bolus. The usual recommended dosage is 25 g per animal weighing 227 kg (500 pounds) or more. One 12.5-g bolus is recommended for calves and the usual dose is 2 to 4 g for ewes and does,[5,29,30] which is an extra label recommendation for sheep and goats. The copper oxide needles are thought to provide copper supplementation for 4 to 12 months. A rumen bolus containing a number of trace minerals (copper, iodine, manganese, selenium, zinc, and cobalt) has been made available in the United States (Reloader 250, Cargill, Minneapolis, Minn.). This bolus contains 6.0% copper and would release an average of 46 mg copper per day over a 250-day period. This would be a biologically significant percentage of the daily 40-100 mg of copper requirement for adult cattle. The report[31] of its efficacy detailed the measurement of plasma copper and found no differences between affected cattle and control animals; however, liver copper concentrations would have been the preferred measurement for copper status. Perhaps future studies will detail the practical pharmacodynamics of this device with regard to copper and other trace minerals. Sheep are particularly susceptible to copper toxicity, and appropriate care is necessary when supplementing them. Sheep can easily be intoxicated when consuming cattle supplements or feeds. Continued monitoring of hepatic copper concentration from slaughtered animals or via liver biopsy is an important tool in evaluating copper supplementation methods in cattle and sheep. Lambs can be given 35 mg of copper sulfate per head twice weekly to prevent swayback in endemic areas.

The usual recommendation by the National Research Council (NRC) is 10 ppm (10 mg/kg) of the total diet on a dry matter basis for cattle. However, diets of 20 ppm are commonly fed to lactating dairy cattle. The 2001 NRC recommendations for dairy cattle state that 40 mg/kg (ppm) of the diet on a dry matter basis is the maximum tolerable level, unless significant interference by molybdenum, sulfur, or other antagonists are present.[32] This is due to a number of copper toxicity episodes in the United States when the total diet contained 40 to 50 mg/kg copper or more in the total ration. In addition, the European Food Safety Authority (EFSA) has decreased the maximum concentration of copper in complete feeds to 15 ppm for pre-ruminant calves, 30 ppm for cattle, 15 ppm for sheep, and 35 ppm for goats.[33] Copper has the smallest margin of safety of all the trace minerals in ruminants. The most important goal of copper supplementation is to provide adequate dietary amounts without over-supplementing or risking toxicity.

Cobalt Deficiency in Ruminants

Robert Bascom Sager • John Maas

Definition and Etiology

A number of syndromes occur in ruminants as a result of a primary cobalt (Co) deficiency in their diet. These include ill thrift or enzootic marasmus and anemia. These conditions are characterized by decreased growth, weight loss, diarrhea, decreased feed efficiency, unthrifty appearance, anorexia, and anemia. A Co deficiency syndrome referred to as *ovine white liver disease* has been described in sheep.[1-3] This syndrome is also characterized by ill thrift, weight loss, serous ocular discharge, and occasionally photosensitization.[1-3] Histopathologic lesions of this syndrome included accumulation of lipid droplets and lipofuchsin particles, dissociation and necrosis of hepatocytes, and sparse infiltration by neutrophils, macrophages, and lymphocytes.[4] Co-deficient animals are more prone to parasitic infestation, particularly *Ostertagia ostertagi* in cattle.[1] Also, Co fed at levels above National Research Council (NRC) minimal recommendations has resulted in increased antibody production to a single antigen in weaned beef calves.[5]

Clinical Signs and Differential Diagnosis

Co deficiency in ruminants is associated with the nonspecific signs of decreased growth, weight loss, diarrhea, ill thrift, pica, emaciation, pale mucous membranes (anemia), and lacrimation. Clinical disease is more common in young, growing animals. Sheep are apparently more susceptible to Co deficiency than cattle. Primary differential diagnoses include helminthic parasitism; protein-calorie malnutrition; coccidiosis; Johne's disease; nutritional deficiencies of selenium, copper, or vitamin D; and other chronic diseases that may be associated with weight loss. Co-deficient ruminants are commonly anorexic and fail to thrive on lush pasture or high-quality feeds. Anemia with Co deficiency is characterized as normocytic normochromic and must be differentiated from other causes of anemia. Co-deficient cattle are more susceptible to infestation with *Ostertagia ostertagi* and to the effects of parasitism.[4] The primary differential diagnosis when considering Co deficiency is invariably internal parasitism.

Clinical Pathology and Diagnosis

Because the role of Co in ruminant nutrition is tied to the formation, absorption, and use of vitamin B_{12}, the most significant biochemical role of Co is correlated with tissue vitamin B_{12} concentrations. However, the effects of starvation tend to increase vitamin B_{12} concentrations in the liver and kidneys.[6] If Co deficiency occurs with other conditions that cause anorexia, the tissue vitamin B_{12} concentrations may appear falsely elevated (normal). The appropriate analytic methods for serum B_{12} vary from humans to ruminants, so extrapolation of ruminant serum B_{12} concentrations analyzed in a human laboratory may not be possible. Serum or plasma vitamin B_{12} levels exhibit a marked diurnal variation.[7] In addition, serum vitamin B_{12} concentration more closely reflects short-term Co intake and can be decreased when adequate liver reserves of vitamin B_{12} remain. In normal, Co-sufficient ruminants' serum vitamin B_{12} values are usually 0.1 to 0.3 ng/mL (parts per billion [ppb]). When serum vitamin B_{12} values decrease, clinical signs of Co deficiency can become evident.[8,9] Because serum B_{12} values can give spurious results, the concentration of Co in hepatic tissue is probably the best current standard for determining Co status and making clinical decisions. The liver concentration of B_{12} for cattle and sheep considered to be adequate is 0.30 to 2.24 µg/mL (ppm) on a wet weight basis.[10,11] Table 32.25 contains reference ranges for cattle and sheep.

TABLE 32.25

Reference Values for Cobalt and Vitamin B_{12}

Analyte	Cattle	Sheep
Serum cobalt	0.1-0.3 ng/mL (ppb)[11,12]	0.1-0.3 ng/mL (ppb)[11,12]
Serum vitamin B_{12}	1-3 ng/mL (ppb)[10,11]	1-3.5 ng/mL (ppb)[11]
Liver cobalt	80-160 ng/g (ppb) wet weight[10-12]	80-160 ng/g (ppb) wet weight[10-12]
Liver vitamin B_{12}	0.3-2.24 µg/g (ppm) wet weight[10,11]	0.3-2.24 µg/g (ppm) wet weight[10,11]

Pathophysiology

Co deficiency in ruminants induces a deficiency of vitamin B_{12} (cyanocobalamin). It is the lack of vitamin B_{12} that is thought to cause the majority of clinical signs and clinicopathologic abnormalities observed. Monogastric species need to ingest vitamin B_{12} preformed, whereas ruminants can manufacture adequate vitamin B_{12} if the rumen microorganisms are supplied with adequate Co in the diet. The rumen microorganisms incorporate Co into vitamin B_{12} and a number of physiologically inactive vitamin B_{12}–like compounds. The production of vitamin B_{12} from dietary Co was estimated to be approximately 15% in Co-deficient sheep and only approximately 3% in Co-sufficient sheep.[13] Approximately 50% of the vitamin B_{12} produced is absorbed in normal animals, but only 3% to 5% of vitamin B_{12} is estimated to be absorbed by Co-deficient sheep.[14] Although the absorption of vitamin B_{12} formed in the rumen is not particularly efficient, with normal dietary Co there are usually no clinical problems, and interference by other dietary components does not appear to be clinically important.

Ruminants use the VFAs acetate, propionate, and butyrate as their primary energy sources. Propionate produced in the rumen is the precursor of glucose for ruminant metabolism. The general metabolic steps for conversion of propionate to glucose are shown[15] in Fig. 32.144 use 32-134 from the 5th edition.

A primary defect in Co-deficient ruminants is the inefficient metabolism of propionate at the point in the pathway at which methylmalonyl-CoA mutase, a vitamin B_{12}–requiring enzyme, catalyzes the conversion of methylmalonyl-CoA to succinyl-CoA.[16] As Co deficiency becomes severe, the rate of propionate clearance from the blood decreases, and the intermediate metabolite methylmalonyl-CoA accumulates. [17] With severe Co deficiency, the amount of methylmalonic acid excreted in the urine increases. As the half-time for propionate clearance increases, the voluntary feed intake of Co-deficient sheep decreases.[17] These changes correlate with the degree of anorexia and weight loss observed in severely Co-deficient sheep.

The decreased growth, weight loss, unthrifty appearance, and anorexia are closely correlated to the observed abnormalities of carbohydrate metabolism. The diarrhea commonly observed with Co deficiency is not well explained; however, an increase in susceptibility to parasitism[4] might explain a portion of this clinical observation.

The anemia that is associated with Co deficiency occurs late in the development of the syndrome and is characterized as normocytic normochromic.[18] Co deficiency results in the depression of the vitamin B_{12}–containing enzyme 5-methyltetrahydrofolate homocysteine methyltransferase.[19] This interference with the recycling of methionine has a marked influence on folate metabolism. In addition to potentially

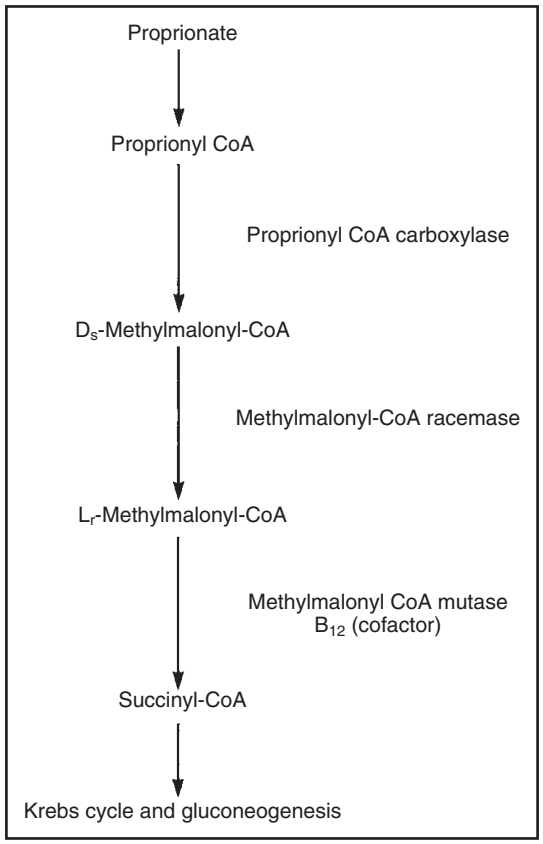

FIG. 32.144 Pathway for conversion of proprionyl coenzyme A (CoA) from proprionate to succinyl CoA.

resulting in anemia through inefficient folate metabolism, the decreased activity of this methyltransferase could lead to a deficiency of methionine; this is a possible reason for nitrogen retention and the decreased body growth and wool growth observed.

Epidemiology and Cobalt Requirements Co deficiency in ruminants occurs in selected regions throughout the world and in association with a variety of soil types. Clinically recognizable Co deficiency is reported in New Zealand, Australia, Brazil, United Kingdom, Ireland, Scandinavia, and North America. In the United States, Co deficiency is most commonly seen in Florida, in the Northeast, along the eastern seaboard, in the upper Midwest, and around the Great Lakes.[20] Although various soil types are associated with Co deficiency, heavy fertilization with limestone reduces the Co available to plants and animals.[21] The dietary requirement of Co by ruminants is generally recommended to be 0.1 mg/kg of dry matter (DM) of the complete ration.[22-24] The Co requirement of young, rapidly growing lambs is thought to be 0.2 mg/kg (ppm) of DM of the diet.[25] When pasture Co concentrations are less than 0.07 mg/kg of DM or 0.04 mg/kg of DM for sheep and cattle, respectively, signs of deficiency can be expected to develop. On a practical basis, diets with 0.1 mg/kg of DM are considered to be adequate. Legumes have relatively high Co concentrations. Rapidly growing grasses have much lower Co concentrations, and cereal grains are poor sources of Co.[22] Oilseed meals are generally good sources of Co. Co supplemented at levels above NRC recommendations (0.2 mg/kg versus 0.1 mg/kg) has been associated with increases in the immune response to one antigen in cattle.[5]

Treatment and Control Treatment is best accomplished in the short term with vitamin B_{12} injections. Ruminants poorly absorb oral vitamin B_{12}; thus injections are the most efficient. Lambs receiving 100 µg of vitamin B_{12} per week or 150 µg B_{12} every other week show remission of clinical signs.[26] Sheep receiving injections of 300 µg of vitamin B_{12} weekly or cattle receiving 2000 to 3000 µg of vitamin B_{12} weekly would also be expected to regain normal status.

Rations with 0.1 to 0.2 mg/kg (ppm) of DM Co would be expected to prevent Co deficiency in ruminants. Salt-mineral mixes containing 0.1% Co also provide adequate supplementation. 0.1% Co in salt can be made by mixing Co carbonate (which is 46% Co) at the rate of 4.35 pounds/ton of salt, or 1 g of Co carbonate per pound of salt. A pound equals 453.59 grams.

Co sulfate as a top dressing for pastures (1.5 kg/hectare every 3 to 4 years or 0.3 kg/hectare every 1 to 2 years) has been used to increase Co concentration of pasture forage. Heavily limed pastures[21] and soils high in manganese oxide[27] decrease Co availability, and Co top dressing of the pastures or Co (B_{12}) supplementation to the animals should be considered.

A variety of rumen pellets containing Co are used to supplement grazing ruminants. These pellets have been successful in maintaining normal Co status in animals.[25-29] The pellets are not commercially available in the United States at this time.

The perennial grass, *Phalaris tuberosa*, can cause a syndrome in ruminants that is referred to as "phalaris staggers." Co supplementation can aid in prevention of this syndrome because it inactivates or decreases absorption of the neurotoxin contained in *P. tuberosa*, *Phalaris minor* (canary grass), or *Phalaris* hybrids (ronpha).[29] The increased level of Co in the rumen is the important factor in preventing this condition; administration of oral or parenteral vitamin B_{12} is not effective.[26] Treatment of clinical phalaris staggers with Co is not effective, however.

Because Co is poorly absorbed, toxicity is an uncommon problem, and diets in excess of 30 mg/kg of DM are necessary for toxicosis to occur in most cases.[22-24]

A recommendation by the National Research Council of increased levels for Co (mg/kg DM) for beef cattle has been made since 2016. This increase has recommended increased Co levels of 20 mg / kg DM from the previous 10 mg/ kg DM. Research has reflected increased NRC Co levels improved performance (ADG) in Simmental bulls (Stangl, et al.). Increased NRC Co levels in feedlot steers showed increased antibody titers of *M. haemolytica* leukotoxin ($P < 0.0565$), decreased BRD (bovine respiratory disease), and increased HCW (hot carcass weights of + 18.1 kg compared to controls; Sager, 2014). These results have demonstrated the need for increased Co in beef cattle for increased health and performance.

Rectal Prolapse in Ruminants and Horses

Spring K. Halland

Definition and Etiology Rectal prolapse is the protrusion of the rectal mucous membranes through the anus. This evagination may be extensive and may include part of the small colon. Rectal prolapse occurs in all domestic animals, with the highest incidence in cattle, sheep, and swine. The age at which prolapse most commonly occurs is 6 to 12 months in sheep, 6 months to 2 years in cattle, and 6 to 12 weeks in swine.[1] Rectal prolapse is much less common in horses and occurs more often in mares than in males.[2]

Rectal prolapse generally is the result of an increase in the pressure gradient between the abdominal or pelvic cavity and the anus. Factors that cause the increased pressure gradient can be divided into four categories: (1) factors that result in increased abdominal fill (2) factors that cause tenesmus; (3) conditions that result in chronic or excessive coughing; and

VetBooks.ir

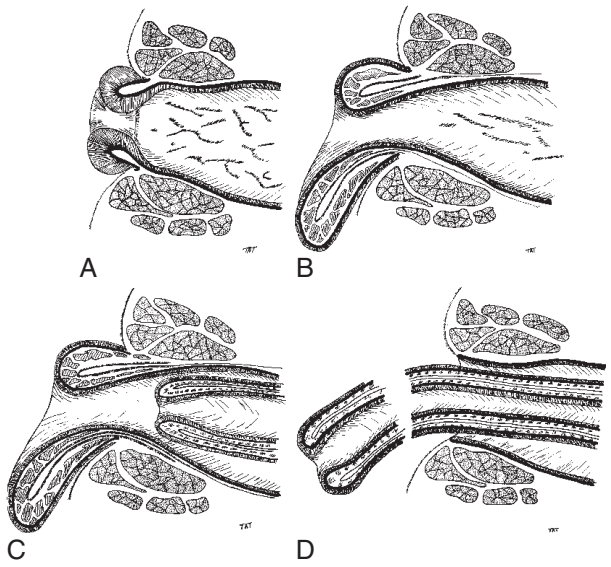

FIG. 32.145 **A,** Type I rectal prolapse: mucosal prolapse, involving only mucosa and submucosa of the rectum. **B,** Type II rectal prolapse: complete prolapse, involving full wall thickness of the rectum. **C,** Type III rectal prolapse: complete prolapse plus intussusception of peritoneal rectum or small colon. **D,** Type IV rectal prolapse: intussusception of the peritoneal rectum or small colon or both. *(From Robinson NE [ed]. 1987.* Current therapy in equine medicine, *ed 2. Philadelphia: Saunders.)*

(4) miscellaneous conditions (e.g., short tail docking). One study strongly revealed that sheep with short docked tails (as close to the body as possible) had a 7.8% higher incidence of rectal prolapse when finished on a high-concentrate diet.[3] Certain toxicities such as from lead, fluoride, estrogen, and zinc have been implicated as playing a role in rectal prolapse.[4] Any combination of factors may precipitate a rectal prolapse. Identification of predisposing factors becomes important in management of the case.

■ ***Clinical Signs*** Four categories have been used to described rectal prolapse (Fig. 32.145).[2] Types I and II are much more common and more amenable to correction. On physical examination, types I, II, and III are continuous with the mucocutaneous junction of the anus, whereas with type IV a protrusion with a palpable trench inside the rectum is seen.[5] Chronic cases can be seen and usually are type I or II. Types III and IV often cause loss of vascular integrity to the rectum or small colon and necessitate more immediate intervention. Types III and IV may accompany dystocias in mares.[6]

■ ***Treatment and Prognosis*** The first aim of therapy is identification and alleviation of the cause if possible. Early identification and correction of the prolapse is essential to saving tissues and the animal. The animal's value and intended use and the affected tissue's viability need to be considered when deciding on conservative or surgical options. The color of the membranes is a good parameter for determining if the tissue is salvageable. In general, the rectum is a forgiving structure, and attempts should be made to salvage the prolapsed tissue unless it is obviously cyanotic, necrosed, and devitalized. To prevent further damage, animals should remain standing and restrained in a small area until the prolapse can be corrected.

Types I and II usually are treated conservatively. A caudal epidural is used to reduce straining and facilitate correction of the prolapse. A range of 4 to 6 mL of 2% lidocaine is usually adequate for juvenile to adult cattle. The addition of a small amount of xylazine to the lidocaine epidural will extend the duration of the anesthetic. Sedation may also be necessary, depending on the individual animal. Effective conservative therapy includes thorough cleansing of the prolapse with warm water and mild soap to remove all debris. This allows evaluation for trauma, tears, necrosis, or sloughing. Edema can be removed by gentle kneading combined with topical application of glycerin or sugar. Generous lubrication and massage allow for reduction of the mass into the rectum. To ensure that the rectum is maintained in place, purse-string sutures with umbilical tape or other nonabsorbable suture are placed circumferentially around the anal sphincter, with care taken not to enter the rectum. The purse-string should not be so tight as to prohibit the passage of feces. If necessary, it should be loosened daily to expedite removal of accumulated fecal material. The purse-string should be removed in 3 to 4 days. Broad-spectrum antimicrobial drugs should be administered if tissue compromise is a factor. When indicated, stool softeners and enemas may be used to ease the passage of feces through the rectum.

Surgical intervention often is necessary if type I or type II prolapse cannot be reduced, if tissue necrosis is extensive, or if prolapse recurs after conservative therapy.[5] Submucosal resection, amputation, or the use of a prolapse ring are all accepted surgical options. Prolapses of types III and IV that cannot be manually reduced often necessitate a celiotomy for surgical reduction of the intussusception or resection or both. An important fact to remember is that even with manual reduction of a type IV prolapse, significant vascular compromise may have occurred, which results in bowel leakage and peritonitis. Vascular damage encountered by the colon may necessitate a colostomy.[6] Broad-spectrum antimicrobial drugs should be administered in these cases.

Unique problems are encountered when conservatively managing equine rectal prolapse, as opposed to ruminant prolapse. Equine patients may experience more hindlimb ataxia with caudal epidurals, which can be prevented with different combinations of xylazine, lidocaine, detomidine, morphine, and mepivacaine in the epidural. Placement of an epidural catheter can facilitate long-term therapy if needed. Another problem encountered is that horse feces often are too large and dry to readily pass through the purse-string in the anus. The use of enemas and stool softeners offers some assistance. The sutures tend to cause greater anal irritation than is seen in ruminants, causing horses to strain against them.

The common complications after rectal prolapse include prolapse recurrence, rectal strictures, obstipation, formation of a pararectal abscess, and peritonitis. The prognosis for all types of rectal prolapse depends on early identification and reduction of the prolapse. Prolapses of types I and II that can be managed conservatively have a favorable outcome. Surgical correction of types I and II also carries a good prognosis but with a higher incidence of postsurgical complications. Because of the cost of surgical repair, market animals often are slaughtered if conservative management fails. Rectal prolapses of types III and IV carry a fair to guarded prognosis, which depends on the extent of tissue involvement and viability, the surgeon's skill, and postsurgical complications.

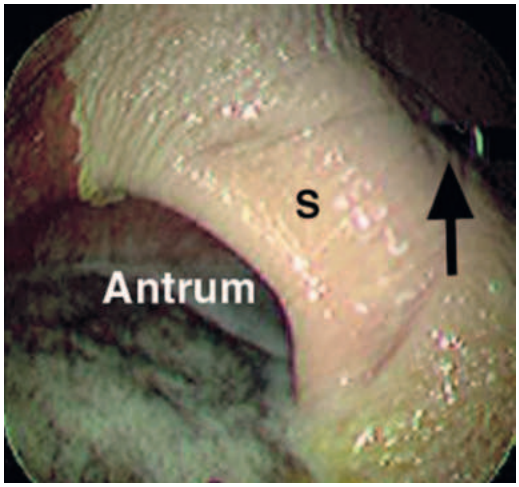
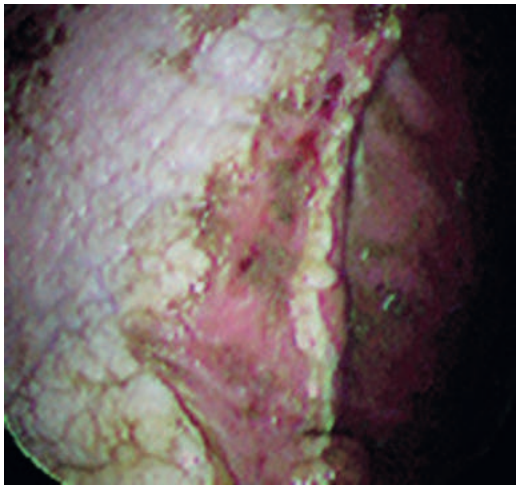
Color Plate 32.1 Endoscopic view of the esophagus of a 20-year-old gelding that presented with a 3-day history of esophageal obstruction. The horse had recently been rescued, and its previous history was unknown. After an obstruction consisting of grass was forcefully relieved by flushing water through a nasogastric tube, endoscopy revealed ulceration of the esophageal mucosa just orad to a stricture of the esophageal lumen. *(Courtesy Dr. M.J. Murray.)*

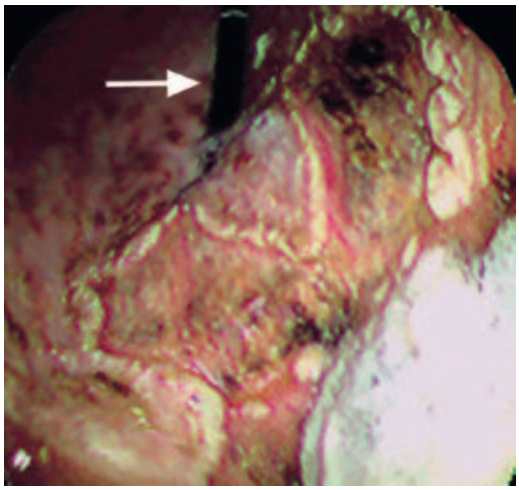


Color Plate 32.2 Endoscopic view of the esophagus of the same horse as in Plate 32.1, 14 days after flushing. The mucosa adjacent to the stricture remained ulcerated, and the diameter of the esophageal lumen had progressively diminished. At this point, it was not possible to advance the 10-mm-diameter endoscope through the stricture. *(Courtesy Dr. M.J. Murray.)*



Color Plate 32.3 Endoscopic view of megaesophagus in a 10-month-old foal (also shown in Fig. 32.45). The esophageal lumen is greatly distended, and the mucosa has multifocal erosion. *(Courtesy Dr. M.J. Murray.)*

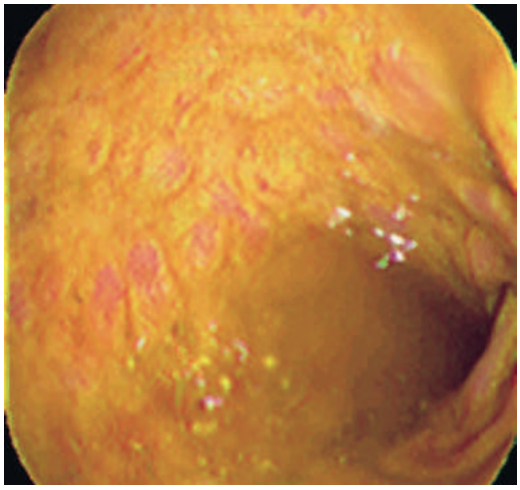
Color Plate 32.4 Endoscopic view of the right side of a normal stomach in a horse. Note the pale squamous mucosa *(S)* and the red glandular mucosa *(G)*.



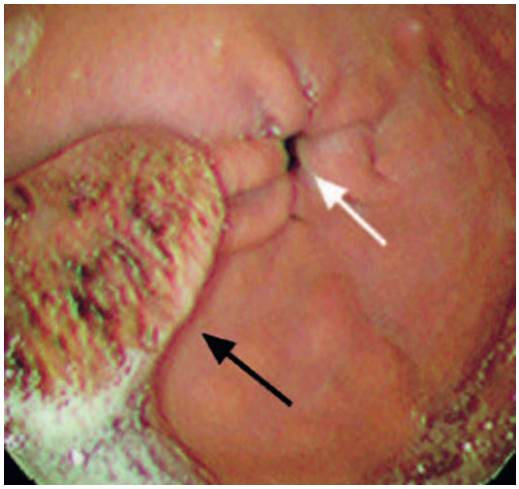
Color Plate 32.5 Endoscopic view of the lesser curvature of a normal stomach in a horse, showing the pale squamous mucosa *(S)*. The antrum lies ventral to a fold formed by the squamous mucosa along the lesser curvature, and the pylorus is immediately ventral to the cardia, through which the endoscope *(arrow)* can be seen entering the stomach.

Color Plate 32.6 Endoscopic view of a large area of ulceration of the squamous mucosa adjacent to the margo plicatus along the right side of the stomach in a horse.

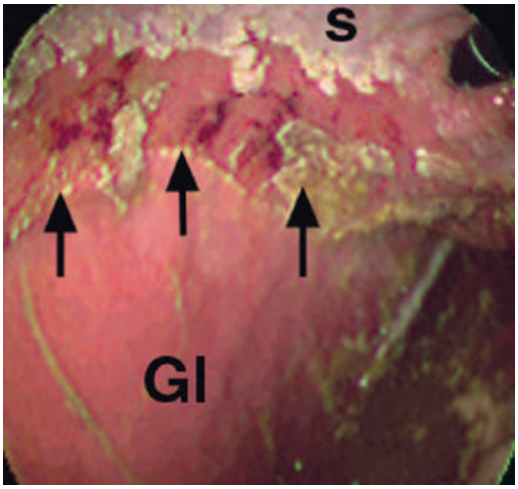
VetBooks.ir



Color Plate 32.7 **Endoscopic view of a large area of ulceration of the squamous mucosa along the lesser curvature of the stomach in a horse.** The ulceration has a "butterfly" pattern, which is typical of ulcers at this site, and this pattern may reflect protection of the mucosa immediately ventral to the cardia by saliva entering the stomach from the esophagus. The endoscope *(arrow)* is entering the stomach through the cardia.



Color Plate 32.10 **Endoscopic view of normal duodenal mucosa in a horse.** The endoscope has advanced aborad to the major duodenal papilla, which in most foals and horses is difficult and unusual to accomplish because of the anatomic configuration of duodenum in relation to the stomach.



Color Plate 32.8 **Endoscopic view of an ulcer in the gastric glandular mucosa in a horse.** The ulcer is in a rugal fold, which is a typical site of ulcers in the glandular portion of the stomach.

Color Plate 32.11 **Duodenum of a foal that presented with fever, depression, leukocytosis, and hyperfibrinogenemia.** This endoscopic view is orad to the major duodenal papilla. The mucosa is inflamed, and a yellow-orange fibrinous exudate adheres to the mucosal surface.

Color Plate 32.9 **Endoscopic view of an ulcer in the antrum of the stomach in a horse.** The *white arrow* points at the pylorus. The *black arrow* points at an area of ulceration and thickening of a rugal fold leading to the pylorus. This is a severe example of a frequent finding in the stomach of adult horses: thickening of a rugal fold in the antrum in association with erosion or ulceration of the mucosa. The cause of these lesions is undetermined.

Color Plate 32.12 **Endoscopic view of the stomach of the foal in Color Plate 32.11.** Severe ulceration of the squamous mucosa *(S)* adjacent to the margo plicatus *(arrows)* was caused by delayed gastric emptying secondary to the severe duodenitis. Many foals with duodenitis present with classic gastric ulcer signs because of delayed stomach emptying, accumulation of acidic peptic secretions in the stomach, and, often, gastroesophageal reflux. *GI*, Glandular mucosa.

Diagnosis of Liver Disease*

Geoffrey W. Smith

In making a diagnosis, the veterinarian should first attempt to determine that the animal *has* liver disease and then move toward trying to identify a specific cause. Therefore this chapter discusses first the diagnosis of liver disease and then the individual conditions causing disease in horses and ruminants. The signs of liver disease are caused by the failure of some of the liver's many functions, but these signs are often not apparent early in the course of disease. Special tests may be necessary to detect early damage or minor impairment of function that has not yet produced clinical signs.

Liver Diseases Versus Liver Failure

As with many other organs like the heart and kidney, the liver can be diseased or damaged long before it fails to function. Early liver diseases are often inapparent to the owner or veterinarian through physical findings alone. Such cases are usually detected by finding elevated levels of liver enzymes in the serum. Pathologic changes in the liver may include biliary hyperplasia, death of hepatocytes, and fibrosis—all potentially occurring long before any signs of failure develop. Some functions may fail before others, and onset of liver failure varies with the species and disease process involved.

Liver Reserve and Regeneration

The liver has a large reserve capacity, and close to 80% of it can be removed before regeneration and recovery are no longer possible. Regeneration can occur in areas receiving portal blood, but most cell division takes place in Rappaport's zone 1 (the portal area), with cells being pushed to the central lobular area. The liver undergoes constant repair, and in humans it is estimated that hepatocytes are renewed every 50 to 75 days.[1]

Normal regeneration does not occur in some cases. For example, antimitotic agents such as pyrrolizidine alkaloid metabolites or antineoplastic drugs can prevent cell division. Regeneration may be restricted by connective tissue. Once fibrosis has bridged the various lobules, additional regeneration is impaired because the fibrosis itself perpetuates the condition. Loss of a stroma to build on or lack of portal blood supply also reduces regeneration.

Signs of Liver Disease and Pathophysiology

Although ultrasound and biopsy may be more accurate indicators of disease, initial suspicion of liver problems in large animals usually arises from abnormal clinical signs or serum biochemistry abnormalities. Many signs can be present with liver disease, but no sign is pathognomonic or present in every case. Table 33.1 lists some of the signs that may be present and other possible causes of the same signs.

The clinical history is useful in some cases but not consistently. For example, liver flukes in cattle are generally restricted to certain geographic areas and occur more commonly when animals are grazing land infested with snails. Another example would be acute serum hepatitis in horses, which often occurs 4 to 8 weeks after administration of equine biologic products. In other cases, the lack of specific history information may not rule in or rule out specific causes of liver disease. For example, there may not be a history of animals consuming plants containing pyrrolizidine alkaloids because of the delay between consumption and the onset of clinical signs.

With the exception of change in liver size and pain over the liver elicited with pressure, most signs are related to failure of some function. Liver flukes may cause anemia and hypoproteinemia because of the effect of the parasite and its metabolites. Liver abscesses and other infections may produce signs like fever and anorexia owing to release of pyrogens and other inflammatory mediators (caused by the organism and not necessarily related to the liver itself).

Icterus is typically seen in acute liver disease in horses but is not seen in many cases of chronic liver disease, and it is seen less often in ruminants unless biliary blockage occurs. Icterus is due to failure of uptake, conjugation, or excretion of bilirubin. Excess production caused by hemolysis must also be considered when icterus is present. This is likely the most common cause of icterus in ruminants and occurs with several hemolytic diseases such as anaplasmosis and copper toxicity. Horses are frequently icteric (up to 6 mg/dL unconjugated bilirubin) from anorexia or fasting even when the liver is normal.

Weight loss is a common but nonspecific finding in some cases of chronic liver disease. It may be caused by anorexia or failure of metabolic functions of the liver and is probably not related to impaired fat absorption. Diarrhea is also seen, especially in cattle with chronic liver disease. It is thought to be related to portal hypertension and increased hydrostatic

TABLE 33.1

Signs of Liver Disease or Failure

Sign	Pathogenesis	Other Causes
Icterus (E)	Failure of uptake, conjugation, or excretion of bilirubin	Massive hemolysis Bile blockage Fasting in the horse
Weight loss (E, B)	Energy demand greater than absorbed or metabolized	Poor nutrition, chronic inflammation, parasites, neoplasia, maldigestion, malabsorption
Ascites (B)	Portal hypertension and lymph leakage caused by cirrhosis or veno-occlusion	Cardiac failure Hypoproteinemia Cushing's syndrome
Change in liver size	Nodular hyperplasia, tumor, cirrhosis Fatty degeneration	Right-sided heart failure Work hypertrophy Anemia
Diarrhea (B)	Bile deficit malabsorption Intestinal edema, portal hypertension	Gastrointestinal (GI) or systemic disease
Pruritus	Retention of bile salts	Dermatologic or central nervous system (CNS) disorders
Dermatitis Unpigmented areas	Hepatogenic photosensitization	Primary phototoxic photosensitization
CNS signs Behavioral change, ataxia, dysmetria, circling, stupor, coma, tremors, bellowing	Hepatic encephalopathy (see text)	Brain diseases Metabolic diseases Toxic diseases
Tenesmus (B)	Hepatic encephalopathy	Rectal or colonic disease CNS disease Urogenital disease
Rectal prolapse (B)	Tenesmus	Rectal or colonic disease
Change in feces color	Bile pigment deficit Undigested fat	Diet GI disease
Hemorrhage	Failure to synthesize clotting factors II, V, VII, IX, X	Other clotting factor or platelet deficit, trauma, disseminated intravascular coagulation
Pain over liver, inflammation, swelling	Abscesses	Traumatic reticulitis
Inspiratory stertor (E) Dyspnea	Hepatic encephalopathy	Upper airway obstruction

B, Frequent sign in cattle; *E*, frequent sign in horses.

pressure, although the exact mechanisms are not completely understood. Diarrhea probably is not caused by fat malabsorption or steatorrhea because the normal herbivore diet contains less than 3% fat.

Ascites can also occur in animals with liver failure. The ascites results from portal hypertension caused by venous blockage producing increased hydrostatic pressure and by protein leakage into the peritoneal cavity. Production of hepatic lymph high in protein (>3 g/dL) is increased. Because the liver sinusoids are permeable to plasma proteins, the protein-containing lymph leaks into the interstitial space and then into the peritoneal cavity.[2,3] Fluid moves into the abdominal cavity secondary to both osmotic and hydrostatic forces, according to the Starling equation. The abdominal fluid present with liver disease is a modified transudate, but the protein content may be relatively high (3 to 3.5 g/dL) owing to leakage of protein from the liver. Hypoalbuminemia can aggravate the ascites, but if it occurs alone, it usually will result in submandibular and brisket edema.

Hepatic photosensitization may lead to dermatitis of the white areas, wherein the skin of these areas first becomes erythematous, then thickened with keratin crusts, and finally necrotic. This is caused by the photodynamic agent phylloerythrin, which is formed in the gastrointestinal (GI) tract of large animals by bacterial degradation of chlorophyll. After absorption into the portal circulation, phylloerythrin should be conjugated by the liver and excreted into the bile. With cholestasis, phylloerythrin may be carried to the skin, where it acts as a photodynamic agent.[4] After bile duct ligation, the level of phylloerythrin steadily increases.[5] Although a small amount is removed by the kidneys, the rate is not fast enough to prevent accumulation in the plasma and skin. Phylloerythrin in the skin reacts to sunlight and emits energy that causes lesions of the white areas.[4]

Pruritus is seen in a few cases of liver disease in horses. In humans, pruritus is assumed to be due to bile acid accumulation in the skin when it is not excreted by the liver. This same process may occur in horses, but pruritus is not usually seen in large animals with liver disease.

A change in fecal color is not usually noted in either adult cattle or horses with liver disease because other pigments like chlorophyll contribute to the color. In young animals with simple digestive tracts, much of the fecal color is from stercobilin, a metabolite of bilirubin, so with cholestasis, feces may be somewhat lighter in color.

A few signs may be seen terminally in liver disease. Hemorrhage may occur when clotting factors are not synthesized in adequate amounts. Factors I, II, V, VII, IX, and X are all produced by the liver,[1,3] but the disease is usually advanced before a deficit develops.

Tenesmus, often followed by rectal prolapse, is seen in some cattle with liver disease. This may be associated with diarrhea, be part of hepatic encephalopathy, or be aggravated by edema of the bowel secondary to portal hypertension.

VetBooks.ir

Pharyngeal or laryngeal collapse with loud stertorous inspiratory noises and dyspnea has developed in some cases of hepatic failure, especially in ponies. The exact mechanism for this is not known, but it may also be part of hepatic encephalopathy.[6] Horses sometimes develop a terminal hemolytic crisis caused by increased red blood cell (RBC) fragility. This has not been observed in ruminants.

Hepatic Encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by hepatic dysfunction or portosystemic shunting of the intestinal blood.[7] It is considered a potentially reversible metabolic or neurotransmitter disorder but is associated with characteristic (although nonspecific) lesions in the central nervous system (CNS), such as altered astrocytes.

Signs of hepatic encephalopathy are often subtle and nonspecific. Behavioral changes may be detected by the owner, who is more familiar with the patient's normal activity. Some docile animals become excitable and difficult to control, whereas other normally unruly animals may become passive. Depression and incoordination are frequent manifestations, and some animals may walk aimlessly or even head press (Fig. 33.1).[8] Apparent blindness is seen in some horses, and foot stomping was reported in 7 of 25 cases.[9] These animals eventually develop a stupor and may end up in hepatic coma. Yawning may be seen in horses, and ponies may have a stertorous respiratory noise. Ruminants show signs of tenesmus and sometimes vocalize excessively. In humans, hepatic encephalopathy is diagnosed by neuropsychological tests, which are not possible in animals.[10]

The pathophysiology of hepatic encephalopathy remains undefined and is controversial.[8] It occurs when portal blood bypasses the liver, as with congenital shunts in dogs or with shunts secondary to portal hypertension induced by alcoholic cirrhosis in humans, or when the blood goes through an inadequately functioning liver. How neurologic function is altered has not been determined, but speculation abounds.

FIG. 33.1 Severe depression and head pressing in a horse with hepatic encephalopathy. Edema of the head developed secondary to the horse hanging its head.

It seems possible to incriminate synergistic neurotoxins that bypass the liver. Most will agree that ammonia levels play a central role in pathogenesis. Blood ammonia is elevated in most cases of hepatic encephalopathy because the liver is not metabolizing ammonia to urea. Encephalopathy can be precipitated in cirrhotic patients by adding ammonia-generating substances, and there is an increase in cerebrospinal glutamine, the product to which ammonia is detoxified. Astrocytes contain the enzyme glutamine synthetase, which adds a molecule of glutamate to ammonia to form glutamine. The amount of glutamine formed in the brain correlates with the severity of hepatic encephalopathy.[11] However, much higher concentrations of ammonia are needed to induce coma in normal animals, and there is poor correlation between ammonia levels and degree of encephalopathy.[9] Cases of hyperammonemia and encephalopathy without liver disease have been reported in horses.[12]

Magnetic resonance imaging (MRI) of human cirrhotic patients reveals increased image intensities from the globus pallidus region, probably caused by manganese deposits.[10] Serum manganese is increased in these patients, which correlates positively with the increased MRI intensities and negatively with neuropsychological tests. This indicates that manganese is another potential toxin that can enter the brain if not effectively removed from the blood by the liver.

There may be an imbalance of true inhibitory and excitatory neurotransmission. γ-Aminobutyric acid (GABA) is an inhibitory neurotransmitter. The increase in GABAergic tone was originally thought to result from an increase in GABA or its receptor sites. More recently, it has been proposed that neurosteroids with GABA-agonist properties could be involved.[13] Ammonia is believed to play a role in the metabolism of GABA in the brain and thus could act synergistically.[14] Also, receptor sites for benzodiazepine are increased in the brain of animals with hepatic encephalopathy.[15] Benzodiazepine augments the activity of GABA in stimulating the inhibitory neuron and causing sedation.

False neurotransmitters have been proposed to cause the abnormal nerve function. Increased amounts of tryptophan, phenylalanine, and tyrosine in the brain could cause more serotonin to accumulate in the brain. Plasma amino acid ratios are altered in horses with pyrrolizidine alkaloid–induced liver disease.[15] Concentrations of branched-chain amino acids (valine, isoleucine, leucine) are decreased, and concentrations of aromatic amino acids (tyrosine, phenylalanine, free tryptophan) are increased, partially because the liver is not adequately metabolizing aromatic amino acids. Amino acids are transported across the blood-brain barrier by a common transport system, so they compete for entry into the CNS. It has been suggested that higher levels of aromatic amino acids in the CNS would lead to formation of increased amounts of inhibitory neurotransmitters or to alteration of catecholamine or monoamine neurotransmitters like GABA or L-glutamate.

Laboratory Tests and Liver-Derived Serum Enzymes

A number of enzymes are compartmentalized in the hepatocyte or in bile duct epithelium. This compartmentalization is useful in holding insoluble molecules close to the enzymes for chemical reactions. Hepatocyte damage may result in release of the enzymes into the circulation, and cholestasis may cause increased release from bile epithelium. Serum levels of these enzymes may therefore be an indication of hepatocyte integrity or bile excretion. Table 33.2 lists frequently tested enzymes and their characteristics. Serum concentrations for some of these enzymes vary with the age of the animal and sometimes even with type or use. Table 33.3 lists some approximate upper limits of normal for animals of various ages. Normal values, especially for the enzymes, should be established by each laboratory.

VetBooks.ir

The cytosol of the hepatocyte contains high activities of the enzymes aspartate aminotransferase (AST, formerly serum glutamic-oxaloacetic transaminase [SGOT]), sorbitol dehydrogenase (SDH, sometimes called L-iditol 2-dehydrogenase), ornithine carbamoyltransferase (OCT), glutamate dehydrogenase (GDH), and lactate dehydrogenase (LDH). These are generally referred to as *leakage enzymes*, since with acute or chronic hepatocellular injury or necrosis the activity of these enzymes increases because they essentially "leak" out of hepatocytes into the serum.[16] Cholestasis increases production of other enzymes such as γ-glutamyltransferase (GGT) and alkaline phosphatase (ALP). Activity of these enzymes generally increases secondary to biliary obstruction caused by conditions like liver fluke infection or cholelithiasis. The cholestatic enzymes are more likely to have high serum concentrations in chronic hepatic disease than the leakage enzymes because of bile duct constriction or obstruction secondary to fibrosis.[16] GGT also is present in pancreas, mammary gland, lung, kidney tubules, and other duct epithelium, but serum levels usually are not elevated with renal disease because the enzyme is lost in the urine. Serum concentrations are normally higher in neonatal calves (sometimes >4000 IU/L after suckling)[17] because the enzyme is concentrated in colostrum.[18,19] GGT levels are also higher in foals than in adult horses, but the higher concentrations may partly be the result of increased production.[20] GGT is elevated in many horses with proximal enteritis or right dorsal displacement of the large colon, possibly caused by transient extrahepatic bile duct obstruction.[21] Elevated GGT is the most sensitive indicator of liver disease in the horse, and levels will remain elevated for several weeks.[9,22]

ALP is often elevated in chronic liver disease of the horse but is variable in ruminants. ALP can come from other sources like bone, intestine, placenta, and macrophages, so it is not specific. Both ALP and GGT are elevated with cholestasis.[23] The dehydrogenases (e.g., SDH, LDH, GDH) are found in hepatocytes and elevated with acute hepatocyte damage, but serum concentrations may return to normal or below normal in chronic liver disease.

SDH is liver specific and extremely useful in detecting active hepatocellular necrosis, but it is not as stable as some of the other enzymes (levels drop significantly after 24 hours of refrigeration). Increased SDH activity can be seen in ruminants with infectious, inflammatory, toxic, or metabolic insults to the liver. In horses, any disease causing decreased perfusion of the tissues secondary to dehydration or hypoxia may result in rapid increases in SDH, with or without underlying liver disease. SDH should therefore always be interpreted in combination with other indicators of acute liver disease. In cases of chronic disease, however, the SDH concentration may be normal because either too few hepatocytes are damaged or the hepatocellular mass is substantially reduced.[24] AST and LDH are found in many tissues other than liver (especially muscle), so they are nonspecific unless isoenzymes are determined. Muscle injury or necrosis, especially in recumbent animals, will often result in marked increases in both AST and LDH. The clinician must evaluate AST and LDH concentrations in conjunction with

TABLE 33.2

Liver-Derived Enzymes

Enzyme	Specificity	Problems
GGT	Liver	High in young animals from colostrum
	Kidney[a]	
	Pancreas	
ALP	Liver	Not specific
	Bone	
	Intestine	
	Macrophages	
	Placenta	
SDH	Liver	Not elevated in chronic disease; short life; not stable
GDH	Liver	Not elevated in chronic disease
AST (SGOT)	Liver	Not specific
	Muscle	
	Heart	
ALT (SGPT)	Liver	Low concentration in cattle and horses; not a good indicator in large herbivores
LDH	None unless isoenzymes	Not elevated in chronic disease; short life; not specific
OCT	Liver	Analysis not routinely available

[a]Elevated in urine, not blood.

ALP, Alkaline phosphatase; *ALT*, alanine aminotransferase (formerly *SGPT*, serum glutamic-pyruvic transaminase); *AST*, aspartate aminotransferase (formerly *SGOT*, serum glutamic-oxaloacetic transaminase); *GDH*, glutamate dehydrogenase; *GGT*, γ-glutamyltransferase; *LDH*, lactate dehydrogenase; *OCT*, ornithine carbamoyltransferase; *SDH*, sorbitol dehydrogenase.

TABLE 33.3

Upper Limits of Normal for Some Liver Function Tests (from Various Sources)

Test	Sheep				Cattle				Sheep	Goat

VetBooks.ir

muscle-specific enzymes like creatine kinase (CK). Elevations in these enzymes together with increased CK activity generally suggest muscle injury. However, AST elevations occurring with CK values that fall within the reference range give a strong suggestion of hepatic disease. AST and LDH are also found in erythrocytes, so if the serum is severely hemolyzed or allowed to remain on the clot for an extended period, falsely elevated values due to leakage from RBCs will result.

Ammonia is produced in the GI tract from the digestion of proteins and amino acids, absorbed by the intestine into blood, and carried to the liver in the portal circulation. Ammonia is converted to urea in the liver by the hepatic urea cycle. Ammonia is a useful test for assessing liver function, but it is generally not included in most serum biochemistry panels because it is highly volatile and requires special sample handling. Serum urea nitrogen (SUN) may also have some value as an indicator of hepatic disease in ruminants, since urea is produced in the liver. In severe cases of liver failure, SUN is usually low and ammonia is often high. However, since rumen bacteria synthesize protein from urea, ruminants that have been off feed have low SUN concentrations because all the urea is being used by rumen bacteria for protein production. Thus low SUN levels are not always specific for hepatic disease.

No single liver enzyme value can consistently confirm or rule out the presence of liver disease. A combination of tests, including serum enzymes, total bile acids, ultrasound, and liver biopsy, may be needed. Some blood constituents may be altered because of failure of certain metabolic functions of the liver, but none of these changes is specific for liver disease. Blood glucose is sometimes slightly lower in severe liver disease, especially in young animals, possibly because of decreased gluconeogenesis, but none of 28 adult cases in one study had low blood glucose concentrations, and in fact, 14 cases had hyperglycemia.[9] In some toxic liver diseases, blood ammonia levels can increase fourfold or more because the urease necessary to convert ammonia to urea is found only in the liver. For the same reason, SUN may decrease, especially in the terminal phases. In the later stages, blood-clotting factors may be diminished, with delayed partial thromboplastin time (PTT) and other clotting times.

Terminally, serum albumin concentration may decrease. Considerable protein synthesis takes place in the liver, which produces all the plasma proteins except γ-globulins. The amount of these proteins in the blood, however, depends not only on the rate of synthesis but also on the rate of removal. The albumin half-life in cattle is about 16.5 days; in the horse, 19.4 days; and in sheep, 14 days.[25] Therefore serum albumin is reduced mainly in chronic liver disease. With liver damage, the synthesis of α-globulins and β-globulins is increased, so total plasma protein concentration is invariably normal or elevated, but the albumin/globulin (A/G) ratio may be decreased. The healthy liver has a large reserve for protein synthesis, and lost protein can be replenished. In one study, 18% of the horses with chronic liver disease and 6% of those with acute liver disease had albumin concentrations below the reference value.[26] In a British study, only 6 of 37 cases of equine liver disease were hypoalbuminemic, and none of these were hypoproteinemic.[9] Therefore it is assumed that hypoalbuminemia is not a common feature in horses with liver disease and that hypoproteinemia is rare. Amino acid ratios are altered in liver disease; short branched-chain amino acids are decreased, whereas aromatic amino acids are increased.[27]

Excretion Tests for Liver Function

Because the liver excretes a number of endogenous compounds and foreign substances injected into the animal, the rate of excretion or clearance of these substances can be used to test the excretory function of the liver. Bilirubin itself can be used and, if elevated above normal, would indicate liver failure, bile blockage, or excess production due to hemolysis. In the horse, bilirubin is also increased during fasting in animals without liver disease.[28] With liver damage in the horse or ruminant, most of the retained bilirubin is unconjugated (indirect reacting), and the direct-to-total ratio is usually less than 0.3. With bile blockage or intrahepatic cholestasis, the direct-to-total ratio may be greater than 0.3 in the horse or 0.5 in cattle.

Bilirubin is the main bile pigment and is produced from heme, 75% of which comes from RBCs. When the erythrocytes are broken down, heme is converted first to biliverdin and then to bilirubin in the macrophage system. This unconjugated bilirubin is insoluble and must be bound to albumin for transfer; the kidneys do not remove this bound bilirubin. Unconjugated bilirubin is taken up by the hepatocytes with cytosolic binding proteins within the hepatocyte. In the hepatocyte, some bilirubin is conjugated to diglucuronide, but in the horse, more than half the bilirubin in bile is conjugated with glucose. Conjugated (direct-reacting) bilirubin is water soluble, and some will enter the general circulation; if concentration is sufficiently high, the kidneys will filter it into the urine. Conjugated bilirubin is secreted into the bile canaliculi by an energy-dependent transport process. In most species, this is the rate-limiting step, but this may not be true in large herbivores. Conjugated bilirubin passes into the intestine through the bile ducts, and if they are blocked, both conjugated and unconjugated bilirubin will increase in the plasma. In the intestinal tract, bilirubin is converted to urobilinogen by anaerobic bacteria. Some urobilinogen is absorbed and reexcreted by the liver, but a small fraction will pass the normal liver and be excreted in the urine. With complete biliary blockage, there will be no urobilinogen in the urine, and with hemolysis, there may be increased urobilinogen in the urine. Urobilinogen is not very stable in the urine, so analysis must be done within 1 or 2 hours or the amount detected will be erroneously low.

Fasting decreases the efficiency of plasma bilirubin removal in all species, but the horse shows a greater rise in plasma bilirubin, often reaching a plateau two to three times the normal state. This increase is due to a decrease in removal of bilirubin by the hepatic transport and not by an increase in its production.[28,29] In normal ruminants, total bilirubin concentrations are low compared to other species, and the magnitude of increase is generally small and inconsistent even with severe liver damage.[2] Ruminants with cholestatic disease may have moderate increases in serum bilirubin, but this is not a consistent finding. Increases in direct bilirubin are usually the result of hemolysis.

Serum total bile acid concentration is a good test of liver function in horses. The concentration of bile acids in the serum will be increased if there is hepatocyte damage, blockage of bile flow, or shunting of portal blood to the systemic circulation, bypassing the liver. The liver synthesizes bile acids from cholesterol. Cholic and chenodeoxycholic acids are the primary bile acids conjugated with amino acids before excretion into the bile. Only conjugated bile acids are present in the intestine; they are soluble and form micelles with fat because of their detergent properties. Most bile acids excreted in bile are resorbed by an active transport system in the ileum and carried by the portal circulation back to the liver for reexcretion. In most species, more than 95% of the bile acids are resorbed and recirculated through the enterohepatic circulation.[30]

Many simple-stomached animals have a postprandial increase in serum bile acid because bile is released from the gallbladder during eating and subsequently resorbed by the ileum. This does not seem to be important in the horse, which has no gallbladder, or in cattle, in which no relationship to feeding could be found.[31] Table 33.3 lists the upper limits

VetBooks.ir

of normal for liver function tests in large animals of various ages. In cattle, there is an hour-to-hour fluctuation in bile acid concentration that could be as much as 60 µmol/L, along with considerable variation between individual cattle.[31,32] In dairy cattle, a significant decrease in serum bile acid concentrations occurs throughout the course of lactation.[33] In the horse, serum concentration above 14 µmol/L would indicate liver damage, bile blockage, or shunting.[33] Serum total bile acid concentration is likely a more sensitive indicator of liver disease in the horse than serum bilirubin; only 8 of 34 horses with liver disease had elevated bilirubin, but 31 of 37 had elevated bile acids.[9] In a more recent study, bile acids were also associated with prognosis in horses with hepatic disease, with values greater than 20 µmol/L relatively specific for nonsurvival.[34] In adult cattle, because of the hour-to-hour variations, bile acid concentration on a single sample would have to be above 126 µmol/L in beef cattle and 88 µmol/L in dairy cattle to be an indication of liver disease.[35,36] Although ruminants have a large normal range for bile acid concentrations, significant increases have been shown to be a specific indicator of hepatic disease.[36]

A number of dyes are excreted primarily by the liver; sulfobromophthalein (bromsulphalein [BSP]) is used most often. In large animals, BSP clearance (half-life) is used much more than the retention test. In the test, 500 to 1000 mg (≈2 mg/kg) of BSP is injected intravenously. Blood samples are taken before the injection and two to four times 5 to 12 minutes after the injection (i.e., at 5, 7, 9, and 11 minutes). These samples are analyzed for color produced by BSP, and a half-life is determined by plotting the points on semilog paper. Normal horses have a BSP half-life of less than 3.5 minutes, and for ruminants it is less than 5 minutes. This may be increased in very young animals (see Table 33.3) and in pregnant females. Other dyes, such as indocyanine green, have some advantage (less renal excretion than BSP) but at present are too costly for use in large animals.

Liver Biopsy

Liver biopsy can be very useful, not only in confirming the presence of liver disease but also in determining or ruling out some etiologies. It is a relatively safe and simple procedure but should be avoided when liver abscesses are suspected. A number of biopsy instruments are available, including aspiration punches, but the Tru-Cut biopsy needle or similar notch-cutting needles seem to work quite well. In all species the skin over the biopsy site should be clipped and prepared for aseptic insertion of the needle. A local infiltration of 2% lidocaine helps reduce the animal's reaction, but it may still flinch when the pleura and peritoneum are penetrated. A small stab wound through the skin at the site of insertion is made with a scalpel blade.

The site of skin puncture for liver biopsy in the horse is the right fourteenth intercostal space at the intersection of a line drawn from the tuber coxae to the point of the shoulder.[37] Some operators recommend more cranial insertion (twelfth or thirteenth space), but more lung is penetrated at points farther cranial. If a more cranial position is selected, it should also be more ventral. If the needle is directed slightly cranial and ventral, it is more likely to remain in the liver parenchyma and not penetrate larger vessels on the visceral surface or pass through into the right kidney, pancreas, or colon. Ultrasound guidance will increase the chances of obtaining liver specimens without penetrating other organs; in fact, recent research indicates that the practice of blind percutaneous liver biopsy in horses should not be attempted due to the high risk of complications.[38]

Cattle must be suitably confined for liver biopsy. A biopsy can often be performed on quiet dairy cows in a stanchion while the tail is elevated ("tailed"). Although identification of the liver with ultrasound is preferable to a blind stick, the puncture site in cattle can be located by extending a horizontal line cranial from the middle of the paralumbar fossa. The needle is inserted where this line crosses the eleventh intercostal space on the right side. The lungs do not extend as far caudal as in the horse, so the liver is more exposed. The needle is directed slightly cranial and ventral, as in the horse.[2]

Liver biopsy in sheep and goats is slightly more difficult; additional sedation is usually required. A site at the ninth or tenth intercostal space at the level of the ventral end of the last rib has been recommended. The biopsy needle is advanced in a craniomedial direction until the liver is penetrated.

Diffuse or zonal lesions, as seen in most toxic, infectious, and metabolic liver diseases, can usually be diagnosed by liver biopsy. Focal lesions (e.g., abscesses, granulomas, neoplasias, as well as liver flukes) are easily missed by liver biopsy. If a liver abscess is suspected, biopsy is contraindicated because of the potential danger of rupturing an abscess. A scoring system has been developed for the prognostic evaluation of equine liver biopsies.[39] Examining liver biopsy tissue can confirm the presence of liver disease, help establish the type of disease, and aid prognosis.

Ultrasound Examination

Ultrasonographic examination of the liver is an extremely useful tool in diagnosing liver diseases (see ultrasound images in Chapter 32). Using ultrasound, the clinician can determine the size of the liver, where it is located, and the diameter of the primary hepatic vessels. Hepatic abscesses, cholelithiasis, neoplasia, and fibrosis can be diagnosed by ultrasound in the horse.[40] In cattle, diseases such as fascioliasis, liver abscesses, neoplasia, thrombosis of the caudal vena cava, and even hepatic lipidosis can often be detected using ultrasound.[41-45] Ultrasound of the liver can also facilitate collection of a biopsy sample, aspiration of an abscess, or even cholecystocentesis (aspiration of a bile sample for diagnosis of liver flukes). Parenchymal pattern of the liver is changed with diffuse fibrosis. The bovine liver is situated immediately underneath the right body wall, with the cranial portion hidden by the lung. Hepatic ultrasonography is performed on the right side of the standing animal. The examination is usually done from caudal to cranial, beginning at the last rib and moving forward past the tenth intercostal space using a 3.5- to 5-MHz linear probe.[41] In sheep, the examination is done on the right side in the seventh through twelfth intercostal spaces.[46] In horses, the ultrasonic examination is performed below and caudal to the lung in the right sixth to fourteenth intercostal spaces.[46] The liver can also be visualized on the left side of the horse in the lower intercostal spaces[47] or ventrally behind the xiphoid.

Prognosis

The severity of clinical signs may be the most useful noninvasive prognostic test in horses with liver disease.[48] Indicators of a poor prognosis in liver disease include an albumin concentration less than 2.5 g/dL in horses or an increased globulin level, a prothrombin time (PT) greater than 30% of normal, and greatly elevated GGT and ALP, especially if SDH or LDH is normal or decreased. Marked fibrosis that bridges the liver lobules on histopathologic examination suggests a poor prognosis. Severe pyrrolizidine alkaloid toxicosis carries a particularly grave prognosis because remaining hepatocytes are inhibited from regeneration by mitotic arrest. Terminal clinical signs include development of hemolytic crisis in the horse and marked hepatic encephalopathy in the patient with a fibrotic liver.

Infectious, Toxic, and Parasitic Liver Disease

Acute Hepatitis in Horses

Joy E. Tomlinson

Etiology *Theiler's disease*, also known as *idiopathic acute hepatic disease*, *serum hepatitis*, *postvaccinal hepatitis*, and *acute liver atrophy*, is the most common cause of acute hepatitis and hepatic failure in horses in North America.[1-5] The disease was first recognized by Sir Arnold Theiler in large numbers of horses in South Africa. Horses developed the disease following immunization against African horse sickness with simultaneous administration of live virus and hyperimmune equine serum.[6] Since then, Theiler's disease has been observed in two forms. First, it has been documented as a potential complication of any equine-origin biologic product used in horses, including plasma and serum products, and has most recently been suspected after allogenic stem cell treatment (unpublished). Theiler's disease has been most often associated with use of either tetanus antitoxin (TAT) or commercial equine plasma.[3,5,7-11] A recent outbreak was also associated with equine antiserum to botulinum toxin.[12] Second, Theiler's disease is occasionally seen without a history of recent equine-origin biologic product administration.[1,7,13] This is often seen as a herd outbreak and may have a seasonal nature, occurring most frequently in the summer and fall.[1,7,13] In addition, in outbreaks of biologic product–associated Theiler's disease, it is not uncommon for in-contact horses to also develop Theiler's disease, suggesting that an infectious agent may be involved.[1,6,7,13]

Theiler's disease is primarily a disease of adult horses.[1,5,7,10,11] There is no clear breed or sex predilection for Theiler's disease.[3,5,6,9-17] Postfoaling mares and postcastration geldings may be at increased risk due to frequent use of prophylactic tetanus antitoxin in those horses.

Little has been known about the etiology of Theiler's disease until recently. An investigation into an outbreak of Theiler's disease in a group of horses receiving prophylactic botulinum antiserum resulted in the discovery of a pegivirus that was named *Theiler's disease–associated virus* (TDAV).[12] Although this was initially suspected to be the cause of the outbreak, TDAV was not present in subsequent cases of Theiler's disease, and a new pathogen, *Equine parvovirus-hepatitis* (EqPV-H) was discovered.[18] EqPV-H was retrospectively found to also be present in the botulinum antiserum outbreak.[12,18] EqPV-H was present in sequential cases of non–biologic-associated cases of Theiler's disease, in biologic-associated cases, and in the biologic products implicated (unpublished). Experimental infection with EqPV-H in two adult horses resulted in acute necrotizing hepatitis.[18] However, not all horses that have EqPV-H-positive serum confirmed by polymerase chain reaction (PCR) testing have clinical or biochemical evidence of hepatitis, which may suggest that other host factors, immune-mediated hypersensitivity reactions, or co-infection with other etiologic agents may be necessary for disease.[12,18] Horses may become chronically infected with virus, with the majority remaining serum PCR positive for at least 1 year (unpublished).

Clinical Signs The clinical effects of Theiler's disease are associated with signs of acute hepatic failure and typically occur 1 to 3 months after administration of blood products.[6,12,13] These signs include depression, jaundice, inappetence, pica, yawning, photoactive dermatitis, and hepatic encephalopathy.[2,3,7,9,14,15] Fever has been described as absent or rare in horses affected with Theiler's disease.[4] Intravascular hemolysis has been reported to lead to hemoglobinuria in some terminal cases of Theiler's disease.[2] Evidence exists for a subclinical component in some cases.[10,12,16] However, some horses that received tetanus antitoxin or botulinum antitoxin have clinicopathologic evidence of liver disease without developing clinical signs, indicating that disease severity may vary.[5,10,12,16]

FIG. 33.2 Characteristic small, "dishrag" liver from a horse with Theiler's disease. *(Photo courtesy Sam Jennings, North Carolina State University.)*

Diagnosis Diagnosis of Theiler's disease is based on the anamnesis, clinical signs, serum biochemical analysis, and hepatic biopsy or necropsy. High serum levels of unconjugated and total bilirubin and serum bile acids, coupled with high serum activity of GGT, SDH, AST, GDH, LDH, and ALP are indicative of hepatic necrosis in horses.[17] Additional findings with severe disease may include decreased blood urea nitrogen (BUN), hyperammonemia,[17] prolonged clotting times (PT and activated partial thromboplastin time [APTT]), and decreased albumin. Theiler's disease may be confirmed by hepatic biopsy or postmortem examination of hepatic tissue. The liver is often small and has a characteristic "dishrag" appearance (Fig. 33.2). Typical histopathologic changes seen in specimens obtained by biopsy or at postmortem examination include widespread necrosis of hepatocytes that is most severe in the centrilobular and midzonal areas.[1,8] The few remaining living cells are confined to the periportal areas and commonly contain cytoplasmic vacuoles.[1,8] The normal architecture of the centrilobular and midzonal areas is replaced by a pale, eosinophilic granular mass in which ghost outlines of necrotic hepatocytes are present.[8] A mild inflammatory cell infiltrate is seen in the portal areas, as are a number of spindle-shaped fibroblastic cells.[8]

Differential diagnoses include a variety of heavy metal and organic hepatotoxins (see the Pyrrolizidine Alkaloid Toxicity and Other Hepatotoxins sections later). Acute onset of chronic pyrrolizidine alkaloid toxicity can cause a similar clinical and histopathologic presentation. Although EqPV-H is highly suspected to be a cause of Theiler's disease, the data remain associative and not definitive to date. PCR testing of serum or liver for EqPV-H is available.

Treatment There is no specific treatment for Theiler's disease.[19] Treatment should be aimed at supporting liver function

VetBooks.ir

and controlling abnormal behavior. Dietary adjustments are important and should consist of reducing the quantity of protein in the diet while increasing carbohydrate intake.[7] Sorghum, milo, or beet pulp, which contains high levels of branched-chain amino acids, can be mixed with molasses to improve palatability and caloric content.[2] Diets high in branched-chain amino acids tend to lessen the degree of abnormal behavior associated with hepatic encephalopathy.[19] Oral (PO) neomycin, lactulose, and mineral oil may be administered to decrease ammonia production and absorption from the GI tract. Xylazine or detomidine may become necessary to sedate horses that display severe signs of hepatic encephalopathy,[19] but high doses that cause extreme lowering of the head should be avoided if possible. Benzodiazepines (diazepam or midazolam) should be avoided. Continuous intravenous (IV) administration of dextrose and balanced electrolyte solutions to reduce hepatic workload and maintain plasma volume are recommended.[16] If spontaneous bleeding occurs at injection sites or at sites of self-inflicted injury, plasma transfusions may be necessary to replace the deficient clotting factors.[2] The use of glucocorticoids for treating Theiler's disease is controversial but may be indicated based on some histopathologic evidence of an immune-mediated etiology.[14,17]

Currently, no preventive measures are available. However, since administration of TAT is associated with substantial risk for development of fatal Theiler's disease,[7,10,16] the routine practices of prophylactic administration of TAT to recently parturient mares or postcastration geldings should be strongly discouraged. TAT use should be restricted to clinical situations necessitating tetanus prophylaxis in which a history of active tetanus (toxoid) immunoprophylaxis is absent or unknown. The risk of postvaccinal Theiler's disease should be addressed with the owner before administration of TAT. Although the prevalence of serum hepatitis associated with administration of commercial plasma appears to be low in horses, it should be considered an uncommon risk that can have a fatal outcome.[11]

Theiler's disease may be observed sporadically or affect a group of horses. Recognition of Theiler's disease in one horse should necessitate careful observation of horses on the same premises for either clinical or serum biochemical signs of Theiler's disease.[12,16] Based on recent case reports, it appears that not all cases of Theiler's disease are clinically apparent, and screening for its presence with routine serum biochemical analysis is useful in detecting subclinical cases.[10-12,16]

Black Disease

Geoffrey W. Smith

Etiology Infectious necrotic hepatitis (black disease) is a peracute, highly fatal disease occurring worldwide. The disease most commonly affects sheep, particularly adults in good body condition, but cattle, horses, goats, and occasionally pigs may also be affected.[1,2] There has even been recent speculation that black disease is the cause of epidemic catarrh of sheep, a significant cause of mortality in Australian sheep dating back to the mid-1800s.[3] Black disease is caused by toxins produced by the bacterium *Clostridium novyi* type B, spores of which are commonly found in the soil and can also be present in the digestive tracts and livers of animals grazing affected pastures. Clostridial organisms require an anaerobic environment for growth, so black disease occurs only when there has been enough damage to the liver to provide the anaerobic environment required for growth of the organism and subsequent toxin production. In practice, the liver insult is almost always caused by larval migration of the common liver fluke, *Fasciola hepatica*. Therefore this is a seasonal disease related to the liver fluke cycle and occurring in animals typically infested by *F. hepatica*. Other liver parasites, such as *Fascioloides magna* or *Dicrocoelium dendriticum* (especially in France), are occasionally implicated, as is damage to the liver by biopsy or trauma severe enough to result in anaerobic conditions in the liver. Such a scenario should be considered when sudden deaths occur at times when flukes are not usually migrating or in families like Equidae that are not normal hosts for *F. hepatica*. Black disease occurs worldwide wherever liver flukes are present.

Pathophysiology The *C. novyi* strains that cause black disease produce at least two potent exotoxins: alpha toxin and beta toxin. The alpha toxin enters cells by receptor-mediated endocytosis and inhibits ras and rho guanosine triphosphatases by glycosylation.[4] The beta toxin is a necrotizing and hemolytic phospholipase C (lecithinase). Other toxins may contribute to the pathophysiology as well.

C. novyi type B is widely distributed in soils, and its spores are continuously ingested and shed in feces of grazing animals. Some of these organisms cross the intestinal mucosa and become disseminated throughout the animal's macrophage system, including the Kupffer cells of the liver. When localized anaerobic conditions occur in the liver, as with migration of liver fluke larvae, these resident spores may germinate and enter a vegetative state. As they proliferate, they release their toxins and create enlarging zones of coagulative necrosis in the liver. The exotoxins produced will enter the circulation, where they cause damage to neurons, vascular endothelium, and other tissues, eventually causing sudden death of the animal.

Clinical Signs Peracute death is the most common clinical presentation associated with black disease. When affected animals are recognized prior to death, clinical signs are relatively nonspecific. The animal will often be isolated from the herd and will appear depressed, anorexic, and possibly in respiratory distress. Temperature is elevated initially (40° to 41° C [104° to 106° F]) but declines before death. Sheep become sternally recumbent and generally die after a clinical course of only a few hours. Venous congestion darkens the skin, giving the disease its common name, *black disease*.[2] Unlike closely related bacillary hemoglobinuria, or "redwater" (see later discussion), affected animals do not show red urine or bleeding from the nose or rectum. Clinical signs in cattle are similar, but the disease course occurs over 1 to 2 days.

Diagnosis Necropsy is often difficult because autolysis of the tissues after death is usually rapid. Fluid is often found in the pericardial sac and pleural and peritoneal cavities. Endocardial and epicardial hemorrhage is also a consistent finding. Urine is grossly normal. Tissues, especially solid organs like liver and kidney, appear to be in a much more advanced state of autolysis than time of death would suggest. The liver is usually swollen and congested with small pale areas of coagulative necrosis, particularly along its diaphragmatic surface. The primary lesions of black disease are single or multiple areas (2 to 3 cm in diameter) of hepatic necrosis that appear yellow to white in color and are surrounded by a broad zone of hyperemia.[4]

Diagnosis of black disease is generally made by a combination of history, clinical presentation, necropsy findings, and isolation of *C. novyi* type B from the liver. A history of sudden death, particularly in endemic fluke areas, is highly suggestive of black disease, especially during warmer weather when fluke transmission is active. Flock or herd vaccination will be either overdue or absent. Time of death should be ascertained as closely as possible. The animal is usually presented in lateral recumbency without signs of struggle. It will be severely bloated even if death has occurred quite recently, giving the impression of a carcass in a more advanced state of decomposition than timing would suggest. Acute liver fluke infection in sheep can have a high mortality by itself, and postmortem findings may

VetBooks.ir

be similar to black disease. Other causes of sudden death (e.g., enterotoxemia, blackleg, anthrax) should also be ruled out.[2]

If necropsy does not confirm a diagnosis of black disease, or if additional documentation is necessary, a simple Gram stain of an impression smear taken from the margin of the liver lesion will typically reveal numerous gram-positive rods. Because clostridial organisms proliferate rapidly after death, such findings must always be interpreted carefully, with consideration of time elapsed between death and necropsy. Further diagnostic measures include anaerobic culture and isolation of *C. novyi* type B, identification of the specific toxins, and fluorescent antibody identification of the organism. Characteristic histopathologic changes may also be seen in fixed sections of liver associated with necrotic lesions. Impression smears obtained from the liver lesions are ideal for fluorescent antibody identification of *C. novyi* type B.

Treatment and Control Treatment of black disease is rarely undertaken because of its peracute presentation; animals are usually found dead. Although *C. novyi* is highly sensitive to penicillin and the tetracyclines, toxin production is usually too far advanced for antibiotics to be of value. If used, they should be administered at high doses, intravenously if possible for most rapid onset (20,000 to 40,000 IU/kg sodium or potassium penicillin or 10 mg/kg oxytetracycline q12h), followed by intramuscular (IM) or IV doses at appropriate intervals. Supportive fluid therapy should be initiated to correct dehydration. Even with aggressive therapy the prognosis is poor and the chances for survival slim. In the event of an outbreak, vaccination should be initiated immediately, along with possible metaphylactic administration of penicillin or oxytetracycline.

A good prevention program involves both proper fluke control and the use of clostridial bacterins. Efforts to clear soils of the offending organism are unrewarding. However, it is recommended that carcasses of animals dying from black disease be burned, buried deeply, or removed from the premises. Commercial bacterin-toxoids against *C. novyi* are available in combination with other clostridial organisms. These products are generally safe and highly effective. Duration of protection is short, however, and should not be relied on for more than 5 to 6 months. Animals vaccinated when younger than 3 to 4 months old require revaccination at weaning. Local reactions at the site of subcutaneous vaccination are common but primarily of cosmetic concern. Intramuscular vaccination should be avoided because it frequently results in permanent damage to muscle tissue, with a negative impact on meat marketing. Timing of vaccination must be determined by the local climate and liver fluke season. In more severe climates where the fluke season is relatively short, a single annual injection before fluke transmission season may be sufficient. In more moderate climates with longer periods of fluke exposure, two vaccinations per year may be required.

Control of liver fluke infestation is also closely linked to prevention of black disease. Control measures include pasture or range management; control of water sources; strategic treatment of animals with appropriate anthelmintics; and limiting access to streams, canals, ponds, and marshes. This is a complex subject, and the reader should refer to the Liver Flukes in Ruminants section for more detail.

Bacillary Hemoglobinuria ("Redwater")

Geoffrey W. Smith

Etiology Bacillary hemoglobinuria (redwater, icteric hemoglobinuria) is a disease causing sudden death in cattle, small ruminants, and occasionally horses. The disease was first reported in California in 1916 and is caused by the toxins of *Clostridium haemolyticum* (formerly *C. novyi* type D). Bacillary hemoglobinuria is quite similar to black disease, where clostridial infections of the liver occur under anaerobic conditions, presumably from liver fluke migration. However, in a recent study involving 20 cattle with naturally occurring bacillary hemoglobinuria, none had gross or histologic lesions indicative of liver flukes, suggesting that some other predisposing factor might be involved.[1] The major toxin in *C. haemolyticum* infection is the beta toxin, which is a phospholipase C that causes hepatocyte necrosis, hemolysis, and damage to capillary endothelium.[1,2] This results in hemoglobinuria and loss of fluids into tissues and cavities. The primary action of beta toxin is to induce localized hepatic necrosis and intravascular hemolysis. Like *C. novyi* type B, *C. haemolyticum* is also found in the soil. Spores are routinely present in the liver and can be passed in feces and urine of healthy animals grazing affected pastures. Disease occurs only when there is sufficient insult to the liver to provide the anaerobic conditions required for bacterial growth and toxin production. In many cases the liver insult is caused by migration of *F. hepatica* (common liver fluke) larvae.[3-5] As in black disease, *F. magna*, *D. dendriticum* (the lancet liver fluke), and *Cysticercus cellulosae* have also been occasionally implicated in the disease, as has liver biopsy or trauma severe enough to result in liver bruising.[6] Bacillary hemoglobinuria is, for the most part, a seasonal disease occurring at the time of larval fluke migration. In the United States, most cases are seen during summer and early fall. However, the disease is sometimes diagnosed in cattle in animals without liver flukes.[1,5]

Bacillary hemoglobinuria is a regionalized disease. It has been reported that *C. haemolyticum* is limited to alkaline soils, but the disease is also endemic in regions with acid soils. Outbreaks often follow flooding, which can bring spores into previously uninfected areas. The factors affecting distribution of the disease are not well understood. Even in areas where it is common, distribution is erratic, with some farms severely affected while others nearby are disease free.

Pathophysiology Spores of *C. haemolyticum* are ingested by susceptible animals, cross the intestinal mucosa, and are transported to the liver and other organs, probably within the phagosomes of cells of the mononuclear macrophage series. The spores can persist in the liver within Kupffer cells for long periods. Any localized anaerobic area of the liver will allow these spores to germinate. Release of toxins from the bacteria further exacerbates the anaerobic environment, favoring accelerated bacterial proliferation, toxin production, and hepatic necrosis. Beta toxin leads to hepatocyte, erythrocyte, and endothelial cell disruption and thrombus formation. The progression of this lesion is likely responsible for the large necrotic foci observed in virtually all cases of the disease.[1] Absorption of toxins into the circulatory system rapidly leads to intravascular hemolysis, icterus, hemoglobinuria, and death.

Clinical Signs Bacillary hemoglobinuria is most common in animals older than 1 year of age. Like black disease, sudden death without obvious clinical signs is common in animals that have peracute disease. In those rare cases where disease is recognized antemortem, signs include depression, anorexia, and fever of 40° to 41° C (104° to 106° F), declining as death approaches. Breathing may be rapid and shallow, and blood or blood-tinged froth may be present in the nostrils. Rectal bleeding or bloody feces may also be observed. Severe hemoglobinuria or passage of dark red, port wine–colored urine is often reported. Blood is thin and watery and coagulates slowly. Mucous membranes are pale and icteric. Severity of signs increases as the disease progresses. Postmortem, the animal is usually in lateral recumbency, severely bloated, and without signs of struggle. Blood is often present in the nostrils, mouth, rectum, or vagina. The carcass appears to be in an advanced

state of decomposition even when it is actually quite fresh. A tentative diagnosis can be made on the basis of history and observation of the carcass.

At necropsy the mucous membranes and tissues can appear icteric. Skinning the animal reveals numerous subcutaneous petechial and ecchymotic hemorrhages, edema, and sometimes emphysema. There will be significant amounts of red-tinged abdominal and thoracic fluid. Hemorrhages are present on all serosal surfaces. Dark red urine is present in the bladder. Lymph nodes are congested and usually hemorrhagic. There may be hemorrhage into the bowel lumen. The spleen is enlarged. The lungs are usually filled with blood-tinged froth or foam. Pericardial fluid is blood tinged, and hemorrhages are present on both the epicardium and the endocardium. Solid organs such as liver and kidney appear to be in advanced stages of autolysis, even in fresh carcasses. The pathognomonic lesion is the so-called ischemic hepatic infarct, which has a zone of hyperemia at its interface with viable liver tissue. This area of coagulative necrosis, sometimes partially liquefied at its center, can reach up to a 30-cm diameter and have a very irregular outline.[4] Unlike a classic infarct, the lesion in bacillary hemoglobinuria results from progressive enlargement of the focus of coagulative necrosis caused by the bacterial toxins. Any thrombosis seen in the lesion is secondary, with the vasculature being included in the necrotic process, along with other hepatic tissue.[6]

Diagnosis Antemortem animals with bacillary hemoglobinuria will be anemic and have elevated hepatic enzymes such as AST and GGT.[7,9] Total bilirubin concentrations are also dramatically elevated.[7,9] If a urine sample can be collected, hemoglobinuria will be obvious. Postmortem, a Gram-stained impression smear from the liver will reveal numerous typical clostridial organisms. Smears may also be made from spleen, blood, or abdominal fluid, with the same outcome. Postmortem presence of clostridial organisms must be interpreted with caution because they are always present and proliferate rapidly after death. It is important to have an accurate estimate of time of death to determine the significance of these findings. Laboratory confirmation depends on identification of both the causative bacteria and the toxin. Fresh (refrigerated) and formalin-fixed liver lesions should be submitted. Fluorescent antibody tests on impression smears taken from a liver "infarct" will be positive for *C. haemolyticum* antigens. Extensive biochemical and toxin identification tests are confirmatory but seldom used if lesions and fluorescent antibody tests are compatible. A PCR assay that can detect *C. haemolyticum* in the blood of affected cattle has also been reported,[7] as have PCR assays to detect the beta toxin.[1]

Treatment and Prevention Although successful treatment of cattle with bacillary hemoglobinuria has been described,[7,10] it is seldom undertaken because of the acute nature of the disease. If there is opportunity for treatment, penicillin at high dosages (at least 20,000 to 40,000 IU/kg IV or IM twice daily) is the antibiotic of choice, although tetracyclines (10 mg/kg IV twice daily) are acceptable. Fluids are given intravenously or intraruminally to correct dehydration. Because of severe hemolytic anemia, blood transfusion is recommended and should be repeated as necessary. In animals that recover, there will be a noticeable reduction in the severity of hemoglobinuria daily.[7]

An effective prevention program requires consideration of both the pathophysiology and immunology of the disease and the natural history of the liver fluke *(F. hepatica)* that is so intimately involved in expression of bacillary hemoglobinuria. Efforts to clear soils of the offending organism are unrewarding, but carcasses of animals dying from bacillary hemoglobinuria should be burned, buried deeply, or removed from the premises.

Commercial bacterin-toxoids against *C. haemolyticum* are available both in monovalent form and in combination with other clostridial vaccines. These products are generally safe and highly efficacious. Duration of protection is short, however, and should not be relied on for more than 5 to 6 months. Animals vaccinated when less than 3 to 4 months old require revaccination at weaning. Local reactions at the site of subcutaneous vaccination are common but primarily of cosmetic concern. Intramuscular vaccination should be avoided because it frequently results in permanent damage to muscle tissue, with a negative impact on beef marketing. Timing of vaccination must be determined by the local climate and liver fluke season. In more severe climates where the fluke season is relatively short, a single annual injection before fluke transmission season may be sufficient. In more moderate climates with longer periods of fluke exposure, two vaccinations per year may be required.

Control measures include pasture or range management, control of water sources, strategic treatment of animals with products effective against flukes, and limiting access to streams, canals, ponds, and marshes. This is a complex subject, and the reader should refer to the Liver Flukes in Ruminants section for more detail.

Liver Disease in Foals

Jennifer L. Davis

Liver disease in foals may be classified as primary or secondary and can be associated with infectious, parasitic, congenital, metabolic, or toxic causes. An initial diagnosis of hepatic disease is often made based on elevations in hepatic enzyme activities on biochemical analysis, but it is important to use age-specific reference ranges to interpret biochemical indicators of hepatic disease. Several hepatic enzymes can have increased activity even in healthy neonates.[1-3] Total bilirubin may be elevated as fetal hemoglobin converts to adult hemoglobin. Elevations may also result from a deficiency in liver binding and conjugating enzymes.[1] ALP remains elevated for an extended time in young horses as a result of increased osteoblastic activity, with normal values as high as 3752 U/L reported.[4] Increased GGT activity may be present in foals for 2 to 4 weeks after birth, whereas only slight increases of SDH are expected during the same period.[1,3] Increased variability in ALP and GGT in healthy foals can make interpretation of hepatic function difficult. Serum bile acids (SBAs) are significantly greater in foals than adult horses for the first 6 weeks of life. According to one study, this is potentially due to upregulation of hepatic production, reduced excretion, differences in bile acid composition of the neonate, or enhanced intestinal or portal uptake.[3] An additional finding of that study was that SBAs were not significantly different between healthy and sick foals.[3] Another study noted that elevated liver enzymes were common in sick foals, and those foals with high liver enzymes were more likely to have sepsis than other diseases.[4]

Tyzzer's Disease

Tyzzer's disease is an acute hepatitis affecting foals 7 to 42 days of age, with no known breed or sex predeliction.[5-13] It has also been reported in calves, lambs, and other species.[14-16] The causative organism is *Clostridium piliforme* (formerly *Bacillus piliformis*), a gram-negative, flagellated, spore-forming intracellular obligate anaerobe.[17] Multiple strains can infect Equidae, and foals are susceptible to at least two distinct strains (isolate E and R1), with no evidence of cross-reactivity of antibodies between isolates.[17,18]

Although the exact pathogenesis is unknown, bacterial spores can be shed in the manure of carrier horses, suggesting a fecal-oral route of transmission with subsequent GI and hepatic

VetBooks.ir

colonization.[19] Farms with multiple cases per year have been documented to feed higher protein diets compared to farms without cases, suggesting that high-protein and nitrogenous diets fed to nursing mares may increase proliferation of *C. piliforme* in the gut of both mares and foals.[13] Several other risk factors, including time of year, age, resident status of the mare, and heavy rainfall in the spring, have been associated with development of disease.[13,20] Foals born between March and May were found to be more likely to develop disease in two different studies, and this was thought to be due to the increased number of animals present on the farm during that time. Foals from younger mares (<6 years of age) and those not from endemic farms were more likely to develop disease, possibly owing to lack of antibodies in the mare's colostrum or antibodies to different strains of *C. piliforme* being present. Early spring rainfall affects the growth of cool-season grasses, and those grasses may be rich in nitrogenous compounds.[13] Immunocompromised foals may also be at greater risk,[11,12] although disease often occurs in previously healthy, rapidly growing foals.[13]

Disease may occur sporadically or as an outbreak.[12,19,20] Clinical signs are acute to peracute, are nonspecific, and may be related to age. Younger foals are more likely to be found dead with no premonitory signs.[13] In older foals, signs observed may include severe depression, fever or hypothermia, colic and diarrhea progressing rapidly to seizures, blindness, coma, and death.[5-13] Icterus may or may not be present, depending on the acuteness of disease. Bloodwork abnormalities indicate overwhelming sepsis characterized by leukopenia, hyperfibrinogenemia, profound hypoglycemia, and severe acidosis, with concurrent elevations in bilirubin, bile acids, SDH, GGT, AST, ALP, and LDH-5.[9,11,20] Diagnosis is usually made at postmortem and is based on the presence of acute, widespread multifocal areas of necrosis and hepatitis, with intrahepatocellular filamentous bacteria present at the periphery of the lesion.[13,21] Silver stains (e.g., Warthin-Starry) and Giemsa stains may help facilitate diagnosis.The fastidious nature of the organism makes culture difficult. PCR techniques have been used for detection of *C. piliforme* in multiple species, including foals.[22] This test may aid in early diagnosis and treatment.

Treatment of Tyzzer's disease can be attempted, but the disease is highly fatal, with most foals dying within 2 to 48 hours (median survival is 30 hours) of showing clinical signs. Initial treatment with IV dextrose may cause an immediate but temporary improvement in clinical signs. There are reports of successful treatment of three suspected cases[20,23] and one confirmed case[22] in foals. When attempted, treatment should be early and aggressive and consist of antibiotics (including high-dose IV potassium penicillin or ampicillin), parenteral nutrition, correction of acidosis, and other supportive care.[22] Currently there are no preventive measures available for Tyzzer's disease in the foal.

Other Bacterial Causes

Leptospirosis was reported to cause jaundice and death in a 10-day-old foal.[24] Although *Leptospira interrogans* serotype Pomona is known to cause abortion and liver disease (giant cell hepatopathy) in the equine fetus, it is only a rare cause of neonatal liver disease. *Actinobacillus equuli* typically causes bacteremic embolic nephritis and acute death in very young (3-day-old) foals. It may also cause widespread multifocal hepatitis, similar in appearance to foals with equine herpesvirus 1 (EHV-1). *Streptococcus zooepidemicus* bacteremia may result in multifocal hepatic abscesses. *Listeria monocytogenes* has been reported as a cause of severe hepatitis with necrosis and fibrinonecrotic typhlitis and colitis.[25] Cholangiohepatitis and photosensitization vasculopathy with secondary pyoderma have been diagnosed as a result of *Bartonella henselae* infection in a 3.5-month-old Thoroughbred colt.[26]

Other bacteria and bacterial toxins may initiate an exaggerated response to sepsis (systemic inflammatory response syndrome [SIRS]), which may result in multiple organ dysfunction, including hepatic failure. Many vasoactive mediators are involved in this process; the hemodynamic system becomes ineffective, and certain organs (e.g., liver) may fail because of hypoxia. Diffuse hepatic necrosis and hepatocellular apoptosis are the characteristic lesions. The clinical signs may be identical to Tyzzer's disease, except the syndrome may affect a much wider age range. Prompt and aggressive treatment is often successful. Appropriate treatments include broad-spectrum antibiotics, fluids, oxygen, and antioxidants such as dimethyl sulfoxide (DMSO) and acetylcysteine.

Bacterial sepsis rarely may cause acute portal vein thrombosis. Variable degrees of hepatic hypoxemia and inflammation accompany the thrombosis. Hyperammonemic hepatic encephalopathy has been reported in foals with *Rhodococcus equi* abdominal lymphadenitis and subsequent portal vein thrombosis.[27,28] The thrombus may or may not be visualized with ultrasound examination. Diarrhea due to portal hypertension may occur in affected foals. Complete recovery requires appropriate long-term antimicrobial therapy. Hyperammonemia has also been associated with gastrointestinal disease in foals and may occur concurrently with cases of enteritis or enterocolitis.[29,30] A lack of elevated hepatic enzyme activity may help differentiate intestinal hyperammonemia from hepatic causes. Prognosis in these cases is good if the underlying disease process can be treated.[31]

Ascending infection of the umbilical vein can result in abscessation or inflammation of the liver with or without a concurrent elevation in hepatic enzyme activity. Bacteria associated with equine sepsis can frequently be cultured from the lesions. Diagnosis is dependent on ultrasonographic evidence of an enlarged umbilical vein extending into the hepatic parenchyma along with appropriate signalment and clinical signs. Treatment may be medical or surgical.

Equine Herpesvirus 1

Equine herpesvirus 1 (EHV-1) infection of a fetus late in gestation typically results in an aborted or stillborn fetus; however, it may occasionally result in the birth of a live foal with hepatic, respiratory, and/or GI disease.[32] Affected foals may have severe neutropenia and lymphopenia, and icterus is a common clinical sign. Secondary septicemia is likely to develop due to immunosuppression. Surprisingly, significant elevations in serum hepatic enzyme activities are not present even though a severe multifocal necrotizing hepatitis with inclusion bodies is present at necropsy.[33] Generally respiratory distress is progressive, and the animal's clinical condition rapidly declines within 5 days after birth despite aggressive and early treatment. Treatment with interferon and oral acyclovir (8 to 16 mg/kg q8h)[34] may improve survival rates.

Neonatal Isoerythrolysis

Foals with severe and prolonged neonatal isoerythrolysis (NI) may develop liver failure,[35] which results from a combination of chronic hepatic hypoxia and multiple blood transfusions. Foals receiving a total volume of blood products of 4 L or more were 19.5 times more likely to develop liver failure than foals receiving a lower volume.[36] Multiple blood transfusions are thought to result in iron overload and subsequent iron toxicity. Deferoxamine, an iron chelator, enhances urinary iron elimination and decreases hepatic iron accumulation after blood transfusion in healthy foals.[37] Administration of 1 g of deferoxamine subcutaneously (SC) q12h prior to blood administration may help prevent liver failure in those receiving multiple transfusions.

Kernicterus, or bilirubin encephalopathy, is another potential complication of NI in foals. Neurologic signs, including seizures,

develop secondary to the neurotoxic effects of unconjugated bilirubin on the CNS.[36,38] Kernicterus is more likely to develop in foals with total bilirubin of 27 mg/dL or greater and is associated with a poor outcome.[36] The use of therapeutic plasma exchange techniques to lower plasma bilirubin concentrations and prevent or treat kernicterus in foals has been performed in practice and holds promise as a successful treatment, if available.[39]

Drug-Induced Hepatotoxicity

Rarely, foals treated with macrolides, trimethoprim-sulfas, or histamine 2 (H_2) blockers for pneumonia or diarrhea develop an increase in serum hepatic enzymes despite clinical improvement. With changes in drug treatment, serum enzymes return to normal, suggesting that these cases may have drug-induced hepatotoxicity.[40] In one study of foals being treated for *R. equi* pneumonia, four of nine foals in the doxycycline-rifampin treatment group developed icterus and hemolytic anemia or increased liver enzymes, while no foals in the other treatment groups developed similar signs, including those receiving doxycycline alone.[41] Steroid-induced hepatic lipidosis has been observed in foals receiving both prolonged and high doses of corticosteroids.

Iron Toxicity

Iron toxicity is the best documented toxic cause of hepatopathy in foals and may occur following administration of nutritional supplements or iron formulations containing ferrous fumarate.[40,42] Toxicity manifests in newborn foals given iron prior to receiving colostrum; colostral-acquired glutathione or other substances may be protective against hepatotoxicity.[42] When iron is given at birth and before colostrum, clinical signs typically develop 2 to 5 days later, although in rare cases signs may develop in older foals. The initial clinical signs are associated with hepatic encephalopathy and include seizures, marked depression, ataxia, aimless wandering, head pressing, and abnormal behavior. Icterus is noted in most foals at the time neurologic signs are exhibited, although some foals die so rapidly that icterus does not have time to develop. Abnormally high ammonia, total bilirubin, GGT and ALP activity, and packed cell volumes were present, as was an abnormally high ratio of aromatic to branched-chain amino acids. PTT and PT were prolonged, and some foals had high SDH activity.[40] Affected foals had small livers with prominent bile duct proliferation, hepatic cell necrosis, and mild periportal fibrosis, and had histopathologic changes in the brain consistent with hepatic encephalopathy.[40-43]

Congenital or Inherited Diseases

Congenital portosystemic shunts (CPSS) occur infrequently in the equine and bovine patient.[44] Clinical signs may not be noted until foals are 2 to 3 months old and begin ingesting large amounts of grain or grass. Encephalopathic signs and tenesmus are characteristic of the disease in calves. Waxing and waning signs of encephalopathy accompanied by elevated bile acids and ammonia levels and normal concentrations of hepatic-derived serum enzymes should arouse suspicion of CPSS in foals. Shunts may be single or multiple and may be intra- or extrahepatic. Diagnosis of CPSS can be made by computed tomography (CT) scan, positive-contrast portography, transrectal portoscintigraphy (in foals), or transabdominal ultrasound examination. Further corroborative evidence can be gained by ultrasound-guided percutaneous transsplenic injection of agitated saline with simultaneous echocardiography to look for contrast in the right atrium and ventricle.[45] Short-term medical management can be attempted with antimicrobials (minocycline, neomycin, metronidazole), anti-inflammatory drugs, enemas, lactulose, and IV fluids. Successful surgical ligation of CPSS has been described in a foal and a calf.[44-46]

A distinct syndrome of hepatic failure has been seen in Morgan foals.[47,48] Clinical signs (depression and weight loss) appear soon after weaning. Liver enzymes and ammonia are elevated, and variable degrees of portal and bridging fibrosis with bile duct hyperplasia, karyomegaly, and cytomegaly are often seen on microscopic examination. The disease is fatal and may end with a terminal hemolytic crisis. The cause is unknown but is thought to be an inherited defect in mitochondrial transporter proteins, such as ornithine, that are required for complete urea synthesis.[48]

Glycogen branching enzyme deficiency is a fatal autosomal recessive disease of Quarter Horses and Paint Horses caused by a mutation of the glycogen branching enzyme 1 *(GBE1)* gene that drastically decreases the amount of GBE protein in homozygotes.[49] Diseased foals cannot store and mobilize glycogen to maintain normal glucose homeostasis. Those that survive to parturition are often born weak, hypoglycemic, and hypothermic but improve with bottle feeding. Other clinical presentations include progressive muscle weakness, inability to rise, collapse, seizures, flexural limb deformities, respiratory failure, and sudden death. Common laboratory findings include leukopenia, intermittent hypoglycemia, and moderate elevations of serum CK, AST, and GGT activities. Genetic testing is available, but diagnosis can also be made based on liver and muscle biopsies from affected foals.There is no treatment, and all cases to date have been fatal.

Chronic Active Hepatitis

Jennifer L. Davis

Chronic active hepatitis (CAH) is an idiopathic progressive hepatopathy with insidious onset. The etiology and pathogenesis are unknown but may be similar to human autoimmune or hypersensitivity conditions. Toxic and infectious etiologies have also been proposed, or it may be a manifestation of chronic cholangitis or cholangiohepatitis. In one retrospective report of 88 cases of liver disease in adult horses, CAH accounted for 9.9% of all cases reported.[1] Seven of nine cases in that report were in ponies, although a true breed predisposition has not been reported.

Clinical signs are those of progressive liver failure and include weight loss, depression, anorexia, colic, icterus, and fever.[2] These signs may be intermittent. Signs of concurrent intra-abdominal diseases or other autoimmune diseases may also be present. In rare cases, a moist exfoliative coronary dermatitis may occur, which is thought to be an immune-mediated issue.[3] Concurrent elevations in hepatic enzymes, particularly GGT and ALP, will be present, with lesser elevations in SDH and AST as well as bile acids and direct bilirubin. The degree of elevation in liver enzymes cannot be used as an indicator of disease severity, since the liver may have significant fibrosis at the time of diagnosis. Other supportive clinicopathologic findings include an inflammatory leukogram, bilirubinuria, prolonged BSP clearance, and a polyclonal gammopathy. Ultrasonography may reveal a small liver with increased echogenicity indicative of hepatic fibrosis. Differential diagnosis includes pyrrolizidine alkaloid toxicity, bile stones, abdominal abscesses, and other chronic wasting diseases.

The final diagnosis of chronic active hepatitis is made histologically via biopsy of the liver or at necropsy. The principal features are localized primarily along the portal or periportal areas and include infiltration of inflammatory cells, biliary hyperplasia, and fibrosis or cirrhosis.[1] A mononuclear cell infiltrate (lymphocytes or plasmacytes) often predominates, but a neutrophilic component may be present with a primary or secondary infectious process. Bacteria, particularly gram-negative enteric bacteria, may be present in some lesions, and biliary hyperplasia may be marked if there is cholangiohepatitis.

VetBooks.ir

VetBooks.ir

Grossly, the liver appears firm and is often pale brown to green in color, and the cut surface may have prominent irregular markings. An antinuclear antibody (ANA) titer and immunofluorescent staining of skin lesions (if present) may reveal evidence of an autoimmune reaction.

Treatment of CAH involves supportive care. Specific treatments can be determined based on biopsy results. If the predominant cell types are lymphocytes or plasma cells, corticosteroids may be beneficial. Dexamethasone (0.05 to 0.1 mg/kg/day IV or IM decreased over 2 to 3 weeks) or prednisolone (1 mg/kg/day PO for several weeks) is recommended. Antibiotics are indicated when a bacterial cholangiohepatitis is suspected on the basis of the histologic features of the liver, culture of the liver biopsy, and presence of a persistent intermittent fever. Other recommended therapies are aimed at resolving inflammation and preventing the progression of fibrosis. Flunixin (0.5 to 1 mg/kg PO q24h) or low-dose phenylbutazone (0.5 g/day PO q24h) can be used. Vitamin E (10,000 U PO q24h) is recommended to protect membrane phospholipids from oxidative damage and suppresses activation of inflammatory cells. Pentoxifylline (8 to 10 mg/kg PO q12h) has been used as a weak inhibitor of the inflammatory cytokines tumor necrosis factor (TNF)–α and interleukin 6 (IL-6), although results are variable, possibly owing to the low oral bioavailability in horses. Colchicine (0.03 mg/kg PO q24h) can be used to inhibit production of collagen and macrophage- or cytokine-induced inflammation.

The prognosis for CAH is variable and depends on the underlying cause and duration of disease prior to diagnosis. A retrospective study reported that five of nine horses with CAH survived, but they were 7.4 times more likely to die than those where a diagnosis of unclassified hepatopathy was made.[1] Liver biopsy and response to therapy are the best guides in formulating a prognosis. The prognosis for improvement and long-term survival is extremely poor in horses that have functional hepatic failure with widespread fibrosis and disruption of normal hepatic parenchyma. The prognosis is fair to good in patients with early (less severe) lesions, particularly those with a lymphocytic or plasmacytic cellular infiltrate that responds well to corticosteroids. The presence of cirrhosis in the biopsy sample warrants a grave prognosis.

Pyrrolizidine Alkaloid Toxicity

Geoffrey W. Smith

Etiology Pyrrolizidine alkaloid (PA) toxicity is a chronic, progressive, often delayed toxicity that results when animals consume plants containing PAs. Plants containing these alkaloids are found all over the world, and poisoning of horses, cattle, poultry, and even humans has occurred in many different countries. PA toxicity primarily manifests as liver failure.[1] More than 350 types of PAs have been identified in over 6000 plant species.[2,3] The primary plants of importance in the United States come from the *Senecio* and *Crotalaria* genera, but others exist. Table 33.4 lists the most common plants causing PA poisoning around the world.

PA toxicity is seen wherever plants containing the alkaloids are found. The plants are not very palatable and in most cases are not readily eaten, but animals may eat them when the growth of the toxic plant is so thick the animal cannot separate it from normal forage or when other forage is sparse. The plants are toxic in hay, including pelleted and cubed hay. PAs also survive ensilage. For example, oat silage contaminated with *Amsinckia* or other PA-containing plants has been responsible for disease in dairy cattle. Seeds of *Heliotropium* plants have also poisoned feedlot cattle.[4]

The approximate toxic dose of dried *Senecio* as a percentage of body weight for each species is horses, 5%; cattle, 2% to 5%; goats, 125% to 400%; and sheep, over 150%. Most tansy ragwort contains less than 0.2% PA by weight, but there are reports of much higher levels in some of the other plants. Horses were consistently poisoned by greater than 250 mg of total PA per kg body weight.[5] The PA in houndstongue *(Cynoglossum officinale)* is extremely toxic to horses.[6] The dose does not have to be eaten all at once, since the effects are cumulative. Because signs often are delayed, some animals may not become ill until a year or more after removal from feed sources containing the toxins.[7,8] Signs do not occur until hepatocyte loss and replacement by fibrous tissue have caused failure of liver function.

TABLE 33.4

Common Plants Containing Pyrrolizidine Alkaloids (PAs)

Botanical Name (Genus and Species)	Common Name
Senecio jacobaea	Tansy ragwort or stinking willie
Senecio vulgaris	Common groundsel
Senecio douglasii var. *longilobus*	Threadleaf groundsel
Senecio riddellii	Riddell's groundsel
Senecio triangularis	Arrowleaf groundsel or tarweed
Senecio alpinus	Alpen-Kreuzkraut (Europe)
Amsinckia intermedia	Fiddleneck
Crotalaria spp.	Rattlebox
Echium plantagineum, *Echium lycopsis*	Patterson's curse, Salvation Jane, or viper's bugloss
Heliotropium europaeum	Common heliotrope
Symphytum officinale	Comfrey
Cynoglossum officinale	Houndstongue
Eupatorium maculatum	Joe Pye weed or Bruner's trumpet
Baccharis pteronioides	Yerba de pasmo
Borago officinalis	Borage or starflower
Erechtites spp.	
Trichodesma spp.	

Pathophysiology There are a number of PAs, and many of the poisonous plants contain four to six different alkaloids. About 50% of the alkaloids are toxic, and some are more toxic than others. The alkaloid concentrations vary slightly among plants from different areas, but there is greater variation in concentrations from different parts of the same plant.[9] PAs are not directly toxic but must be bioactivated to toxic alkaloids (pyrroles) in the liver. After absorption, the portal circulation carries the alkaloids to the liver, where they are metabolized by microsomal enzymes of the hepatocyte to more toxic pyrroles.[3,10] The pyrroles may crosslink double-strand DNA in a dose-dependent manner.[11] The degree of DNA crosslinkage depends on the concentration of the pyrrole but not on the base sequence of the oligonucleotide target.[12] The crosslinking of DNA produces an antimitotic effect.[13] The hepatocytes cannot divide and often become megalocytes as cytoplasm expands without nuclear division. As cells die, they are replaced by connective tissue rather than new hepatocytes. This antimitotic effect may explain why megalocytosis (large hepatocytes and large nuclei) is commonly seen with PA poisoning.

With progressive death of hepatocytes and subsequent fibrosis, liver function begins to fail. Blood supply through the hepatic lobule is disrupted by fibrosis, making regeneration impossible. This becomes a veno-occlusive disease, resulting in marked portal hypertension. The increased portal hydrostatic pressure leads to diarrhea and ascites in ruminants. It is unclear

why diarrhea and ascites are seen infrequently in horses with PA toxicity.

Clinical Signs The clinical signs of PA poisoning are basically those of liver failure. The most common signs of PA toxicity in the horse are weight loss, slight to moderate icterus, and abnormal behavior (e.g., wandering, ataxia). Signs seen less frequently in horses include photosensitization of the white areas and, in rare cases, diarrhea. A few cases in ponies have shown loud, stertorous inspiratory noises, possibly caused by pharyngeal-laryngeal paralysis.[13,14] Abortion may occur from ingestion of sublethal doses.[15] Subtle signs such as poor performance (inability to race up to previous standards) may be seen in horses with pyrrolizidine-induced liver damage before the onset of liver failure. Secondary gastric impaction has been reported in ponies.[16] Cattle more frequently show diarrhea, weight loss, tenesmus, prolapsed rectum, and ascites. Calves are much more susceptible to PA toxicity than mature cattle. Behavioral changes or subtle neurologic signs may also be seen in cattle, but icterus is uncommon. Differential diagnosis includes other diseases causing liver failure (e.g., aflatoxicosis or liver flukes) and some chronic debilitating diseases such as GI parasites and Johne's disease.

Sheep and goats are more resistant to PA toxicosis but can be affected by certain alkaloids at doses 30 times or more than the dose that affects cattle and horses. A consortium of ruminal microbes from sheep degrades PAs found in *Senecio jacobaea* to less toxic metabolites.[17] Liver microsomal enzymes in sheep may also play a role in detoxifying PAs, but this alone does not seem to account for the differences in susceptibility.[18]

Diagnosis Hepatic enzyme activities are generally elevated during periods of active hepatocyte destruction caused by PA poisoning. Although the dehydrogenases (e.g., SDH, GDH, LDH) are elevated initially, they may have returned to normal by the time the animal first shows clinical signs of functional failure. Because lesions are largely in the portal region, GGT and ALP tend to be consistently elevated.[7,19] In a study of sublethally poisoned horses, AST and the ratio of branched-chain to aromatic amino acids were persistently elevated.[15] Bile acid concentrations are increased, and levels above 50 µmol/L would be a poor prognostic indicator in the horse.[5] Serum protein concentration is usually normal, and only terminally does albumin decrease or blood clotting become altered. Bilirubin, both direct and indirect, tends to be increased in the horse at the later stages of the disease process.

Although liver biopsy can be very useful in the diagnosis of PA toxicity, other causes of chronic hepatitis (e.g., aflatoxins) may produce a similar histologic appearance. The triad of fibrosis, bile duct proliferation, and megalocytosis is characteristic of PA poisoning. Modest changes in hepatocytes and biliary hyperplasia are reversible. Fibrosis bridging portal areas indicates an eventually fatal condition, as does the extensive fibrosis of an end-stage liver.

Cattle dying of PA poisoning have ascites and prolapsed rectums and are thin and emaciated. Horses are usually thin and may be icteric. In all species, the liver tends to be small, pale brown to yellow, and firm and may appear to be scarred. Hepatic megalocytosis is considered the hallmark of PA poisoning, but it has also been seen in aflatoxicosis and is not always apparent in the earliest stages of PA toxicity. Biliary hyperplasia may occur early in the disease. Nonspecific nuclear changes, such as invaginations of cytoplasm into the nucleus, have been seen.[7,9] Isolated hepatocyte necrosis is seen later, and finally portal or massive generalized fibrosis develops. Once bridging of connective tissue between the portal areas occurs, the disease is fatal.

Treatment Liver failure may occur with either acute or chronic liver disease. The two must be differentiated for prognosis because end-stage fibrosis caused by PAs has virtually no chance for regeneration and recovery. No satisfactory treatment for PA poisoning exists. Once obvious clinical signs of liver failure develop, the animal usually dies within 5 to 10 days. Horses with mild clinical signs and reversible histologic lesions survived if they retained an appetite and were not exposed to any more PA-contaminated feed.[15] An accurate prognosis concerning mildly affected cases may best be obtained from a combination of consecutive liver biopsies and liver-derived serum enzyme activity, as well as from SBA concentrations.[5,15] Preventing further exposure to the toxic plants is indicated and may delay or stop the progression of the liver lesions, particularly if an uncontaminated feed source is provided before clinical signs develop.

Therapy of liver failure is inappropriate if severe fibrosis has occurred because regeneration is impossible. If the animal still has a reasonable appetite and only modest degrees of fibrosis histologically, treatment may be attempted by providing a low-protein, high-energy diet.

Prevention and Control PA poisoning is prevented by keeping susceptible animals from pasture, hay, cubed hay, or seeds that contain PA plants. Because most poisonings are attributed to contamination of forages or feed, careful inspection of feed is recommended. *Senecio vulgaris* tends to contaminate mainly first-cutting alfalfa, whereas *Amsinckia intermedia* is often found in planted fields of oat hay. *Senecio* can be controlled by cultivation because it is a biennial or by herbicide spraying in the early rosette stage. Species-specific herbicide regimens have been developed for most plants containing alkaloids and are widely available through state weed and extension services. Sheep are sometimes used to graze *Senecio*-infested pastures to control the weed, because they are less susceptible to PA poisoning.

Other Hepatotoxins

The liver is particularly vulnerable to toxic insults because it is the first organ to receive toxins absorbed from the GI tract. Enzymes in the hepatocyte may either activate a toxin or in some cases metabolize it before it can cause damage. Most hepatotoxic agents are described in more detail in Chapter 54. Some of the more common liver toxins are listed in Tables 33.5, 33.6, and 33.7, but these are not complete lists because many other plants and chemicals can damage the liver under the right conditions. Once a toxic liver disease has been diagnosed, possible sources of the toxin might be identified from these tables. A more detailed description of toxins affecting the liver can be found in Chapter 54.

Liver Flukes in Ruminants

John B. Malone

Etiology The common liver fluke, *F. hepatica*, causes a disease of production in ruminants that mimics the production effects and clinical appearance of the GI nematode-parasite complex. The disease often has its maximum economic effect in late fall and winter when animals are most likely to be under seasonal nutritional stress. *F. hepatica* is unique among the common helminths of ruminants in that it has an asexual multiplication phase of the life cycle in snail intermediate hosts that is highly sensitive to environmental conditions. *F. hepatica* is well known for its exponential propagation of infective stages under favorable conditions, sometimes leading to explosive seasonal outbreaks of severe parasitism, especially in sheep. In addition, liver parenchyma migration forms leave necrotic tracts in their wake that are a primary predisposing factor in some areas for acute fatalities caused by *C. novyi* types B (black

TABLE 33.5

Hepatotoxic Plants

Common Name (Botanical Name)	Approximate Ld50 (%Bw)[a]	Geographic Distribution	Liver Lesion
For pyrrolizidine alkaloid–containing plants, see Table 33.4.			
Lantana *(Lantana camara)*	1	Northern North America	Necrosis, canalicular collapse
Littleleaf horsebrush *(Tetradymia glabrata)*	0.5	Dry desert	Necrosis
Sacahuista or bear grass *(Nolina texana)*	1.1	Southwestern U.S.	Fatty and centrilobular necrosis
Lechuguilla *(Agave lechuguilla)*	4-15	Southern U.S., Mexico	Necrosis, photosensitivity
Bindii or puncture vine *(Tribulus terrestris)*	?	Warmer regions	Biliary fibrosis, necrosis (big head)
Whitebrush *(Aloysia gratissima)*	?	Southern U.S., Mexico	Fatty degeneration
Panic grasses (*Panicum* spp.)	?	Texas-California, South America	Biliary fibrosis, necrosis
Kleingrass *(Panicum coloratum)*	?	Southern U.S.	Necrosis, obstructed bile ducts
Scutch grass or Bermuda grass *(Cynodon dactylon)*	?	North America	?
Cocklebur *(Xanthium orientale)*	0.75-3	North America	Hemorrhagic centrilobular necrosis
Lupine (*Lupinus* spp.) Mycotoxin from *Phoronopsis inferior*	Varies	Western North America	Necrosis
Cottonseed (*Gossypium* spp.) Gossypol pigment	Varies; gossypol content	Southern U.S.	Necrosis Cardiac lesions
Poisonous mushrooms *(Amanita phalloides, Galerina venenata)*	Few mushrooms	North America	Necrosis, central nervous system signs
Blue-green algae *(Microcystis aeruginosa, Nodularia spumigena)*	? 0.001	Ponds, worldwide	Necrosis, dissociation
Alsike clover *(Trifolium hybridum)*	Varies	Cultivated	Portal fibrosis, biliary hyperplasia
Mexican fireweed *(Kochia scoparia)*	?	Southwest U.S.	?
Coffee senna *(Cassia occidentalis)*	0.05 (horse); 0.5-2 (cattle)	North and South America, Africa, Asia and Australia	Pericentrolobular vacuolar degeneration and necrosis
Cycad palm (*Cycas/Zamia* spp.)	?	South America, Australia	?
Yellow-wood or rosewood *(Terminalia oblongata)*	?	Australia, Africa	Centrilobular necrosis
Sneezeweed (*Helenium* spp.)	0.25	Northern U.S., Canada	?
Moldy alfalfa *(Medicago sativa)*	?	Wet areas	Biliary hyperplasia, necrosis
Bitterweed (*Hymenoxys* spp.)	1	Southwestern U.S.	?

disease) and *haemolyticum* (bacillary hemoglobinuria), discussed earlier in the chapter.[1]

The geographic distribution of *F. hepatica* in the United States is limited mainly to areas in the south-central states and Florida and to the Pacific Northwest, where neutral well-buffered soils are found and local hydrologic conditions provide suitable habitats for lymnaeid snail intermediate hosts. The important vector species in temperate climates, recently renamed based on molecular evidence as *Galba* spp. or *Lymnaea* spp.,[2] are semiaquatic "mud" snails found in disturbed mud banks and hoofprints in shallow depressions in fields, drainage channels, and temporary water bodies in alluvial river basins, bottomlands, and coastal regions of the southeastern United States. Springs, small streams, seeps, and sloughs serve as habitats in areas of greater terrain relief in the western states. Most infections occur by grazing in and around water in fluctuating habitats that stay wet for more than half the year.

The life cycle development of both the snail host and the parasite in the snail occurs only when temperatures are above 10° C (50° F) and snail habitats are wet. This leads to a distinct seasonal transmission in the mild, wet winter and spring of the south-central states and Florida and a late spring to fall transmission in the cooler climates of the western states (Figs. 33.3 and 33.4). It takes a minimum of 42 days at 25° C (77° F) or the accumulation of approximately 600 growing-degree days to complete intramolluscan development, with release of cercariae that encyst as infective metacercariae on pasture vegetation (600 growing-degree days = 25° C minus the base temperature of 10° C = 15 growing-degree days × 42 days; an equivalent value for the life cycle is 15° C or 5 growing-degree days × 120 days). Using soil water budget analysis to indicate the length of time habitats are wet and the accumulated sum of growing-degree days over 600, a climate forecast index can be calculated for use in describing the pattern of seasonal transmission at a given site and to provide an indicator of the risk of economic losses in a given climate year. Two weeks of sustained summer heat and drought ends the transmission season by killing pasture metacercariae and forcing snail populations to estivate in soil or perish. In the cooler climates of the western United States, the season ends with drying of springs, seeps, sloughs, and other habitats or with the onset of sustained cold winter weather. Variation in the annual climate alone may lead to a hundredfold variation in fluke burdens in different climate years.[3]

The amount of snail habitat present on individual farms related to pasture wetness conditions, such as premises with

low-lying heavy clay soils with a high water table, is also an important consideration in evaluating the need for fluke control. This factor has also been shown to lead to a hundredfold variation in the risk of fluke losses in the same year on different premises in otherwise ecologically similar areas.[4] The snail habitat area on most enzootic livestock operations typically is only 1% to 5% of the total land area; operations with more than 5% habitat may be associated with a high risk of liver fluke losses.

Clinical Signs Subclinical production effects of *F. hepatica* include reduced rate of gain and feed efficiency in growing stock. Economic effects have been experimentally demonstrated in calves on a marginal nutritional plane in the first 5 to 6 months after infection, resulting in an 8% loss in the rate of gain with a mean of 40 flukes and a 28% loss with 140 flukes. In cattle it is estimated that herd economic losses are "negligible" with a burden of less than 10 flukes per animal, "possible" at 10 to 40 flukes, and "probable" with more than 40 flukes. Clinical disease is seen with a burden of more than 200 flukes. In cow-calf operations, flukes often act in concert with periods of nutritional stress and concurrent heavy GI nematode infections, causing further reduction of body condition, poor milking ability, and slower return to estrus. This translates to reduced reproductive efficiency, prolonged calving interval, and lightweight calves at weaning.[5]

In cattle, flukes may lead to chronic disease or, in rare cases, subacute disease. When clinical signs occur, the typical population "overdispersion" (individual variation in parasite burdens) is manifested first in the 10% to 20% minority of the herd that harbor most of the parasite numbers. Signs may consist of weight loss, emaciation, depression, anorexia, rough hair coat, anemia, hypoproteinemia, submandibular edema, and in rare cases, mild icterus. The anemia associated with *F. hepatica* infections is more than can be accounted for by fluke blood feeding. Evidence indicates that depression, anemia, and biliary

TABLE 33.7

Drugs Used in Large Animals That Could Damage the Liver

Drug	Lesion[a]
Carbon tetrachloride	Centrilobular necrosis or fatty degeneration
Hexachloroethane	Centrilobular or massive necrosis
Carbon disulfide	Necrosis
Alcohol	Necrosis/cirrhosis
Tetracycline	Fatty degeneration (also renal damage)
Clindamycin	Cholestasis, icterus
Erythromycin	Cholestasis, icterus
Isoniazid	Active hepatitis → cirrhosis/ massive necrosis
Rifampin	Cholestasis, icterus
Rifampin/doxycycline combinations	Hemolytic icterus, elevated liver enzymes
Nitrofurantoin	Active hepatitis → cirrhosis
Anabolic steroids	Cholestasis, icterus
Phenothiazine	Cholestasis, icterus tranquilizers
Halothane	Active hepatitis → cirrhosis/ massive necrosis
Fluothane	Active hepatitis/massive necrosis
Isoflurane	Active hepatitis/massive necrosis
Some diuretics	Cholestasis, icterus
Diazepam	Cholestasis, icterus
Phenobarbital	Necrosis/cholestasis icterus
Aspirin	Active hepatitis → cirrhosis
Oil of pennyroyal	Centrilobular necrosis
Tannic acid	Centrilobular necrosis, fatty degeneration (renal damage)
Dantrolene	Active hepatitis → cirrhosis
Copper disodium edetate	Massive centrilobular necrosis
Iron (injectable)	Necrosis, portal, cirrhosis, hemosiderosis
Glucocorticoids	Hepatocellular vacuolization
Ionophores (salinomycin)	Hepatic lipidosis, necrosis

[a]May vary with dose and time.

hyperplasia result from high levels of proline, a product of fluke metabolism.[6] Cattle are able to mount a protective immune response, with partial acquired resistance to *F. hepatica* beginning at 5 to 6 months after initial exposure.[7] This and the short life span of flukes in cattle typically lead to a linear reduction of fluke numbers, with few surviving by the end of 1 year. Sheep and goats are more susceptible, and fatal acute disease with ascites, abdominal hemorrhage, pallor, and icterus can occur in association with massive entry to the bile ducts at 6 to 10 weeks after infection by 1000 to 5000 or more migrating immature forms from the liver parenchyma. Subacute disease has been associated with a burden of more than 800 flukes acquired over time. Chronic clinical disease in sheep with submandibular edema, ascites, and emaciation has been associated with fluke burdens above 200.[8]

Liver flukes in horses are sometimes reported as an incidental finding during postmortem examination. In one study, prevalence was 9.5% in a population of horses from Ireland.[9] Horses with weight loss and diarrhea that respond to flukicide treatment provide anecdotal evidence that flukes may result in detectable clinical disease, although the association is unproven.

Necropsy findings attributable to migrating young flukes are caused by tortuous tunnels of coagulative necrosis that organize and fibrose, ultimately leading to a diffusely fibrotic liver parenchyma, especially in the ventral lobe, which in severe cases undergoes marked atrophy. Fibrous tags may result from fibrinohemorrhagic deposits left by large numbers of flukes at liver penetration 3 to 4 days after infection. Inflammatory events associated with penetration of the bile ducts at 6 to 8 weeks after infection are especially pathogenic. Once in the bile ducts, flukes grow rapidly from 1 mm to 2.5 cm or more and induce a proliferative cholangiohepatitis. The spines and suckers of flukes erode and denude the bile duct epithelium, leading to a fibrosed, thickened duct wall that is irregularly dilated and stenotic and begins to calcify in cattle (but not sheep) at about 20 weeks after infection. The bile becomes darkly discolored and laden with regurgitated fluke ingesta, plasma proteins, and inflammatory cells. The extent of pathologic change is generally proportional to the fluke burdens of current or recurring previous infections.[8]

Diagnosis Fecal sedimentation methods are the standard means of diagnosing liver flukes, although classical methods are cumbersome. A reusable commercial "nematode counting chamber" (1-mL volume of sediment fluid) is available (Chalex, Wallowa, Ore.) and can be examined on a standard microscope stage. It reduces sample processing time by half and is suitable for use by practitioners for quantitative examination of individual animals or 10- to 15-animal herd composite samples. For herd or lot evaluations in cattle, egg counts of less than 1 egg per 2 g (EP2g) and 25% prevalence 2 to 4 months after the transmission season ends have a "low probability" of economic losses; 1 to 3 EP2g indicates "possible" economic loss; and 10 or more EP2g indicates "high probability" of heavy infections and economic loss. It is important to differentiate *F. hepatica* eggs from the eggs of *Paramphistomum* species, a nonpathogenic "rumen fluke" often found in the same herds in both the southern and the western enzootic areas. Flukecides used against *F. hepatica* are ineffective against rumen flukes, and egg counts thus persist after treatment. *Paramphistomum* eggs are gray (rather than amber), slightly smaller, and more pointed at the operculum end than *F. hepatica*. *Paramphistomum* egg counts can be used as a general indicator of the probable risk of *F. hepatica* in the absence of control in the southern states because *Paramphistomum* flukes are known to be transmitted by the same snail vector in that region.[5]

Diagnostic enzyme-linked immunosorbent assays (ELISAs) have been developed to detect serum antibodies or coproantigen in the feces of infected animals or in bulk milk samples.[10,11] These tests have not yet found wide use outside of research laboratories in the United States but are marketed in Europe.[11] ELISAs for the major *F. hepatica* excretory-secretory protein, CL1, have high specificity, but low sensitivity in horses, compared to ELISAs for the liver fluke 2.9-kDa antigen, which have high sensitivity and specificity in horse serum.[9] Blood and serum clinicopathologic results reflect the anemia, hypoproteinemia, and mild eosinophilia caused by *F. hepatica*. Pathologic changes in the liver bile ducts and parenchyma are reflected by an elevation in serum liver enzymes (e.g., GGT, GDH).

Treatment and Prevention Prevention is the key to control in foundation herds and flocks because even low numbers of eggs shed can multiply asexually in snails and lead to significant infection rates during the following transmission season. A single routine fall or late fall–winter treatment after the end of the transmission season with a highly effective drug is recommended to remove adult flukes before winter stress and to prevent egg shedding and snail infection in the next season (see Figs. 33.3 and 33.4). Most of the pathogenic and

VetBooks.ir

economic effects of flukes in cattle are reported to occur within the first 5 to 6 months after the major exposure period and may be related to metabolic products associated with the rapid growth and heavy egg production phases of the life cycle. This, coupled with linear loss of heavy fluke burdens in cattle and the onset of effective immunity at 20 weeks after exposure, suggests the value of early flukecide treatment within 2 to 3 months after the transmission season ends. In some herds an optional curative treatment in spring may be needed in very high-risk years or on high-risk premises, or as a second treatment to remove flukes acquired during late, extended transmission on irrigation pastures or wet coastal areas in the west.

Flukecidal drugs available in the United States are effective against mature flukes in bile ducts (albendazole, 10 mg/kg; closulon, 2 mg/kg). Closulon at 7 mg/kg has added efficacy against juvenile flukes over 6 weeks old in the bile ducts. The optimum time to treat should be based on the estimated susceptibility of mature fluke populations (>12 weeks old after end of transmission season) but early enough to remove flukes while they are most pathogenic (<6 months old). Triclabendazole, which is widely used in other countries, is reported to be more than 90% effective against migrating flukes over 2 weeks old and 99% effective against mature flukes and thus can be effectively given just after transmission ends. However, significant triclabendazole drug resistance issues have emerged.[11,12] Worldwide, a number of other drugs are available, including oxyclozanide, niclofolan, bithionol, and hexochlorophene (80% to 99% of adult flukes), nitroxanil, closantel (>90% adult and 50% to 90% juvenile bile duct flukes), rafoxanide (>50% late migratory flukes, >90% juvenile and adult bile duct flukes), and diamphenathide (>90% migratory flukes, 50% to 80% bile duct flukes).

The economic benefit of routine flukecide treatment of feedlot calves from enzootic areas in the United States has not been consistently demonstrated industry-wide because of the high variability of fluke burdens in animals from enzootic areas or because lots are often of mixed origin. Fluke-related losses would be expected to be mainly absorbed by stocker operations, where lightweight calves are typically placed on small grain pastures for extended periods before feedlot, a common practice in the south-central states. The economic return of treatment at feedlot should be evaluated on a case-by-case basis because significant losses may occur if the lot originates from the same premises and the history suggests a high risk of recent heavy infection rates, such as in favorable climate years or use of irrigated pastures in fluke areas. Fecal egg counts on 10 to 15 randomly selected animals may aid in herd evaluation. An example case of the explosiveness of the life cycle is the greatly reduced feedlot performance and 100% liver condemnations of a lot from a stocker operation in the Pacific Northwest. The animals originated from irrigated pastures where some habitats stayed wet year-round, and untreated calves from fluke areas were allowed to contaminate pastures with eggs, which translated to infection later in the grazing season and to the next stocker group rotated onto the premises.

Other Flukes

Fascioloides magna, the large American liver fluke, may infect cattle and sheep that graze common areas with deer, the natural host. The life cycle is similar to that of *F. hepatica*, but with a wider variety of lymnaeid snail hosts and a broader geographic distribution in the Gulf States, the Great Lakes area, and the Northwest. Cattle are abnormal dead-end hosts that react with an intense encapsulation response, forming a closed cyst that does not allow escape of eggs and obviates diagnosis by fecal examination. The liver parenchyma and regional lymph nodes have a characteristic diffuse black pigmentation. The major economic effect of *F. magna* in cattle is condemnation of livers and other organs, such as lungs, in which aberrant migration sometimes occurs. In sheep and goats, however, *F. magna* does not encyst and migrates uninterrupted. One or two *F. magna* flukes kill sheep before the flukes have time to mature, and this parasite limits sheep production in some areas. Albendazole given at high dosage is moderately effective against *F. magna*.

In tropical regions, *F. hepatica* is replaced by *Fasciola gigantica*, a similar species that is somewhat larger, has a longer prepatent period (10 to 12 weeks), and is of somewhat greater pathogenicity. *D. dendriticum* occurs worldwide but in North America is an unimportant species, mainly limited to areas of central New York, with smaller foci in Pennsylvania, New England, Quebec, and British Columbia. Albendazole (20 mg/kg) and high doses of thiabendazole (150 to 300 mg/kg) are effective treatments.[1]

Hepatic Abscesses

T.G. Nagaraja

Hepatic abscesses occur sporadically in most animals but are most common in ruminants, particularly cattle fed high-grain diets. Hepatic abscesses occur at all ages and in all types of cattle but are most common and have the greatest economic impact in feedlot cattle. The incidence in feedlot cattle ranges from 1% to 2% to a high of 60% to 80% but averages 10% to 20% in most feedlots.[1] Because hepatic abscesses are generally a direct result of feeding practices, diet is an important factor influencing their incidence. Hepatic abscesses do occur in dairy cows, and in a survey of gross pathologic conditions in cull cows at slaughter, the incidence of liver abscesses was reported to be 32.1%.[2] In the United States, it has become increasingly common to raise Holstein bull calves in feedlot production systems for beef production. Liver abscess data collected at slaughter have shown that the incidence of liver abscesses in Holstein feedlot steers is greater than in crossbred beef cattle.[1,3] In addition, the proportion of more severe abscesses (one or more large or multiple small abscesses, often with adhesions to diaphragm and visceral organs) is greater in Holstein feedlot steers than in beef breeds (50% to 60% versus 30% to 40% of the total abscesses, respectively).

Etiology Hepatic abscesses in cattle are generally polymicrobial infections, and in most cases the organisms are anaerobes.[4,5] *Fusobacterium necrophorum*, a gram-negative, pleomorphically rod-shaped anaerobe, is the primary etiologic agent.[3] The organism also is implicated as the primary pathogen in necrotic laryngitis (calf diphtheria), foot rot, and foot abscesses in cattle.[6,7] *F. necrophorum* is a normal inhabitant of the rumen, and its role in ruminal fermentation is mainly to use lactic acid to produce volatile fatty acids and also digest ruminal epithelial and feed proteins.[8] The organism is in higher concentration in grain-fed cattle than forage-fed cattle, possibly because of the increased availability of lactic acid from fermentation of starch in the grain. Several virulence factors have been implicated in the pathogenesis of *F. necrophorum* infections.[8,9] These include leukotoxin, endotoxic lipopolysaccharide (LPS), hemolysin, hemagglutinin, platelet aggregation factor, dermonecrotic toxin, adhesins (outer membrane proteins), and extracellular enzymes (e.g., proteases, deoxyribonucleases). Leukotoxin is believed to be the major virulence factor.[9] The leukotoxin is cytotoxic to polymorphonuclear neutrophil leukocytes (PMNs), macrophages, hepatocytes, and ruminal epithelial cells. Because of leukotoxin, the organism is able to survive, proliferate, and establish to set up infection of the ruminal wall and liver. There are two subspecies of *F. necrophorum*, subsp. *necrophorum* (formerly biotype A) and subsp. *funduliforme* (formerly biotype B). These two subspecies differ in cell morphology, colony characteristics, growth patterns in broth, and most importantly, in virulence factors. Subspecies *necrophorum* is more

virulent (produces more leukotoxin) and thus more frequently encountered in liver abscesses than subsp. *funduliforme*, which tends to occur more often in mixed infections.[7,8]

In most situations, *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), a gram-positive rod-shaped organism, is the second most frequent pathogen isolated from liver abscesses.[10,11] The ruminal wall appears to be the niche for *T. pyogenes*, a facultative bacterium, because the wall provides an aerobic microenvironment in an otherwise anaerobic environment of the rumen.[12] The occurrence of *T. pyogenes* in liver abscesses is likely indicative of the ruminal damage that allows the entry of the organism into the portal circulation to reach the liver. In liver abscesses and other infections (foot rot in cattle, metritis in dairy cows), the organism acts in synergy with *F. necrophorum*.[1] In recent years, *Salmonella enterica* has been found be associated with liver abscesses of cattle. In a study of bacteriology of liver abscesses of crossbred beef cattle and Holstein steers collected at slaughter, the prevalence of *S. enterica* was reported to be 25.3%.[13] A predominant serotype of *Salmonella* isolated from liver abscesses was Lubbock with the antigenic designation 6,7:g,m,s:e,n,z,15, a novel serotype closely related to Mbandaka. The Lubbock serotype has been isolated from lymph nodes of cattle at slaughter.[14] The contribution of *Salmonella* to the cause of abscesses is not known, but there are reports of *Salmonella* causing liver abscesses in humans.[15] A couple of features of *Salmonella* make its presence in liver abscesses not surprising. First, it is able to grow robustly in anaerobic conditions,[16] and second, it is a facultatively intracellular pathogen, hence able to reach the liver through phagocytic cells.[17]

A variety of other anaerobic and facultative bacteria, such as *Bacteroides* spp., *Clostridium* spp., *Escherichia coli*, *Klebsiella pneumoniae*, *Mobiluncus* spp., *Mitsuokella* spp., *Pasteurella* spp., *Peptostreptococcus* spp., *Porphyromonas* spp., *Prevotella* spp., *Propionibacterium* spp., *Pseudomonas aeruginosa*, *Staphylococcus* spp., *Streptococcus* spp., and many unidentified gram-positive and gram-negative bacteria are often isolated from liver abscesses of cattle.[3,5,10]

Pathophysiology

Abscesses in the liver result from entry and establishment of *F. necrophorum* either alone or with other bacteria. The routes by which bacteria can gain access to the liver include the portal vein, hepatic artery, umbilical vein (in newborns with omphalophlebitis), bile duct system, and direct extension. Entry through the hepatic artery (after an episode of septicemia) or the bile ducts (usually from obstruction, infection ascending from duodenum, or migration of flukes) is a rare occurrence. Direct extension of infection from adjacent tissues and organs, usually of traumatic origin (e.g., direct puncture of the liver by a foreign body lodged in the reticulum), is more likely to occur in dairy cows. Traumatic reticuloperitonitis caused by metallic objects lodged in the reticulum and perforating through the reticular wall, rarely involving the ruminal wall, is often a predisposing factor for liver abscesses in dairy cows. However, in both dairy cows and feedlot cattle, the most common route of entry of bacteria into the liver is the portal vein.

Liver abscesses are secondary to the primary foci of infection in the ruminal wall. Evidence to support this is the high correlation between ruminal wall lesions (rumenitis) and liver abscesses, thus the term *rumenitis–liver abscess complex* (Fig. 33.5). In a recent study of the relationship between ruminal wall lesions and liver abscesses in beef cattle at slaughter, Rezac and colleagues[2] observed that 32% of cattle with mild or severe rumenitis had liver abscesses compared with 19% of cattle with healthy ruminal walls. However, not all studies have shown an association of liver abscesses with ruminal lesions.[18] More direct evidence for the pathogenesis of liver abscesses was obtained by restriction fragment length polymorphism analysis of rRNA genes (ribotyping) of *F. necrophorum* and

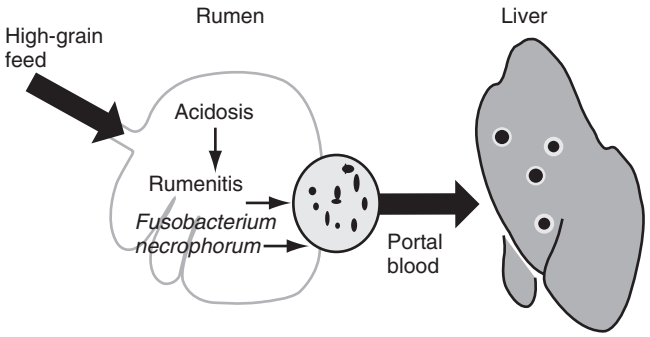

FIG. 33.5 Pathogenesis of liver abscesses in cattle fed high-grain diets. *(Modified from Nagaraja TJ, Chengappa MM: Liver abscesses in feedlot cattle: a review. J Anim Sci 76:287, 1998.)*

T. pyogenes isolates from the rumen and liver abscesses of the same animal. The genetic similarity between the isolates from liver abscesses and ruminal walls supported the hypothesis that *F. necrophorum* and *T. pyogenes* isolates of liver abscesses originated from the rumen.[12,19] It is well accepted that ruminal lesions resulting from acidosis are the predisposing factors for hepatic abscesses. Acid-induced rumenitis and damage of the protective surface usually are associated with a sudden change to high-energy diets and other dietary indiscretions, such as a change in feeding patterns, letting cattle become overly hungry, feeding unpalatable diets, and feeding very little roughage. The ruminal damage often is aggravated by foreign objects in the feed, sharp feed particles, or hair.[20] The ruminal wall that is damaged from acidity or penetration of foreign objects becomes susceptible to invasion and colonization by *F. necrophorum*. Once colonization has occurred, *F. necrophorum* can gain entry to the blood or cause ruminal wall abscesses and subsequently shed bacterial emboli to the portal circulation. Bacteria from the portal circulation are filtered by the liver, leading to infection and abscess formation.

The virulence factors of *F. necrophorum* play a critical role in the penetration and colonization of the ruminal epithelium and entry and establishment of infection in the liver.[8,9] The protease activity, dermonecrotic activity, and cytotoxic effect of leukotoxin on ruminal cells may aid in penetration and colonization of the ruminal wall. *F. necrophorum*, being an anaerobe, must overcome both high oxygen concentrations and phagocytic mechanisms to survive, proliferate, and initiate abscess formation. The leukotoxin may protect it from phagocytosis. Also, the release of cytolytic products such as lysosomal enzymes and oxygen metabolites, resulting from destruction of phagocytes, has a detrimental effect on the liver parenchyma. Synergism with facultative bacteria, intravascular coagulation induced by endotoxic LPS and platelet aggregation factor, formation of fibrin-encapsulated abscesses, and impairment of oxygen transport by damaged erythrocytes (action of hemolysin) all may contribute to the establishment of an anaerobic microenvironment conducive to the growth of anaerobic bacteria within the ruminal wall and liver.

Pathology

Abscesses found in the liver at slaughter or necropsy often are well encapsulated, possessing thick, fibrotic walls (Fig. 33.6). The earliest lesion is a microabscess induced by an embolus of *F. necrophorum* in the sinusoid, and the lesion then progresses to coagulative necrosis by involving adjacent hepatocytes. Subsequently, the lesion gradually changes into a pus-filled, encapsulated, true abscess. Histologically, a typical abscess is pyogranulomatous with a necrotic center, encapsulated, and often surrounded by an inflammatory zone.[11] Hepatic abscesses are pus filled, have capsules that vary in thickness, and range in size from a minute pinpoint to more than 15 cm

(6 in) in diameter. The number of abscesses in the liver can vary from one to hundreds, and sizes range from less than 1 cm (0.4 in) to greater than 15 cm in diameter, often encircled by a hyperemic zone. The larger abscesses may result from small abscesses coalescing early in development. The distribution of abscesses in the liver shows no consistent pattern, with superficial and deep abscesses distributed almost evenly. Often small abscesses are scattered throughout the organ, whereas large abscesses are located close to the portal entry. Abscesses eventually become sterile and are replaced by fibrous scars, with eventual resorption.

Clinical Signs and Diagnosis

Liver abscesses are detected only at the time of slaughter. Cattle, even those that carry hundreds of small abscesses or several large abscesses, seldom show any clinical signs. Occasionally the rupture of a superficial abscess or erosion and perforation of the caudal vena cava could lead to extensive spread and massive infection of other organs and eventual death. Generally, hematology and liver function tests have not proved to be good indicators of liver abscesses.[21] In animals in which abscesses were induced by experimental inoculation of *F. necrophorum*, hepatic dysfunction was documented by elevated serum protein, bilirubin, and enzymes such as GGT and SDH concentrations.[22] In a group of Holstein dairy cattle where the presence of liver abscesses was diagnosed via ultrasound or exploratory laparotomy, the most common clinical sign was anorexia.[22]

Ultrasonography is a useful technique in the diagnosis of various hepatic diseases in cattle because of the location and tissue consistency of the liver (Fig. 33.7).[23] The technique has been shown to be useful for monitoring the onset and progression of experimentally induced abscesses where the site of injection is known.[22] The development of abscesses in feedlot calves has been recorded by ultrasonographic examination at regular intervals from weaning to slaughter.[21] However, its application to the diagnosis in feedlot cattle is limited because the ultrasonographic scanning cannot visualize the whole liver, particularly the left side facing the internal organs, and parts of lobes are covered by other organs (e.g., lungs, kidneys).

Treatment and Prevention

Both *F. necrophorum* and *T. pyogenes*, but not *S. enterica*, are susceptible to penicillins and macrolides.[5,24] Although successful treatment of cattle with liver abscesses has been described,[25] antibiotic treatment is seldom practical in cattle because complete recovery is difficult to attain. Cattle with sequelae (e.g., caudal vena cava thrombosis syndrome) are generally culled for slaughter, for economic reasons. According to the U.S. Feed Additive Compendium, five antibiotics (bacitracin methylene disalicylate, chlortetracycline, oxytetracycline, tylosin, and virginiamycin) are approved for prevention of liver abscesses in feedlot cattle.[26] Of these, only chlortetracycline, oxytetracycline, and tylosin are used for prevention. Tylosin, a macrolide, is the most effective antibiotic and the most commonly used feed additive (8 to 10 g/ton or 60 to 90 mg/head/day) in the feedlot. Studies show that tylosin feeding reduces abscess incidence by about 40% to 70%. Although there is no evidence of resistance development in *F. necrophorum*,[5] the future of tylosin use as a feed additive in feedlot cattle is uncertain. According to the Center for Veterinary Medicine (CVM) of the U.S. Food and Drug Administration (FDA), the judicious use of medically important antimicrobial drugs in food-producing animals should be based on two principles: (1) limit medically important antimicrobial drugs to uses in animals that are considered necessary for assuring animal health, and (2) limit medically important antimicrobial drugs to uses in animals that include veterinary oversight or consultation. Because tylosin is used to prevent liver abscesses and not intended for growth promotion, it could be categorized as use to assure animal health. As of January 2017, the use of tylosin in feedlot cattle for the prevention of liver abscesses is under veterinary oversight.[27] There is considerable interest in evaluating antibiotic alternatives, such as probiotics, essential oils, and vaccines, to control liver abscesses. In a feedlot study in cattle fed a finishing diet, inclusion of a product containing limonene, an essential oil, tended to reduce the incidence of liver abscesses compared to the control, but the difference was not significant.[28]

Because the pathogenicity and virulence factors of *F. necrophorum* have been studied widely, there has been considerable interest in and efforts to develop an effective vaccine.[1] The use of vaccines has dual benefits: control of liver abscesses and alleviation of public health concerns associated with the continuous use of medically important antimicrobials in the feed. A bacterin vaccine (Fusogard [Elanco Animal Health, Greenfield, Ind.]), injected subcutaneously in 2-mL doses 21 days apart, is commercially available and has been shown to be effective in reducing the incidence and severity of liver abscesses in feedlot cattle. In a randomized and blinded field trial, vaccination reduced prevalence of liver abscesses in cattle with a low prevalence (10%) but was not effective in cattle with a high (30%) prevalence of liver abscesses.[29] Two antigens of *F. necrophorum* that have been targeted as potential candidates for vaccine development are leukotoxin, a critical virulence factor for bacterial survival and establishment of infection,[30] and outer

membrane proteins, which mediate adhesion of *F. necrophorum* to bovine cells.[31] Both proteins have been recombinantly expressed and efficacy has been demonstrated in vitro and in a mouse model.[31,32] However, the efficacy of the recombinant proteins in cattle has not been evaluated. Machado and colleagues[33] have reported a vaccine formulation containing different combinations of proteins of *E. coli*, *F. necrophorum*, and *T. pyogenes* to prevent puerperal metritis in dairy cows, leading to improved reproductive performance.

In addition to inclusion of antimicrobial compounds in the feed or vaccination, prudent bunk management to minimize fluctuations in intake and ruminal acidosis is well accepted as a key factor for effective control of liver abscesses. Management recommendations include gradual adaptation to high-grain diets, avoiding either underfeeding or overfeeding, increasing feeding frequency to spread out intake, increasing roughage content of the feed, inclusion of grain by-products like distiller's grains, imposing quality control in mixing feeds, and providing adequate bunk space and fresh clean water.[34]

Sequelae Septic cardiac and pulmonary emboli are also associated with liver abscesses in feedlot and dairy cattle. Occasionally, sudden death has been reported in cattle secondary to rupture of liver abscesses, with septic embolization in the right side of the heart. Generally, the condition starts as phlebitis caused by the extension of liver abscesses involving caudal vena cava. The phlebitis leads to thrombus formation anywhere between the liver and right atrium but most often at the point of entry of caudal vena cava into the diaphragm. The clinical syndrome and the extent of lesions observed depend on the degree of thrombosis and type of organisms involved. The syndrome can range from death caused by rupture of caudal vena cava to various degrees of pulmonary embolism, pneumonia, infarction, endocarditis, hemoptysis, and epistaxis. Collectively, these lesions are categorized under caudal vena cava thrombosis (CVCT) syndrome.[35,36]

Economic Importance Liver abscesses are a major economic liability to the producer, the packer, and ultimately the consumer of beef. According to a National Beef Quality Audit report, 20.9% of livers were condemned at slaughter, and liver abscesses accounted for approximately two thirds of liver condemnations.[37] The greatest economic impact of hepatic abscesses is not from the condemnation of liver but from the reduced animal performance and reduction in carcass yield. Cattle with abscessed livers have reduced feed intake, reduced weight gain, decreased feed efficiency, and decreased carcass dressing percentage. These effects are evident only in cattle with the most severe abscesses (one or more large abscesses or multiple small abscesses).[38]

Hepatic Abscesses in Horses

Hepatic abscesses occur sporadically in horses and are generally part of the intraabdominal abscess complex. In studies that have evaluated horses with intraabdominal abscesses, 12% (3 of 25)[39] and 5% (3 of 61)[40] of horses had abscesses in the liver. Hepatic abscesses in horses are usually associated with gastrointestinal diseases, including proximal enteritis, inflammatory bowel disease, or ileal diverticulitis, and may develop as a sequela to abdominal surgery or following intestinal perforation with foreign bodies.[41,42] A variety of bacterial species, particularly anaerobes, have been cultured from the pus. The most frequently isolated bacteria include *Streptococcus equi*, *E. coli*, *Bacteroides fragilis*, *Corynebacterium pseudotuberculosis*, *F. necrophorum*, and *Peptostreptococcus* species.[39-41]

Clinically, horses with hepatic abscesses cannot be differentiated from those with other intraabdominal abscesses. Generally, horses have a history of fever, loss of appetite, signs of colic, depression, and weight loss. Clinicopathologic changes are typical of chronic bacterial infection and include leukocytosis, thrombocytosis, hypoalbuminemia, and decreased A/G ratio.[39-41] The prognosis is generally poor because of failure to respond to antimicrobial treatment. Percutaneous or surgical drainage is an effective treatment in humans with hepatic abscesses and has been reported as a successful treatment in one horse.[43]

Hepatic Lipidosis*

Vincent Dore

Fat Cow Syndrome and Lipid Mobilization Syndrome

Hepatic lipidosis (fat cow syndrome) is a multifactorial condition that occurs in dairy cows after parturition. The syndrome is characterized by progressive depression and failure to respond to treatment of other predisposing diseases. It is associated with excessive mobilization of fat to the liver in well-conditioned or overconditioned cows. This mobilization of fat is induced by the negative energy balance and hormonal changes that occur around the time of calving. This negative energy balance in most cases is aggravated by concurrent periparturient diseases that reduce feed intake and increase energy needs.[1-3]

Fat cow syndrome occurs sporadically in dairy cows but more frequently in cows that become overconditioned during late lactation and during the dry period.[2] The overconditioning may be caused by a poor breeding program associated with cows having very long lactations or extended dry periods and having excessive weight gain. Mortality can exceed 25%, with even higher rates occurring without intensive treatment and correction of concurrent diseases. Clinical disease in obese cows that enter the dry period can be minimized by carefully controlling their diets to meet National Research Council (NRC) requirements and preventing milk fever.

Clinical Signs The clinical condition occurs in the postparturient period. Most affected cows are either obese or very well conditioned, with a large amount of omental and subcutaneous fat. Presenting signs usually include depression, anorexia, weight loss, and weakness that can lead to recumbency. Most have nonspecific signs like decreased rumen motility and decreased milk production. Other signs vary and are related to concurrent diseases. The concurrent diseases most frequently seen are metritis, retained fetal membranes, mastitis, parturient paresis, and displaced abomasum.[1] It is important to look for these other diseases; even if mild, they could be significant in these cases and must be treated.

Diagnosis Most laboratory tests are poor indicators of hepatic lipidosis and are of little value in determining disease severity.[4] Liver-derived enzymes are usually elevated above the level in the dry cow but are often within normal ranges. Liver enzymes most consistently elevated in cases of hepatic lipidosis are OCT, total bilirubin, and AST.[5] Bile acid concentrations have not been shown to be significantly increased in most cows with fatty liver.[5] Many cows with hepatic lipidosis have leukopenia and a degenerative left shift, but this is not specific. As expected, non-esterified fatty acid (NEFA) levels will be increased, and triglycerides and cholesterol will be decreased. Most of the total cholesterol is in lipoproteins. The sulfobromophthalein dye excretion test may be useful prognostically because those with a half-life longer than 9 minutes have a more guarded prognosis.[6] Measurement of serum paraoxonase

1, an enzyme exclusively synthesized by the liver, was recently assessed for its ability to diagnose hepatic lipidosis and showed promising results.[7] Decreases in some amino acids, such as glycine and glutamine, can also be observed with increasing severity of hepatic lipidosis.[8]

Several recent studies have examined ultrasound as a tool to detect hepatic lipidosis in cattle. With increasing fat accumulation in the liver, an increased gray level (hyperechogenicity) is seen in the ultrasound image, and the liver appears brighter. Overall, hepatic vessels seem to be smaller. However, this is subjective and is also dependent on the settings of the machine. One study found that the liver increases in size and becomes rounded with increasing severity of lipidosis; however, measuring the thickness of the liver and angle of the ventral margin had limited diagnostic value.[9] Another study used digital analysis of hepatic ultrasound images via a computer-aided ultrasound system and found that imaging findings correlated well with liver triacylglycerol concentrations.[10] Digital analysis of B-mode liver images used a computer program to correct for abdominal wall effects and removal of artifacts. Although not commonly available at this point, the use of ultrasound and computer-aided correction has the potential to help determine the severity of hepatic lipidosis and to estimate with high accuracy the triacylglycerol content of the liver.[11]

Although clinical chemistry and ultrasound may be helpful in diagnosing hepatic lipidosis, a liver biopsy is the gold standard. Liver biopsy may confirm the fatty infiltration of the hepatocytes, but a moderate to high amount of fat is present in the liver of all postparturient, high-producing dairy cows, even those that remain healthy.[12] Fat is usually quantified using histologic methods by determining percentage of hepatocytes containing lipid vacuoles, measuring total hepatic fat on a wet-weight basis, or floating in copper sulfate solutions of various specific gravity (to estimate total fat on a wet-weight basis).[13] Classification schemes characterizing severity of hepatic lipidosis based on percentage of hepatocytes containing fat vacuoles have been presented (e.g., <50%, 50% to 75%, and >75% being equal to mild, moderate, and severe lipidosis, respectively).[4] More recent studies have advocated the use of triacylglycerol analysis on a wet-weight basis to differentiate degrees of hepatic lipidosis.[3] These studies categorized hepatic lipidosis as normal, mild, moderate, and severe by triacylglycerol concentrations of less than 1% (<30 mg/g), 1% to 5% (30 to 50 mg/g), 5% to 10% (50 to 100 mg/g), and greater than 10% (>100 mg/g), respectively.[3] At present, triacylglycerol analysis of hepatic tissue is not a routine procedure in veterinary diagnostic laboratories, so total hepatic fat concentrations remain the gold standard for laboratory diagnosis. A recent study evaluated the correlation between cytology of the liver biopsy and triglyceride concentration. The study showed that hepatic triglyceride concentration could be estimated with better accuracy by making touch imprint preparations of liver biopsy specimens than by measuring BHBA or NEFA.[14] Clinically, little correlation exists between the amount of hepatic fat and signs of disease until the fat is more than 34% wet weight, at which point the liver tissue will float in distilled water with a specific gravity of 1.000.

Generalized obesity is noted at necropsy unless the animal has been sick for more than 1 to 2 weeks. Changes in the liver are most striking; it is enlarged with swollen and rounded edges, is pale yellow in color, and may float in water. Histologically, there is fatty infiltration of the hepatocytes, especially in the centrilobular and intermediate areas. However, these liver tissues are sometimes not much different from those of healthy, high-producing dairy cows in early lactation.

■ ***Pathophysiology*** Storage of excess energy as fat and the periodic mobilization of fat for use as energy by the body is crucial.[2,3] The liver plays a major role in lipid metabolism and must process the absorbed chylomicrons, the volatile fatty acids, and many of the fatty acids and much of the glycerol obtained by mobilization of fat from adipose tissue (Fig. 33.8). The liver of large herbivores has unique functions because much of the dietary energy is absorbed as volatile fatty acids and not glucose. Glucose is still needed (in high amounts in lactating animals) and must be produced by gluconeogenesis, 85% of which takes place in the liver.[15]

Negative energy balance is induced by lactation, fetal growth, exercise, decreased feed consumption, environmental chilling, and diseases (Fig. 33.9). During these periods of negative energy balance and before lactation, blood glucose may drop slightly, the insulin/glucagon ratio drops, and these and other hormones (e.g., catecholamines, growth hormone) activate hormone-sensitive lipases that convert tissue fat to free fatty acids (FFAs) or NEFAs and glycerol (Fig. 33.10). After a 4-day period of fasting in cattle, plasma insulin concentrations decreased and insulin-stimulated blood glucose reduction was decreased as compared to cows that were not fasted.[16] In this study, insulin response was negatively correlated with plasma NEFA and liver triglyceride concentrations, suggesting that decreased insulin response may be an important complication of negative energy balance. In the liver, the glycerol may be used to produce glucose or may be recombined with FFAs to make triglycerides (TGs). In addition to being recombined with glycerol to make TGs, the fatty acids may be degraded through β-oxidation, and the two carbon fatty acids converted to acetyl coenzyme A (CoA). The acetyl CoA combines with oxaloacetate to enter the tricarboxylic acid (Krebs) cycle for the production of energy. This pathway is in competition with the use of oxaloacetate for gluconeogenesis.[2] If there is not enough oxaloacetate available, the acetyl CoA is converted to ketone bodies, which in high concentrations can reduce feed consumption and perpetuate the negative energy balance.

When the liver is overwhelmed with mobilized NEFAs, greater amounts of TGs are deposited within the hepatocytes. These TGs eventually leave the liver as very low-density lipoproteins (VLDLs), which are plasma-soluble complexes of phospholipid, cholesterol, TG, and apolipoprotein A. Hepatic lipidosis results when the rate of hepatic triglyceride formation exceeds oxidation of fatty acids and the formation and release of VLDLs into the peripheral circulation. A number of factors have been incriminated in the inability of the liver to secrete adequate VLDLs to keep up with the deposition of TGs brought about by FFA mobilization from fat. Ruminants have a poor ability to export excess lipid from the liver as VLDLs. This is particularly true in bovine hepatic lipidosis[17,18] and is theorized to result from a shortage of apolipoprotein A. Hepatic lipidosis can be induced in cows by inhibiting the production of apolipoprotein,[19] and the lowest concentrations of lipoproteins occur in the serum of cows with the most severe hepatic lipidosis.[18] Cows on low-protein diets in the dry period are more likely to develop hepatic lipidosis than those on higher protein diets, regardless of the energy content.[17] Depression in dry-matter intake in the final week before calving will increase the liver TG content after calving in dairy cows.[20] Hepatic lipidosis can be consistently reproduced experimentally in cattle by limit feeding or fasting overconditioned cows immediately after calving.[2] In the past, a lack of phospholipid or its precursor choline has been incriminated but never substantiated. However, in the face of an energy shortage, it seems redundant and a waste of energy to repackage fat and send it back to the tissues, even if the liver is being overwhelmed with fatty acids. Some of the same endocrine hormones that activate hormone-sensitive lipase and inhibit lipogenesis and glycogen synthesis may also inhibit production of VLDLs.

It has also been suggested that subclinical liver damage may inhibit the production of VLDLs, but experimental studies have indicated no significant elevation in liver-specific enzymes before

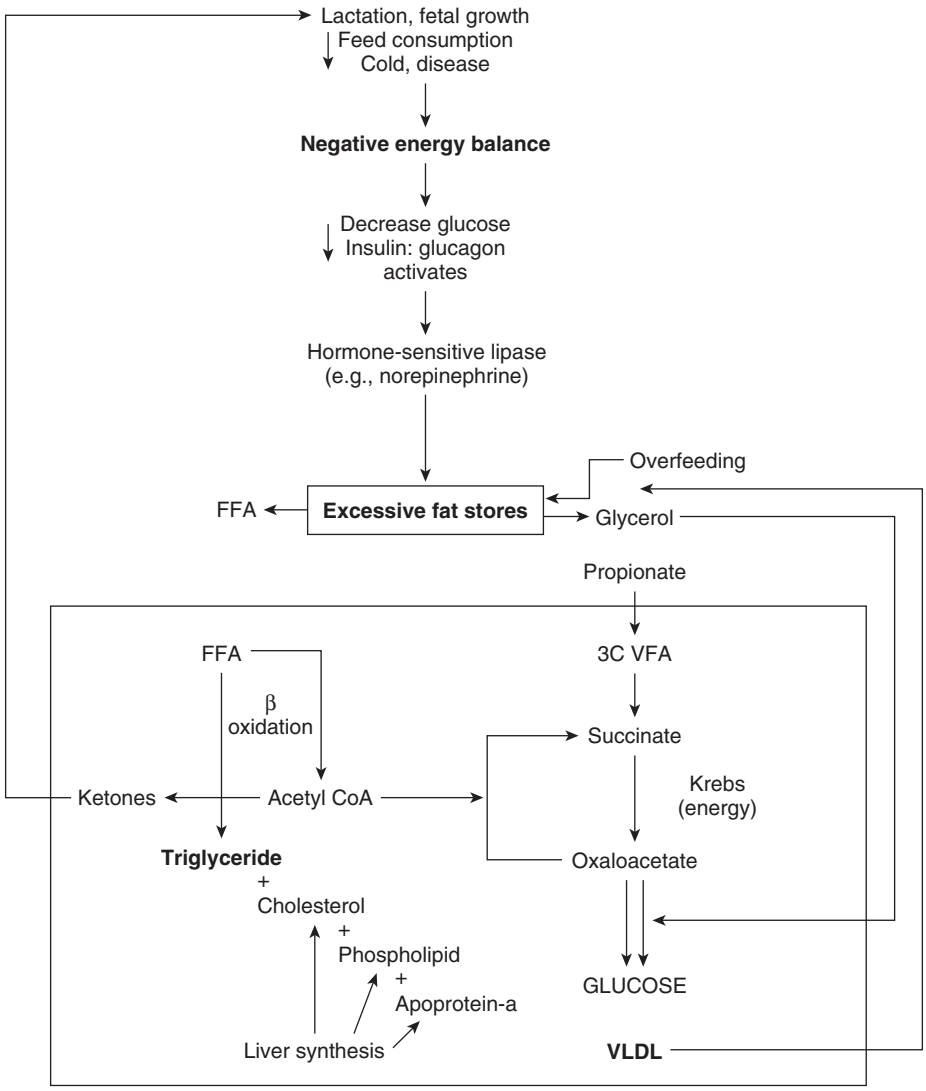

FIG. 33.8 Metabolism of fat in animals with hepatic lipidosis. *3C VFA*, Volatile fatty acid; *CoA*, coenzyme A; *FFA*, free fatty acid; *VLDL*, very low-density lipoprotein.

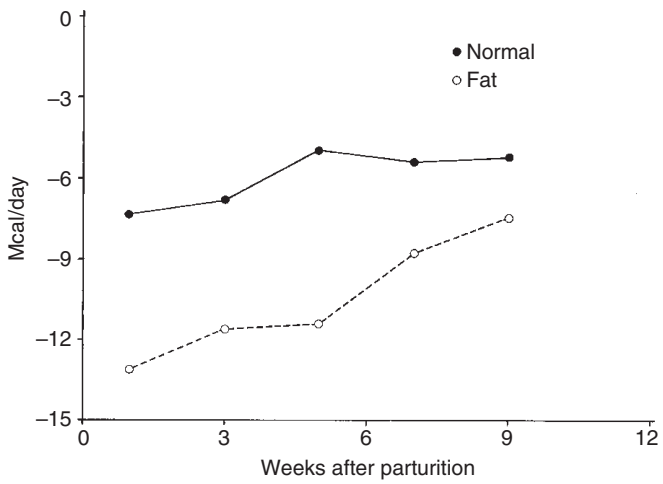

FIG. 33.9 Energy balance (megacalories per day) in normal-condition and obese dairy cows after parturition. *(From Perkins B: PhD thesis. Cornell University, Ithaca, NY, 1983.)*

lipid accumulation.[12] Function may eventually be impaired by the accumulation of fat, because fasted cows have a decrease in the surface area of rough endoplasmic reticulum and the number of mitochondria per unit volume.[21] Changes in the liver seem to be functional and not degenerative.[22] Hepatic lipidosis appears to be a reversible condition if the cause is removed and energy balance becomes positive (less negative). In cows fasted and then returned to full feed, all major liver functions returned to normal within 18 days of refeeding, and all lactating dairy cows with postparturient hepatic lipidosis had normal liver fat content (<15%) at 6 months after calving.[21]

All high-producing dairy cows have increased amounts of fat (15% to 32% by weight) in the liver before calving and during the first few weeks after parturition.[12,22] These fat accumulations in the liver begin before calving as the animal prepares for lactation, and the blood glucose concentration is actually lower before calving.[23] The amount of fat in the liver depends on the amount available and the extent of negative energy balance. Fatter cows tend to lose weight more rapidly and have more fat accumulation in the liver.[9]

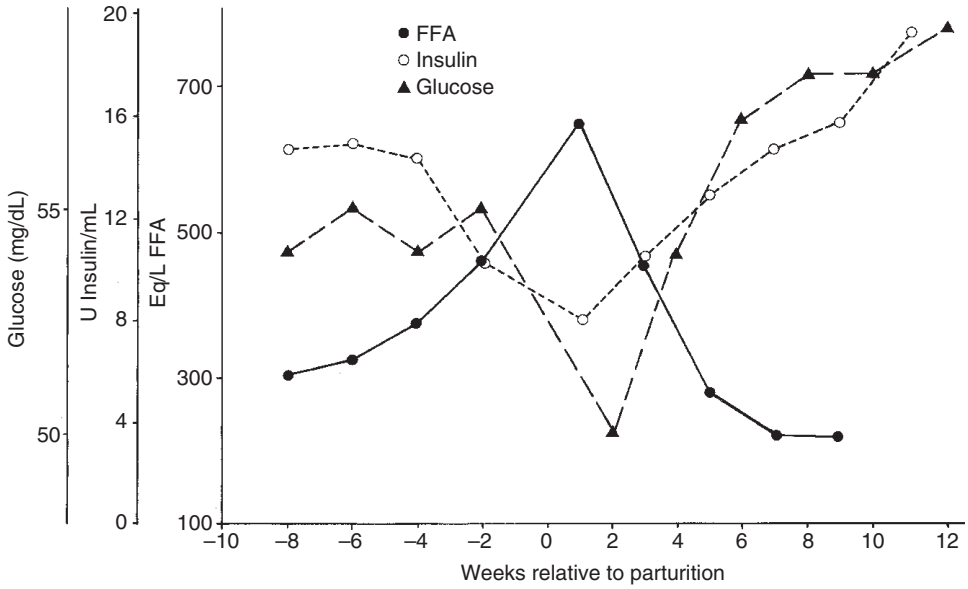

FIG. 33.10 Plasma levels of glucose, insulin, and free fatty acids *(FFA)* in dairy cows before and after parturition. *(From Perkins B: PhD thesis. Cornell University, Ithaca, NY, 1983.)*

Treatment Treatment of mild to moderate fatty liver closely parallels that of traditional ketosis. With severe hepatic lipidosis, the most important principle of therapy is elimination of negative energy balance and the factors or diseases causing it. Continual IV glucose at a rate of approximately 100 to 200 mg/kg/h may provide continuing energy and induce an insulin/glucagon ratio that will decrease hormone-sensitive lipase mobilization of fatty acids and stimulate production of VLDLs. Insulin itself may be given to alter this ratio directly. In cattle, 200 IU of protamine zinc (NPH or Lente) insulin has been given every 12 hours per 1000 pounds of body weight, along with glucose. In cattle not on a continuous drip of glucose, the clinician must use insulin with caution because even low doses can result in profound hypoglycemia. Administration of glucagon at doses of 7.5 to 15 mg/day has been shown to increase glucose and insulin concentrations and decrease plasma NEFA and liver triacylglycerol concentrations,[24] but clinical use of glucagon is prohibitively expensive. Cows with severe ketosis are generally treated with glucocorticoid injections (10 to 30 mg of dexamethasone, 2 to 5 mg of flumethasone, or 100 to 200 mg of prednisolone) and with glucose precursors such as propylene glycol, glycerol, or other compounds that can be administered orally or parenterally.[3]

Precursors of lipoproteins such as choline, which is a component of phospholipid, have been advocated to increase the rate at which TGs leave the liver as phospholipids (VLDLs), but no controlled studies have proved their efficacy. Choline is degraded in the rumen,[25] but theoretically, choline chloride (25 g in 250 mL of sterile saline) given subcutaneously could have limited efficacy. Choline should *not* be given intravenously because it acts as a neuromuscular blocking agent. Rumen-protected choline fed (45 g/day to 75 g/day) from 21 days prepartum to 60 days postpartum has shown a decrease in liver capacity to accumulate NEFA and increased glycogen liver content. There were trends for increased milk yields, fat and 3.5% fat milk-correction, but no significant increase.[27] Addition of inositol both before and after birth did not reduce the incidence or severity of hepatic lipidosis.[26] Methionine at 40 to 50 g/day has also been used for the same purpose. Nicotinic acid (niacin) fed at 6 to 12 g/head/day may help reduce lipolysis at the tissue level and thus reduce the amount of fat presented to the liver.[28] Treatment of hepatic lipidosis with nicotinic acid is often associated with a rebound of clinical signs, and its use as a preventive measure is recommended.

Despite the treatments listed previously, it is imperative to get cows suspected of having fatty liver eating again. Everything possible should be done to encourage dry-matter intake. Appetite can sometimes be enhanced by transfaunating with rumen fluid from a normal cow. This may increase the absorption of volatile fatty acids used for energy and for glucose precursors. Prognosis must be guarded unless the concurrent diseases can be treated successfully and the liver fat mobilized. It is most important to treat the primary disease. Reducing the negative energy balance and treating the hepatic lipidosis must be attacked vigorously.

Prevention Prevention is based on preventing overconditioning during the late lactation period and dry period and treating periparturient diseases in a timely manner. Hepatic lipidosis and associated conditions are most common in dairy cattle. Preventing obesity in cows during late lactation is an important factor in controlling this disease. This process involves a successful breeding program (maintaining a 12- to 13-month calving interval), monitoring body condition (calving, breeding, mid-lactation, and dry periods), and closely matching energy in the ration to the level of milk production during late lactation. Once the cow reaches 7 months of pregnancy and the dry period, any dietary restriction below requirements for maintenance and pregnancy are certain to be counterproductive.

Prevention of hepatic lipidosis involves minimizing or eliminating the primary risk factors associated with disease both pre- and postpartum. The primary prepartum risk factors for fatty liver include obesity (body condition score ≥4.0), severe feed restriction, feeding excess energy, and long calving interval. Postpartum risk factors include other concurrent diseases, anorexia or fasting, feed restriction, and sudden feed changes.[3] Adequate protein in the dry period is essential.[15,19] It has been shown that cows fed higher protein diets during the dry period will perform better in the lactation that follows. Feeding good- to excellent-quality roughages (hay, silages) to meet most of these requirements is preferred. Additional grain 2 to 4 weeks before parturition is important to acclimate the ruminant to anticipated changes in the rations fed after calving. It must be stressed that high-quality dry cow rations be fed

VetBooks.ir

but not overfed. Dry-matter consumption should be limited to approximately 2% of body weight per day while meeting requirements. Other factors in the dry cow ration also must be considered to prevent periparturient diseases such as milk fever, displaced abomasum, mastitis, metritis, ketosis, ruminal lactic acidosis, and retained placenta. Rations should be adequately supplemented with cobalt, the precursor of vitamin B_{12} that is a cofactor in the rate-limiting step in conversion of propionate (the primary glucose precursor) to succinyl CoA. Nicotinic acid has been included in the dry cow ration at 6 g/head/day and in the early-lactating cow ration at 12 g/head/day to aid in the prevention of ketosis, which is a major risk factor for the development of hepatic lipidosis. The use of monensin in the dry cow ration and the early-lactation ration shows promise to aid in preventing ketosis and thus may be of some benefit in preventing hepatic lipidosis.[29,30] Other approaches such as sodium borate or administration of glucose precursors in the dry period have also been attempted.[3]

Immediately and aggressively treating cows (particularly obese cows) for other diseases that occur after calving is important in preventing fatty liver. This includes both infectious diseases (e.g., mastitis, metritis) and metabolic diseases like hypocalcemia. It is important to limit stress on fresh cows and provide adequate bunk space, good ventilation, and high-quality feed. Anything possible to encourage dry-matter intake is important. Several different therapies have been promoted to improve the metabolic state of cows during late gestation by supplying an extra source of glucose and decreasing the mobilization of NEFAs from fat. For example, subcutaneous injections of glucagon beginning 2 weeks prior to calving increased glucose and insulin concentrations and decreased plasma NEFA levels in a model of hepatic lipidosis.[31] Feeding an oral drenches of 1 L/day of propylene glycol for the last 10 days prior to calving also increased glucose and insulin level with decrease in NEFA and BHBA concentrations.[3,32] Slow-release doses of insulin (0.14 IU/kg) have also shown some efficacy in preventing triacylglycerol accumulation in the liver, but higher doses (0.29 IU/kg) can result in profound hypoglycemia.[33] Growth hormone had no beneficial effect.[34]

Protein-Energy Malnutrition and Pregnancy Toxemia of Beef Cows

Protein-energy malnutrition (PEM) and pregnancy toxemia of beef cows are conditions of pregnant beef cattle on marginal diets, usually occurring in the winter and characterized by weight loss, weakness, depression, and sometimes inability to rise. The condition is the result of the negative energy balance caused by decreased quality and quantity of feed when caloric requirements are increased by fetal development and cold weather. Growing, pregnant heifers are especially susceptible because energy requirements for growth are superimposed on the other caloric requirements. A number of other factors, such as unpalatable feed, snow cover, and diseases, may reduce caloric intake. Fatty infiltration of hepatocytes occurs transiently in early PEM, and at necropsy the liver is smaller than normal.

Animals are usually thin and have a long hair coat. In some cases, they are down and unable to rise but are still alert. The body temperature may be normal or subnormal. Occasionally the cows also develop diarrhea. Most animals die 7 to 14 days after becoming recumbent.[35] Differential diagnosis includes Johne's disease, lymphosarcoma, parasitism, chronic pulmonary disease, other deficiencies, and debilitating diseases.

Diagnosis

Diagnosis is usually based on demonstrating decreased caloric intake and ruling out other chronic diseases that could cause debility. Laboratory tests support but do not rule out the disease. Total serum calcium may be decreased. Packed cell volume also may be decreased, and serum insulin levels may be reduced. Ketonuria is not typical in PEM. At necropsy, muscle mass usually is decreased. Serous (brown) atrophy of fat is often present, especially in the coronary groove, bone marrow, and perirenal areas. Lesions of concurrent disease also may be found if PEM is acute, and a fatty yellow liver may be noted.

Treatment

Treatment is often unrewarding. Efforts to reverse an advanced catabolic state may fail. A 454-kg cow requires 13 Mcal of metabolizable energy daily, or approximately 6.5 L of 50% glucose solution by continuous drip. Alfalfa pellet gruels are helpful if force-fed, and approximately 11 kg/day of alfalfa is recommended. Propylene glycol (150 to 200 mL) orally twice daily can be helpful as a glucose precursor. Treatments include IV fluids, improving the energy balance, and treating any concurrent disease.

Prevention

Nutrient requirements increase greatly for beef cattle during the third trimester of pregnancy. As forage quality (digestibility) decreases, the time feed material stays in the rumen increases (increased rumen turnover time). Therefore as quality decreases, the maximum dry-matter intake (DMI) decreases, which greatly decreases the maximum nutrient (energy) intake. This compounding effect of poor-quality forage on maximum intake is particularly important for preventing hepatic lipidosis and the accompanying protein-calorie malnutrition (PCM) of pregnant beef cattle in the winter. The approximate maximum DMI of forage of poor quality (oat straw, corn stover), medium quality (meadow grass hay), and excellent quality (alfalfa hay [25% crude fiber], corn silage) is 1% to 1.5%, 2%, and 2.5%, respectively. Environmental temperature can increase energy needs for beef cattle on pasture or range; as the temperature falls from 20° C (68° F) to 10° C (50° F), roughly 10% more energy is necessary for maintenance, and at freezing temperatures, 0° C (32° F), 20% additional energy is required. The key to preventing PEM in pregnant beef cattle is adequate body condition (scores of 5 to 7) entering the third trimester and availability of good-quality to excellent-quality forage in adequate amounts.

Pregnancy Toxemia in Ewes and Does

Pregnancy toxemia, also known as *ketosis* or *twin lamb disease*, is a condition that occurs in ewes and does during the last 2 to 4 weeks of gestation. It is characterized by anorexia, weakness, and depression. Nearly 80% of the fetal growth occurs in the last 6 weeks of gestation, which can result in a negative energy balance occurring from the increased energy demands of rapid fetal growth in late gestation and insufficient feed intake. The incidence of pregnancy toxemia is greater in ewes with more than one fetus, during the last 2 to 4 weeks of gestation, and in does with three or more fetuses.[36] Poor-quality feed, cold weather, lack of exercise, and stress of movement during the period at risk also may increase the incidence. Overweight animals are also more likely to suffer from negative energy balance and develop the disease. Does seem to be more resistant to pregnancy toxemia than ewes, in that three or more fetuses are usually required to produce the condition. Prevalence in the herd varies from less than 5% to up than 20% in some herds, depending of the predisposing factors and nutritional state.

Initial clinical signs include partial to complete anorexia and separation from the rest of the flock or herd. The disease will progress to severe depression and recumbency. Neurologic signs such as tremors, star-gazing, incoordination, circling, blindness, and grinding the teeth may precede terminal depression. If untreated, animals will appear comatose in lateral recumbency and will die shortly after developing neurologic signs. Differential diagnosis includes other periparturient

diseases, such as mastitis and hypocalcemia, as well as polioencephalomalacia, enterotoxemia type D, and toxicoses.

Diagnosis Ketonuria is usually present and detected before ketonemia. Hypoglycemia is not a consistent finding but is sometimes present. Some authors associated sudden hyperglycemia in previously hypoglycemic goats suffering from pregnancy toxemia with death of the fetus.[37] Affected ewes and does often are generally acidotic and may have lowered serum calcium and potassium levels.[38] Blood urea nitrogen (BUN) and creatinine levels are elevated terminally in some cases. Fatty acid concentrations in the plasma are usually elevated above 500 μEq/L. Serum β-hydroxybutyrate (BHB) concentrations are elevated (>1 mmol/L) using electronic on-farm test in goat and sheep.[39-42] A nonspecific but marked neutrophilia may be found in some affected animals and is particularly dramatic in does, sometimes reaching 35,000 neutrophils/μL.

Treatment Treatment of pregnancy toxemia is based on two principles: (1) administering exogenous energy sources (i.e., glucose) and (2) removing the factors increasing the energy demand on the animal (i.e., fetuses). Mortality is high unless treatment is started early and the fetuses are removed—the most important step—either by inducing parturition or by cesarean section. Parturition can be induced in ewes with 15 to 20 mg of dexamethasone; in does the dose is either 10 mg of dexamethasone or 10 μg of prostaglandin $F_{2\alpha}$.[42,43] A cesarean section may be performed if the animal's value warrants it and there does not seem to be enough time to induce parturition. Besides removing the fetuses, the ketotic condition should be treated with IV glucose (250 to 500 mL of 10% to 20% glucose as an IV bolus followed by a slow IV drip of 5% to 10% glucose). Acidosis and hypocalcemia must be corrected if present. Administration of oral propylene glycol as a glucose precursor has also been advocated. Although recommended doses vary, an initial treatment of two doses (150 to 200 mL) given at a 12-hour interval followed by 60 mL per dose thereafter for 3 to 6 additional days appears to work well.[43] Giving recombinant bovine somatotropin at a dose of 0.15 mg/kg of body weight also has shown some benefit.[44] The energy intake must be increased. If the ewe is down and unable to stand, removal of the fetuses should be performed by cesarian section as soon as possible. In such cases the prognosis is often poor, so euthanasia of the ewe or doe must be considered. Immediately after parturition or cesarian section, the animal should be started on broad-spectrum antibiotics along with flunixin to prevent metritis.[43]

Prevention Preventing pregnancy toxemia and the associated severe hepatic lipidosis in ewes and does requires measures similar to those outlined for PEM in beef cattle. Both overconditioned and thin ewes and does in the third trimester of pregnancy are at increased risk. Because of the common occurrence of twins and triplets, nutrient requirements for pregnant ewes greatly accelerate during this period. Good-quality to excellent-quality forage for feeding sheep is very important. An additional tool for diagnosing underfeeding in ewes and goats is measurement of plasma BHB during the last month of pregnancy.[45] This test greatly facilitates assessment of nutritional inadequacy in pregnant ewes. Plasma BHB concentrations of 0.8 mmol/L or higher are diagnostic of the need for increased energy consumption by pregnant ewes. Does have been shown to have a significant decrease in blood pH, bicarbonate concentration, and base excess values well in advance of the clinical signs associated with pregnancy toxemia.[38] Therefore these parameters could also be early indicators of disease in pregnant sheep or goats. Measures of the cardiac biomarker troponin I could also be used as a prognostic indicator in sick goats prior to cesarean section.[46]

Hyperlipemia and Hypertriglyceridemia in Ponies

Hyperlipemia is a life-threatening condition that occurs in horses, ponies, and occasionally donkeys.[47-49] It is characterized by a fatty liver and serum that is cloudy with accumulation of lipids. Triglycerides are usually much higher than 500 mg/dL.[47] The condition is caused by decreased caloric intake, which causes fat mobilization and fat accumulation in the liver and accumulation in the plasma. The decreased food intake may be secondary to other diseases. Suggested predisposing factors include hypophagia, pregnancy, or lactation, often in obese ponies, American Miniature horses, or donkeys.[48-50] The incidence of hyperlipemia is greater in ponies than in horses. It is seen more often in the winter, especially from February to May in animals receiving poor feed. Pregnant animals and those that are lactating are affected more frequently.

Equine hyperlipemia is characterized by production of an abnormal VLDL fraction ($VLDL_1$) that has a reduced content of apolipoprotein B-100 and an increased content of apolipoprotein B-48.[51] The substitution of B-48 for B-100 is thought to allow greater TG content because B-48 is the apolipoprotein of importance in chylomicrons. The activities of lipoprotein lipase and hepatic lipase, the enzymes responsible for VLDL catabolism, were increased in hyperlipemic ponies.[51] It was concluded that overproduction of VLDL is the cause of hyperlipemia, possibly complicated by defective catabolism.

Hyperlipidemia is a mild condition of ponies and horses characterized by mildly elevated TG concentrations (100 to 500 mg/dL), clear plasma, and no evidence of hepatic dysfunction.[47] An increase in caloric intake is usually sufficient to reverse the condition. The more severe condition, hyperlipemia, is discussed further.

Clinical Signs The clinical signs of hyperlipemia are nonspecific. Ponies usually are anorexic, depressed, weak, and uncoordinated. Diarrhea, colitis, cachexia, ventral edema, and abdominal pain are frequently seen in presenting cases.[52,53]

Diagnosis Definitive diagnosis is based on an increased level of circulating TGs (>500 mg/dL). Gross examination of the blood and plasma to detect the white to yellow opacity caused by the presence of lipids is a fast method to evaluate the presence of lipemia. TG level and presence of gross lipemia and clinical disease are used to differentiate between the types of hyperlipidemias in horses. Those values are summarized in Table 33.8. Bilirubin usually is elevated, as in most horses that are fasted. Fatty acids are also increased. Bromosulfophthalein clearances are delayed and, terminally, a large base deficit may be caused by metabolic acidosis.[47]

Postmortem examination reveals fatty infiltration of the liver and kidneys, which are pale and swollen and have a greasy texture. In ponies the liver is sometimes ruptured, resulting in intraabdominal hemorrhage and death. Renal lesions may be seen histologically. There may be a primary disease that produces anorexia and secondarily has resulted in hyperlipemia.

Treatment It is most important to treat any primary disease to alleviate the cause of anorexia and correct the negative energy balance. Resting energy requirements of a sick, hospitalized horse have been estimated at 22 to 23 kcal/kg/day.[53] Nutritional support is critical, in the form of either dextrose-supplemented fluids or partial parenteral nutrition. Oral supplementation using a 60-mL dose of corn syrup (4 kcal/mL) given orally every 2 hours will provide around 5 kcal/kg/day to a 500-kg horse and is usually well tolerated.[53] Heparin is also recommended in some cases and has been shown to decrease triglyceride concentrations in affected horses.[52] Regular insulin (0.2 IU/kg) IM every 3 to 6 hours can be used initially for severely

TABLE 33.8

Types of Hyperlipidemias in Horses

Equine Hyperlipidemias	Serum Triglyceride Concentration	Presence of Gross Lipemia in Serum Sample	Fatty Infiltration of Organs	Clinical Disease	Breed Affected
Hypertriglyceridemia	>100 mg/dL	No	No	No	All
Hyperlipidemia	<500 mg/dL	No	No	No	All
Severe hypertriglyceridemia	>500 mg/dL	No	Rare	Rare	Large-breed horses
Hyperlipemia	>500 mg/dL	Yes	Yes	Yes	Predisposed: ponies, miniature horses, donkeys Rare: large-breed horses

Modified from McKenzie H: Equine hyperlipidemias. *Vet Clin Equine* 27:59-72, 2011.

lipemic animals; however, this is usually discontinued within 24 hours and a longer-acting product is used for maintenance. Protamine zinc insulin (PZI) has been used at an IM dose of 30 IU twice daily with 100 g of PO glucose for a 200-kg pony. This is continued on odd days; on even days, IM injections of 15 IU of PZI are given twice daily.[47] Ultralente insulin can be given at a dose of 0.4 IU/kg SC q24h.[52] The use of a continuous rate infusion at 0.07 IU/kg/h with concomitant IV drip of glucose to avoid hypoglycemia can also be used. If the hyperglycemia (>180 mg/dL) is not adequately controlled after 2 to 3 hours at the initial rate, increase the rate by 50%. Further increases can be made; however, it is important to allow the dose to equilibrate over a period of several hours before adjusting the dosage. Close monitoring of blood glucose levels is required while using insulin therapy. Slow IV drip of glucose for several days or until lipemia clears may be indicated. Heparin (100 to 250 IU/kg SC twice daily) has been used to alter the lipoprotein lipase activity and inhibit hormone-sensitive lipase of adipose tissue, but it may alter coagulation enough to cause hemorrhage.

The presence of hyperlipidemia is readily detected and easily solved by increasing caloric intake. Although therapy of hyperlipemic ponies and horses is often unrewarding, the diagnosis is relatively straightforward, and prevention depends on providing adequate feed of good quality and avoiding high-stress situations.

Prognosis High mortality rates have been seen with hyperlipemia in ponies and donkeys. Previous studies reported mortality rates between 22% to 80% in hyperlipemic ponies.[54] A recent study from the United Kingdom revealed a mortality rate of 48.5% in donkeys due to hyperlipemia.[55] The donkeys were from a donkey sanctuary, and the disease prevalence was 10.7% over the study period. Development of hyperlipemia was highly associated with the presence of a concurrent disease (odds ratio [OR]: 76.98). Other risk factors associated with development of the disease were cardboard bedding, movement to the sanctuary in the previous 2 weeks, weight loss of more than 10 kg in the last month, dental disease, and concentrate feeding. Even if the prognosis is often grave, decreased mortality rates have been observed when adequate and aggressive treatment is performed.[49]

Congenital Hyperbilirubinemia

Geoffrey W. Smith

Gilbert's Syndrome

Gilbert's syndrome is an unconjugated hyperbilirubinemia in the presence of normal erythrocyte life span. It occurs occasionally in humans and has been described in Southdown sheep.[1] Gilbert's syndrome involves a failure of unconjugated bilirubin to cross the liver cell membrane and be conjugated. This is most likely due to a defect in carrier proteins or the conjugating enzyme.[2] Hepatic bilirubin clearance is about 30% of normal when tested with a loading dose of radiolabeled bilirubin.[3]

Affected Southdown sheep may show icterus or at least elevated plasma bilirubin levels, both conjugated and unconjugated. Affected sheep also cannot excrete BSP into the bile. No histopathologic lesions are present, other than some pigment in the hepatocytes. The condition is inherited as an autosomal dominant trait in humans.[2] The bile acid levels are normal in humans, but one sheep exhibited defects in hepatic bile acid clearance.[4]

Dubin-Johnson Syndrome

Dubin-Johnson syndrome is a failure of conjugated bilirubin to enter the bile canaliculi. This has been diagnosed sporadically in humans and in Corriedale sheep.[5] There may be an impairment not only in bilirubin but also in excretion of other conjugated organic anions. Sheep affected by this syndrome may be jaundiced or have hyperbilirubinemia. Both conjugated and unconjugated bilirubin are increased, and BSP clearance is delayed. Bile acids are reported to be normal in humans, but delayed clearance was reported in three Corriedale sheep.[4] Histologically, the hepatocytes contain a black, melanin-like pigment.[5]

Persistent Hyperbilirubinemia in Thoroughbreds

A persistent hyperbilirubinemia has been reported in a Thoroughbred racehorse that had no evidence of liver damage, cholestasis, or hemolysis and was not fasting.[6] The horse was persistently icteric and had serum total bilirubin concentrations of 8.7 to 9.4 mg/dL; 90% or more of the plasma bilirubin was the unconjugated form. Serum bile acid concentration, along with the liver enzymes GGT, AST, and SDH, were within normal limits. The horse acted clinically normal, and the plasma fatty acid concentration was also within normal limits. The condition was similar to Crigler-Najjar syndrome type 2 in humans, which involves a deficiency in bilirubin uridine diphosphate glucuronyltransferase needed to conjugate bilirubin, but this was not verified.

Miscellaneous Liver Diseases

Geoffrey W. Smith

Rift Valley Fever

Rift Valley fever, also known as *enzootic hepatitis*, is an acute febrile arthropod-borne disease of sheep, goats, cattle, and humans present in most countries of sub-Saharan Africa.

VetBooks.ir

With the current threat of bioterrorism, it could appear in other parts of the world.[1,2] Rift Valley fever is caused by a virus of the genus *Phlebovirus*. More than 20 species of mosquitoes have been implicated as possible vectors for the virus, including some North American mosquitoes that are competent laboratory vectors.[2] The disease causes abortion in pregnant females and a febrile condition with rapid death in lambs, kids, and calves. The mortality rate in young animals approaches 100% but it is much less (20% to 30%) in older animals.[2] Clinical signs may include fever, anorexia, weakness, salivation, diarrhea, and sometimes abdominal pain, and almost all pregnant animals will abort. The primary gross lesion is hepatomegaly and hemorrhage. Histologically, a focal hepatic necrosis is identified, and eosinophilic intranuclear inclusion bodies are present. Confirmation of the diagnosis is made in the laboratory by virus isolation or immune tests. If the disease is suspected, state and federal regulatory veterinarians should be contacted.

Telangiectasia

Hepatic telangiectasia, commonly known as "sawdust livers" in packing houses, is a focal degeneration in liver lobular circulation characterized by red-brown foci 1 to 5 mm in diameter. These lesions account for more than 10% of the bovine liver condemnations but do not result in any clinical signs.[3] Microscopically, hepatocytes are distorted and sinusoids congested.[4] Hypotheses proposed to explain the pathogenesis of the lesions include necrotizing hepatitis, ischemia induced by emboli or other vascular pathologies,[5] dilation of Disse spaces, reduced density of the reticulin framework, vitamin E–selenium deficiency, alteration of the sinusoidal barrier, and immune-mediated disease.[3] Some human pathogens have been isolated from these livers as well as normal livers, but livers are condemned on the basis of aesthetics according to current U.S. Department of Agriculture (USDA) regulations.[3]

Ischemia, Hypoxia, and Congestion

Ischemia and hypoxia can lead to death of hepatocytes, but less severe insults cause fatty infiltration because lipoprotein synthesis depends on oxidative metabolism. This damage is more apparent in the centrilobular areas, which are the last to receive blood and oxygen. Chronic passive congestion causes the grossly visible "nutmeg liver" caused by distention of the sinusoids and central veins with blood. The liver may be enlarged in these cases, but other signs related to the liver are not usually present. More significant findings will be detected in the cardiovascular system.

Fetal Liver Damage

The liver of the fetus may be damaged by infectious and toxic agents, but the result is usually abortion or birth of a weak neonate with signs related to other systems. The lesions in the liver may be diagnostic of the disease. Equine herpesvirus infection of the fetus causes hepatocyte necrosis, with acidophilic intranuclear inclusion bodies in more than 50% of the hepatocytes. Aborted fetuses of cattle with infectious bovine rhinotracheitis may have some focal necrosis of the liver, but this is not enough to be diagnostic.

Failure of Drug Metabolism and Excretion

Jennifer L. Davis

Hepatic disease can affect drug metabolism in several ways. Ascites, if present, can alter drug distribution, and drug dosages should be adjusted based on lean body weight, estimating the amount of fluid present.[1] Also, since the liver is the primary organ involved in the metabolism of exogenously administered substances and represents an important method for excretion of drugs via the bile, liver disease can affect drug metabolism and clearance.

Factors influencing hepatic drug metabolism and clearance include hepatic blood flow, hepatic metabolism, and protein binding. Drugs are often classified as having high hepatic extraction ratios (flow-limited drugs) or low hepatic extraction ratios (capacity-limited drugs). Flow-limited drugs are quickly and efficiently extracted by the liver, and their rate of elimination is limited only by hepatic blood flow. Chronic liver disease with decreased parenchymal blood flow or hepatic shunts can decrease blood flow in the liver and greatly compromise clearance of flow-limited drugs like morphine, verapamil, and lidocaine.[1] These drugs undergo a high first-pass metabolism following oral administration and, as such, are usually given at high oral doses. The dosage of these drugs may need to be decreased by up to 50% in patients with liver disease because bioavailability will be greatly increased and elimination decreased, possibly resulting in toxic levels of the drug.[1,2] The opposite may be true for drugs that require hepatic activation (prodrugs), and thus subtherapeutic levels may be present.[3]

Capacity-limited drugs are slowly extracted by the liver, and their elimination is independent of blood flow but highly dependent on hepatocellular uptake and metabolism. The effect of liver disease on drug metabolism in these cases is more variable, and drug clearance can be increased, as with atenolol, or decreased, as with diazepam and chloramphenicol.[1,2] The majority of phase I (oxidation-reduction) reactions and phase II (glucuronidation) reactions take place in the hepatocytes, and diseases that result in hepatocellular destruction can reduce the ability of the liver to metabolize drugs. The purpose of these reactions is to make compounds more water-soluble and prepare them for excretion via the kidney. Clearance of drugs eliminated by phase I reactions can be significantly decreased with hepatic disease, whereas phase II reactions are often not affected unless severe disease is present or certain types of glucuronidation are needed.[4,5] For example, ester glucuronidation will be decreased in patients with cirrhosis of the liver, and drugs cleared via this pathway will have lower clearance rates compared to drugs metabolized by ether glucuronidation.[4]

Humans with intrahepatic cholestasis showed a decreased activity of phase I cytochrome P450 enzymes and impaired microsomal drug metabolism in vitro, and this was well correlated with serum concentrations of total bilirubin and bile acids.[6] Making direct correlations between human drug metabolism and veterinary species is difficult, as there is a large interspecies variation in the types and activity of hepatic metabolizing enzyme among humans, horses, and cattle.[7,8] In addition, polymorphisms within some metabolizing enzymes (i.e., CYP2D50) have been demonstrated in horses, resulting in poor, extensive, and ultra-rapid metabolism of related drugs.[9] Further classification of the equine and bovine P450 enzymes and their roles in drug metabolism is needed.

Cholestatic diseases have been shown to decrease biliary excretion of a number of drugs in both animal models of disease and human patients with naturally occurring biliary obstruction. Increased plasma levels, prolonged mean residence times, increased area under the concentration-time curve, and decreased total body clearance have all been demonstrated.[10-12] In horses administered enrofloxacin intravenously, those animals with GGT activity greater than 200 U/L had a lower clearance and higher area under the curve than horses with GGT activity less than 200 U/L.[13] Renal clearance of some drugs may be increased as a compensatory response for the impaired biliary excretion, as is the case with cefpiramide in cholestatic human patients.[14] This decreased biliary clearance can be used to an advantage in certain instances when treating biliary tract

infections in order to attain higher concentrations of the drug in the bile ducts, as long as the drug has a large therapeutic index.[14]

A deficiency in hepatic drug metabolism capacity may impair drug metabolism and elimination in young animals. This has been demonstrated in foals administered chloramphenicol, which is extensively metabolized in the liver via glucuronic acid conjugation and primarily excreted through the biliary system into the feces. Clearance was decreased and half-life prolonged in animals less than 1 week of age.[15] Nonsteroidal antiinflammatory drugs (NSAIDs) also show impaired metabolism in neonatal foals. Phenylbutazone, ketoprofen, and flunixin meglumine all have prolonged terminal half-lives over the first few weeks of life.[16-18] Neonatal foals also have a low capacity to metabolize enrofloxacin to ciprofloxacin. Ciprofloxacin was not detectable in foals, whereas in adult horses ciprofloxacin concentrations are about 17% of the enrofloxacin concentrations.[19] Drug metabolism also differs in neonatal calves and sheep, which may result in prolonged withdrawal times necessary for veal calves and lambs. Studies have shown that hepatic metabolic enzymes are similar to adult levels in sheep and calves by 7 days of age.[20,21] At this point, no quantitative research that specifically examines the development of metabolic pathways in the neonatal foal has been performed. It is likely these pathways are decreased in the early stages but rapidly develop and are within a range similar to adult horses within the first 1 to 4 weeks of life, as is seen in other veterinary species.

Neoplasia of the Liver

Geoffrey W. Smith

Primary neoplasia of the liver is uncommon in large domestic species. Only 0.011% of slaughterhouse animals seen in one study had liver tumors.[1] Metastatic tumors such as lymphoma are more common (Fig. 33.11), but the clinical signs of these are more likely to reflect changes at the primary site. Metastasis of lymphosarcoma in cattle is most common, but signs produced by growth in other organs (e.g., lymph nodes, abomasum, heart, uterus, spinal cord) are more predominant. In the horse, lymphosarcomas and carcinomas have metastasized from the digestive tract.[2]

Horses

Although uncommon, a number of different primary hepatic neoplasias have been reported in horses.[3,4] The nomenclature seems inconsistent throughout the years of reporting, and the signs are usually more consistent with neoplasia in general than with hepatic failure. Weight loss, weakness, anorexia, lethargy, and occasionally colic may be seen in these animals. Serum concentrations of liver-derived enzymes are elevated in many cases. The tumor can often be located by ultrasonography, but the definitive diagnosis of the type of tumor is based on histopathologic examination of biopsy tissue.

Hepatoblastoma has been reported in foals, young horses, and an equine fetus.[4,5] Young horses present with weight loss or failure to grow, lethargy, anorexia, and possibly icterus. Serum concentrations of several hepatic enzymes are increased. Ultrasonography reveals hepatomegaly and a heterogeneous appearance of the hepatic parenchyma. Erythrocytosis due to a paraneoplastic syndrome and increased production of erythropoietin is seen in some cases.

Hepatocellular carcinoma is seen in both old and young horses. These horses lose weight and are listless. Serum concentrations of LDH, GGT, and AST are often elevated. Erythrocytosis with a normal concentration of serum protein is seen in most cases as a result of paraneoplastic syndrome with elevated erythropoietin.[3,4,6]

Cholangiocarcinoma or cholangiocellular carcinoma arises from the intrahepatic bile duct epithelium and appears to be a disease of older horses.[4,7] Lethargy, fever, abdominal pain, anorexia, and ventral edema have been reported with this tumor. Hypoglycemia has been associated with hepatic cholangiocarcinoma as a suspected paraneoplastic syndrome.[8] Some of these animals have anemia rather than the erythrocytosis reported with hepatocellular tumors. GGT and ALP concentrations may be elevated, but SDH comes from hepatocytes and is usually within normal range.

Cattle

In addition to the lymphosarcomas, primary hepatocellular carcinomas have been described in cattle.[9] The most common presenting clinical signs are anorexia and weight loss of weeks to months in duration.[10] Liver-derived enzymes are generally elevated, and polycythemia (erythrocytosis) is a common laboratory finding in these cases.[10,11] Ultrasound of the liver may be helpful in diagnosing hepatic tumors in cattle.[10]

Hemochromatosis

Hemochromatosis is a disorder caused by deposition of hemosiderin in the parenchymal cells, resulting in tissue damage and dysfunction of the liver and other tissue. It is most frequently seen in humans and mynah birds, but hemochromatosis has been described as a new disease of Salers cattle[12] and has been reported in three horses.[13] In humans, the types include idiopathic hemochromatosis, an autosomal recessive familial condition associated with increased iron stores, cirrhosis, and saturation of the iron transport capacity.[14] Both horses and cattle show increased iron deposits in the liver; histopathology of liver biopsy specimens reveals brown pigment that stains for iron in the hepatocytes as well as Kupffer cells. An increased concentration of iron can be measured in the liver, and there is fibrosis and elevated liver-derived enzymes.

In Salers cattle the condition appears to be a homozygous recessive condition more like the human familial type. There is an inappropriate absorption of iron by the GI tract, with subsequent hepatic storage (iron overload) and eventual loss of hepatic function. It has been reproduced by experimental breeding in Salers cattle.[15] The primary clinical signs in cattle are decreased weight gain, poor body condition, dull hair coat, loss of incisor teeth, and sometimes diarrhea. Serum concentrations of liver enzymes are elevated, and there is marked hepatic fibrosis, in addition to the hemosiderin deposits in the liver. Total serum iron, total iron-binding capacity (TIBC), and saturation of transferrin (>60%) are increased, similar to the familial disease in humans. Liver iron concentration will be

VetBooks.ir

greater than 5000 μg/g (ppm) on a wet basis (normal herdmates of affected cattle, 84 to 100 ppm).

Horses with hemochromatosis present with evidence of liver disease. Serum concentrations of the liver enzymes ALP, GGT, and AST are elevated, and serum total bile acids are greater than 40 μM/L. In the cases reported, total serum iron was not elevated, and unlike the idiopathic human condition or the cattle cases, there was no saturation of the iron-binding capacity. Total liver iron has been as high as 6700 ppm (normal, 100 to 300 ppm).[13]

Hemochromatosis should be suspected in animals with emaciation or elevated liver enzymes and in Salers cattle with greater than 60% saturation of transferrin. It can be confirmed by histopathologic examination of the liver, with excessive iron accumulation in hepatocytes. Clinicians should differentiate hemochromatosis from hemosiderosis, in which iron accumulates in the reticuloendothelial system and not hepatocytes, and which can be caused by hemolysis and other conditions.

In humans, hemochromatosis is treated by reducing the iron stores through phlebotomies and blood removal. The one horse on which this was tried had advanced disease with severe cirrhosis, and it succumbed a few days after the blood removal. Removal of 160 L of blood over 12 months failed to reduce liver iron concentration in one heifer[12] but produced some improvement in other calves.[15] Deferoxamine is given to some human patients to induce a negative iron balance and reduce the rate at which iron accumulates.

Gallbladder and Biliary Tract Disease

Jennifer L. Davis

Biliary tract disease in large animal medicine is rare and results from both intrahepatic and extrahepatic causes. Intrahepatic causes of cholestasis include cholangitis, cholecystitis, choledocholithiasis, and presence of a foreign body. Extrahepatic causes include abscess formation, obstructive or inflammatory intestinal disease, and neoplasia.

Choledocholithiasis, Cholelithiasis, and Hepatolithiasis*

By definition, *cholelithiasis* describes the presence of biliary calculi in either the bile ducts or the gallbladder, whereas *choledocholithiasis* describes stones found in the common bile duct. *Hepatolithiasis* indicates the presence of calculi in the intrahepatic bile ducts above the right and left hepatic ducts and is a variation of cholelithiasis. These conditions have been described in horses, cattle, sheep, and pigs, but they do not seem to be recognized as a clinical problem in sheep, and rarely in cattle.[1-15] Choledocholithiasis is the most common cause of biliary obstruction in large animals and occurs more frequently in horses.[1-9]

Biliary stone formation begins with precipitation or aggregation of normally soluble components of bile. Other mechanisms involved in the pathogenesis include ascariasis, ascending biliary infection or inflammation, biliary stasis, changes in bile composition, and presence of a foreign body.[14] Several pathogenic bacteria (*Salmonella* spp., *E. coli*, *Aeromonas* spp., *Citrobacter* spp., group D *Streptococcus* spp., *Clostridium perfringens*) have been cultured from the bile ducts of horses and cows with cholelithiasis.[2,6,9,16] Whether these bacteria were the cause or the result of the stone formation remains unclear. In most reports the chemical analysis has shown that choleliths have a mixed composition, containing bilirubin, bile pigments, cholesterol esters, esters of cholic and carboxylic acid, calcium phosphate, and sodium taurodeoxycholate.[6,8,9] In one study, 80% of the choleliths contained less than 10% cholesterol.[9]

Cholelithiasis should be suspected in horses when a triad of clinical signs exists: recurrent abdominal pain, intermittent pyrexia, and icterus. Hyperammonemic hepatic encephalopathy, photosensitization, and weight loss are other, less common features of cholelithiasis.[3,5,6,14,16] A subclinical presentation due to partial obstruction of the biliary tree may be recognized only on postmortem examination.[11] A large cholelith was the cause of duodenal obstruction in a horse presented for colic.[12]

Elevations in the serum activity of ALP, AST, GGT, SDH, and total bilirubin are associated with cholelithiasis.[3,6,9,14,16] The rise in total bilirubin is due to an elevation in both direct and indirect bilirubin. Serum bile acid concentrations also increase when bile flow is obstructed. Other laboratory abnormalities that may be seen include hyperammonemia, increased urine bilirubin, and prolonged partial thromboplastin and thrombin times.[5,6,9] The most common alterations in the leukogram include a neutrophilic leukocytosis. Elevations in globulin and fibrinogen may also occur.[5]

Ultrasound examination of the liver is a safe, noninvasive tool for diagnosing cholelithiasis. Hepatomegaly and bile duct dilation are seen in horses with biliary calculi. The echogenicity of the hepatic parenchyma is increased compared with that of normal horses and may approach that of the spleen. The bile ducts are thick and distended. The *parallel channel sign* (dilation of interhepatic biliary radicals adjacent to the portal vein) may also be seen. Several choleliths are generally seen, but a single stone may be present (Fig. 33.12). Choleliths may be hyperechoic, casting acoustic shadows, or they may be sonolucent. Choleliths are most likely to be visualized in the cranioventral part of the right hepatic lobe, especially in the sixth to eighth intercostal spaces. Cholelithiasis can be diagnosed accurately by ultrasound in at least 75% of horses if an adequate scanning image of the liver is obtained and bile duct dilation and choleliths are visualized.[8]

The differential diagnosis for a horse with the clinical signs associated with cholelithiasis include other causes of liver disease and mild recurrent abdominal discomfort, including verminous arteritis, mesenteric abscesses, sand enteropathy, enterolithiasis, abdominal neoplasia, and urolithiasis.[3]

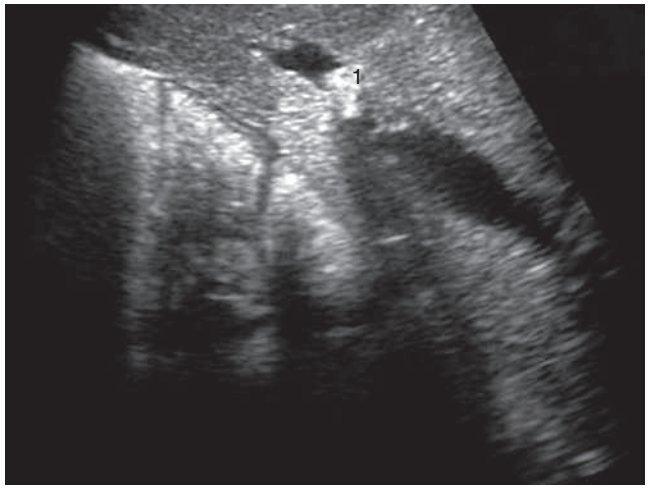

FIG. 33.12 Ultrasound image of a cholelith taken from the right side of a horse. Note the hyperechoic stone *(1)* visible inside a distended bile duct. Hyperechoic parenchyma is also noted beneath the stone, which may represent hepatic fibrosis.

*Contributions to previous editions by Terry C. Gerros are acknowledged.

FIG. 33.13 Multiple choleliths present with the bile ducts of a horse.

Hepatomegaly is usually noted at necropsy, although a shrunken liver may be observed. The liver is firmer than normal, has a consistent texture, and varies in color from red to green-brown. The hepatic ducts and common bile duct are generally dilated and may contain the calculi (Fig. 33.13). Histologically, periportal fibrosis is a common finding. Bile duct stasis and hyperplasia are usually noted; suppurative cholangitis is less common.[9,14,16]

Treatment of cholelithiasis initially includes broad-spectrum IV antibiotics (penicillin plus gentamicin or enrofloxacin) and oral metronidazole. This is followed by long-term oral antibiotics, based on culture and sensitivity of a biopsy specimen, if available. If culture and sensitivity results are not available, treatment should be aimed at suspected gram-negative enteric bacteria or anaerobes. Potentiated sulfonamides or enrofloxacin plus metronidazole are good choices. Chloramphenicol has a good spectrum against most cultured bacteria, but since it is highly metabolized by the liver, it should not be used if hepatic function is severely compromised. Antibiotic treatment should continue for 6 weeks past the time when GGT values return to normal. DMSO (0.5 to 1 g/kg IV as <10% solution for 3 to 5 days) has also been recommended as a treatment to help dissolve intrabiliary sludge or small calcium bilirubinate stones. DMSO may cause hemolysis at higher concentrations, and horses with liver disease may already have fragile RBCs, so care should be taken with treatment. Fluid therapy may also help to thin secretions and promote bile flow. Anti-inflammatory drugs (low-dose NSAIDs) are also recommended. Choledocholithotomy and choledocholithotripsy, described in horses, have had limited success.[5-7] The prognosis is related to the degree of hepatic fibrosis, severity of clinical signs, and number and location of the stones. Recent reports show a 75% to 80% survival rate with medical or medical plus surgical therapy.

Cholangitis and Cholangiohepatitis

Clinical disease of the bovine gallbladder is rare. Obstructive gallbladder disease has been associated with abdominal fat necrosis, choleliths, fascioliasis, foreign bodies, hepatic abscesses, neoplasia, and suppurative cholecystitis.[17,18] Adenomas and adenocarcinomas (most common tumors found in gallbladder), papillomas, and lymphosarcoma (rare) can cause obstruction.[17,19] Rupture of the gallbladder was found on necropsy of a cow in which icterus, anorexia, decreased milk production, and diarrhea had been present.[20]

Cholangitis and cholangiohepatitis may be primary or secondary and can result from cholelithiasis, duodenal inflammation, intestinal obstruction, neoplasia, parasitism, and certain toxins.[21] Sporidesmin, a fungal toxin from *Pithomyces chartarum*, causes cholangiohepatitis in cattle and sheep. Cholestasis and ascending infection resulting in cholangiohepatitis have been noted in horses with primary intestinal diseases such as proximal enteritis, right dorsal displacement of the large colon, and less frequently, left dorsal displacement of the large colon.[22-24] Duodenal strictures secondary to severe gastroduodenal ulceration have also been reported as a cause. Clinical signs associated with cholangitis and cholangiohepatitis in the horse may include anorexia, pyrexia, subtle behavioral changes, chronic weight loss, colic, and icterus. Septic peritonitis may occur as an extension of bacterial infection into the intraperitoneal space.[25] Alterations in hepatic enzyme activity may indicate hepatocellular damage, cholestasis, or both. Histopathologic examination and bacterial culture are indicated to further identify the causative agent. In cases of suspected bacterial etiology, long-term antibiotic therapy is indicated.[25] Antibiotic choice should be based on bacterial sensitivity, but in cases where no bacterial organism is identified, an antibiotic that is effective against enteric organisms and secreted or cleared in the bile is warranted.

Therapy of Liver Failure

Jennifer L. Davis

Antibiotic Therapy

Antibiotic therapy is indicated in cases of cholelithiasis, cholangitis, and cholangiohepatitis, as well as liver dysfunction secondary to systemic diseases causing sepsis in horses. Initial treatment should include broad-spectrum IV antibiotics, such as potassium penicillin plus either gentamicin or enrofloxacin, and oral metronidazole to cover *B. fragilis*. This is followed by long-term oral antibiotics based on culture and sensitivity (if available).[1] If no culture is available, the clinician should suspect gram-negative enteric bacteria with or without concurrent anaerobic infection. Trimethoprim sulfonamide combinations or enrofloxacin plus metronidazole are good choices. Chloramphenicol has a good spectrum against most cultured bacteria, but since it is highly metabolized by the liver, it should not be used if hepatic function is severely compromised. High levels of IV penicillin and an aminoglycoside should be administered to foals with suspected Tyzzer's disease.[2]

Cattle with single or multiple liver abscesses often respond to penicillin therapy, but long-term therapy is required, and there is a significant rate of recurrence of clinical signs after therapy is withdrawn. Echolucent abscesses of small to medium size have the best prognosis. Abscesses with an echodense appearance are difficult to treat. Single large abscesses are best treated by surgical drainage, especially those interfering with vagal nerve function.

Treatment of Hepatic Encephalopathy

Treatment of hepatic encephalopathy (HE) involves treatment of the underlying hepatic disease combined with supportive and palliative care. This includes IV fluids, broad-spectrum antibiotics, and gastroprotectants. Padding and wraps should be provided to help prevent self-trauma. Sedation may be necessary to control behavior or aid in treatments, but many of these drugs are metabolized in the liver, so care should be

VetBooks.ir

taken during dosing. Small doses of α_2-adrenergic agonists like xylazine or detomidine are recommended. However, these drugs can cause respiratory depression at higher doses, and hypoventilation may aggravate signs of HE. Doses should also be low enough to cause sedation without resulting in prolonged lowering of the head below the level of the shoulder, which may result in worsening cerebral edema. Diazepam and other benzodiazepines should *not* be used; they may enhance the effects of GABA on inhibitory neurons, worsening HE.[3] Based on this, use of the benzodiazepine receptor antagonists has been recommended to lessen HE signs in humans.[4] The overall success of flumazenil in treating HE in humans and dogs has been low, and it has rarely been used in the horse. Sarmazenil, a partial inverse agonist at the benzodiazepine receptor, appears to be more promising for reversing signs of HE in dogs[5] and has been used for treating moxidectin intoxication in a foal.[6]

Dietary management of HE is very important. Liver failure results in increased serum glucagon, and muscle catabolism releases amino acids. At the same time, hepatic metabolism of aromatic amino acids (AAAs) is reduced and accumulation occurs, whereas muscle and adipose tissue can metabolize branched-chain amino acids (BCAAs), resulting in less accumulation. AAAs cross the blood-brain barrier and can act as false neurotransmitters, aggravating signs of HE, so a low-protein diet with a high BCAA/AAA ratio is recommended.[7,8] Low-protein, high-starch feeds include grass or oat hays, beet pulp, cracked corn, milo, sorghum, barley, and oats. Feed small amounts frequently (q2-4h). If affected horses are anorexic, forced enteral or partial parenteral nutrition may be used. Special formulations of amino acids that consist mainly of BCAAs should be used, and lipids should not be added if there is any possibility that lipidosis is present.

Other treatments for HE are designed to reduce intestinal ammonia absorption. Neomycin is an aminoglycoside antibiotic that suppresses enteric ammonia production. Because it is more nephrotoxic than gentamicin and can be irritating to intestinal mucosa (causing diarrhea), treatment duration is often limited to 3 days or less. Reported doses also vary widely, with some reports recommending higher and more frequent dosing (10 to 20 mg/kg PO q6-12h)[9] and others recommending lower doses to decrease the risk of adverse effects (4 to 8 mg/kg PO q8h day 1, followed by 2-4 mg/kg PO q12h for 2 additional days).[10] Oral metronidazole (10 to 15 mg/kg twice daily) may be used as an alternative in cases that do not tolerate neomycin. Metronidazole should be used with caution because it is metabolized by the liver, and signs of toxicity may mimic HE. Lactulose (0.2 to 0.5 mL/kg PO q6-8h; equivalent to up to 333 mg/kg) is poorly absorbed by the small intestine and therefore reaches the ileum and large intestine intact. Once in the distal GI tract, it is metabolized to organic acids, acidifying the intestinal contents causing a pH gradient to occur and ammonia to migrate from the blood into the colon, where it is trapped as ammonium and expelled. Acetic acid (vinegar, 0.5 mL/kg PO q12h), mineral oil, and magnesium sulfate administered by nasogastric tube have also been used to decrease ammonia absorption. However, induction of hemorrhage during the procedure may result in swallowing of blood and worsening of enteric ammonia production.

Treatments aimed at reducing cerebral edema may also be necessary. Drugs frequently used include furosemide (1 mg/kg IV/IM q8-12h), mannitol (0.5 to 1 g/kg as a 20% solution IV over 20 to 30 minutes q12-24h), and hypertonic saline (2 to 4 mL/kg IV). The prognosis for HE is poor unless the underlying disease can be treated quickly.

Fluid and Colloid Therapy

Dehydration should be corrected with a balanced electrolyte solution, preferably without lactate. Lactate is normally metabolized to bicarbonate in the liver and has an alkalizing effect. However, in horses with severe hepatic dysfunction, lactate may build up in the system and cause a worsening of acidosis. Acetate buffer solutions can be used as an alternative since acetate is mainly metabolized in the muscle. Sodium chloride (0.9%) with added calcium, dextrose (2.5% to 5%), and supplemental potassium (20 to 40 mEq/L) also can be used. Additional potassium can be given orally (5 to 20 g twice daily) to prevent or treat hypokalemia, since low potassium increases production and absorption of ammonia from the kidney.[11] Acidosis may be severe in many horses with hepatic failure, but attempts at correction must be made slowly.[12] Too rapid an increase in pH may exacerbate HE. Bicarbonate therapy should be carefully instituted only when the venous pH remains less than 7.1 after appropriate fluid therapy. The prognosis is poor in horses that remain persistently acidotic.

Glucose decreases ammonia concentration, reduces the reliance on catabolic gluconeogenesis, decreases protein catabolism, and spares hepatic energy consumed in hepatic gluconeogenesis, so it should be supplemented in cases of hepatic disease. The goal is to maintain blood glucose concentrations in the range of 90 to 120 mg/dL. In the case of hypertriglyceridemia with concurrent insulin resistance, supplemental insulin can be administered, as described in the Hepatic Lipidosis section earlier.

Polycythemia may be relatively unresponsive in some cases of hepatic failure and should not be used as the primary guide for judging adequate fluid therapy. Fresh or fresh frozen plasma can be used to increase colloidal oncotic pressure, clotting-factor transport proteins, and antiproteases. Stored whole blood should not be used because ammonia levels may be high. Hetastarch should also not be used in hepatic failure, owing to its potential effects on coagulation.

Treatment of Inflammation and Fibrosis

Corticosteroids may be beneficial in treating lymphocytic and plasmacytic variants of chronic active hepatitis. Dexamethasone (0.05 to 0.1 mg/kg/day IM or IV decreased over 2 to 3 weeks) or prednisolone (1 mg/kg/day PO for several weeks) are recommended. Other recommended therapies for resolving inflammation and preventing progression of fibrosis include NSAIDs. Flunixin meglumine (0.5 to 1 mg/kg PO q12h to q24h) or low-dose phenylbutazone (0.5 g/day PO q24h) can be used for anti-inflammatory effects. Vitamin E (10,000 U PO q24h) is recommended as an antioxidant and anti-inflammatory agent. Pentoxifylline (8 to 10 mg/kg PO q12h) is a methylxanthine derivative and works as a nonselective phosphodiesterase inhibitor, resulting in weak inhibition of the inflammatory cytokines TNF-α and IL-6. It also acts to increase RBC deformability, perhaps preventing microthrombosis. In horses, results with pentoxifylline are variable, possibly because of the variable bioavailability with extended dosing.[13] Colchicine (0.03 mg/kg PO q24h) can be used to inhibit production of collagen and macrophage- or cytokine-induced inflammation, potentially resulting in decreased fibrosis. Numerous side effects are reported in humans, including nervous system, renal, and dermatologic problems; therefore its use in horses is not currently recommended.

Miscellaneous Treatments

Supplemental S-adenosylmethionine (SAMe) (20 mg/kg PO q24h) is used for treatment of liver diseases; endogenous production is reduced secondary to reductions in methionine adenosyltransferase.[14] Presumed beneficial effects of SAMe in liver disease include augmentation of glutathione synthase levels in the hepatocyte, stabilization of membrane function, modification of cytokine expression, and inhibition of apoptosis

in normal cells. *N*-acetylcysteine (NAC; 70 mg/kg IV q6h × 8 treatments) is a cysteine donor thought to be cytoprotective. It may improve hepatic microcirculation and oxygen delivery, enhance hepatic metabolic functions by restoring glutathione levels, block TNF-α release, and act as a free radical scavenger.[14] DMSO (0.5 to 1 g/kg IV as <10% solution for 3 to 5 days) may act as an antioxidant as well as aid in dissolving intrabiliary sludge or small calcium bilirubinate stones. However, it may also precipitate a hemolytic crisis in animals with fragile RBCs secondary to end-stage liver disease. Ursodeoxycholic acid (also known as ursodiol) and silymarin/silibilin are often used for hepatic disease in small animals, and there are anecdotal reports of use in horses, but safety and efficacy have not been proven. Ursodiol at 15 mg/kg PO q24h has been reported to be beneficial, subjectively, when combined with antibiotics, fluids, DMSO, and pentoxifylline for treatment of cholangiohepatitis or choledilithiasis in horses.[10] Silibilin pharmacokinetics and pharmacodynamics have been studied in healthy horses.[15,16] Administration at doses up to 26 mg/kg PO q12h for 7 days resulted in no adverse effects. Despite a low oral bioavailability, an increased antioxidant capacity was noted, suggesting that treatment may be useful in horses with hepatic disease.

Treatment of concurrent diseases should also be considered. If the hyperlipemia is thought to be associated with a pituitary adenoma, treatment with pergolide (1 to 2 mg/day PO) is warranted. Hyperlipidemia associated with diarrhea and azotemia may also occur in horses in late pregnancy, and abortion may be advisable.[17,18] Hepatic failure in cattle associated with septic metritis or mastitis, as well as biliary obstruction due to hepatic abscesses, often can be treated successfully by force-feeding (e.g., alfalfa gruel, electrolytes) and systemic antibiotics.[19] Treatment of hepatic fascioliasis should be instituted as previously discussed.

Pancreatic Disease

Jennifer L. Davis

Pancreatic disease is rare in both cattle and horses. In the horse, acute and chronic disease has been reported, whereas only chronic disease has been reported in cattle. One retrospective study of pancreatitis in horses noted a 0.4% incidence based on postmortem diagnosis.[1]

Recognized causes of pancreatitis include migrating parasites, bacterial and viral infections, immune-mediated damage, biliary or pancreatic duct inflammatory disease, vitamin D toxicity, and deficiencies of vitamin A or E, selenium, and methionine.[2-5] Drugs known to induce pancreatitis in humans that are used frequently in horses include furosemide, tetracycline, estrogen, and certain corticosteroids and sulfonamides.[2,4] One case report in a pony suggests an association with Cushing's syndrome.[6] The cause of acute pancreatitis in the horse is unknown, but it has been associated with grain overload and severe abdominal pain.[7] Three reports of acute pancreatitis in the foal suggest a possible relationship with sepsis, GI disease, vasculitis, and pancreatic lymphatic obstruction.[8,9] Pancreatitis was diagnosed postmortem secondary to severe gastroduodenal ulceration in a foal[10] following reproductive tract surgery in a mare.[11] In cattle, an association has been demonstrated between obesity and severity of pancreatic disorders, including fatty pancreas and pancreatitis.[12] The final common pathway may result from autodigestion by activated enzymes, but the exact mechanism remains speculative.

Clinical signs associated with acute pancreatitis are nonspecific and mimic those associated with an acute GI crisis. Characteristic clinical features are moderate to severe abdominal pain, gastric reflux, hypovolemic shock, and cardiovascular compromise.[2,5,13,14] Gastric distention accounts for the pain and gastric reflux associated with acute pancreatitis. Hypovolemic shock, occurring secondary to fluid losses into the peritoneal cavity and bowel lumen, results from release of vasoactive substances from the pancreas. Tachycardia, tachypnea, prolonged capillary refill, and congested mucous membranes result from hypovolemia and cardiovascular compromise. Pancreatitis should also be considered as a differential diagnosis in chronic or intermittent signs of colic, due to potential adhesion of bowel to the inflamed pancreas, or a mass-like effect within the abdomen.[15,16] In foals, neurologic signs including dilated pupils, blindness, obtundation, and seizures have also been reported.[8] Hypoglycemia or pancreatic encephalopathy due to cerebral microthrombosis and infarction, as seen in humans, may be implicated.

Laboratory confirmation of pancreatic disease is difficult and not routinely attempted. The diagnosis is usually confirmed on histologic evaluation of the pancreas after necropsy. Laboratory tests that may be of value in the diagnosis of pancreatitis in the horse include measuring serum amylase and lipase activity, peritoneal fluid (PF) amylase concentrations, fractional excretion of amylase, and plasma trypsin levels.[5] Serum amylase values from normal horses range from 14 to 35 IU/L (mean, 21 ± 6), whereas PF values range from 0 to 14 IU/L (mean, 5 ± 4).[17] Serum lipase values from normal horses range from 23 to 87 IU/L (mean, 58 ± 19), whereas PF values range from 0 to 36 IU/L (mean, 14 ± 12).[17] Elevations of pancreatic enzyme activity are difficult to interpret because the enzymes may be elevated in horses with proximal enteritis, colic, primary renal failure, and damage to intestinal mucosal cells, as well as pancreatitis.[5,17,18] Amylase also originates from the salivary glands, and lipase can be released from the liver. Clinical cases documented at necropsy had serum amylase activity greater than 700 IU/L; this magnitude of elevation may be helpful in differentiating acute pancreatitis from other causes of elevated amylase. In acute pancreatitis, PF amylase levels are higher than serum levels.[18] Plasma trypsin levels increase in horses with suspected pancreatic damage and may be a better indicator of pancreatic disease.[19] Trypsin is specific to the pancreas and activates its own zymogen and those of all the other pancreatic enzymes. In one study of horses with acute abdominal disease in which pancreatic damage was suspected, trypsin activity was significantly higher than in healthy horses (196 ± 128.2 ng/mL versus 28.5 ± 19.2 ng/mL).[19] In cattle with experimentally induced pancreatitis, serum amylase and lipase concentrations increased rapidly but returned to normal within a few days, suggesting that this may not be a useful test for cases of chronic pancreatitis.[20] GGT does not appear to be a sensitive indicator of pancreatic disease in horses. In foals, an inflammatory peritoneal effusion with increased peritoneal protein and triglyceride concentrations, along with hypertriglyceridemia, has been documented.[8] Pancreatitis has not been successfully imaged with ultrasonography in the horse.[21] A technique for ultrasound examination of the right lobe of the pancreas in healthy cattle has been described.[22] Using this technique, experimentally induced acute pancreatitis was monitored in cattle. Twenty-four hours after induction of pancreatitis, an increased echogenicity was noted, but within 3 days, hypoechogenicity was noted secondary to necrosis, hemorrhage, and inflammatory exudates, as confirmed at necropsy.[20]

Medical management of acute pancreatitis is symptomatic. Prevention of gastric rupture by continuous gastric decompression and control of abdominal pain are crucial in the treatment of pancreatitis.[4] Large volumes of balanced polyionic electrolyte solutions are necessary to maintain the circulating volume and prevent shock. Because hypocalcemia may be a problem, serum calcium concentration should be monitored. Broad-spectrum antibiotics are warranted because of the potential for secondary bacterial infection. NSAIDs and analgesics are used to control inflammation and pain.

Chronic interstitial pancreatitis (CIP) in horses and cattle seldom has clinical significance. In horses, *Strongylus equinus*

VetBooks.ir

VetBooks.ir

and *Stronglyus edentatus* are most often identified as the etiologic agent of CIP; however, *Parascaris equorum* has been identified in one case report.[4,23,24] In cattle, CIP has been primarily associated with the trematodes *Eurytrema pancreaticum* and *Eurytrema coelomacticum*; these parasites have not been isolated in the United States.[18]

Pancreatic disease in adult cattle is related to endocrine dysfunction.[25-27] The most frequently reported disorder is type 1 diabetes mellitus, but the etiology in most cases is not determined.[25-27] Histopathologic examination generally reveals an absence of beta cells in the islet tissue. Foot-and-mouth disease virus has been associated with diabetes mellitus in cattle after convalescence.[18] Hypoplasia of the acinar pancreatic tissue has been described in calves.[18] Clinical signs include steatorrhea and diarrhea. Insulin-dependent diabetes mellitus with pancreatic beta cell dysfunction has been documented rarely in horses.[28,29] Transient type 1 diabetes has also been diagnosed in the foal,[30] and recent work shows that method of delivery (spontaneous versus induced foaling) may have a significant effect on pancreatic function.[31] Induced parturition was associated with two- to threefold higher cortisol levels and with differences in the absolute and age-related changes in basal concentrations of glucose, α-amino nitrogen, and insulin.[31] Adenocarcinoma of the exocrine pancreas is reported in rare equine cases and should be considered in horses exhibiting the clinical signs of pyrexia, depression, weight loss, and icterus.[3,32,33]

Pancreatic calculi found in older cattle (>5 years) during necropsy are considered incidental findings.[18] The calculi are composed primarily of calcium carbonate and calcium phosphate. Their presence may be associated with grazing on silica-rich soil, vitamin A deficiency, or chronic inflammation of the pancreatic ducts.[18] In two reported cases of pancreatic calculi in cattle, the cause for euthaniasia was fracture of the lumbar vertebrae.[34,35] The correlation between pancreatic disease and bone pathology in cattle is unknown, but osteoporosis is a known consequence of chronic pancreatitis in humans.

Equine Renal System

Alexandra J. Burton

Acute Renal Failure

Thomas J. Divers • Alexandra J. Burton

Acute renal failure (ARF) in the horse is usually due to exposure to nephrotoxins or vasomotor nephropathy (e.g., hypoperfusion or ischemia). The most common pathologic lesion with ARF is acute tubular necrosis (ATN).

Toxic Nephropathies

Aminoglycosides

Administration of aminoglycoside (AG) antibiotics (gentamicin or amikacin) is one of the most common causes of ATN in horses; however, irreversible ARF due to AGs is uncommon. Aminoglycosides exert their main toxic effect by accumulating within renal proximal tubular epithelial cells. After filtration through the glomerulus, the cationic charge of AGs causes them to bind to tubular epithelial cell phospholipid membranes.[1] Once within the cell, AGs disrupt a myriad of ultrastructural cellular elements causing cell swelling, death, and sloughing into the renal tubular lumen.[1] More recently, AGs have been found to also cause some glomerular damage and additionally, a decrease in renal blood flow, directly medicated by an AG-induced increase in vascular resistance.[7] The detailed molecular mechanisms of tubular cell necrosis, glomerular, and vascular effects caused by AGs are beyond the scope of this text, but in-depth reviews are available.[1,2]

Most cases of AG nephrotoxicity are not due to single-instance drug overdose. Horses with normal renal function can usually tolerate a single major overdose without detrimental effects. Thus, AG toxicity is almost always the cumulative effect of *repeated* administration (e.g., in order to induce a gentamicin nephrotoxicosis model in the healthy equine, doses of 20 mg/kg q8h several days are required; the standard equine dose is 6.6 mg/kg IV q24h).[3] Because AGs are water soluble and highly distributed in extracellular fluid (ECF), their clinical pharmacokinetics are influenced by variations in patient ECF volume owing to *disease state* or *age*, so different doses and dose intervals may be required to attain desired serum/plasma peak and trough concentrations depending on patient specifics.[4-10] Gentamicin is the most commonly used AG in horses. A retrospective study in hospitalized horses showed significant clinical variability in peak gentamicin concentration for a given dose and emphasized the importance for therapeutic drug monitoring (TDM) when using gentamicin to ensure adequate peak plasma concentrations, which is important for AG efficacy.[6] However, because renal cellular uptake of gentamicin is saturable, nephrotoxicity is associated with insufficiently low plasma trough (i.e., sampled just before the next IV dose), rather than excessively high peak concentrations.[1] The maximal trough concentration permissible to minimize the risk of nephrotoxicity is unknown in horses. In humans, gentamicin trough concentrations greater than 2 μg/mL have been associated with nephrotoxicity.[11,12] However, the optimal trough concentration of gentamicin to minimize nephrotoxicity in humans is still controversial, with recommendations ranging from attaining a trough less than 2 μg/mL once in 24 hours to maintaining a concentration of less than 0.5 μg/mL for at least 4 hours.[13-15] Recently in human medicine, there have been developments of gentamicin pharmacokinetic models to facilitate opportunistic TDM and to move away from daily trough concentration monitoring.[16,17] The rationale behind this is to avoid repeated daily timed venopuncture, especially in neonates and children, and allow AG concentrations to be evaluated within the model at times when blood would be taken anyway for other analyses.[16,17] Nephrotoxicity typically develops after several days of AG administration to horses with diarrhea or septicemia that are not adequately hydrated or because of other factors that may exacerbate a decrease in renal perfusion (e.g., concurrent treatment with nonsteroidal antiinflammatory drugs [NSAIDs]).[7-10] The shift to once-daily AG dosing in humans and horses, compared with previous dosing of AGs, which was two to three times daily, has become a standard practice that reduces the potential for nephrotoxicity (by ensuring a longer period of the day with sufficiently low serum trough concentrations) but still provides a similar therapeutic response.[18-21]

Prolonged administration of AGs without TDM or serum creatinine concentration monitoring is a common history with

AG nephrotoxicity in the horse. Typically, AGs may be safely administered for longer than 10 days if the patient is adequately hydrated and appropriate serum AG trough and serum (or plasma) creatinine concentrations are maintained. However, with regard to using serum creatinine concentration to monitor AG toxicity, in one instance, experimental induction of gentamicin nephrotoxicity in ponies was reflected by a rather small increase (0.3 mg/dL) in creatinine concentration.[22] Thus, TDM and measurement of the trend in urinary γ-glutamyltranspeptidase ($_U$GGT), which always increases rapidly with AG administration (even in the absence of nephrotoxicity), and trend in $_U$GGT:urinary creatinine ($_U$Cr) concentrations in at-risk patients will give a much earlier indication of impending nephrotoxicity than serum creatinine concentration alone.[23-25] Although it has not been proven, the neonatal equine kidney is likely more susceptible to AG toxicity than the adult kidney. This is probably reflective of the prolonged elimination half-life seen in foals.[4,26] Critically ill neonatal foals may be at greater risk for AG nephrotoxicity, although this may simply reflect an increased incidence of septicemia in neonates and longer courses of treatment with AGs.

When AGs are administered to high-risk patients (e.g., those with severe dehydration, sepsis or neonates), volume deficits must be continually replaced, and TDM and UGGT:UCr concentrations or, at the bare minimum, serum creatinine concentration monitored frequently.[27] In horses receiving appropriate fluid therapy, AG nephrotoxicity rarely develops. Increased urinary sodium (Na^+) excretion and fluid diuresis appear to have a protective effect on the kidney. In contrast, hypokalemia (or total body potassium (K^+) depletion) and low calcium (Ca^{2+}) intake may predispose horses to aminoglycoside nephrotoxicity by decreasing urine output.[25] Supplementation with oral electrolytes (e.g., 1 to 2 oz of NaCl and KCl daily) may be of benefit to horses being treated with AGs by increasing water intake and urine output and by replacing K^+ deficits in anorectic horses. Furosemide should not be administered prophylactically in an attempt to prevent AG nephrotoxicity as it is a potassium-wasting diuretic. In patients with prerenal azotemia that receive AGs, it is important to monitor serum creatinine closely (i.e., to make sure that it is decreasing in the face of AG therapy) and consider prolonging the administration interval, until volume deficits are corrected, or, if possible, select an alternative antimicrobial. However, because nephrotoxicity is a cumulative effect of repeated dosing, delaying administration of the initial dose of an AG in a critical septic patient pending rehydration is often unwarranted.

When ARF from AG use develops, it usually manifests as nonoliguric to polyuric renal failure. Outcome is generally favorable, so long as the duration of ARF is not prolonged and other underlying disease processes can be corrected; however, an elevated serum creatinine may take several days (and occasionally weeks) to return to within reference range. Nephrotoxicity should be considered in horses that become inexplicably depressed and inappetent while being treated with AGs or within a few days after AG therapy is discontinued. Renal failure can develop even after the drug is withdrawn, so monitoring renal function for 2 to 4 days after discontinuing AG therapy is advised in high-risk patients. Polyuria may be observed before the onset of depression and anorexia, or, if the patient becomes oliguric, mild stranguria and repeated posturing to urinate may be observed. A tentative diagnosis of nephrotoxicity is based on history of AG use and supportive laboratory data. Abnormal laboratory findings associated with tubular damage that may be detected before onset of azotemia include enzymuria (e.g., GGT) and cylindruria (casts in urine).[22,23,27] Although these parameters can be monitored for early detection of tubular injury, enzymuria does not necessarily indicate nephrotoxicity per se, nor does it necessarily indicate if or when AGs should be discontinued or to what degree the interval of administration should be prolonged. A rising trend in serum creatinine concentration (even if within reference range) and TDM (e.g., gentamicin 24-hour trough >2 μg/mL) are often more useful indicators of a need to increase concurrent fluid therapy (diuresis), prolong AG dose interval, or discontinue AG therapy.

Pigment Nephropathy (Myoglobin and Hemoglobin)

Acute tubular necrosis (ATN) and ARF subsequent to a severe episode of rhabdomyolysis due to myoglobin from muscle necrosis, especially if the associated dehydration is prolonged.[28,29] Dehydration and administration of NSAIDs for analgesia may both increase the risk of ARF by decreasing renal blood flow. Pigment nephropathy can also occur secondary to any other cause of muscle necrosis (e.g., muscle trauma, prolonged recumbency). Rhabdomyolysis with ARF has been reported secondary to severe clenbuterol toxicosis in three Quarter Horse racehorses. Observation of grossly discolored urine is not a prerequisite for development of ARF in cases of myoglobin pigment nephropathy. Hemolysis (hemoglobin), which may be secondary to a variety of toxins and primary conditions, appears to be a less common cause of pigment nephropathy than myopathy. Horses with severe hemolysis and those suffering from disseminated intravascular coagulation (DIC) are at greater risk of developing hemoglobinuria and pigment nephropathy. In one study, 41% of 32 horses with red maple toxicosis and hemolysis had evidence of renal insufficiency, but it was not found to be an important risk factor for mortality.[31] Hemolysis with associated ARF is also a feature of acute severe cases of equine piroplasmosis caused by either of the erythrocytic protozoa *Theileria equi* or *Babesia caballi*.[32] Pigment nephropathy should be suspected in horses that become anorectic and depressed during the week after an episode of tying up or during a hemolytic crisis. Measuring serum concentrations of creatine kinase (CK) and aspartate aminotransferase (AST) may help identify rhabdomyolysis, if no other etiologies of ARF are suspected. There is little preformed creatinine in muscle, so rhabdomyolysis alone does not produce an increase in serum creatinine concentration. Even if normal initially, it is also prudent to recheck serum creatinine 2 to 3 days after an episode of rhabdomyolysis.

Vitamin K_3

Vitamin K_3 was a common cause of ATN before its withdrawal from the North American market. Nephrotoxicity can occur rapidly after a single parenteral dose of the menadione sodium bisulfite form of vitamin K_3.[33,34] Development of ARF was thought to be idiosyncratic and likely involves direct tubular damage via oxidative stress and pigment nephropathy subsequent to hemoglobinuria.[33,34] Although horses are sensitive to its nephrotoxic effects, oral supplementation of vitamin K homologs with a view to enhancing bone strength has been investigated in horses in Japan, and no nephrotoxicity was reported.[35,36]

Nonsteroidal Antiinflammatory Drugs

Most horses do not experience appreciable adverse renal effects from NSAIDs as long as they are administered at the correct dose to euvolemic patients. However, NSAIDs may produce ARF in an occasional horse when excessive doses are administered, maximal recommended doses are administered chronically, and/or when dehydration is not corrected promptly or is ongoing.[37] A typical situation where this might occur is in a horse that has been on daily NSAIDs for several months/years and then is administered excessive additional NSAIDs for severe colic. The lesion produced by NSAID toxicity in horses is papillary necrosis in the renal medulla, also termed *medullary crest necrosis* (Fig. 34.1), which can be manifested by

FIG. 34.1 Diffuse renal medullary necrosis *(yellow arrows)* in a 3-year-old gelding following a 21-day administration of phenylbutazone (2 g [approximately 4.4 mg/kg] q12h PO). This was aggravated by concurrent hypovolemia and hypoproteinemia due to hypoalbuminemia. *(Courtesy Montague N. Saulez.)*

gross hematuria.[37-39] Unless severe, this lesion rarely causes overt clinical signs. One study suggested that ketoprofen was less nephrotoxic in comparison with flunixin and phenylbutazone (PBZ), but this study was short term (12 days) and used an atypically high-frequency dosing regimen of all three drugs, so extrapolation of this finding to inform clinical use is not clear.[39] Occasionally, chronic interstitial nephritis (CIN) and nephrolithiasis may occur after prolonged administration (months to years) of NSAIDs at recommended doses.[40] The *renal medullary rim sign*, an ultrasonographic abnormality consisting of a hyperechoic band parallel to the corticomedullary junction, has been demonstrated in NSAID toxicity in adults and foals.[41,42] Presence of concurrent gastrointestinal (GI) ulceration (right dorsal colitis, nonglandular gastric and duodenal ulceration) and protein-losing enteropathy (hypoproteinemia) would further support NSAID toxicity. Interestingly, acute interstitial nephritis (rather than papillary necrosis) was the predominant renal histopathologic lesion recorded in clinically normal miniature donkeys administered NSAIDs (ketoprofen, flunixin, or PBZ) for 2 weeks.[43] In contrast to horses that may not show increases in serum creatinine while on fluid therapy or until severe renal compromise occurs, donkeys may show more acute increases in serum creatinine with NSAID toxicity.[43]

The kidney is an important source of prostaglandins (PGs), particularly PGE_2, which plays a central role in control of renal blood flow.[44] The cyclooxygenase (COX) enzymes COX-1 and COX-2 are required from the production of PG (from arachidonic acid), and both isoforms (COX-1 and COX-2) are expressed by the kidney.[44] In humans, broadly speaking, COX-1 is expressed more in the renal medulla and COX-2 in the cortex, but there is considerable variation in expression site dependent on, for example, disease state, hydration, and even age.[44] During periods of renal hypoperfusion due to dehydration or hypovolemia, COX-2 expression is upregulated to increase PGE_2 and maintain renal blood flow.[44] Thus, it is not surprising that NSAIDs, which inhibit the COX enzymes, have increased nephrotoxicity in the dehydrated or hypovolemic patient. Indeed, an early study in horses demonstrated increased renal papillary necrosis when PBZ was administered after water deprivation.[45] There are no data concerning differential COX-2 versus COX-1 production in equine renal tissue. Further, there is not enough evidence in horses to conclude whether NSAIDs that more selectively inhibit COX-2 (e.g., meloxicam, firocoxib) are truly less nephrotoxic as opposed to NSAIDs that inhibit COX-1 and COX-2 (e.g., PBZ, flunixin). Indeed, a recent study comparing administration of PBZ with meloxicam to horses that had been administered furosemide or dobutamine found that both NSAIDs similarly reduced urine flow rate.[46] Interestingly, NSAIDs and COX-2 selective inhibitors, especially at low to moderate doses, have been shown to be protective in various animal models of acute kidney injury.[44]

Vitamin D

Although generally uncommon in horses, Vitamin D intoxication may result from ingestion of feed additives or plants (e.g., *Cestrum diurnum*) containing high amounts of vitamin D metabolites or parenteral administration of vitamin D.[47-49] Cholecalciferol (D_3) is thought to be more toxic than ergocalciferol (D_2) in the horse.[48] In general, horses do not need dietary supplementation with vitamin D if they are exposed to adequate sunlight and have access to green forages. The effect of vitamin D supplementation is cumulative, so signs of toxicity may not develop until several weeks after supplementation was started.

Clinical signs of vitamin D intoxication may be referable to mineralization of the musculoskeletal, cardiovascular, and urinary systems.[49] Abnormal laboratory findings with vitamin D intoxication include azotemia, isosthenuria, hypochloremia, and increased serum calcium and phosphorus concentrations. Hypercalcemia with hyperphosphatemia is unusual for any other disease in the horse, except for certain neoplasias. A definitive diagnosis of vitamin D toxicosis can be made by measuring serum concentrations of 25-OHD_3, 25-OHD_2, and 1,25-$(OH)_2D$. Treatment of vitamin D intoxication includes identification and removal of the inciting cause (feed or medication), fluid diuresis, and corticosteroid administration. Provision of feeds low in both calcium and phosphorus may be of benefit in less severely affected horses, but treatment is usually unrewarding once clinical signs due to tissue mineralization have developed.

Heavy Metals

Accidental ingestion of heavy metals may result in ATN and ARF in horses. Mercury, cadmium, zinc, arsenic, and lead are all nephrotoxic but are rare causes of ARF in clinical practice. Mercury has been used experimentally to induce ARF in horses, and there are reports of ARF in horses that have had legs "blistered" or "sweated" with products containing inorganic mercury.[50-53] Because inorganic mercury also causes severe damage to GI mucosa, signs of GI irritation (e.g., salivation, oral erosions, colic, hemorrhagic diarrhea) predominate with mercury intoxication. Further evaluation may reveal oliguria. Exposure to excessive amounts of zinc and cadmium can result in nephrocalcinosis and oliguric renal failure, but gait deficits (resulting from osseous effects, particularly in foals) and ill thrift are more likely presenting complaints.[53] Laboratory findings with heavy metal intoxication are characteristic for ATN: azotemia, hyposthenuria to isosthenuria or anuria (depending partly on concurrent hydration status), hyponatremia, and hypochloremia. In horses with ARF with concurrent GI disease, as with mercury toxicity, severe hypocalcemia may be present. A tentative diagnosis of mercury intoxication may be made from history of exposure, clinical signs of erosive GI disease, and oliguric renal failure. The diagnosis can be confirmed by measuring increased blood and tissue (kidney and liver) concentrations of the suspected metal. In addition to judicious fluid therapy, treatment of ARF induced by exposure to heavy metals should include parenteral dimercaprol and activated charcoal via nasogastric tube (see Chapter 54, Disorders Caused by Toxicants). Visceral analgesics and/or sedatives are often necessary to control abdominal pain.

VetBooks.ir

Acorn Poisoning

Although less commonly seen in horses than cattle, acorn poisoning can result in equine ATN.[54,55] Death in horses is usually due to erosive, hemorrhagic GI disease, changes in vascular permeability, and resulting shock rather than a consequence of ARF. Immature leaves and green acorns are considered more toxic than mature acorns as they have a higher tannin content. Clinical signs may include diarrhea, edema, and body cavity effusion, and laboratory evaluation usually reveals azotemia, isosthenuria to hyposthenuria, hyponatremia, and hypochloremia. Detection of increased urinary excretion of phenols may be useful to confirm the diagnosis. There has recently been a suggestion that the prevalence of acorn poisoning in horses is increasing in the United Kingdom.[55]

Miscellaneous Drugs and Agents

Several other drugs and agents (oxytetracycline, polymyxin B, amphotericin B, imidocarb dipropionate, ethylene glycol, ochratoxins, pyrrolizidine, cantharidin toxicosis [blister beetle poisoning]; the nematode *Halicephalobus gingivalis;* and the apicomplexan parasite *Klossiela equi*) have been suspected of causing ARF in horses. When high doses of oxytetracycline (usually around 44 mg/kg IV diluted in saline) are administered to neonatal foals for correction of limb contracture, ARF is a potential complication, especially if the foal is dehydrated or has concurrent sepsis or hypoxic-ischemic encephalopathy.[56] Polymyxin B is sometimes used as an adjunct treatment for endotoxemia, and it is prudent to remember that it has nephrotoxic potential. However, studies in adult horses and foals with experimentally induced endotoxemia have demonstrated that the risk of polymyxin B nephrotoxicity is low, especially when it is conjugated with dextran 70.[57-59] Amphotericin B also has considerable nephrotoxic potential but is rarely administered systemically to horses. Imidocarb dipropionate, used in treating *Babesia equi* infections, has been shown to cause reduced renal function after multiple dosing.[60] Blister beetle poisoning (cantharidin toxicosis) may cause abdominal pain, shock, hematuria, diaphragmatic flutter, dysuria, and renal dysfunction in horses fed alfalfa hay grown in regions where the beetles are prevalent.[61] There are some reports of renal failure, as well as brain involvement, associated with granulomas caused by the nematode *Halicephalobus gingivalis*.[62,63] The coccidian parasite *K. equi* infects the kidneys of equids and can cause ATN and interstitial nephritis if infection is heavy and/or the patient immunocompromised.[64] Many anecdotal reports exist of horses developing renal disease after administration of bisphosphonates for treatment of orthopedic disease, especially when administered frequently and in conjunction with NSAIDs. Renal disease is a reported complication in other species after bisphosphonate administration.[65]

Vasomotor Nephropathy

Any condition that causes sustained marked hypotension or release of endogenous pressor agents may initiate hemodynamically mediated (vasomotor) ARF. Although poorly documented, renal compromise due to a combination of vasomotor and nephrotoxic mechanisms probably occurs more frequently than clinically identified, especially in sick horses receiving drugs with nephrotoxic potential.[66] Hemorrhagic shock, severe intravascular volume deficit (e.g., enterocolitis), septic shock, and coagulopathy are important risk factors for vasomotor ARF in horses.[66] Another cause may be adverse drug reactions, including those accompanying IV administration of vitamin and mineral products or immunomodulators. The predominant lesion in vasomotor nephropathy is ATN, although diffuse renal cortical or renal medullary necrosis may also occur. Clinical signs of vasomotor ARF are nonspecific and more often referable to the primary disease (e.g., hemorrhage or diarrhea). Additional subtle signs (e.g., more marked depression and anorexia than would be expected with the primary disease), with or without signs of mild colic, should increase suspicion of ARF. Occasionally, horses with severe vasomotor ARF are markedly ataxic and/or manifest neurologic signs similar to hepatic encephalopathy. Oliguria, often seen as a lack of expected urination in response to fluid therapy, is an important early indicator of vasomotor ARF, and production of dilute urine (urine specific gravity [USG] <1.020) that may be discolored (hematuria or hemoglobinuria) can be observed when urine is eventually voided. If urine is grossly clear, microscopic hematuria is usually present, producing a positive result on a urine dipstick. Glucosuria, due to severe proximal tubular damage, may also be detected. Although the pathophysiologic relationship to ARF is not well defined, diarrhea and severe laminitis can develop in more serious cases of vasomotor ARF.

Acute Glomerulopathy

Subclinical glomerular damage likely accompanies several diseases affecting horses, especially immune-mediated disorders (e.g., purpura hemorrhagica), but acute glomerulonephritis (GN) causing ARF is rarely perceived to be a clinical problem.[67] However, a recent multicenter study identified glomerular disease in 34/142 (24%) diagnostic renal biopsies in horses, suggesting that glomerular disease may be clinically underrecognized.[68] A syndrome of arteriolar microangiopathy and intravascular hemolysis that caused distention of glomerular capillary loops with fibrin thrombi and accumulation of large amounts of proteinaceous debris in the Bowman capsule was described in two horses.[69] Affected horses presented with oliguric ARF accompanied by hematuria, proteinuria, and intravascular hemolysis; response to treatment was poor.[69] The cause of the syndrome in horses is not definitively known. Renal lesions resemble those found with hemolytic-uremic syndrome (HUS) in humans, which is caused by toxins of *Escherichia coli*.[69] In a case report of HUS with glomerular thrombotic microangiopathy in a postpartum mare, *E. coli* O103:H2 was isolated from the uterus and gastrointestinal tract.[70] Glomerulopathy with ARF caused by *Streptococcus mitis* has also been documented as a component of toxic shock in a horse.[71] Bacterial toxins, coagulopathy, immune complex deposition, vasoactive amines, and hemodynamic alterations may all be contributors to this syndrome in horses. Acute glomerulopathy should be considered in horses with severe ARF that do not have a predisposing primary disease leading to vasomotor ARF and that have not been exposed to nephrotoxins. Gross hematuria, proteinuria, and oliguria would support an acute glomerulopathy, and renal biopsy can be pursued to confirm the lesion.[68]

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is a syndrome of ARF accompanied by rapid elevations in creatinine and clinical signs of uremia. In a recent multicenter study of equine renal biopsies, tubular interstitial disease/interstitial nephritis was the most common histopathologic finding, accounting for 63/142 (44%) of diagnostic biopsies.[68] With that said, not all of these cases may have presented as fulminant ARF and interstitial nephritis is the most common finding in horses with chronic renal failure (CRF). Lesions in AIN include interstitial edema with a mild inflammatory infiltrate. Adverse or idiosyncratic drug reactions may be a cause, but the main etiopathogenesis of this disease in horses is unknown. In humans, eosinophilic infiltrates in renal biopsy tissue are supportive of adverse drug reaction. Although there are no published reports of the syndrome in horses, one of the authors (TJD) has examined three horses with apparent AIN. However, experimentally, in miniature donkeys, interstitial nephritis (rather than medullary crest necrosis) was the predominant renal histopathologic lesion recorded following IV administration of NSAIDs twice daily for 2 weeks.[43]

Leptospirosis

Krista E. Estell

VetBooks.ir

The bacteria *Leptospira* spp. is commonly found in the horse. It is predominantly a cause of uveitis and abortion but can also infect the equine kidney, causing renal disease in some instances. Several case reports document *L. interrogans* as a cause of interstitial nephritis in adults and foals.[72-75] Infection with *L. interrogans* should be considered in equine ARF when an underlying renal or vasomotor disease is not apparent and there has been no exposure to nephrotoxins. The most frequent clinical sign in both experimental and natural infection is fever, but anorexia and depression may also be present, and hematuria has also been observed.[74-76] Clinical pathologic abnormalities include azotemia and isosthenuria. Leptospiruria is not a consistent finding with ARF due to leptospirosis, making definitive diagnosis difficult. Diagnosis of *Leptospira* spp. can be achieved by urine polymerase chain reaction (PCR); administering furosemide and testing the second voided sample may increase sensitivity of this test. Serum titers performed by microscopic agglutination rise quickly after experimental infection.[76] Demonstration of a rising titer or a high baseline titer above 1:6400 indicates active infection. Treatment includes fluid and antimicrobial therapy (see section on Bovine Leptospirosis).

Diagnosis of Acute Renal Failure

ARF should be suspected in patients showing more marked depression and anorexia than would be expected with the perceived primary disease process and in those that fail to produce urine within 6 to 12 hours of initiating fluid therapy. Diagnosis of ARF is confirmed on the basis of history, potential exposure to nephrotoxins, clinical signs, and laboratory findings. Azotemia (elevated serum or plasma blood urea nitrogen [BUN] and creatinine concentrations) is present with clinical ARF, but note that azotemia of purely renal origin only manifests when 65% to 75% of total functioning nephrons are lost. Relative to baselines, the increase in serum creatinine is often several-fold greater (e.g., up to 5 to 15 mg/dL) than BUN (e.g., up to 50 to 100 mg/dL), often resulting in a serum BUN–to–creatinine ratio less than 10:1. It is important to remember that serum creatinine concentration may be as high as 8 mg/dL with purely prerenal azotemia (e.g., due to dehydration). A BUN–to–creatinine ratio of greater than 20:1 is suggestive of prerenal azotemia. With ARF, hyponatremia, hypochloremia, and hypocalcemia are usually present. In more severe cases, with oliguric or anuric ARF, hyperkalemia, hyperphosphatemia, hypercalcemia, and metabolic acidosis may also be detected and indicate a guarded prognosis. Urinalysis and USG should be performed on all horses in which ARF is suspected. A low USG (<1.020) in the face of dehydration and gross or microscopic hematuria are common findings with ARF. It is important to remember that in many horses with ARF, prerenal azotemia is often present in conjunction with renal azotemia, due to dehydration/hypovolemia compounding acute kidney injury. In some cases (e.g., urinary tract obstruction or rupture) significant postrenal azotemia will also be present. Thus, assessment of renal function based on azotemia can sometimes only be made once factors contributing to prerenal and postrenal azotemia have been corrected, which may take several days. Azotemia may still take several days (and in rare cases, even weeks) to correct following severe ARF; therefore, a diagnosis of permanent renal damage (i.e., CRF) cannot be made immediately on the basis of the persistence of azotemia after symptomatic recovery.

In a few cases, rectal palpation in horses with ARF may reveal enlarged, painful kidneys. Enlargement can be confirmed by renal ultrasonography (US), which may also reveal perirenal edema, loss of detail of the corticomedullary junction, or dilation of renal pelves.[77,78] However, subtle changes in renal architecture can be difficult to detect via US, and sensitivity of this diagnostic modality largely depends on operator experience and image quality. Evidence of more substantial proximal tubular damage, including increased urinary enzyme activity and glucosuria, may be detected in some horses, dependent on etiology. Significant proteinuria (urine protein–to–creatinine ratio >2:1 [see Chronic Renal Failure section later]) suggests the presence of glomerular disease. Examination of urine sediment may reveal casts and increased numbers of erythrocytes and leukocytes, as well as a decreased amount of urine crystals. Increased fractional clearances of sodium and phosphorus are also common findings with ARF. However, it is important to remember that administering IV fluids to healthy horses will also result in increased fractional clearances of sodium, chloride, and phosphorus.[79] Electrolyte clearances are ideally determined using the initial urine sample voided after admission or a sample collected by catheterization (i.e., before urine is substantially altered by fluid therapy).

The most accurate assessment of renal function is glomerular filtration rate (GFR), which can be measured by performing timed urine collections and measuring inulin and endogenous or exogenous creatinine clearances, or assessing plasma disappearance of several exogenous compounds including radiolabeled substances (see Diagnosis in Chronic Renal Failure section later).[80] Computed tomography (CT-GFR) has also been used to determine GFR in small animals and a foal with upper urinary tract disease.[81] In a clinical setting, measurement of GFR in cases of ARF is rarely pursued because multiple measurements are required to assess changes in GFR, and prognosis for recovery is more likely related to the duration of decreased GFR rather than to the magnitude of the decrease. Because of the inverse relationship between GFR and creatinine, changes in GFR can be more practically and economically assessed by *trend* in serum creatinine concentration measured q12-24h. Symmetric dimethylarginine (SDMA) is a renal biomarker specific to kidney function used in small animals, but it has not been investigated in horses.

Renal damage may be further confirmed by performing a renal biopsy.[68] However, biopsy is often not indicated in horses with ARF because the diagnosis is usually evident and response to initial therapy will serve as a better prognostic indicator. Immunofluorescent (IF) testing and electron microscopic (EM) examination are routinely performed on human renal biopsy samples to assess specific mechanisms of renal injury and extent of damage to glomerular and tubular basement membranes. If such detailed evaluation of renal biopsy tissue were routinely performed in horses with ARF, then more informed information regarding antemortem etiopathogenesis and prognosis could likely be obtained. At present, renal biopsy is most often indicated to evaluate horses with ARF when exposure to nephrotoxins or another underlying primary disease process is unapparent. Life-threatening hemorrhage is a potential complication of renal biopsy. A multicenter study of 151 horses that underwent renal biopsy found complications in 11.3%, generally associated with hemorrhage or signs of colic, and there was only one fatality.[68] Risk factors for complications included biopsy of the left kidney, a diagnosis of neoplasia, and low USG.[68] Biopsy of the right kidney with US guidance, usually through the 17th intercostal space, is the preferred procedure.[82] Proper instrumentation (automatic or spring-loaded biopsy instruments) and adequate restraint (stocks and sedation) are important considerations. Renal tissue collected should be placed in formalin for histopathologic examination, plain tube and swabbed for culture if indicated, as well as frozen (or placed into additional media specified by the testing laboratory) for immunofluorescent (IF) and electron microscopy. Although biopsy of the right kidney alone is usually adequate for assessment of the disease process affecting both kidneys, samples of

the left kidney can also be collected, by guiding the biopsy instrument through the spleen. When collecting a biopsy from the left kidney or when biopsy of a specific area of either kidney is desired, US guidance is vital.

General Principles of Treatment for Acute Renal Failure

Initial therapy should always focus on judicious IV fluid administration to replace volume deficits and to correct electrolyte and acid-base abnormalities. The magnitude of azotemia and serum concentrations of sodium, chloride, potassium, and bicarbonate should be monitored q12-24h. Horses with polyuric ARF require sodium chloride (NaCl) replacement, accomplished by administering IV 0.9% NaCl with or without supplementation of NaCl in grain feedings or as oral pastes. Some horses require an initial dose of hypertonic NaCl (2 mL/kg), but care should be taken not to correct hyponatremia too quickly if it is suspected to have been present for several days. Serum potassium concentration in horses with nonoliguric ARF is often normal, except in cases of postrenal problems (e.g., obstruction or rupture), where hyperkalemia is often present, therapy to lower serum potassium is usually unnecessary. Similarly, it is usually unnecessary to correct the mild hypocalcemia that can accompany ARF in horses.

After correcting volume deficits and electrolyte and acid-base abnormalities, an attempt should be made to determine whether the animal is oliguric or nonoliguric (polyuric); the prognosis for recovery appears to be more favorable with nonoliguric ARF. This often becomes apparent by simple observation: Oliguric horses fail to produce expected amounts of urine in the initial 12 to 24 hours of IV fluid therapy, and the bedding remains dry. Nonoliguric horses repeatedly void moderate volumes of dilute urine during the initial 6 to 12 hours of treatment. Fluid and sodium replacement in horses with oliguric or anuric renal failure must be monitored closely as overzealous fluid administration will result in rapid edema formation, often initially noticed in the conjunctiva. Other manifestations include generalized subcutaneous swelling of dependent areas, progressing to tachypnea and altered mental status if pulmonary and/or cerebral edema develop. In horses with prerenal azotemia (as opposed to intrinsic ARF), serum creatinine concentration should decrease by at least 30% to 50% within the initial 24 hours of fluid therapy. In contrast, creatinine concentration may remain unchanged or even increase in ARF.

During therapy for ARF, regular assessments of attitude, vital parameters, packed cell volume (PCV), and total plasma protein concentration are important. Monitoring should also include measurement of body weight q12-24h: Patients that are responding to treatment should *not* gain weight with continued fluid therapy after initial rehydration. An attempt should be made to compare fluid input (IV fluids) and intake (voluntary drinking) with urine output. Although there is no convenient method of collecting all urine voided by ambulatory foals or mares, urine output can be quantified in male horses by placing a urine collection bag, slung around the abdomen. When desired, monitoring urine output in critically ill foals and mares can be accomplished by use of an indwelling Foley catheter and urine collection bag (closed system), but ascending microbial infection is a serious risk.

In horses with severe ARF, especially those with vasomotor nephropathy, systemic blood pressure (BP) should be monitored to confirm that fluid therapy has been adequate to restore BP. Recent studies have demonstrated that indirect BP monitors have good precision and accuracy for measuring mean arterial pressure when corrected for height.[83,84] Some horses may remain hypotensive (systolic BP <80 mm Hg) despite administration of large volumes of IV fluids, owing to extravascular accumulation as edema or a third-space fluid. If systemic BP remains low, hypertonic saline, dobutamine, or other pressor agents may be required in an attempt to restore BP and GFR. Central venous pressure (CVP) can also be monitored as a more precise measurement of fluid balance in critical patients. It is measured with a manometer with the baseline at the level of the right atrium, attached to an IV catheter placed into the anterior vena cava via the jugular vein (normal CVP in horses, 7.1 to 9.4 cm H_2O)[85]; values as high as 12 cm H_2O have been reported in normal horses.[86]

In horses that remain oliguric after 12 to 24 hours of appropriate fluid and electrolyte replacement and restoration of systemic BP, furosemide at 1 to 2 mg/kg IV q2h up to four times should be administered (intermittent use [1 mg/kg IV q8h over 24h] in one study). A constant rate infusion (CRI) of furosemide at 0.12 mg/kg/h, preceded by a loading dose of 0.12 mg/kg IV, was considered superior to intermittent use in one study.[87] Unfortunately, furosemide treatment is often ineffective in increasing renal blood flow, GFR, and tubular flow in horses with ARF. It should be remembered that NSAIDs have been shown to attenuate the diuresis and increased GFR produced by furosemide and thus should be avoided.[46] If urine is not voided after the second dose of furosemide, a CRI of dopamine (3 to 7 µg/kg/min IV diluted in 5% dextrose) can be instituted. If dopamine does not increase urine production in 2 to 4 hours, it should be discontinued, but if it is successful, it may be continued for up to 48 hours if necessary. Dopamine administration should only be performed in a hospital setting where heart rate and BP can be monitored frequently and thus development of tachycardia and hypertension avoided; in the author's (TDJ) experience, the mean BP should not rise above 110 to 120 mm Hg. Dopamine use for selective renal vasodilatory and natriuretic actions has been called into question because most studies in humans have not demonstrated prevention of ARF in high-risk patients or improved outcome in those with established ARF, and in one study dopamine actually worsened renal perfusion in human patients with ARF.[88] Further, the drug may precipitate serious cardiovascular and metabolic complications in critically ill patients. As an alternative to dopamine, fenoldopam CRI (0.04 µg/kg/min IV) may be tried in foals. In oliguric patients with a normal CVP but low-normal BP, a dobutamine infusion (1 to 12 µg/kg/min IV, diluted in D_5W or 0.9% NaCl to a concentration of 500 µg/mL) or mannitol (0.5 to 1.0 g/kg IV) can be tried. Dobutamine should not be used concurrently with furosemide. Mannitol should not be used in anuric horses. If these treatments are successful in converting oliguria to polyuria (may require 24 to 72 hours), they should be discontinued, but maintenance of urine production must be monitored closely over the next few days. Fortunately, the majority of horses with ARF resulting from ATN are nonoliguric rather than oliguric, and thus furosemide, mannitol, dobutamine, or dopamine are unnecessary.

When this treatment approach to oliguria remains unsuccessful for more than 72 hours, the prognosis becomes grave. One study of horses with colic or colitis found that horses with persistent azotemia after 72 hours of fluid therapy were three times as likely to die or be euthanized as were horses without persistent azotemia.[89] Dialysis therapy may be a further treatment option in selected patients. Hemodialysis has been successfully used to treat an adult horse with myoglobinuric ARF and a neonatal foal with oxytetracycline-induced ARF.[90,56] Continuous-flow peritoneal dialysis has been used to successfully treat ARF in an adult horse, and continuous flow (rather than intermittent peritoneal dialysis) helps avoid the problem of omentum blocking the peritoneal tubing.[91] Recently, renal replacement therapy (RRT), a blood purification modality, has been investigated in horses and a foal and appears to be a viable option, where finances permit and equipment is available.[92,93] Pleural dialysis is another option for which fluid exchange is less problematic but has not been investigated in horses. Hemodialysis or dialysis would likely be most effective

in horses with nephrotoxic ARF rather than those with vasomotor ARF.

After volume deficits have been restored and polyuria achieved, patients usually need only continued fluid therapy (0.9% NaCl + 20 mEq/L KCl or another balanced electrolyte solution, at a rate of 40 to 80 mL/kg/day) to promote a continued diuresis and decrease in serum creatinine. Fluid therapy may have to be continued (20 to 40 mL/kg/day) for several days until serum creatinine returns to the normal range or a steady-state value and the horse is eating and drinking adequate amounts. Supplementation with oral electrolytes (1 to 2 ounces of NaCl twice daily) will also promote greater oral fluid intake and diuresis. Potassium supplementation (1 oz KCl PO twice daily) may also be required because diuresis results in kaliuresis. When horses remain anorectic during treatment, the addition of 50 to 100 g dextrose/L fluids can provide immediate calories in the short term. If anorexia persists for several days, caloric intake may have to be provided by nasogastric tube feeding or via total parenteral nutrition (TPN). Within the week after fluid therapy is discontinued, serum creatinine should be measured again to ensure it has not increased. Occasionally, creatinine may not decrease to below 2 to 3 mg/dL despite continued fluid therapy. As long as the horse is eating and drinking well, IV fluids can be discontinued. In some horses, further recovery will be seen as a return of creatinine to normal range within the next couple of months, whereas in other patients a persisting elevation in creatinine indicates permanent loss of renal function. In the author's experience, some normal Quarter Horses have a serum creatinine in the range of 2 to 2.5 mg/dL.

Serum Creatinine Elevations in Newborn Foals

Thomas J. Divers • Alexandra J. Burton • Lisa E. Fultz

During the first 1 to 3 days of life, the serum creatinine concentration in foals is often 30% to 40% higher than in their dams.[94] The cause is unclear but likely related to an inability of creatinine to equilibrate rapidly across placental membranes. As supportive evidence, creatinine concentration of normal amniotic fluid (which contains fetal urine) at term is approximately 10 mg/dL (and may be >30 mg/dL in some mares).[95] The term "spurious hypercreatinemia" is used to describe the condition in foals that have truly increased serum creatinine levels but no other markers of renal injury (e.g., normal urinalysis, electrolyte and BUN concentrations). The increased creatinine is often related to placental dysfunction during gestation and can occasionally exceed 20 mg/dL in premature foals. In one study, 20/28 foals with spurious hypercreatinemia had a clinical diagnosis of neonatal encephalopathy (neonatal maladjustment syndrome).[96] The association between neonatal encephalopathy and hypercreatinemia is unclear. Surprisingly few foals were from mares with documented placental pathology in one study, but these foals often had evidence of periparturient stress including premature placental separation or dystocia.[96]

Therefore, when elevated creatinine is detected in an otherwise healthy foal (that has also been observed to urinate normally), there may be no cause for alarm, but if levels do not decline rapidly after birth (or remain >2.5 mg/dL on day 3 of life), peritoneal or retroperitoneal accumulation of urine, renal hypoplasia, or other causes of renal failure should be considered. Unlike creatinine, serum BUN values in foals are typically low (<10 mg/dL) after day 2 and remain low for the first several months of life.

Urinalysis results in normal neonatal foals are also different from those in adult horses. Specifically, for 1 to 2 days after birth, normal foals may have marked proteinuria resulting from filtration of small-molecular-weight proteins absorbed with colostrum. Fluid intake on a predominantly milk diet is high in foals (250 mL/kg/day, compared with 50 mL/kg/day of water intake by adults), so after day 2 of life, foal urine is hyposthenuric (USG = 1.002 to 1.006) and remains that way for several months. Urinary enzyme activity and sodium and chloride clearances may be greater than in adults, and urine pH is neutral to acidic in foals.[97] Fractional electrolyte clearance values are similar to those of adult horses.[98]

Electrolyte Abnormalities in Azotemic Foals

Lisa E. Fultz

Urinary tract disorders and azotemia are primary causes for varying degrees of serum electrolyte abnormalities in foals. Severe hyponatremia (<122 mmol/L) occurred in 4% of Thoroughbred foals presenting to intensive care units and were most often related to urinary-tract related disorders (26.1% due to renal disease and 21.7% related to uroperitoneum).[99] Potential mechanisms include water retention due to reduced GFR, increased sodium loss with renal tubular damage, and interrupted aldosterone activity.[98-100] Hyponatremic encephaolopathy has been documented in azotemic neonatal foals; these foals commonly have seizure activity or central blindness, severe hyponatremia and hypochloremia in the absence of diarrhea, and variable (but typically mild) azotemia.[101] In one case series, 15.9% of foals with severe hyponatremia displayed signs of encephalopathy, likely related to cerebral edema and increased intracranial pressure.[99] Sodium-losing nephropathy with ARF has been confirmed in some cases.[101] In azotemic foals, hyponatremia due to ARF is often related to confirmed or suspected neonatal sepsis.[101] One study found no difference in the severity of hyponatremia and short-term survival rate (72.5%).[99] Azotemic foals experiencing hyponatraemic encephaolopathy typically respond well to IV fluid administration with gradual sodium replacement (0.5 mmol/h).[101]

Acute Renal Failure in Foals

Thomas J. Divers • Alexandra J. Burton • Lisa E. Fultz

Acute tubular necrosis (ATN) is the most common pathologic lesion causing ARF in neonatal foals. Many cases develop during or after episodes of diarrhea, likely caused by poor renal perfusion (vasomotor nephropathy) subsequent to varying degrees of dehydration. Surprisingly, the diarrheal disease in some affected foals does not appear to be serious, but the foals may still develop ARF. Similar to adult horses with ARF, the prominent clinical signs are depression and development of edema. Abnormal laboratory findings include azotemia, hyponatremia, hypochloremia, and hypocalcemia. In foals with ARF, both serum BUN and potassium in ARF tend to be significantly higher than in foals with spurious hypercreatinemia.[96] Foals are more likely to develop significant hyperkalemia and hyperphosphatemia than are adult horses with ARF. A USG of less than 1.018 and microscopic hematuria are also typical of foals with ARF. Urine output of sick neonates should be monitored closely because they may become oliguric to anuric 12 to 24 hours before significant depression or azotemia is recognized. In addition, fluid retention during incipient ARF is another cause of inappropriate weight gain (e.g., >2 kg in 24 hours), which can often be detected before obvious edema or other clinical signs develop.

Nephrotoxicity, most often due to aminoglycoside (AG), tetracycline, or NSAID administration, is a cause of ARF (usually nonoliguric) in neonatal foals, particularly those that are dehydrated. As in adult horses, the recent change to once-daily dosing appears to have decreased the incidence of

VetBooks.ir

AG-induced ARF in foals. Seriously ill and/or premature foals appear to be at even greater risk of nephrotoxicity than term foals, owing to reduced renal clearance.[102] Although there is a general impression that amikacin may be less nephrotoxic than gentamicin in foals, no data exist to support this notion. Regardless of which AG is selected, TDM (24-hour trough concentrations <2 μg/mL for gentamicin, <4 μg/mL for amikacin) is warranted to decrease the risk of AG toxicity in high-risk neonates. It should be noted that the actual optimal trough concentrations are unknown in horses and are based on those used in human medicine.[11,12] Dosage adjustment may be necessary in seriously ill neonates or premature foals because renal clearance may be decreased, necessitating an increased dosing interval to achieve low enough trough concentrations.[26] Judicious fluid therapy to correct dehydration and maintain BP is an important precaution. To complicate matters, foals also have a larger volume of distribution than adult horses and require an increased dose of AGs to attain therapeutic peak concentrations.[4,103] Volume of distribution may be increased even further in premature foals and with certain disease processes that increase extracellular fluid volume.[26]

Treatment principles for ARF in neonates are essentially the same as for adult horses (see earlier section General Principles of Treatment for Acute Renal Failure). However, even greater attention must be paid to monitoring responses to fluid therapy, including twice-daily measurement of body weight. Renal replacement therapy (RRT) is a viable option in foals and may have more potential to effectively treat foals with ARF due to their relatively small blood volume compared with adult horses. The hemodiafiltration process of RRT can allow for a slow and gradual clearance of toxins and metabolites and correct fluid volume overload.[92,93] In one case report, RRT was instituted in conjunction with a furosemide CRI in an anuric 3-day-old foal with postresuscitation ARF due to hypoxic injury.[93] Despite a 33% urea reduction ratio and establishment of urine production, the foal was euthanized after a single 6-hour session, so long-term follow-up has not been documented.[93] No long-term study has been performed examining the risk of developing CRF in the future following neonatal ARF.

Septic Renal Disease in Foals

Thomas J. Divers • Alexandra J. Burton • Lisa E. Fultz

Multifocal renal abscesses or infarcts may be a complication of neonatal septicemia and can lead to ARF. *Actinobacillus equili* is one of the most common pathogens isolated from renal abscesses, but affected foals often die or are euthanized because of overwhelming sepsis before clinical signs of ARF develop. Foals 2 to 4 days of age appear to be at greatest risk of developing acute *Actinobacillus* septicemia; when this problem is suspected, aggressive IV fluid therapy with concurrent penicillin or ampicillin plus gentamicin or amikacin is recommended. Subsequent fibrin deposits in the kidney have also been identified in some foals with septicemia and ARF.[104] Unilateral nephrectomy has been attempted as therapy for severe renal abscesation in a foal.[105]

Chronic Renal Failure

Thomas J. Divers • Theresa L. Ollivett • Erin McConachie Beasley

Chronic renal failure (CRF) in horses may be divided into two broad categories: primary glomerular disease and primary tubulointerstitial disease.[1,2] However, ongoing pathology in one portion of the nephron usually leads to altered function and eventual pathology in the entire nephron. Thus, CRF is an irreversible disease process characterized by a progressive decline in glomerular filtration rate (GFR). The rate of decline in GFR is variable among horses with CRF, making the short-term (i.e., months to ≈2 years) prognosis guarded to favorable, while the long-term prognosis remains poor. It is important to note that CRF with azotemia only develops after 65% to 75% of the total functioning nephrons are lost. This explains why a unilateral nephrectomy (e.g., for nephrolithiasis) can be performed in horses with a contralateral kidney that is nondiseased and functioning normally.

Primary *glomerular* diseases that can lead to CRF in horses include glomerular nephritis (GN), nonspecific glomerulopathy, glomerular hypoplasia, and amyloidosis. Primary *tubulointerstitial* diseases causing CRF include incomplete recovery from acute tubular necrosis (ATN), pyelonephritis, nephrolithiasis, hydronephrosis, renal dysplasia, and papillary necrosis. Collectively, the latter disorders produce pathology categorized as *chronic interstitial nephritis* (CIN). Unfortunately, because CRF is often advanced when horses are first presented for clinical evaluation, the initial inciting cause may be difficult to ascertain and end-stage kidney disease (ESKD) may be the pathologic diagnosis. The inciting cause may more likely be discerned from taking a detailed long-term history (e.g., chronic drug administration, possible toxin ingestion/exposure, episodes of myopathy, failure to thrive or attain expected adult size) rather than clinical findings at presentation, especially for primary tubulointerstitial diseases.

Causes of Chronic Renal Failure

Proliferative Glomerulonephritis

Proliferative GN, indicating increased cellularity of the glomerular tufts consequent to influx of inflammatory cells and proliferation of mesangium, is the most common glomerular disease causing CRF in horses, and accounted for 53% of acquired causes of CRF in one retrospective study of 99 horses with CRF.[2] It is thought to result from deposition of circulating immune complexes along the glomerular capillaries or in situ formation of immune complexes along the glomerular basement membrane (GBM). Deposition of immune complexes causes activation of complement and vasculitis (type III hypersensitivity response). In one study, deposits of immunoglobulin (Ig)G and complement along the GBM were found through immunofluorescence (IF) staining in a large proportion (22/53) of horses at necropsy.[3] However, only 1/53 horses had developed CRF. Thus, although immune (antigen-antibody) complex deposition and subclinical GN may be common in horses, progression to CRF appears to be an infrequent occurrence. In this necropsy survey, the predominant IF staining pattern was granular (patchy deposits of immune complexes and complement along GBM), but linear deposits were found in two horses.[3] The latter finding was supportive of true autoimmune disease with more diffuse deposition of anti-GBM antibodies (type II hypersensitivity response) along the basement membrane.[3] Streptococcal antigens and purpura haemorrhagica have been suggested as an important trigger for development of proliferative GN.[4,5] In one report, a 12-year-old gelding developed CRF due to GN 3 months after a lower respiratory tract infection with *Streptococcus zooepidemicus*.[5] In this instance, group-C streptococcal antigens and IgG were confirmed to be present in diseased glomeruli at necropsy.[5] Equine infectious anemia (EIA) virus is the only other antigen that has been detected in glomeruli of horses with proliferative immune-mediated GN.[6] However, diffuse subclinical GN likely accompanies many other chronic infections in horses. It has also been suggested that equine GN may also be associated with either mixed or monoclonal cryoglobulins forming antibody-antibody and/or complement glomerular deposits resembling human cryoglobinemia.[7] In one horse, with no

VetBooks.ir

evidence of viral or bacterial infection, deposits consisting solely of IgM were identified within the GBM.[8]

Chronic Interstitial Nephritis

Chronic interstitial nephritis (CIN) and fibrosis are probably the most common causes of CRF in older horses. In one retrospective study of 99 horses with CRF, CIN accounted for 39% of acquired cases of CRF.[2] Interstitial nephritis (tubulointerstitial disease) usually develops as a long-term sequela to ATN caused by nephrotoxins or vasomotor nephropathy. Other causes of CIN include drug-induced interstitial nephritis, urinary obstruction, pyelonephritis, renal hypoplasia/dysplasia, and papillary necrosis. Although the majority of horses that develop ARF attributable to these causes recover with apparently normal renal function (they remain nonazotemic), a few may survive with significant loss of renal functional mass and subsequently (often years later) develop signs of CRF due to CIN.[9] In horses younger than 5 years of age that develop CRF unattributable to other causes, anomalies of development (e.g., renal hypoplasia, dysplasia, polycystic kidney disease [PCKD]) should be strongly suspected.[2,10-13]

Pyelonephritis

Bilateral septic pyelonephritis is a rare cause of CRF in horses.[14-16] Pyelonephritis is usually due to an ascending infection and is often accompanied by nephrolithiasis or ureterolithiasis. However, in septic neonatal foals, it may occur due to hematogenous bacterial seeding of the kidneys. Multiparous mares (especially those with a history of dystocia) and horses with bladder paralysis are at greater risk for lower urinary tract infection (UTI) and subsequent development of ascending upper UTI. Bladder paralysis with chronic distention compromises the integrity of the ureteral orifices and leads to vesicoureteral reflux and pyelonephritis. If paralysis is long-standing, ureteral orifice(s) may appear wide open on cystoscopy and, occasionally, the scope can be advanced into the ureter with little resistance. With unilateral pyelonephritis, adequate renal function is usually maintained by the contralateral kidney. Gram-negative organisms appear to be the most common causative agents, although *Staphylococcus*, *Streptococcus*, or *Corynebacterium* spp. may be isolated and mixed bacterial infections are not uncommon (see the Urinary Tract Infections section later).

Miscellaneous Causes

Other reported causes of CRF in horses include amyloidosis, neoplasia, focal glomerulosclerosis–like disease, and chronic oxalate nephrosis.[17-20] One study described CRF secondary to PCKD in an aged pony with hematuria; the pony also had hepatic cysts.[21] Renal amyloidosis has only been reported in horses used for production of antiserum.[17] So-called oxalate nephropathy in horses is likely a misnomer; the presence of oxalate crystals in renal tissue of horses with CRF is typically a consequence rather than the cause of CRF.[20]

Clinical Signs and Laboratory Findings

The most common presenting complaint in horses with CRF is weight loss.[2] A small plaque of ventral edema, usually between the forelimbs, is another frequent finding.[1,2,22] Moderate polyuria and polydipsia (PU/PD) are often present but may not be noticed except by the astute owner or trainer.[1,2] Rough hair coat, partial anorexia, and poor performance are also reported.[1,2] Dysuria is generally not reported unless CRF is due to pyelonephritis, which may be associated with bladder paralysis, urolithiasis, and lower UTI. Hematuria ± pyuria (gross or microscopic) may be present in some (but not all) horses with pyelonephritis, urinary calculi, renal hypertension, or neoplasia. Urine produced by horses with CRF is often light yellow and transparent because it is relatively devoid of crystals and mucus.

FIG. 34.2 Dental tartar caused by chronic azotemia in a 5-year-old Standardbred with chronic renal failure.

Accumulation of dental tartar (especially on the incisors and canine teeth [Fig. 34.2]), melena, and oral ulcers may also be found in horses with CRF. Growth may be stunted in horses with renal hypoplasia, dysplasia, or PCKD. Colic signs are variable in horses with nephrolithiasis or urolithiasis producing obstruction of the upper urinary tract and may or may not be (intermittently) present.[9,23] Rarely, signs of uremic encephalopathy such as obtundation, anxiety, head pressing, and seizure may be present, but this is more common with severe, fulminant ARF.[24,25]

Clinicopathologic findings in horses with CRF vary depending on appetite, diet, cause, and severity of renal damage. Most horses with clinical signs of CRF have moderate to severe azotemia (serum or plasma creatinine usually ≥5 mg/dL). The serum or plasma BUN–to–creatinine ratio may vary depending on protein intake, muscle mass, hydration, and degree of azotemia but is usually greater than 10:1.[2] Mild hyperkalemia, hyponatremia, and hypochloremia are typically found in horses with CRF. Hypercalcemia, with serum concentrations sometimes greater than 20 mg/dL, appears to be a laboratory finding with CRF that is unique to the equid. One study of horses evaluated at referral hospitals for renal failure reported 56% of 39 horses with CRF to be hypercalcemic, and a larger study of 99 horses with CRF found 67% to be hypercalcemic.[2,26] Hypercalcemia in horses with CRF is not due to hyperparathyroidism; its presence or absence appears to be more closely related to dietary intake than to the magnitude of azotemia.[27] For example, 4/4 bilaterally nephrectomized ponies fed alfalfa hay developed marked hypercalcemia, whereas serum calcium concentration remained within the normal range in 4/4 bilaterally nephrectomized ponies fed grass hay.[28,29] Similarly, hypercalcemia in horses with spontaneously occurring CRF can resolve within a few days of changing diet from alfalfa to grass hay. Serum phosphorus concentration in horses with CRF is usually normal to low, and hypophosphatemia is more often detected with concurrent hypercalcemia. Hypermagnesemia may also be detected in some horses with CRF. Acid-base balance usually remains normal until CRF becomes advanced, but metabolic acidosis is a common finding in horses with ESKD.

Many horses with CRF are moderately anemic secondary to decreased erythropoietin production by the diseased kidneys. Those with CRF resulting from GN frequently have hypoalbuminemia and hypoproteinemia. Horses with advanced CRF due to any cause may also have mild hypoproteinemia associated with GI ulceration. Hyperglobulinemia may be detected in horses with immune-mediated diseases or chronic pyelonephritis. Horses with CRF can also develop hypercholesterolemia

and hypertriglyceridemia (hyperlipidemia), and with advanced CRF may occasionally have grossly lipemic plasma.[30]

Urinalysis varies depending on the cause of CRF but is usually relatively devoid of normal mucus and crystals and thus may appear more transparent than normal equine urine. Isosthenuria is typical (USG = 1.008 to 1.014), although heavy proteinuria in GN cases may produce USG values up to 1.020. Laboratory quantification of urine protein concentration (rather than a dipstick) is required to accurately assess proteinuria. Urine protein concentration in normal horses is usually less than 100 mg/dL, and the urine protein ($_U$Pro)–to–creatinine ($_U$Cr) ratio is less than 1 : 1.[31,32] With significant proteinuria, the $_U$Pro:$_U$Cr ratio is usually greater than 2 : 1.[5] In the earlier stages of GN, excessive urine protein is primarily albumin, but with progression of glomerular pathology an increasing amount of globulin is also lost in the urine. Horses with CIN usually do not have significant proteinuria. Hematuria (gross or microscopic) can produce trace proteinuria, but the $_U$Pro:$_U$Cr ratio usually remains less than 2 : 1. Horses with septic pyelonephritis would be expected to have pyuria (>5 leukocytes/high-power field) and significant bacteriuria on sediment examination, but these findings are not consistently detected; a urine sample should be submitted for quantitative bacterial culture in all horses with CRF.

Diagnosis

A diagnosis of CRF is most often made in horses with azotemia and isosthenuria that present with a complaint of weight loss and/or decreased performance. Determining the inciting cause of CRF can be difficult because the disease has often advanced to ESKD when horses are initially presented for evaluation, although a detailed long-term history can help. Trends in serum creatinine and body condition score over weeks to months probably provide the most useful prognostic information in the horse with CRF. Urinalysis does not often reveal the cause of CRF except in some horses with pyelonephritis. Assessment of urine protein concentration and $_U$Pro:$_U$Cr ratio should be helpful in separating glomerular disease from tubulointerstitial disease, but in practice these laboratory measures have not consistently been elevated in horses with histopathologic evidence of GN. However, detection of moderate to heavy proteinuria ($_U$Pro:$_U$Cr ratio >2 : 1), *without* hematuria, provides support for glomerular disease.[29]

Rectal examination may be helpful as horses with pyelonephritis and/or ureteral calculi often have enlarged ureters that can be palpated dorsolaterally in the retroperitoneal space. Although kidneys of horses with CRF are often small with an irregular surface, these changes are not always apparent on palpation of the caudal pole of the left kidney *per rectum*. The right kidney cannot usually be palpated in the horse unless it is greatly enlarged or displaced caudally by the liver or a mass. US is useful for evaluating kidney size and echogenicity, and it may reveal fluid distention (indicating hydronephrosis, pyelonephritis, or PCKD) or presence of nephroliths.[33-35] Horses with significant renal parenchymal damage and fibrosis often have loss of detail of the corticomedullary junction, and echogenicity of renal tissue may be similar or even greater than that of the spleen (Fig. 34.3, *A*). The contralateral kidney may be normal or hypertrophic in cases with unilateral kidney disease (Fig. 34.3, *B*). Intravenous pyelography (IVP) provides little information in adult horses and is generally limited to foals less than 50 kg. When hematuria or dysuria accompanies CRF, cystoscopic examination can be helpful in determining from which kidney(s) hematuria is originating and allows assessment of ureteral orifice size and urine flow. A single case report of a stallion with hematuria due to unilateral nephritis described severe renal hypertension secondary to fibrotic constriction of the renal vein.[36] Nephrectomy of the affected kidney was curative in that stallion.

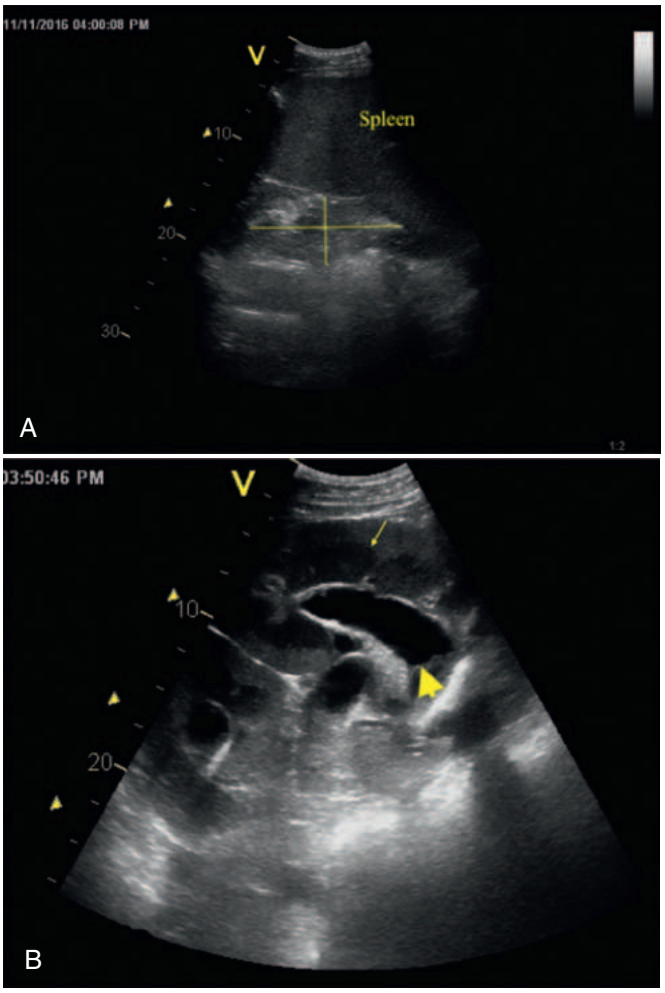

FIG. 34.3 **A,** Ultrasonographic image of the left kidney in a 4-year-old Quarter Horse gelding with chronic renal failure secondary to unilateral renal hypoplasia and exposure to nephrotoxic agents in the 6 months before onset of clinical signs (weight loss, polyuria, and polydipsia). The left kidney is measured in the 17th intercostal space (ICS) and is small (10.5 cm length × 5.8 cm width; reference range: 12.6 ± 2.2 cm length × 7.9 ± 1.1 cm width), hyperechoic relative to the spleen, and has a loss of corticomedullary distinction. **B,** Ultrasonographic image of the right kidney in the same horse measured in the 16th ICS is enlarged (23 cm length × 9 cm width; reference range: 16.0 ± 0.7 cm × 7.9 ± 1.0 cm width), with a distended renal pelvis *(wide arrow)* and distinct hyperechoic and widened renal cortex *(arrow)* (2.0 cm; reference range 1.3 to 1.6 cm). This kidney was suspected to be hyperplastic.

Measurement of GFR provides the most accurate assessment of renal function, and repeated measurements at monthly (or longer initially) intervals can be useful to monitor rate of progression of CRF and thus prognosis and remaining lifespan. It is also a useful measure to document a reduction in renal function in horses that are thought to have early CRF, before significant azotemia has developed. Measurement of GFR can be by several methods, including urinary clearance of endogenous or exogenous creatinine, inulin, or technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) (all require timed urine collections), and plasma disappearance of sodium sulfanilate, phenolsulfonphthalein, or radiolabeled compounds (e.g., ^{99m}Tc-DTPA).[13,37-40] Assessment of renal function by nuclear scintigraphic imaging of the kidneys has also been described, but in horses this technique appears to be better for documenting decreased individual kidney function (i.e., with unilateral disease) than for quantitative assessment of GFR.[40,41] In most clinical settings, performing a 24-hour endogenous creatinine clearance is the most practical and

VetBooks.ir

economical method for measuring GFR. The major challenge is application of a urine collection device for collection of *all* urine produced, via a method that does not pose a risk of introducing ascending infection into the urinary tract. Once urine has been collected, a well-mixed sample is submitted to the laboratory, along with a sample of serum obtained during the collection period, and GFR is estimated by the following standard clearance formula:

$$GFR(mL \cdot kg^{-1} \cdot min^{-1}) = \{([Cr_{urine}]/[Cr_{serum}])\} \times UF/bwt$$

where *UF* is urine flow (mL min^{-1}) and *bwt* is body weight in kilograms.[38,39] In horses with normal renal function, GFR ranges from 1.5 to 3.0 mL/kg/min, and values <1.0 mL/kg/min are indicative of a decreased GFR. Repeated measurement of endogenous creatinine clearance provides useful information about the rate of decline in GFR in horses with CRF. However, it is much simpler and more economical to perform a physical examination, assess body condition, and measure serum creatinine concentration at monthly (or longer) intervals to evaluate the progression of CRF in affected horses.

Systemic blood pressure (BP) monitoring should be a component of a comprehensive database for horses with CRF. A recent case series describing hypertensive cardiomyopathy in horses revealed that the documented cardiac hypertrophy and systemic hypertension were associated with CRF or chronic laminitis.[42] The horses diagnosed with hypertensive cardiomyopathy were all euthanized due to the severity of their underlying disease, suggesting that CRF in these cases was at an end stage. Recent studies have demonstrated that indirect BP monitors have good precision and accuracy when measuring mean arterial pressure (MAP) in normotensive and hypertensive horses; these monitors allow trends to be followed in standing horses with hypertension.[43,44] Further diagnostic investigation, such as echocardiography, as well as consideration of antihypertensive medical therapy such as an angiotensin-converting enzyme (ACE) inhibitor, might be warranted if there is documentation of persistent systemic hypertension (uncorrected noninvasive BP MAP >116 mm Hg).[45]

The inciting cause of CRF can sometimes be confirmed by renal biopsy. Renal biopsy should be approached somewhat cautiously and pursued only if findings are likely to change treatment or prognosis. However, a recent multicenter study on equine renal biopsies found that histopathologic diagnosis by biopsy had a 72% agreement with histopathology at necropsy.[46] This same study found a complication rate of 11.3%, generally associated with hemorrhage or signs of colic, and there was only one fatality.[46] Risk factors for complications included biopsy of the left kidney, a diagnosis of neoplasia, and low USG.[46]

Treatment

Treatment of horses with CRF is most likely to produce improved renal function if there is an acute reversible component exacerbating CRF (i.e., acute-on-chronic disease). Similar to ARF, sudden exacerbation can be caused by exposure to nephrotoxins or vasomotor nephropathy secondary to diseases producing hypovolemia (e.g., diarrhea). Ascending UTI or obstruction can also exacerbate CRF. If an acute component is detected, it should be corrected rapidly (as described for ARF) with the goal of minimizing further loss of functional nephrons. In addition, surgical removal or fragmentation of stones may be indicated in horses with calculi thought to be disrupting urine flow.

In horses with relatively stable CRF, management changes should be kept to a minimum and, when necessary, made gradually. Treatment of horses with stable CRF consists of supportive care: fluids, electrolytes, and nutritional support. Water should be available at all times, and salt can be provided freely so long as edema and/or hypertension are absent. If edema develops, salt should be restricted, even in the face of hyponatremia. In addition to serum creatinine, electrolyte concentrations and acid-base balance should be measured regularly (e.g., monthly or initially longer intervals). If serum sodium and chloride concentrations are decreased, 60 to 120 g (≈2 to 4 oz) of salt may be added to the feed, provided edema is not present. If metabolic acidosis is detected (e.g., blood pH <7.35 or serum bicarbonate concentration <20 mEq/L) and the patient is not edematous, sodium bicarbonate ($NaHCO_3$) powder (100 to 200 g/day) or a mix of $NaHCO_3$ and salt should be added to the diet. The goal of supplementation with salt and $NaHCO_3$ is to maintain serum electrolyte concentrations and acid-base balance within reference ranges. However, the effect of electrolyte supplementation on progression of CRF is unclear because high-salt diets may actually hasten the decline in GFR and exacerbate proteinuria in human patients with CRF.[47]

Although no adverse effects of hypercalcemia in horses with CRF have been documented, decreasing calcium intake (e.g., replacing alfalfa or other legume hays with grass hay) may result in a return of serum calcium concentration to the normal range. The hypophosphatemia that usually accompanies hypercalcemia in horses with CRF may prevent mineralization of soft tissues. There appears to be no need for vitamin D supplementation in horses with CRF, but regular administration of vitamin B complex and anabolic steroids may be helpful to stimulate appetite. If the appetite remains good, anabolic steroids may further limit muscle wasting and may increase PCV. Attenuation of anemia in human and canine patients with CRF by administration of recombinant erythropoietin has been one of the most significant advances in the management of this disease; its application to equine CRF remains to be investigated.[48] In an occasional horse with advanced CRF, marked hyperlipemia may develop and administration of heparin (40 to 100 units/kg subcutaneously [SC] twice daily) may stimulate lipoprotein lipase and decrease plasma triglyceride concentration.[49] This treatment is not without risk, however, as it may cause a further decline in PCV and potentiate bleeding tendencies in a uremic patient. Corticosteroids and NSAIDs are best avoided in horses with CRF due to primary tubulointerstitial disease. If these drugs are essential for treatment of a complicating problem, they should be used judiciously. Management of CRF due to GN appears to be even less rewarding than that for CRF caused by tubulointerstitial disease. Immunosuppressive therapy has been of limited benefit in slowing the progression of the disease and may even hasten weight loss, although short-term improvement with dexamethasone therapy has been documented in one horse that had an immune-mediated (selective IgM) glomerulonephropathy.[8] For patients with significant edema, treatment with diuretics may result in transient improvement, and plasma transfusions may be of temporary benefit to horses with edema and hypoalbuminemia.

As CRF progresses, partial anorexia and lethargy lead to more rapid loss of body condition, so nutritional management aimed at maintaining body condition is probably the most important aspect of supportive care for these horses. Increasing carbohydrate (grain) feeds and adding fat to the diet are recommendations to increase caloric intake. Fat can be added by feeding corn oil (up to 16 oz/day) or a commercial fat supplement (often more palatable). Increased intake of omega-3 fatty acids (e.g., available in linseed oil or flaxseed oil) has been demonstrated to slow the progression of renal failure in experimental models, but potential benefits in spontaneously occurring CRF are less clear.[50,51] Restricting dietary protein intake by human and veterinary patients with CRF was once thought to have beneficial effects.[52] However, the current recommendations in humans with CRF are mixed and complex, with no clear benefit of restricting protein in metanalyses of

multiple studies.[53] Rather, the literature supports individually tailored diets based on stage of disease, age, comorbidities, body condition, and the use of dialysis or not, and they may be high, moderate, or low protein depending on the individual patient.[53] In horses with CRF, appropriateness of dietary protein intake can be assessed by the serum BUN–to–creatinine ratio; values greater than 15:1 suggest excessive protein intake, and values less than 10:1 may indicate protein-calorie malnutrition. Finally, an important aspect of nutritional management of horses with CRF is provision of a highly palatable diet. Feeding smaller meals more frequently and varying the diet are helpful methods to increase food intake. It should be remembered that if the horse with CRF becomes anorectic or will eat very little, quality of life is an important factor to consider.

Additional treatments for CRF in human patients include antihypertensive agents, including diuretics, β-adrenergic blockers, and ACE inhibitors.[54] The ACE inhibitors may have an additional benefit of limiting proteinuria.[55] In dogs and cats, ACE inhibitors and/or angiotensin receptor blockers are considered standard of care for managing chronic kidney disease with proteinuria.[56] Little is known about the roles of systemic or intrarenal hypertension in progression of renal disease in horses. There are no research reports of potential benefits of use of antihypertensive medications in horses with CRF. Oral administration of the ACE inhibitor benazepril was evaluated in healthy horses following exogenous administration of angiotensin 1 and modestly attenuated a rise in systemic blood pressure at a dose of 1 mg/kg.[57] Future studies are needed to determine the optimal dose, frequency, safety, and efficacy for horses with CRF.[57]

Horses with end-stage CRF often develop oliguria and uncontrollable metabolic acidosis. At this stage, CRF can only be managed by hemodialysis or peritoneal/pleural dialysis. However, pursuit of either hemodialysis or peritoneal dialysis in horses with CRF is of questionable logic because even when successful, dialysis is likely to prolong the life of the horse for only a short time.

Prognosis

As soon as the diagnosis of CRF is made, the owner should be made aware that it is a terminal condition, so as to prepare him or her well in advance for making the decision to euthanize on humane grounds at the appropriate juncture, most likely within 2 years after the diagnosis of (stable) CRF. With patient-tailored management and monitoring, many horses with early CRF may be able to continue in performance or live as a "pasture pet" for months to a few years. In general, as long as creatinine remains less than 5.0 mg/dL and the BUN–to–creatinine ratio is less than 15:1, affected horses seem to maintain a reasonably good attitude, appetite, and body condition. Once creatinine is greater than 5.0 mg/dL, the rate of progression of CRF appears to accelerate and signs of uremia (e.g., anorexia, poor hair coat, loss of body condition) often become more apparent. Although this threshold for creatinine concentration is a useful figure for informing an initial prognosis for most horses, it is important to remember that progression of CRF is highly variable. Thus, each case must be handled on an individual basis, with the emphasis on maintenance of body condition until humane euthanasia becomes necessary.

Urinary Tract Infections

Thomas J. Divers • Dominic R. Dawson-Soto • Alexandra J. Burton

UTI can be anatomically divided into two categories: those affecting the upper urinary tract (kidneys and ureters) and those involving the lower urinary tract (bladder and urethra). Lower UTI usually results from anatomic or functional causes of abnormal urine flow, especially bladder paralysis (see Urinary Incontinence section later). Although recognized less frequently, upper UTI is often a more serious, potentially life-threatening problem. In horses, UTI is also frequently accompanied by urolithiasis and partial obstruction.[1]

Risk Factors and Causes

The most common risk factors for development of UTI are bladder paralysis, urolithiasis, and urethral damage (e.g., foaling trauma in mares, neoplasia or habronemiasis in males). However, in the case of urolithiasis, with the exception of single large cystoliths (which predispose horses to lower UTI), it is often difficult to determine whether concurrent nephroliths, ureteroliths, multiple small cystoliths, and/or urethroliths are a cause or consequence of UTI. The shorter urethra and its location near the anus can increase the risk of lower UTI in mares and fillies. One study in healthy horses showed that mares had significantly more colony-forming units (CFUs) of bacteria in their urine than males.[2] In humans, silent lower UTIs and pyelonephritis resulting from infection with bacteria shed from the GI tract can develop in prepubertal girls and during pregnancy or after menopause in adult women.[3] In certain instances, this increased risk has been further attributed to a lack of estrogen, which appears to be important for production of glycosaminoglycans that cover uroepithelial surfaces and inhibit attachment of bacteria.[4] Whether fillies or pregnant mares are at increased risk for UTI has not been studied. Horses with bladder paralysis or decreased urethral sphincter tone are at greater risk of UTI. Immunosuppression should also be considered an important risk factor, especially in today's aging equine population (i.e., if uncontrolled pituitary pars intermedia dysfunction [PPID] is present). Finally, as bladder catheterization cannot be performed in a completely sterile manner due to normal bacterial flora in the vestibule and distal urethra, iatrogenic lower UTI is a risk of this procedure. However, UTI is an unlikely complication of bladder catheterization in otherwise healthy animals because host defense mechanisms, including urine flow, are highly effective in eliminating contaminating bacteria. When urethral or bladder mucosa has been damaged or urine stasis (e.g., bladder paralysis) is present, bladder catheterization has a greater risk of producing UTI.

Bacterial UTI is most common. In one study on urine from healthy male and female horses, multiple bacterial species were cultured, regardless of whether urine was obtained via midstream free catch or catheterization, with the predominant isolates being *Streptococcus* spp., *E. coli*, *Enterobacter* sp., *Bacillus* sp., *Staphylococcus* spp., *Diptheriods* sp., *Proteus* spp., and *Enterococcus* sp.[2] In one author's experience (TJD), *E. coli*, *Proteus mirabilis*, *Klebsiella* spp., and *Enterobacter* spp. are the most common pathogens isolated from individual horses with UTI. Historically in the literature, *E. coli*, *Staphylococcus* spp., *Corynebacterium* spp., *Streptococcus* spp., and *Pseudomonas aeruginosa* were the microbes isolated most frequently from horses with UTI.[5,6] A more recent study found *E. coli* (36%), *Streptococcus* spp. (20%), and *Enterococcus* spp. (20%) in urine cultures from equine clinical cases.[7] In a group of seven horses with pyelonephritis, *Pseudomonas aeruginosa*, *E. coli*, and *Streptococcus zooepidemicus* were cultured.[8] Individual case reports of cystitis in horses due to *Corynebacterium matruchotii* infection and a combined *E.coli* and *Enterococcus* spp. infection have also been described.[9,10] In horses with instrumentation of the urinary tract (e.g., indwelling bladder catheters, ureteral stents), UTI with nosocomial, antimicrobial-resistant pathogens should always be considered a risk. In septicemic foals, hematogenous infection of the kidney(s) with *Actinobacillus* spp., *Rhodococcus equi*, and *Salmonella* spp. has occurred.[11-13] Lower UTI with yeast (*Candida* spp.) occurs in neonatal foals receiving broad-spectrum antibacterial therapy, especially if they are recumbent and/or have indwelling urinary catheters. The spirochete *Leptospira interrogans* can

infect the equine kidney, occasionally causing acute interstitial nephritis, but it is more commonly implicated in uveitis and abortion.[14]

Equine parasitic UTIs do not commonly cause clinical disease. The coccidian parasite *Klossiella equi* infects the renal parenchyma of equids but has only been reported to cause disease (interstitial nephritis and tubular necrosis) in instances of heavy infection or host immunosupression.[14-18] The nematode *Halicephalobus gingivalis* is primarily a cause of equine neurologic disease (meningoencephalitis) but may also result in granulomatous nephritis via hematogenous spread.[14,19-21] Both *K. equi* sporozoites and *H. gingivalis* parasites can sometimes be found in the urine sediment of infected animals.[14,15,19,21] There is one report of two horses developing tubularinterstitial nephritis in association with productive, lytic equine polyomavirus infection.[22] The etiopathogenesis in these two horses was hypothesized to be similar to BK polyomavirus nephropathy of immunocompromised humans.[22,23] In horses without any obvious predisposing factor for UTI, primary immune dysfunction or other immunocompromise (e.g., uncontrolled PPID) should be considered, especially in cases where uncommon pathogens are identified as causative agents.[15,17,22] Sterile ulcerative cystitis due to phenylbutazone administration has been reported.[24] In addition, a newly described entity of equine sterile idiopathic hemorrhagic cystitis was recently documented in a cases series of 11 horses (see the Urinary Tract Neoplasia section later).[25]

Clinical Findings

Clinical signs of UTI usually reflect the location, severity, and duration of infection. Lower UTI seldom causes signs of systemic illness and infection and is typically characterized by disturbances in urine flow (dysuria, dysuria, stranguria, pollakiuria, and incontinence). An exception to this is in mares with subclinical cystitis/urethritis, where outward signs may not be present or recognized. Urine scalding of the perineum may develop with chronic UTI in mares but should not be confused with estrus or fecal crusting/scalding due to diarrhea or a sunken anus (poor conformation or as a result of low body condition score). The sheath opening and dorsal aspects of the hindlimbs may be coated with urine crystals or blood in males with UTI. In an occasional horse, gross pyuria may also be observed as passage of mucopurulent debris in otherwise clear urine but should not be confused with the normal turbid appearance of equine urine (see Chapter 10, Fig. 10.2). Gross hematuria can be seen with urinary calculi, neoplasia, or if the bladder and/or urethral mucosa is eroded or very inflamed. Hematuria of bladder origin typically produces hematuria throughout urination, with gross discoloration of urine most obvious at the end of urination. Hematuria can also be caused by upper urinary tract hemorrhage. Renal hemorrhage was a major component of bacterial pyelonephritis reported in seven horses and has also been seen with clinical *K. equi* infection.[7,15] Horses with upper UTI are much more likely to have signs characteristic of a systemic infection, including fever, inappetence, lethargy, colic, and weight loss. However, because upper UTI is often accompanied by concurrent lower UTI, dysuria may also be present.

Diagnosis

A diagnosis of UTI is based on clinical signs, analysis of blood and urine samples, US, and cystoscopy. With lower UTI, the complete blood cell count (CBC) and serum biochemical profile are usually normal, whereas the CBC with upper UTI often supports a systemic inflammatory response. Detection of azotemia, low USG, and white blood cell (WBC) casts in urine sediment are indicative of upper UTI, especially when accompanied by signs of systemic illness. With chronic upper UTI, increased total protein and globulin concentrations are also often detected. In human medicine, pyuria (increased number of WBCs in the urine) is defined as the presence of greater than 10 WBCs per mm^3 urine or greater than or equal to three WBCs per microscopic high-power field (HPF).[26] In horses, to the author's (AJB) knowledge, there has been no peer-reviewed study specifically assessing the cellular content of urine in a large number of healthy adult horses. However, in horses, pyuria is generally considered to be the presence of greater than 10 WBCs per HPF of a midstream-voided or catheterized sample, with the urine of healthy horses generally said to have fewer than five WBCs per HPF.[27] That said, one study in healthy males and females found that no horse had a WBC count greater than one per HPF in midstream free catch sample.[2] This suggests that the generally accepted number of greater than 10 WBCs per HPF to diagnose pyuria may be too high for horses, and it should be diagnosed if greater than five WBCs per HPF are seen, providing collection is aseptic or midstream and there is clinical suspicion of urinary tract disease. When bacterial infection is the cause of pyuria, there are typically more than 20 organisms visible per HPF. Urine samples should be examined and processed for bacterial culture within 30 minutes after collection or be refrigerated because bacteria can continue to proliferate when urine is stored at room temperature. Culture results should be interpreted in light of the clinical picture, as not all organisms cultured may be causative and some may be innocuous contaminants.

Rectal examination and transrectal US may help confirm a predisposing cause of lower UTI (e.g., enlarged and atonic bladder, cystic calculi, bladder mass). Chronic cystitis also usually leads to bladder wall thickening, visible via US.[25] The ureters are not usually palpable during rectal examination of the normal horse, but in horses with upper UTI, careful palpation of the dorsolateral aspects of the caudal abdomen (retroperitoneal space) usually reveals enlarged ureters, and transrectal US can help confirm this finding. With pyelonephritis, rectal palpation may further reveal an enlarged, painful, or shrunken and misshapen left kidney, while the right kidney is usually not palpable. Transabdominal US of the kidneys is useful for detecting abnormal renal size, shape, or consistency in horses with upper UTI.[8,27-32] Horses with pyelonephritis may have a focus of septic infection with adjacent dilation of the renal pelvis (Fig. 34.4), which may be detected by US if it distorts renal architecture and echogenicity sufficiently.

Cystoscopic examination of the lower urinary tract is useful for evaluating the integrity of urethral and bladder mucosa, detecting small uroliths, and assessing urine flow from each ureteral orifice.[1,8,27,32] With long-standing cystitis, especially when bladder paralysis is the underlying cause, ureteral orifices may become dilated (and appear wide open), allowing for vesiculo-ureteral reflux and development of ascending pyelonephritis. When unilateral pyelonephritis is suspected on the basis of US findings, cystoscopy with catheterization and collection of urine samples individually from each ureter can be helpful to document unilateral disease. Ureters may be catheterized by passing sterile polyethylene tubing through the biopsy channel of the endoscope during cystoscopy or can be accomplished in mares by directing blunt-ended catheters (e.g., 8-Fr polypropylene) through the urethra into each ureteral orifice.[33]

Treatment

Treatment of UTI consists of proper antimicrobial therapy and correction, if possible, of predisposing anatomic or functional causes. Selection of the appropriate antimicrobial agent is best determined by prior knowledge of susceptibility patterns of the causative pathogen(s), concentration of the antimicrobial in renal tissue and urine, activity of the antibiotic at different pH values, toxicity, compatibility with other antimicrobial drugs, ease of administration, and expense. In addition, with

VetBooks.ir

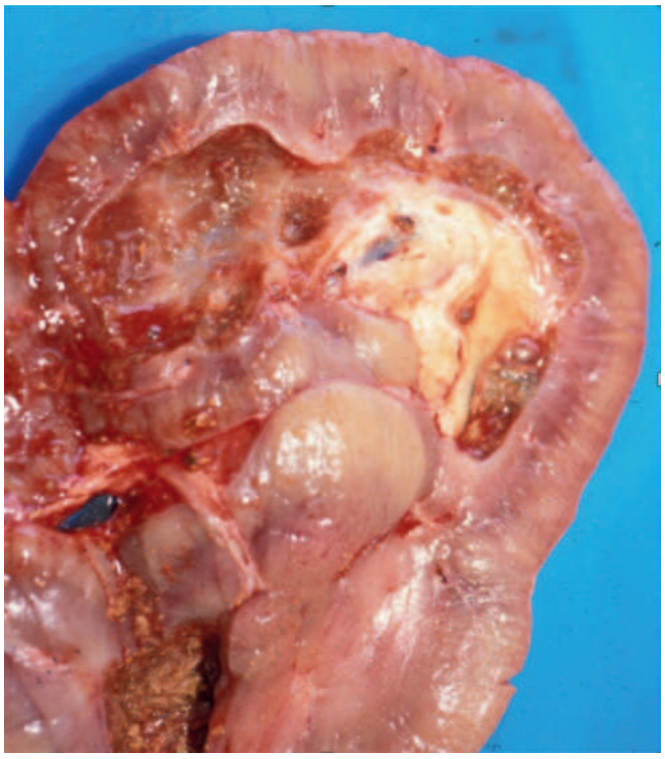

FIG. 34.4 A transected kidney from a horse with pyelonephritis. Note the severely dilated renal pelvis adjacent to a septic purulent focus. *(Courtesy The University of Pretoria, Faculty of Veterinary Science.)*

the increasing emergence of antimicrobial-resistant pathogens, especially within hospital settings, antimicrobial stewardship through rational antimicrobial therapy is vital (see Chapter 45). Resistance in vitro to a particular antibiotic may not preclude successful treatment with the drug, providing high enough concentrations are achieved in urine. Similarly, in vitro susceptibility does not always guarantee a successful response to treatment. Penicillin, ampicillin, cephalosporins, trimethoprim-sulphonamide (TMS), and gentamicin are all concentrated in urine. The antimicrobials of choice for horses with lower UTI are TMS or ceftiofur, or a broad-spectrum combination (i.e., penicillin or ampicillin or ceftiofur, plus gentamicin or amikacin).[34] Gentamicin and amikacin should be avoided in patients with severe azotemia or suspected renal failure, as these are potentially nephrotoxic. Fluconazole is the antifungal drug of choice for UTI involving *Candida* spp.[34] Treatment should be continued for 7 to 14 days and then urine recultured. For upper UTI (pyelonephritis), TMS, ceftiofur (or other third-generation cephalosporins), penicillin or ampicillin, or enrofloxacin are the antimicrobials of choice.[34] Therapy for upper UTI is usually required for 2 to 3 weeks and often longer.[34] Although less of a risk with newer preparations, horses with acidic urine, dehydration, or poor renal perfusion may develop hematuria and crystalluria with sulfonamides.[35] With presumed lower UTI, if the UTI recurs and the same organism is isolated, a focus of upper UTI should be suspected. In contrast, recurrence of UTI with a different pathogen suggests an anatomic or functional cause of abnormal urine flow as a predisposing cause of UTI.

Although unstudied in horses, the use of lactobacillus suppositories in women predisposed to UTI enhanced cure rates in some studies but showed no efficacy in others.[32,36,37] Preliminary research on vaccines against bacterial virulence factors to reduce the incidence of UTIs in predisposed populations of humans and mice appears promising.[38] There is no research into these alternative therapies in horses to date.

Urinary Incontinence

Elizabeth A. Carr • Dominic R. Dawson-Soto • Alexandra J. Burton

Risk Factors and Causes

Urinary incontinence in the horse can result from urolithiasis, congenital anomalies or defects of the lower urinary tract, trauma, neoplasia, neurologic diseases accompanied by bladder dysfunction, and decreased urethral tone. Bladder and urethral calculi frequently result in transient or intermittent incontinence secondary to sabulous cystitis or partial obstruction.[1-4] Ectopic ureter and other congenital malformations of the urinary tract generally produce incontinence from birth, although it may not be recognized until several weeks or months of age. Presentation of incontinence in adult horses due to congenital anomalies has also been described.[5-8] Trauma-induced incontinence may develop after breeding injury or dystocia in mares, or in both genders after sacral or spinal injury. Incontinence may also develop with severe long-standing lumbosacral or back problems if they make it difficult and/or painful for the horse to posture to urinate. In these instances, over time, *incomplete bladder emptying* allows the crystals normally present in equine urine to accumulate in the ventral aspect of the bladder. This crystalloid sediment becomes heavy (and in some cases quite firm), further preventing complete bladder emptying. This condition, which is termed *sabulous urolithiasis*, can accompany bladder paralysis of any cause but also may itself cause myogenic bladder dysfunction, in the absence of any underlying neurologic problem.[1,2] The weight of the sediment may induce chronic stretching of the bladder wall, contributing to myogenic dysfunction. Horses with lower urinary tract neoplasia can also present with incontinence, but other complaints (e.g., stranguria or hematuria) are usually reported as well.

Neurologic disorders that most commonly result in bladder paralysis and incontinence include equine herpesvirus-1 myeloencephalopathy (EHM), cauda equina neuritis syndrome, polyneuritis equi, sorghum toxicosis, and aberrant larval migrans *(Halicephalobus gingivalis)* and equine protozoal myeloencephalitis (EPM), dependent on parasite location within the nervous system.[9-14] These diseases, along with other problems affecting gray matter of the sacral segments, result in loss of lower motor neuron (LMN) function, whereas lesions of the lumbar or higher portions of the spinal cord result in loss of upper motor neuron (UMN) function. Loss of detrusor muscle function and overflow incontinence is seen with LMN damage, and a large, easily expressed bladder is found on rectal palpation. Initially, UMN disease is characterized by increased urethral resistance, which leads to increased intravesicular pressure before voiding can occur. Voiding may occur as short bursts of urine passage with incomplete bladder emptying, and rectal examination may reveal a turgid bladder that is variable in size. Although UMN signs are initially different from those of LMN disease, incontinence is not usually recognized until overflow incontinence develops as a result of sabulous urolithiasis and progressive loss of detrusor function. The latter progression can explain why bladder paralysis and incontinence may be found in horses with other neurologic diseases like cervical stenotic myelopathy (CVM), equine degenerative myelopathy (EDM), and even viral encephalomyelitis other than EHM. Presence of other signs associated with LMN dysfunction (e.g., loss of anal or tail tone) or UMN dysfunction (e.g., ataxia) may aid in differentiating the inciting cause of bladder paralysis. Despite many possible causes, the prognosis for recovery from incontinence resulting from bladder paralysis is generally poor because sabulous concretions and UTI rapidly complicate the problem. However, successful management of sabulous cystitis has been described in five horses for up to 3 years with medication in combination with bladder catheterization

VetBooks.ir

FIG. 34.5 Extensive thickening of the perineum and caudomedial thigh region due to chronic dribbling of urine (incontinence) in a 17-year-old mare with a large cystic calculus (see Fig. 34.10). *(Image courtesy Montague N. Saulez.)*

and lavage.[2] A syndrome of estrogen-responsive incontinence caused by decreased urethral sphincter tone has been reported in a few mares.[15,16]

Diagnosis

In addition to taking a complete history and performing physical and neurologic examinations, it is helpful to take time to observe the incontinence or any attempts to urinate. Clinical signs often include stranguria and urine scalding of the perineum and hind legs in females, sometimes with tissue thickening if the incontinence has been long-standing (Fig. 34.5). Rectal palpation, transrectal US of the bladder and upper urinary tract, transabdominal US of the kidneys, and cystoscopy are useful to rule out uroliths, neoplasia, cystitis, and congenital anomalies as causes of incontinence. If trauma or sacral bony abnormalities leading to incontinence are suspected, radiographs and pelvic ultrasound should be attempted. Nuclear scintigraphy may further help in identification of a traumatic lesion, especially in large patients where radiography is limited. CT or magnetic resonance imaging (MRI) should be considered in foals and small ponies.[17] Although most affected horses remain nonazotemic (unless significant obstruction or bilateral pyelonephritis has developed), laboratory analyses of blood and urine, including a quantitative urine culture, should be performed in all horses with incontinence, because UTI is a common sequela. Urethral and bladder pressure profiles can be used to assess urinary sphincter and detrusor muscle function. Normal values for both mares and geldings have been reported.[18-20] Where an underlying neurologic problem is suspected, cerebrospinal fluid (CSF) collection and analysis may also be of value.

Treatment

Treatment for incontinence varies with the underlying cause. Removal of calculi and appropriate antimicrobial therapy are effective treatments for urolithiasis and UTI. Surgical correction is generally required for treatment of congenital anomalies, but owners should be discouraged from using affected animals for breeding. Incontinence due to EHM or EPM carries the most favorable prognosis for recovery, although in one author's (DRD) experience, with EHM, bladder paresis may persist for several weeks to months. To prevent continued distention and further damage to the detrusor function, removal of sabulous crystalloid material by bladder lavage with saline and temporary placement of an indwelling bladder catheter are indicated in cases of recent onset of bladder paresis. Debate exists in the human literature regarding the preference of intermittent versus continuous urinary catheterization. In animals, both methods carry potential risks—infection and/or trauma from repeated catheterization—and each case should be evaluated individually to choose the most appropriate method.[1,2,21] Antimicrobial treatment, ideally based on urine culture results, is also indicated in all horses with bacterial cystitis secondary to bladder paralysis.

Bethanechol (0.03 to 0.04 mg/kg SC or IV q6-8h, or 0.22 to 0.45 mg/kg PO q6-8h [poorly absorbed]), a parasympathomimetic agent that has a somewhat selective effect on smooth muscle of the gastrointestinal tract and bladder, has been recommended for improving detrusor tone and strength of contraction in horses with bladder paralysis. However, response to treatment is often disappointing, perhaps because of long-standing paralysis before incontinence is recognized, although bethanecol-responsive bladder atony has been reported in a foal.[22] Use of phenoxybenzamine (0.4 mg/kg PO q6h), an α-adrenergic blocker that decreases urethral sphincter tone, has also been recommended in combination with bethanechol in cases with UMN bladder dysfunction. In horses with evidence of urethral sphincter hypotonia, the sympathomimetic agent phenylpropanolamine (0.5 to 2 mg/kg PO q8-12h) has also been used. Dosing regimens for these autonomic drugs have been extrapolated from other species because no pharmacokinetic data are available for the equine species.

In general, treatment with these autonomic drugs has largely been ineffective in controlling incontinence due to bladder paralysis, and overall the long-term prognosis for recovery is usually poor. On a more positive note, treatment of a few mares with urethral sphincter hypotonia with estradiol cypionate or benzoate (5 to 12 μg/kg IM every day for 3 days, then every other day) has been effective at resolving incontinence as long as detrusor function is normal. Historically in the literature, estrogen-responsive incontinence has been reported in a total of three mares.[15,16] Estrogen may modulate the effect of norepinephrine on α-receptor activity in the urethral sphincter, thereby improving urethral sphincter tone. There is also a report of successful surgical repair of an incompetent (damaged during removal of a cystic urolith) urethral sphincter in a mare.[23]

Ectopic Ureter

Thomas J. Divers • Stephanie A. Brault • Alexandra J. Burton

Although rare, ectopic ureter is the most frequently reported developmental anomaly of the equine urinary tract and there are many case reports and series.[1-13] This abnormality is the result of an error in embryologic development causing one or both ureters to empty into the urethra, uterus, or vagina instead of attaching normally to the dorsal wall of the urinary bladder.[1] Of the cases reported, almost all have been fillies, and the primary complaints were urinary incontinence and perineal

dermatitis (urine scalding).[1-13] However, this gender distribution may reflect easier recognition of partial urinary incontinence in females rather than a true gender predilection. In the male, intermittent urine dripping from the end of the penis is less easily recognized; further, urine entering the pelvic urethra may pass retrograde into the bladder.

Diagnosis

Ectopic ureter should be suspected in young horses with incontinence observed shortly after birth. Renal function is usually normal, but the affected ureter may be extremely dilated. In young foals (e.g., <50 to 75 kg), an excretory urogram (after IV administration of contrast agent) or pyelography (after percutaneous injection of contrast agent into renal pelvis via ultrasonographic guidance) may aid in diagnosis of ectopic ureter.[3-6,8] Unfortunately, most patients are not presented until they are too large for this procedure to be performed. Ultrasonographic examination may reveal mild dilation of the renal pelvis on the affected side(s).[3,5] Vaginoscopic and cystoscopic examinations should also be pursued in older foals to determine whether the problem is unilateral or bilateral and, when unilateral, to determine which ureter is ectopic. In the latter case, cystoscopic examination should reveal urine entering the bladder from only one normal ureteral opening, located at either 2 or 10 o'clock in the bladder neck. Urine can be seen squirting from normal ureteral openings approximately every 20 to 30 seconds. Observation of normal bouts of voiding, in addition to incontinence, further supports a unilateral problem. To determine the location of the opening of the ectopic ureter, visual examination of the vestibule and vagina (using a blade speculum) should be performed initially to look for intermittent urine flow from the area of the urethral papilla. Ectopic ureteral openings are usually not apparent unless urine flow is seen. Intravenous (IV) administration of dyes including sodium fluorescein (11 mg/kg IV; yellow-green color), indigotindisulfonate (indigo carmine, 0.25 mg/kg IV; blue-purple color), azosulfamide (1.9 mg/kg IV; red color), or phenolsulfonphthalein (0.01 mg/kg IV; red color) to discolor the urine may help locate ectopic ureteral openings.[1,4] Nuclear scintigraphy has been employed to assess renal function and anatomy of involved urinary tract structures before correction.[11] CT has also been used to diagnose ectopic ureter in a filly.[7] Magnetic resonance (MR) urography is the diagnostic tool of choice in children with ectopic ureter and thus may have utility for diagnosis in young foals if size and cost permit.[14]

Treatment

If the ectopic ureter is unilateral, ultrasonographic examination of the opposite kidney appears normal, and azotemia is not present, the preferred treatment may be surgical removal of the kidney on the affected side and ligation of the ureter.[6,9,12,13] Nephrectomy may produce an increase in creatinine (0.5 to 1.0 mg/dL) for a few days, but creatinine usually returns to the prenephrectomy concentration within a week. If both ureters are ectopic, which is not unusual, implantation of the distal ureters into the bladder neck should be attempted. Several surgical techniques have been described.[1,4,6,8,10-12] Complications can include ascending infection, resulting from dilated ureters, and development of adhesions, but successful repairs have also been reported.[1,4,6,8,10-12]

Urinary Tract Neoplasia

Thomas J. Divers • Stephanie A. Brault • Alexandra J. Burton

Neoplasia of the urinary tract has generally been considered rare in horses. That said, two recent retrospective post mortem studies identified a higher proportions of urinary tract neoplasia than expected.[1,2] A study in Germany, prompted by an observed increase in cases of equine kidney tumors, identified renal neoplasia in 20/1069 horses necropsied.[1] Another study in Indiana, specifically looking at horses 15 years of age and older submitted for necropsy, found that 12 of the 241 horses had squamous cell carcinoma, and the most common site for it to be found was the urinary bladder (5/12).[2] These recent findings likely reflect today's aging horse population, supported by the fact that the majority of horses with renal or urinary tract neoplasia in both studies were older than 20 years of age.[1,2] This assumption is further supported by another recent study comparing idiopathic hemorrhagic cystitis with bladder neoplasia: The median age of horses with bladder tumors was 24 years (range 16 to 30 years of age).[3]

Primary kidney neoplasms include renal cell carcinoma (Fig. 34.6, *A*), adenoma, and nephroblastoma, with carcinoma and then adenoma being the most common.[1,4-14] Renal cell carcinoma (or adenocarcinoma) and adenoma occur more frequently in older horses, older than 10 years of age and most often older than 20 years old. Nephroblastomas may be detected in young horses.[15] Lymphosarcoma (Fig. 34.6, *B*), hemangiosarcoma,

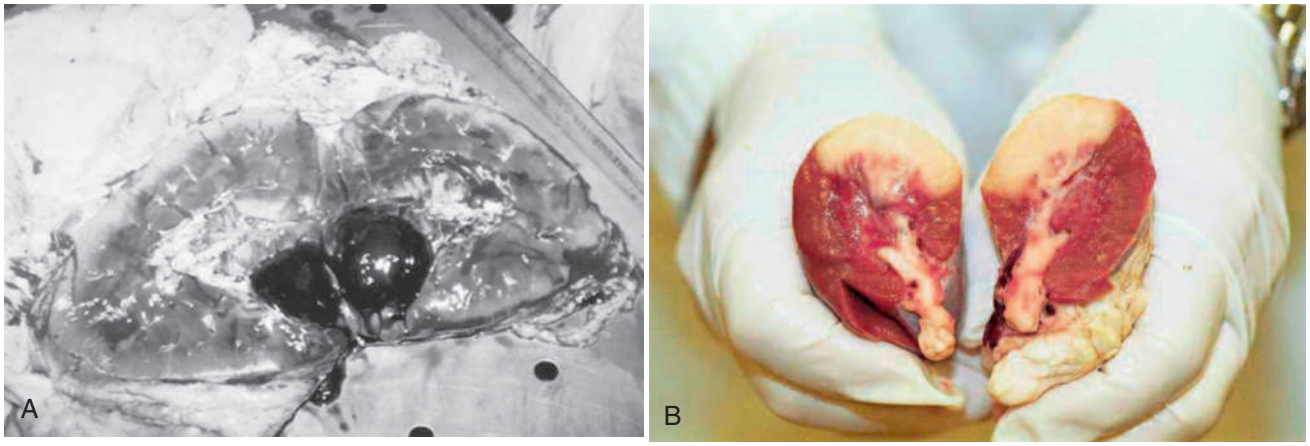

FIG. 34.6 **A,** Cut section of the left kidney from a 25-year-old horse with chronic weight loss, hematuria, and severe anemia. The kidney appeared normal except for a small 4 × 5 cm carcinoma with surrounding hemorrhage. **B,** Cut section of an equine kidney with metastatic lymphoma infiltration (pale tissue). *(A, Courtesy Thomas J. Divers. B, Courtesy Montague N. Saulez.)*

multiple myeloma, and melanoma may also involve the kidneys and, on rare occasions, the bladder.[13] Squamous cell carcinoma is the most common bladder tumor, but horses may also develop transitional cell carcinoma, adenocarcinoma, and undifferentiated carcinomas of the bladder.[3,4,19] Fibromatous bladder polyps may occur in younger horses and a poorly differentiated aggressive leiomyosarcoma of the urogenital tract with extensive bladder involvement has been described in a 2-year-old filly.[4,19,20]

Clinical Signs and Diagnosis

Clinical signs in horses with renal neoplasia include hematuria, weight loss, and recurrent colic. Sudden death may occur if the neoplasm hemorrhages into the abdomen or thorax. Renal tumors may result in marked enlargement of the kidneys such that both left and right kidneys may be found on rectal palpation. In other cases, tumors may be circumscribed lesions within a kidney that disrupt the renal architecture but cannot be felt during rectal palpation. Ultrasonography may be invaluable for detecting such tumors, however, if very small, renal tumors may still be difficult to detect. Affected horses are usually not azotemic, but anemia may be detected when gross hematuria is observed. Although neoplastic cells are unlikely to be found in urine, cytologic examination of urine sediment is still warranted. Renal biopsy has been found to be associated with a low rate of serious complications and provided a histopathologic diagnosis in agreement with necropsy in 72% of cases.[21] Although horses with a diagnosis of renal neoplasia had a greater risk of complications than those with any other histopathologic diagnosis, only 4/151 horses in the study had neoplasia.[21] Nephroblastoma usually remains limited to the kidney; renal cell carcinomas typically metastasize. The liver and lungs are the most common sites of metastasis, but tumors can also spread to unusual sites, leading to variable adjunct clinical signs such as lameness or an ulcerated mass on the premaxilla.[7-10,14] Multiple myeloma involving the kidney resulted in hypercalcemia and a high serum parathyroid hormone–related protein concentration.[17] Hypoglycemia was the chief clinical sign in a 6-year-old horse with renal cell carcinoma producing insulin-like growth factors.[12]

Bladder tumors most commonly present with hematuria, weight loss, pollakiuria, and stranguria. A mass can usually be palpated on rectal examination, but it should not be confused with a cystolith or accumulation of sabulous concretions in the ventral aspect of the bladder.[3] There may be mild to moderate anemia and sometimes hypoproteinemia (hypoalbuminemia). Other than hematuria and associated proteinuria, urinalysis results are often unremarkable, but with bladder tumors, cytologic examination of urine sediment is more likely to reveal neoplastic cells than with renal tumors.[18,19] A diagnosis of bladder neoplasia may be confirmed by cystoscopic examination (Fig. 34.7) and biopsy. A recently described new syndrome of *idiopathic hemorrhagic cystitis* in horses closely resembles bladder neoplasia in clinical pathologic presentation.[3] Unfortunately, biopsy and histopathology were not helpful in discriminating between bladder neoplasia and idiopathic hemorrhagic cystitis in this study.[3]

Treatment

The treatment of choice for unilateral renal neoplasia is nephrectomy.[7,13] Unfortunately, most cases of renal cell carcinoma have metastasized by the time the diagnosis is made, and surgical intervention is of little benefit to horses with disseminated disease. In addition, many horses with renal neoplasia will be aged. Thus, careful evaluation for metastatic disease, assessment of comorbidities (e.g., PPID, poor dentition), and consideration of age should be undertaken before contemplating a nephrectomy. Survival following diagnosis of renal carcinoma ± nephrectomy has been reported to be very poor (median 11 days, range 0 to 365 days).[7] However, of interest, there is one report of a renal tubular cell carcinoma (confirmed by renal biopsy) considered too large to be operable, in a 15-year-old mare. No treatment was implemented, and the mare was reported to still be stable and in foal 1 year later.[22] Treatment of confirmed bladder tumors includes surgical excision, and/or topical chemotherapy using either 5-fluorouracil or triethylenethiophosphoramide and systemic doxorubicin has also been used but prognosis is guarded to poor.[19,20] Again, as affected horses are likely to be aged (often >20 years old), careful consideration of comorbidities and quality of life is important before under taking treatment.

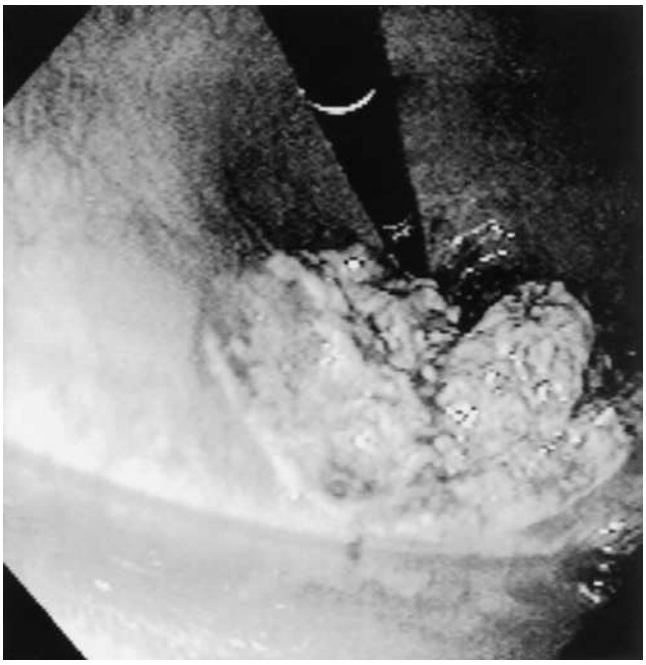

FIG. 34.7 Cystoscopic image of a squamous cell carcinoma of the bladder causing intermittent hematuria in a 14-year-old warmblood mare. The endoscope has been passed beyond the tumor and retroflexed to provide a view directed caudally; a pool of urine is in the foreground, and the tumor can be seen in the ventral aspect of the bladder neck.

EQUINE IDIOPATHIC HEMORRHAGIC CYSTITIS. Idiopathic hemorrhagic cystitis in horses is a newly described syndrome in horses presenting with stranguria and hematuria.[3] In a case series of 11 horses from California with this condition, pyuria was present but not bacteria, and no bacterial growth on urine culture (aside from one horse, which was deemed a contaminant).[3] Other than bacterial cystitis, which is often precipitated by urolithiasis and/or bladder dysfunction, sterile ulcerative cystitis in horses has been described in two horses in association with long-term phenylbutazone administration.[23] Of note, idiopathic hemorrhagic cystitis was almost indistinguishable from bladder neoplasia in terms of clinicopathologic presentation, even by histopathology following mucosal bladder biopsy.[3] However, horses with idiopathic hemorrhagic cystitis made rapid (within approximately 8 weeks), full recoveries, with antimicrobial ± nonsteroidal antiinflammatory treatment. Horses with idiopathic hemorrhagic cystitis were significantly younger (median age = 16, range, 9 to 30 years) compared with those with neoplasia (median age = 24, range, 16 to 30 years), and much more likely to be male—10/11 horses were male, whereas all horses with neoplasia ($n = 7$) were mares.[3] Finally, although gross cystoscopic findings were not different, horses with bladder neoplasia were more likely to have a mass visible on transrectal US.[3] Thus, in a horse with clinicopathologic signs that could be attributable to either neoplasia or idiopathic cystitis, it may be worth treating conservatively as described earlier and waiting a few weeks to see if the signs and lesions resolve, rather than immediately employing chemotherapy or euthanizing the patient.

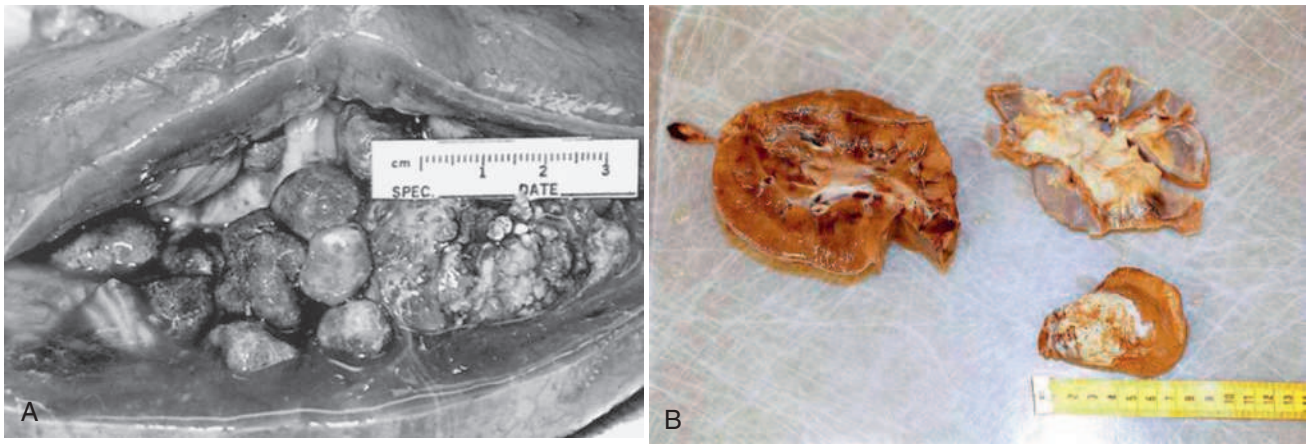

FIG. 34.8 **A,** Multiple nephroliths in the left kidney of a 12-year-old Thoroughbred that presented with a complaint of intermittent hematuria. The right kidney appeared normal on ultrasound examination, and renal function was normal. **B,** A single nephrolith in the kidney of a 10-year-old mare discovered incidentally at necropsy. *(A, Courtesy Thomas J. Divers.)*

Urolithiasis and Obstructive Disease

Montague N. Saulez

While the prevalence of obstructive disorders affecting the equine urinary tract is low, morbidity is high and the consequences thereof can be permanent and fatal. Obstructions may occur throughout the urinary tract and clinical symptoms are dependent on the location and degree of obstruction. Partial obstructions may not initially be recognized and can lead to intermittent dysuria, stranguria, hematuria, incontinence, and variable signs of pain. Horses with complete obstruction exhibit severe abdominal pain (colic) leading to bladder or urethral rupture followed by depression and metabolic deterioration. Unfortunately, reoccurrence is frequent irrespective of treatment modality followed or the elimination of potential risk factors.

Renal and Ureteral Calculi

Following renal tissue damage, calcium carbonate and calcium oxalate crystals can tightly adhere to the renal parenchyma, forming a nidus that allows repeated crystal precipitation and enlargement of the calculus.[1] Underlying renal disease should always be suspected in horses with nephrolithiasis.[2,3] It is thought that in horses, a risk factor for nephrolithiasis is prolonged use of nonsteroidal antiinflammatory drugs (NSAIDs), which can cause renal medullary necrosis (Fig. 34.1), thereby increasing the risk of nephrolith formation in the renal pelvis and terminal recess.

Clinical symptoms are dependent on the degree of luminal obstruction and include anorexia, dullness, and weight loss. This may progress to severe colic, hematuria, and stranguria. Bilateral nephrolithiasis may lead to chronic renal failure (CRF).[2,3] Horses can also remain clinically asymptomatic with the presence of renal calculi incidentally discovered at necropsy[4] (Fig. 34.8, *A* and Fig. 34.8, *B*). Diagnosis of renal or ureteral calculi is made by rectal examination revealing an enlarged kidney, ureter, or bladder. Ureters are not normally palpable but can be detected if enlarged, and the entire ureter should be carefully palpated as calculi may easily be missed. Transabdominal or transrectal ultrasonography should be used to confirm the presence and location of ureteral calculi, which most commonly occur near the entrance to the bladder (Fig. 34.9). In horses affected by a nephrolith and/or ureterolith, typical ultrasonographic findings include hydronephrosis, hydroureter, and a hyperechoic structure with acoustic shadowing in either/both the renal pelvis or ureter.[5-8] Horses affected by hydronephrosis typically have marked distention of the renal pelvis, thinning of the renal cortex, as well as fibrosis within the kidneys. Serum biochemistry analysis may reveal azotemia in horses with bilateral disease and subsequent CRF, but not in those affected by unilateral disease. Further examination of the urine may reveal isosthenuria, pigmenturia, and microscopic hematuria. Culture of the urine and calculus/calculi is worthwhile, especially in the presence of pyuria, bacteriuria, and in horses with systemic indications of infection (e.g., pyrexia, alterations in the complete blood count and inflammatory markers). Calculi should also be analyzed, and the mineral composition determined.

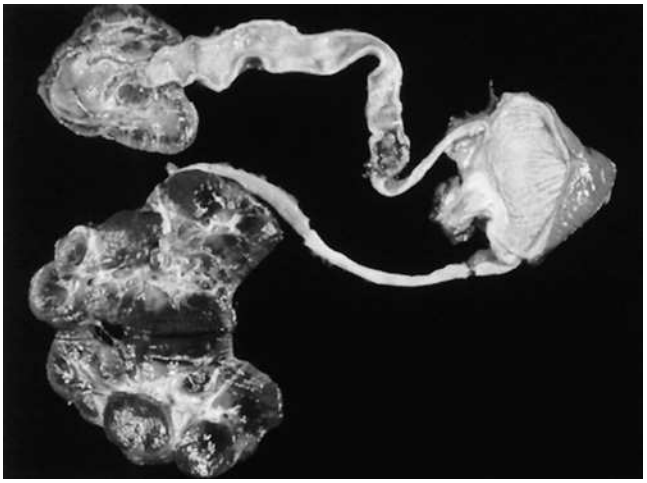

FIG. 34.9 Urinary tract removed from a 5-year-old Standardbred with chronic renal failure caused by intermittent or persistent obstruction by renal and ureteral stones. Note the location of the ureteral obstruction near the bladder. This is the most common site for the obstruction to occur. *(Courtesy Thomas J. Divers.)*

Nephrectomy should be considered in horses affected solely by unilateral nephrolithiasis without the presence of renal azotemia and concurrent damage to the contralateral kidney.[9,10] The advantages of a nephrectomy include prevention of calculus reoccurrence and elimination of any unilateral upper UTI. A nephrostomy or ureterotomy can be performed to manage ureteroliths.[11,12] Transendoscopic laser or electrohydraulic lithotripsy may be considered for noninvasive fragmentation of ureteral stones; however, this technique is time-consuming and often causes tissue trauma.

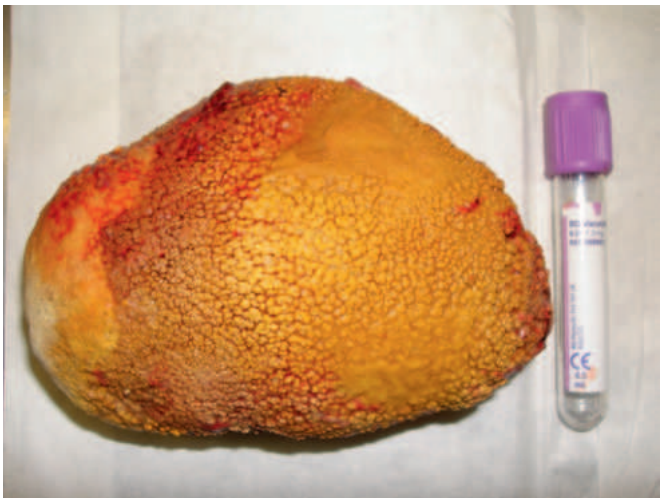

FIG. 34.10 A large cystic calculus composed of calcium carbonate crystals retrieved from a 17-year-old mare through manual distention of the urethra. Note the easily recognizable spiculated surface that caused chronic cystitis. The mare had urinary incontinence with perineal and hindlimb scalding (see Fig. 34.5).

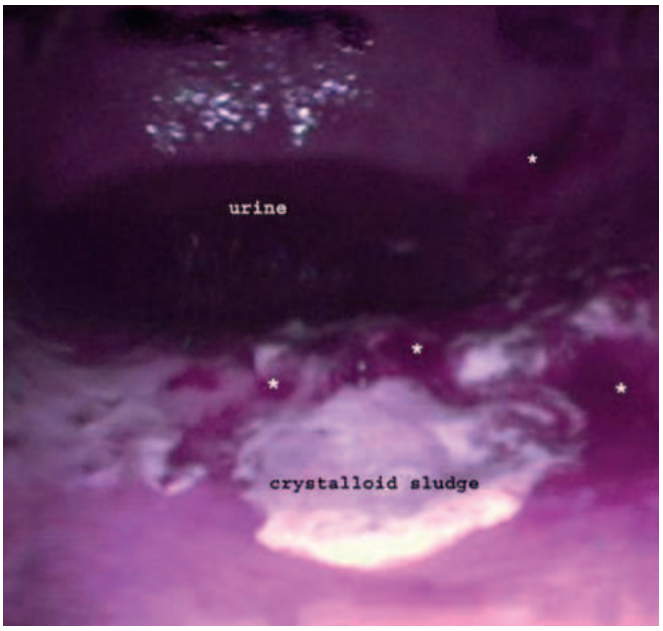

FIG. 34.11 Encrusted cystitis and sabulous urolithiasis due to infection with *Corynebacterium matruchotii* in a 17-year-old Quarter Horse × Thoroughbred gelding. Note the accumulation of crystalloid sludge and ulceration of the bladder mucosa. *(Reprinted with permission from the Journal of American Veterinary Medical Association.)*

Cystic Calculi

Cystolithiasis is most commonly observed in geldings.[13] Typically, cystic calculi present as single, large, spiculated stones composed of $CaCO_3$ crystals (Fig. 34.10).[1] Less often, calculi consisting of both $CaCO_3$ and $CaPO_4$ crystals may be found; these tend to be smooth and are resistant to fragmentation.[13,14] Although the precise etiology is unknown, contributing factors may include neurologic disease causing bladder dysfunction, renal injury, incomplete bladder emptying, underlying cystitis, anatomic defects, bladder trauma or surgery, and neoplasia. Although equine urine is normally supersaturated with $CaCO_3$ crystals, in the healthy horse, the secretion of mucus produced by glands in the renal pelvis and proximal ureter serves as a lubricant to prevent crystal adherence to the uroepithelium.

Clinical symptoms in horses affected by cystic calculi include intermittent hematuria, stranguria, polyuria, dysuria, oliguria, and incontinence. If chronic, then weight loss; urine scalding of the ventral abdomen, preputium, perineum, and hind limbs (see Fig. 34.5); and intermittent colic may occur. The presence of cystic calculi can be confirmed by palpation of the bladder per rectum following bladder catheterization to remove urine. Advanced diagnostics such as US and cystoscopy should be employed. Due to the possibility of calculi present in multiple locations, US of the entire urinary tract should be performed.[1] Cystoscopy allows improved planning for extraction of the calculus or calculi (size vs. shape and quantity), determines the degree of luminal obstruction and mucosal damage, and allows for visualization of urine production from both ureteral openings. Due to urine volume, mucoprotein secretion, and normal sediment, the bladder may require lavage and suction before a complete cystoscopic examination can be performed. It is important to be able to differentiate between sediment and the presence of calculi in the bladder. Sabulous urolithiasis is the accumulation of urine sediment in the ventral aspect of the bladder and often occurs with a concurrent encrusted cystitis and infection (Fig. 34.11).[15-17] In turn, over time, sabulous urolithiasis itself leads to a degree of bladder paralysis (myogenic dysfunction), thereby creating a vicious cycle of incomplete voiding, which further predisposes the patient to urolithiasis. Long-standing sabulous cystitis with inherent bladder paralysis may lead to sabulous urolithiasis in the form of an inspissated sphere.[16] Care must be taken to avoid confusing inspissated sabulous urolithiasis with the presence of discrete cystoliths. Hematology and serum biochemistry are usually normal with cystolithiasis, but elevation of inflammatory markers should raise suspicion for concurrent upper UTI, and azotemia should prompt careful investigation for concurrent upper urinary tract disease and CRF. In addition, cytology and culture of an aseptically collected urine sample and culture of a bladder mucosal biopsy may expand the minimum database and help initiate appropriate antimicrobial therapy.

Using sedation and caudal epidural anesthesia, small fragmented calculi may be manually removed using a perineal urethrotomy in male horses.[13] Care must be taken to avoid further soft tissue trauma and damage to the pelvic urethra, bladder, and rectum. Larger calculi may need to be removed by laparocystotomy through a paramedian, ventral midline incision or with laparoscopic guidance under general anesthetic.[18-20] It is the author's (MNS) opinion that the most superior surgical technique is laparocystotomy under general anesthetic, as this allows complete removal of the calculus without fragmentation, thereby reducing the chance of reoccurrence and urethral obstruction, as well as postoperative cystitis and urethritis. Most recently, successful laparoscopic removal of cystic calculi has been described in standing sedated horses, which has the advantage of avoiding general anesthesia.[21,22] Gokel's cystotomy, using a perirectal incision, can also be used to remove intact, cystic calculi in the standing horse.[23] In mares, following caudal epidural anesthesia and manual distention of the urethra, calculi may be easily retrieved intact. Laser (Ho:YAG or pulsed dye laser) or shock wave lithotripsy in the standing horse is also an attractive, noninvasive treatment option for fragmenting large stones.[24] Electrohydraulic lithotripsy can be used transendoscopically or via a perineal urethrotomy to fragment large calculi using electrical energy; however, this technique is time-consuming and results in many fragments, which can cause obstruction.[25] It is important to submit retrieved stones for analysis and mineral composition. Management of sabulous cystitis has been described in five horses for up to 3 years with medication in combination with bladder catheterization and lavage.[17]

VetBooks.ir

Unfortunately, calculi may frequently reoccur regardless of treatment modality. Horses with perineal urethrostomy tend to have greater incidence of reoccurrence than horses with cystotomy most likely due to remaining fragments of calculi. As the precise etiopathogenesis is unknown, preventative measures are difficult to prescribe. Recommendations include urinary acidification with ammonium chloride (50 to 200 mg/kg q24h PO) or ammonium sulfate (200 to 300 mg/kg q24h PO) and changing from a diet of legumes to grass hay to help decrease urinary calcium excretion.[26,27] Lastly, the addition of 25 to 50 g NaCl in the feed daily may help promote diuresis by stimulating increased water intake.

Urethral Obstruction

Urethral obstruction is typically caused by urethroliths located over the ischial arch where the urethra is narrowest. These stones may move further distally and cause luminal obstruction (see Fig. 34.12, *A* and *B*). Mares seldom develop urethral obstruction due to a much shorter, nontortuous, and more distensible urethra. Patency of the urethra may also be affected by neoplasia, congenital disorders, edema, inflammation, and trauma. Should complete urethral obstruction persist, bladder rupture is likely to develop and can be confirmed by abdominal ultrasonography and paracentesis of urine in the abdomen.

Urethral obstruction is best diagnosed by careful urethroscopy. Therapeutic urethroscopy may be used for direct retrieval of stones, thereby minimizing potential trauma, mucosal irritation, and stricture formation. Retrieval of urethroliths that are large and immovable may be performed by a perineal urethrostomy or a distal urethrotomy. However, this may lead to urethral stricture formation and urine fistulization. Urethroscopic lithotripsy can be considered if instrumentation is available. Radial extracorporeal shockwave therapy may be also considered for urethrolith fragmentation in the male horse.[28] In horses with urothelial tumors, ureteroscopy will allow improved visualization and treatment by resection using a Nd:Yag laser. Larger obstructive tumors such as squamous cell carcinoma affecting both the penis and prepuce may be treated by surgical resection with topical application of 5-fluorouracil.

The spiculated calculus caused severe mucosal irritation and damage. **B**, Urethroscopic image of an impacted stone in a 15-year-old gelding with intermittent colic and hematuria.

Idiopathic Renal Hematuria

Harold C. Schott II • Alexandra J. Burton

Idiopathic renal hematuria (IRH) is a syndrome characterized by sudden onset of gross, often life-threatening hematuria.[1] Hemorrhage arises from one or both kidneys and is manifested by passage of large blood clots in urine. Endoscopic examination of the urethra and bladder usually reveals no abnormalities of these structures, but blood clots may be seen exiting one or both ureteral orifices. Although a definitive cause of renal hemorrhage may be established in some horses (e.g., renal adenocarcinoma, arteriovenous or arterioureteral fistula, renal pseudoaneurysm), the disorder is termed *idiopathic* when a primary disease process cannot be found.[2-5] Both genders, a wide age range, and several breeds of horses (including donkeys and a mule) have been affected. However, more than 50% of animals with IRH have been Arabians.

Use of the term *idiopathic renal hematuria* to describe this syndrome of horses was adopted from its use in human patients and dogs with severe renal hemorrhage.[6-10] *Benign essential hematuria* and *benign primary hematuria* are other terms that have been used to describe less severe hematuria that is not associated with trauma or other obvious causes of hematuria.[6-10] In humans and dogs, hematuria is more often a unilateral than a bilateral problem, similar to what has been observed in the few affected horses. The pathophysiology remains poorly understood, but macroscopic hematuria has been associated with immune-mediated glomerular damage (e.g., acute postinfectious glomerulonephritis [GN], membranoproliferative GN, IgA nephropathy, or Berger disease), thin basement membrane nephropathy, and the loin pain–hematuria syndrome in human patients. One of the authors (AJB) has seen a case of IRH in a donkey in conjunction with simultaneous onset of severe laminitis. The donkey recovered over the course of 6 weeks with extensive supportive care.

Hematuria and pigmenturia can accompany several systemic diseases in horses.[11] However, patients affected with IRH appear to have spontaneous severe hematuria, in the absence of any other signs of disease. Although one report suggested that severe renal hemorrhage was caused by pyelonephritis, supportive data were lacking.[12] In cases managed by the author (HCS), neither UTI nor urolithiasis were detected, and the magnitude of hematuria often resulted in the need for repeated

VetBooks.ir

blood transfusions. As with hemorrhage associated with guttural pouch mycosis, the syndrome may produce episodic hemorrhage. Initially, hemorrhage is noted by finding a large amount of clotted blood in stall bedding or in the pasture. However, other client complaints (e.g., depression, anorexia, weight loss) are typically absent. Examination may reveal dried blood at the end of the penis or in the sheath of males or on the vulvar lips and between the hindlimbs of mares. In both genders, neoplasia of the external genitalia or urinary tract is an important differential diagnosis, and in mares, varicosities in the area of the vestibulovaginal sphincter also must be considered, especially in multiparous mares. When blood is not detected in the sheath or vulvar areas, further evaluation may be unrewarding because the renal bleeding may cease spontaneously. In the absence of positive urine culture results, bleeding has anecdotally been attributed to cystitis and pyelonephritis, because hemorrhage stops during a course of antimicrobial therapy. More likely, spontaneous resolution has occurred. The magnitude of hematuria is considerably greater with IRH than most UTIs, pyuria is absent, and urine culture results are negative. In the author's (HCS) experience, one or two initial episodes of hemorrhage are followed by a more severe hemorrhagic crisis within months to 2 years after observation of the initial bleeding episode. Signs of colic have been notably absent in the history of affected horses.

Diagnosis

A diagnosis of IRH is made by exclusion of systemic disease, other causes of hematuria, and alterations in hemostasis. Physical examination may reveal tachycardia, tachypnea, and pale membranes, consistent with acute blood loss. Rectal palpation may reveal an enlarged, irregular bladder resulting from the presence of blood clots. Azotemia is uncommon. Endoscopic examination is important to document that hematuria is originating from the upper urinary tract and to determine whether hemorrhage is unilateral or bilateral (Fig. 34.13). Repeated examinations may be required to answer the latter question. Ultrasonographic imaging is necessary to rule out nephrolithiasis or ureterolithiasis and may occasionally reveal a distended vascular space or renal vascular anomaly as the cause of hematuria. Renal scintigraphy can be a useful technique in affected horses, providing semiquantitative information about renal function when a nephrectomy is being considered. Renal biopsy and immunofluorescence (IF) staining may assist in documenting immune-mediated glomerular injury, but the significance of such results is not well understood at this time.

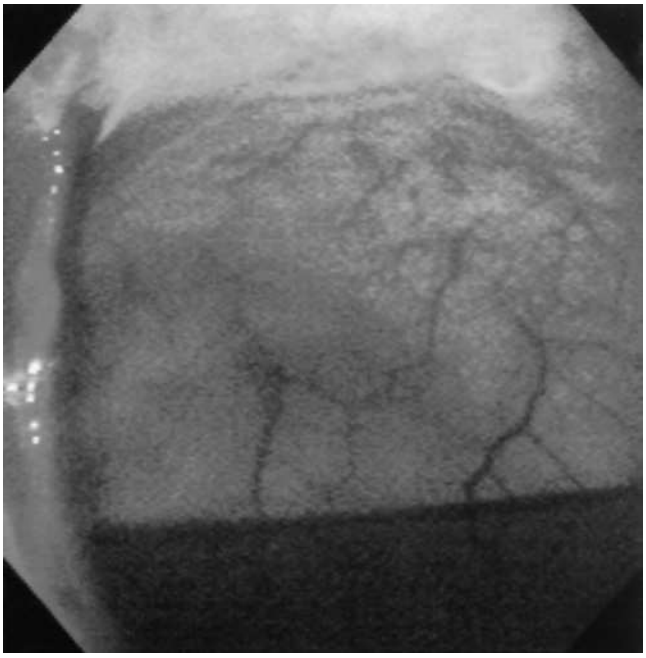

FIG. 34.13 Cystoscopic image of a 19-year-old Arabian mare with idiopathic renal hematuria. A large blood clot can be seen exiting the left ureter, whereas the right ureteral opening appears normal.

Treatment

Treatment for IRH consists of supportive care for acute blood loss, including blood transfusions. Medications intended to promote hemostasis (e.g., α-aminocaproic acid, formalin) have also been administered, but their efficacy has not been validated. Because the condition may be self-limiting in some patients, supportive care is warranted. With severe and recurrent hematuria of unilateral renal origin, a nephrectomy may be indicated, but owners should be warned of the risk of hematuria developing in the contralateral kidney. In the author's (HCS) experience, risk of contralateral renal bleeding appears to be greater in the Arabian breed. Recently, topical sclerotherapy of the renal pelvis using 5% povidone iodine ± silver nitrate via ureteral stents has been reported as a treatment for IRH in dogs.[13,14] This therapy shows some promise, as it was successful in the short term, but longer-term follow-up and a larger case cohort are needed to fully evaluate this technique.[13,14]

Urethral Hemorrhage

Harold C. Schott II • Alexandra J. Burton

Although a recognized cause of hemospermia in stallions, defects or tears of the proximal urethra at the level of the ischial arch are a more recently described cause of hematuria in geldings.[1-4] Urethral defects typically result in hematuria at the end of urination, in association with urethral contraction. Affected horses generally void a normal volume of urine that is not discolored. At the end of urination, a series of urethral contractions results in squirts of bright red blood. Occasionally, a smaller amount of darker blood may be passed at the start of urination. In most cases, the condition does not appear painful or result in pollakiuria. Interestingly, the majority of affected stallions with hemospermia and geldings with hematuria have been Quarter Horses or Quarter Horse crosses that have been free of other complaints. Treatment with antibiotics for a suspected cystitis or urethritis has been routinely unsuccessful, although hematuria appears to resolve spontaneously in about 50% of affected horses. Because the defects are difficult to detect without use of high-resolution videoendoscopic equipment, previous reports of urethral bleeding have been attributed to urethritis or hemorrhage from "varicosities" of the urethral vasculature. However, vasculature underlying the urethral mucosa becomes quite prominent when the urethra is distended with air during endoscopic examination, especially in the proximal urethra (to the point that blood can be seen flowing in the submucosal vasculature). Thus, it would be logical to suspect that hemorrhage could arise from an apparent urethritis or urethral varicosity, although these problems are poorly documented in horses.

Examination of affected horses is often unremarkable, and laboratory analysis of blood reveals normal renal function, although mild anemia can be an occasional finding. Urine samples collected midstream or by bladder catheterization appear grossly normal. Urinalysis may have normal results, or an increased number of red blood cells may be found on sediment examination, a finding that would also result in a positive reagent strip result for blood. Bacterial culture of urine yields negative results. The diagnosis is made with endoscopic examination of the urethra, during which a lesion is typically seen along the dorsocaudal aspect of the urethra at the level

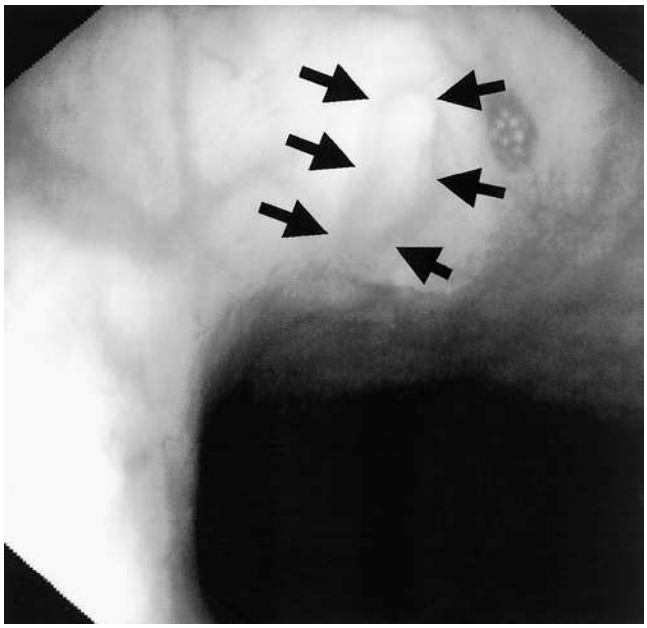

FIG. 34.14 Endoscopic image of the proximal urethra of a gelding with hematuria at the end of urination. A urethral defect can be seen between the *arrows* along the caudal aspect of the urethra as it passes dorsocranially over the pelvic brim.

of the ischial arch. External palpation of the urethra in this area is usually unremarkable but can assist in localizing the lesion, because external digital palpation can be seen through the endoscope. With hematuria of several weeks' duration, there is little evidence of inflammation; rather, the lesion appears as a fistula communicating with the vasculature of the corpus spongiosum penis (Fig. 34.14).

Although the pathophysiology of this condition remains unclear, it has been speculated that the defect is the result of a "blowout" of the corpus spongiosum penis (cavernous vascular tissue surrounding the urethra) into the urethral lumen.[3] Contraction of the bulbospongiosus muscle during ejaculation causes a dramatic increase in pressure in the corpus spongiosum penis, which is essentially a closed vascular space during ejaculation. The bulbospongiosus muscle also undergoes a series of contractions to empty the urethra of urine at the end of urination, so the defect into the urethra may develop by a similar mechanism in geldings. Once the lesion has been created, it is maintained by bleeding at the end of each urination, and the surrounding mucosa heals by formation of a fistula into the vascular tissue. An explanation for the consistent location along the dorsocaudal aspect of the urethra at the level of the ischial arch has not been documented but may be related to the anatomy of the musculature supporting the base of the penis and an enlargement of the corpus spongiosum penis in this area. Narrowing of the lumen at the distal extent of the ampullar portion of the urethra may also contribute to the location of the defects. An anatomic predisposition in Quarter Horses has not been documented but could be speculated on the basis of an apparent increased risk in this breed.

Because hematuria may resolve spontaneously, no treatment may be initially required. Resting of breeding stallions for several months may facilitate healing of the rent and cessation of recurrent bleeding. If hematuria persists for more than a month or if significant anemia develops, surgical intervention is indicated. Surgical approaches are aimed at reducing decreasing pressure within the corpus spongiosum, with the goal of reducing tension on the urethral rent site and thus allowing it to heal.[3] A temporary subischial "incomplete" urethrotomy has been successful in some affected geldings. After sedation and epidural or local anesthesia, a catheter is placed in the urethra and a vertical incision is made into the corpus spongiosum penis but not the urethral lumen. The surgical wound requires several weeks to heal, and moderate hemorrhage from the corpus spongiosum penis is apparent for the first few days after surgery. Hematuria should resolve within a week after this procedure. Additional treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for 7 to 10 days. Most recently, a case series (1989 to 2013) of 33 male horses (stallions and geldings) with urethral rents treated with perineal urethrotomy (PU) or corpus spongiotomy (CS) has been described.[4] Both PU and CS were successful in the long term for resolving hematuria in horses with urethral rents but did not always resolve hemospermia in stallions.[4] Repair of a urethral defect using subischial urethrotomy and a buccal mucosal urethroplasty has been described as a successful treatment for recurrent hemospermia in one stallion.[5]

Polyuria and Polydipsia

Harold C. Schott II • Theresa L. Ollivett • Alexandra J. Burton

Polyuria and *polydipsia* (PU/PD) are defined as urine output in excess of 50 mL/kg/day (PU) and fluid intake of more than 100 mL/kg/day (PD).[1,2] These values equate to production of 25 L of urine and consumption of 50 L of water for a 500-kg horse. It is important to remember that urine production and water consumption vary hugely with age, diet, workload, environmental temperature, prolonged periods of water deprivation, and gastrointestinal water absorption.[2-4] For example, urine production increases by 50% to 100% when the diet is changed from a grass to legume hay.[5] Similarly, horses in heavy exercise, hot climates, or with chronic diarrhea may have water intake in excess of 100 L/day yet produce normal volumes of urine. Young foals urinate much more frequently than adult horses due to a predominantly fluid (milk) diet. The major causes of PU/PD in horses include chronic renal failure, PPID, and primary or "psychogenic" polydipsia. Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus (DI), diabetes mellitus (DM), sepsis/systemic inflammatory response syndrome (SIRS), and iatrogenic causes (e.g., α_2-agonists, corticosteroids, diuretics).[2]

Polyuria/Polydipsia With Pituitary Pars Intermedia Dysfunction

Adenoma of the pituitary pars intermedia results in PPID (formerly termed equine Cushing's disease), with elevated adrenocorticotrophic hormone (ACTH) and hyperadrenocorticism. The syndrome has been well recognized and clinically characterized in equids for more than 40 years and is common in older horses (see Chapter 41).[6,7] Generally, the most consistently reported clinical signs in horses are delayed shedding, hirsutism, and muscle wasting. Although a degree of PU/PD is nearly always present in horses with uncontrolled PPID, it may not be readily noted or reported by the owner/trainer. This is because PU/PD associated with PPID is generally of lesser volume than that observed with psychogenic PD or DI and also because if the horse is out with others in a pasture, PU/PD is difficult to assess.

Several mechanisms may lead to PU/PD in horses with PPID. Firstly, PU may be the result of an osmotic diuresis. The renal threshold for glucose in horses (≈150 to 175 mg/dL) appears to be lower than in small animals.[8] When plasma glucose concentration exceeds the renal threshold, the resultant glucosuria can lead to an osmotic diuresis. Although often implicated as the cause of PU/PD in horses with PPID,

VetBooks.ir

hyperglycemia and glucosuria are not always present with the disease and are often only found in more advanced cases or those with concurrent equine metabolic syndrome (EMS). A second mechanism implicated in the development of PU with PPID is antagonism of the action of antidiuretic hormone (ADH) on the collecting ducts by excess cortisol. Vasopressin, arginine vasopressin (AVP), and argipressin are all other names for ADH. Although frequently cited as the mechanism of PU in canine hyperadrenocorticism, experimental evidence to support this mechanism is lacking in both dogs and horses. There is considerable species heterogeneity in the effects of corticoids on ADH activity, and in some species, a primary dipsogenic (thirst-stimulating) effect may be more important. Growth of the adenoma (as PPID becomes more advanced) may lead to impingement on the posterior pituitary and hypothalamic nuclei (located immediately dorsal to the pituitary gland), the sites of ADH storage and production, respectively. Decreased ADH production and release would result in central DI as a third mechanism for PU. Finally, if not body clipped, horses with hirsutism will become excessively hot and sweaty in warm climates or during exercise and thus PD may develop as a normal physiologic response to fluid loss in sweat. Therefore, PU/PD seen in horses with PPID is likely the combined result of several mechanisms.

Primary Psychogenic Polydipsia

Primary, or "psychogenic," PD is rare but probably the most common cause of PU/PD in adult horses for which clients will have a primary complaint of excessive urination.[2,4,9] This is because the magnitude of their PU/PD is typically dramatic, with owners reporting that horses drink two to three times more water than other horses on the premises, and stalls can be flooded with urine. Horses with this problem are generally in good body condition and not azotemic but will be hyposthenuric with a USG <1.005.[2] In some horses, primary PD appears to be a stable vice that reflects boredom, whereas in others it may develop after a change in environmental conditions, stabling, diet, or medication administration. Anecdotally, it has been reported to be more common in southern states of the United States during periods of high temperature and humidity.

The diagnosis of primary PD is made by exclusion of renal failure, PPID, diabetes insipidus (DI), and chronic, persistent hyperglycemia. Other factors (e.g., salt supplementation, medication) must also be excluded. Exclusion of DI is achieved by demonstrating urinary-concentrating ability after water deprivation.[10,11] After water deprivation of sufficient duration (12 to 24 hours) to produce a 5% loss of body weight, USG should exceed 1.025 in normal horses. In horses with long-standing PU, the osmotic gradient between the lumen of the collecting tubule and the medullary interstitium may be diminished (medullary washout). In these horses, insensitivity to ADH activity may fail to increase USG over 1.020. Consequently, in horses with primary PD of several weeks' duration that fail to concentrate their urine (>1.020 USG) after 24 hours of water deprivation, a modified water deprivation test may be tried. During the modified water deprivation test, water intake is restricted to about 40 mL/kg/day, for 3 to 4 days. By the end of this period, USG should exceed 1.025 in a horse that has had medullary washout. If USG remains in the isosthenuric range (1.008 to 1.014), the polyuric horse should be further evaluated for early chronic renal failure, in which the ability to concentrate urine may be compromised before the onset of azotemia. In theory, this could only occur when 65% to 75% of functional nephrons have been lost. Subtle signs of decreased performance and mild weight loss would also support early renal failure.

Management of horses with primary PD is empirical. Because primary PD is a diagnosis of exclusion, once it has been established that the horse does not have significant renal disease, it is safe to continue restricting water intake to meet maintenance, work, and environmental requirements of the horse. In addition, steps should be taken to improve the attitude of the horse by reducing boredom or any other potential stress trigger factors. Increasing the amount of exercise and turning the horse out to pasture are possible options, along with providing a companion or diversions in the stall. Increasing the frequency of feedings or amount of roughage in the diet may increase time spent eating and thereby reduce the habitual drinking. That said, the more roughage a horse eats, the more it needs to drink; thus, slow hay feeders or nibble nets might be preferable to free-choice loose hay.

An occasional case of primary PD may be attributed to "psychogenic salt eating" (excessive salt consumption) and is manifested by an increased fractional sodium clearance.[3,4] However, salt intake may have to exceed 5% to 10% of dry matter intake before significant PU/PD develops.[12,13] Successful management consists of limiting water intake and preventing or limiting access to excess salt. However, this must be balanced against any salt loss via sweat due to very high ambient temperatures and exercise. In these situations the horse may need to be allowed some (regulated) salt and mineral lick consumption to replace high losses in sweat. In addition, in one author's experience (AJB) removal of a salt block/lick from a psychogenic salt eater can lead to consumption of excessive amounts of soil/dirt instead, as salt is a natural component of soil. This could potentially lead to sand colic, dependent on the soil composition.

Diabetes Insipidus

Diabetes insipidus (DI) is generally rare in horses. It may be divided into two types: inadequate secretion of ADH (neurogenic [central] DI) or decreased sensitivity of the renal epithelial cells of the collecting ducts to circulating ADH or loss of ADH receptors on these cells (nephrogenic DI).[1,2,14] With both forms of DI, dramatic PU/PD may be reported and affected animals fail to concentrate urine in the face of water deprivation.

In human patients, neurogenic DI is the more common form of DI, with both hereditary and acquired forms described.[15] In two well-documented cases of neurogenic DI diagnosed in adult horses, neither horse could concentrate urine in response to water deprivation, but administration of exogenous ADH resulted in an increase in USG and a decrease in urine volume.[16,17] In a Welsh pony in which the condition was considered idiopathic, the absence of an increase in plasma ADH concentration after water deprivation further supported a diagnosis of neurogenic DI.[16] Acquired neurogenic DI secondary to encephalitis was confirmed histologically in the other horse.[17] Presumed congenital neurogenic DI has also been described in a 10-day-old Friesian colt with tachypnea and polyuria, documented by a modified fluid deprivation test and a rise in plasma ADH (vasopressin) after treatment with exogenous synthetic ADH (desmopressin).[18] Neurogenic DI has also been reported in a 20-year-old gelding with PPID and PU/PD that was normoglycemic, did not respond to a water deprivation test, but did respond to desmopressin administration.[19]

Nephrogenic DI is most often a familial disorder in humans, with an X-linked semirecessive mode of inheritance.[15] Therefore, the disorder is carried by females and expressed in male offspring. Nephrogenic DI has been described in two full sibling Thoroughbred colts, suggesting that an inherited form may also occur in horses.[20] These two colts could not increase USG in response to water deprivation, although they did show appropriate increases in plasma ADH concentration. Nephrogenic DI has also been reported in a 14-year-old gelding with PU/PD and urinary incontinence.[21] In all three cases, a lack of response to exogenous ADH administration confirmed resistance of the renal collecting ducts to ADH. Nephrogenic

DI can also develop in association with drug therapy (e.g., lithium or tetracyclines in humans) or a variety of metabolic, infectious, or mechanical (postobstruction) disorders. Anomalous or neoplastic disorders resulting in structural deformation of the kidneys are other potential causes of nephrogenic DI.[15]

After determining that an equine patient with PU/PD is not azotemic, the initial diagnostic test to differentiate DI from primary PD is a water deprivation test.[2,14] However, horses with suspected DI should be monitored closely during water deprivation because horses that do have DI will continue to excrete excess water in the face of water deprivation. As a result, they may become substantially dehydrated (10% to 15%) within the first 12 hours of water deprivation. When a patient fails to concentrate urine during water deprivation, neurogenic DI can be differentiated from nephrogenic DI by measuring plasma ADH (AVP) concentration or by administration of synthetic ADH (aqueous synthetic vasopressin or 1-desamino-8-d-arginine vasopressin [DDAVP or desmopressin] may be used).[2,14] After administration of exogenous ADH, if USG rises in response, then this indicates neurogenic DI, whereas a lack of urine concentration indicates nephrogenic DI.[2,14,16-21]

Treatment of DI is directed at managing PU/PD. With neurogenic DI, hormone replacement therapy with desmopressin (DDAVP), a potent ADH analog administered as a nasal spray or orodispersible tablet (humans), eyedrops (dogs) or orally (cats), has been a successful treatment for neurogenic DI.[22,23] There is a report of a 10-day-old Friesian colt with suspected neurogenic DI being successfully temporarily treated using human desmopressin acetatehydrate nasal drops administered as eye drops.[18] With nephrogenic DI, hormone replacement therapy is ineffective, and the only practical form of treatment for many years has been to restrict sodium and water intake and administer thiazide diuretics. The latter treatment may reduce PU by 50% in human and canine patients.[15,24] Thiazide diuretics inhibit sodium reabsorption in the distal tubule (the diluting segment of nephron) and increase solute delivery to the collecting duct, but the mechanism by which such therapy benefits patients with nephrogenic DI is not well understood. Administration of prostaglandin inhibitors (e.g., NSAIDs) or amiloride may also decrease PU in patients with nephrogenic DI. Interestingly, in humans, NSAIDs reduce urine volume further if used in combination with thiazide diruretics and probably work by decreasing renal blood flow and glomerular filtration rate. Amiloride is a sodium channel blocker and is thought to act similarly to the thiazide diuretics. No reports have documented the use of these treatments for nephrogenic DI in horses.

Diabetes Mellitus

Diabetes mellitus (DM) is a state of chronic hyperglycemia usually accompanied by glucosuria. The resultant osmotic diuresis by glucose causes PU/PD. In one horse, DM resulted in water intake in excess of 80 L/day.[25] Although generally rare in horses, there are several reports of type I and type II (more common) DM.[25-29] Lately, equine DM has received more attention, probably due to increasing recognition and understanding of the equine endocrinopathies equine metabolic syndrome (EMS) and PPID, both of which may result in persistent chronic hyperglycemia in a subset of severe cases. In EMS, peripheral insulin resistance and subsequent hyperinsulinemia are classic features. Occasionally, the pancreas becomes "exhausted" with pancreatic ß cell dysfunction (inadequate insulin production), with the result being persistent hyperglycemia and DM.[29,30] Blood glucose concentrations are often mildly to moderately elevated in horses with PPID due to elevated ACTH and cortisol, but these horses do not usually develop chronic persistent hyperglycemia that exceeds renal threshold until PPID is quite advanced. However, if the horse has prior and/or concurrent EMS, then significant, persistent hyperglycemia is much more likely to occur and DM to develop. As discussed previously, PPID may also lead to PU/PD by a variety of other mechanisms.

Iatrogenic Polyuria

The most obvious iatrogenic cause is fluid therapy, for which PU is a desired response. Diuretics such as furosemide also cause intentional PU in horses. Polyuria has also been observed with exogenous corticosteroid administration, although the mechanism remains unclear. Humans and dogs appear to experience a potent thirst response to exogenous corticosteroids, so PD may be an important cause of the PU observed. Further, in horses receiving chronic dexamethasone treatment for immune-mediated disorders, profound glucosuria (2 to 3 g/dL) may be observed and could lead to an osmotic diuresis. A transient diuresis or PU accompanies sedation with the α_2-agonists xylazine and detomidine, even when water has been withheld for 24 hours previously.[31,32] Although these agents also cause transient hyperglycemia and occasional glucosuria, a more likely mechanism for PU is existence of α_2-adrenoreceptors on collecting duct epithelial cells. Activation of these receptors is another mechanism by which the action of ADH can be antagonized.[33]

Renal Tubular Acidosis

Luis G. Arroyo • Krista E. Estell • Monica Aleman

Renal tubular acidosis (RTA) occurs due to improper functioning of the renal tubules and is characterized by hyperchloremic metabolic acidosis with a normal anion gap. It can occur primarily, from genetic or idiopathic causes, or secondarily, from underlying disease processes or as a complication of drug administration. Drug-induced RTA has been well documented in human patients following administration of certain antimicrobials that are also used in horses, including amphotericin B, trimethoprim-sulfamethoxazole, tetracyclines, gentamicin, cephalosporins, carbonic anhydrase inhibitors, lithium carbonate, and other organic compounds. Carbonic anhydrase deficiency was documented in a Friesian stallion, but the inciting cause in most affected horses has not been determined.[1] Other predisposing causes suggested in horses include pyelonephritis, hyperparathyroidism, and hypervitaminosis D.[2]

Two types of RTA have been reported in dogs, cats, and horses, and both types result in a hyperchloremic metabolic acidosis with a normal anion gap.[3-6] Type I develops when *distal* tubular excretion of hydrogen ions (H^+) is compromised, and affected patients are unable to produce acidic urine. Type II results from decreased *proximal* tubular bicarbonate resorption and subsequent urinary loss of bicarbonate. Normally, H^+ is excreted when bicarbonate is reabsorbed in the proximal tubules. Thus, acidosis with both type I and type II RTA results from decreased H^+ excretion. Hyperchloremia develops as a result of an increased renal absorption of chloride ions subsequent to bicarbonate loss. Type I RTA results in more severe acidosis and electrolyte abnormalities, since the distal tubule is responsible for maximal acidification of the urine. In the absence of H^+ excretion, potassium ions (K^+) are excreted in exchange to maintain electroneutrality, which can result in severe hypokalemia. Mixed type I and II RTA has been documented in horses and is notably refractory to treatment, likely because of widespread tubule dysfunction.[7] Type II RTA is often a self-limiting problem but may be accompanied by more widespread proximal tubular dysfunction known as *Fanconi syndrome*, which is characterized by defective resorption of glucose, amino acids, phosphate, potassium, sodium, calcium, magnesium, uric acid, and other organic acids. As with RTA, Fanconi syndrome may be a primary (inherited) disorder or can develop secondary to renal, metabolic, and autoimmune

diseases or drug administration.[4-6] A transient Fanconi syndrome has been reported in two unrelated adult Quarter Horses.[8]

Equine RTA has been sporadically reported, mostly in North America and Europe. Across the literature, there is no obvious sex predilection. Quarter Horses (QHs) ($n = 11$), QH-crosses ($n = 4$), Friesians ($n = 6$), and Arabians ($n = 5$) accounted for approximately 70% of RTA cases.[1,2,7,9-18] Affected horses range in age from 2 months to 27 years. Several genetic mutations in ion transport genes have been associated with heritable forms of RTA in humans, but there is no documented evidence of an inherited form in horses.

Typical presenting complaints and clinical signs include dullness, anorexia or poor appetite, weight loss, poor performance, weakness, decreased borborygmi and fecal output, and mild colic signs of variable duration. Vital parameters are generally within normal ranges, and horses do not appear clinically dehydrated. Hematologic and clinical chemistry abnormalities are usually mild or within reference ranges, with the exception of electrolyte concentrations and acid-base balance. Electrolyte concentrations and acid-base balance abnormalities can be profoundly abnormal but are variable between cases. A severe metabolic acidosis (venous blood pH range 6.98 to 7.25), low plasma bicarbonate concentration (<13 mEq/L), and hyperchloremia (serum chloride concentration of 105 to 124 mEq/L) are characteristic for horses with RTA. A compensatory decrease in carbon dioxide partial pressure (P_{CO_2}) is also observed in most horses. Hypokalemia (and total body potassium depletion) due to the combined effects of anorexia and ongoing loss of potassium in urine may occur in horses, particularly with type I RTA.

Mild to moderate azotemia—persistent in some cases—may be detected in horses with RTA, particularly those dehydrated at presentation or with renal damage. Affected horses may also have evidence of renal tubular damage detected on urinalysis (e.g., pigmenturia, glucosuria), and USG may be low. Despite profound metabolic acidosis, urine pH is generally neutral to alkaline. Ultrasonographic examination has shown hyperechoic kidneys in some cases, and several histopathologic abnormalities in renal biopsy samples have been found, generally showing tubulointerstitial disease.

Differentiation of type I from type II RTA in human and canine patients is most easily accomplished by assessing urine pH; it remains neutral to alkaline with type I and should be neutral to acidic with type II.[4-6] Most horses with RTA have had neutral to alkaline urine, but because herbivores normally have alkaline urine, this distinction may not be useful. A few reports have described horses with acidic urine, supporting type II RTA, but urine pH values near neutral are difficult to interpret.[12-14] Assessment of all laboratory abnormalities (Table 34.1), along with additional testing (e.g., ammonium chloride challenge, urinary ammonium concentration, administration of thiazide diuretics), may allow further discrimination between type I and type II RTA.[9,13,19] Regardless of RTA type, however, the treatment approach and the prognosis are similar for both in horses.

TABLE 34.1

Classification of Type I and Type II Renal Tubular Acidosis

	Distal or Type I	Proximal or Type II
Acidosis	Severe	Self-limiting
Hypokalemia	Severe	Mild to moderate
Serum phosphate	Normal	Low
Urine pH	Neutral to alkaline	Neutral to acidic

Treatment consists primarily of intravenous (IV) and oral administration of sodium bicarbonate ($NaHCO_3$). For initial correction of acidosis, IV $NaHCO_3$ must be administered aggressively, and large amounts (3000 to 9000 mEq) are often required to return plasma bicarbonate concentration to values above 20 mEq/L. Half the estimated bicarbonate deficit is generally replaced with IV $NaHCO_3$ over 6 to 12 hours, and the remaining deficit is replaced with a combination of IV and oral $NaHCO_3$ (initial oral dose: 100 to 150 g twice daily; 1 g contains 12 mEq $NaHCO_3$). Close monitoring of serum electrolyte concentrations and acid-base balance is required to adjust the rate of IV $NaHCO_3$ replacement. Marked improvement in attitude and appetite usually accompanies correction of the acidosis, but relapse after discontinuation of IV therapy can occur. Continued oral administration of $NaHCO_3$ for months to years may be required for maintenance of a normal acid-base status. Because potassium excretion is proportional to bicarbonate delivery to the distal tubule, initial correction of acidosis with $NaHCO_3$ promotes kaliuresis and may exacerbate potassium depletion. Therefore, concurrent supplementation with IV or oral potassium chloride (KCl) is advisable during initial correction of the acidosis. Complications associated with rapid correction of acidosis have not been described, but transient diarrhea ± mild colic may develop if large quantities of $NaHCO_3$ (>200 g) are given by nasogastric tube to horses that are completely anorectic.

Recurrence of metabolic acidosis also can occur when oral $NaHCO_3$ is discontinued, especially in horses that have evidence of renal damage. Relapses can be immediate or delayed for weeks to months. Reinstitution of $NaHCO_3$ supplementation usually corrects the metabolic abnormalities and accompanying depression and anorexia. The short-term prognosis for horses with RTA is good, with some horses reported to recover and compete successfully, but the long-term prognosis is still largely undocumented.[2,9,10,20]

Bladder Rupture in Adult Horses

Thomas J. Divers • Dominic R. Dawson-Soto • Alexandra J. Burton

Although more common in foals, on rare occasions, bladder rupture can also occur in adult horses. The problem can develop in association with urolithiasis, foaling, prolonged recumbency, or trauma.[1-11] Two cases of ureteral tears have also been reported in adult horses.[12,13] Bladder rupture in mares occurs most commonly due to foaling trauma.[1-5] In male horses, urolithiasis is the most common cause of bladder rupture.[7-9] Bladder rupture has also been reported as a complication following endoscopic electrohydraulic shockwave lithotripsy for treatment of urolithiasis.[10] There is one report of bladder rupture in a 2-year-old horse that had previously had a bladder rupture repair as a foal, the bladder retorn at the same site (old surgical scar) after recovery from routine cryptorchid castration.[11]

Following bladder rupture, azotemia develops and affected horses become depressed and inappetent. Clinical signs may not be apparent for several days, depending on how large the tear is and how fast urine leaks into the abdomen. Stranguria may be observed depending on the cause of the rupture. If severe, uroabdomen may produce signs of abdominal discomfort, tachycardia, and abdominal distention. Abdominal distention may not be as apparent in adult horses as in foals. The diagnosis is based on history, rectal examination findings, laboratory results, and findings on urinary US or cystoscopic examination. Postrenal azotemia develops within 24 hours after rupture and is accompanied by hyponatremia and hypochloremia. Unlike uroperitoneum in neonates, hyperkalemia is not a consistent finding. Transabdominal US examination of the abdomen reveals a large amount of free peritoneal fluid. Abdominocentesis

yields a peritoneal fluid with a creatinine concentration that is twofold or greater than that of serum; this finding confirms a diagnosis of uroabdomen. Detection of calcium carbonate crystals on cytologic examination of peritoneal fluid is also diagnostic for uroperitoneum. Endoscopic examination of the bladder should allow determination of the location and extent of the bladder tear. Rarely, uroperitoneum may also develop in some horses without full-thickness disruption of the bladder wall, and it is difficult to establish definitively the cause of uroperitoneum in these cases.[9]

Surgical repair is indicated in horses with large tears in the ventral half of the bladder. In mares, standing surgical repair may be feasible.[3-5] In patients with small dorsal tears or incomplete tears, use of an indwelling bladder catheter (closed system) to keep the bladder small may allow the tear to heal without surgery.[7,9] A temporary ureteral stent may be used to allow healing of ureteral tears.[12] Before surgery, IV fluids (0.9% NaCl) should be administered to correct dehydration, and if severe hyperkalemia is present, $NaHCO_3$ and/or 5% dextrose administered IV to drive potassium intracellularly. Broad-spectrum antibiotics should be administered as prophylaxis against sepsis. If the abdomen is distended, urine accumulated in the abdomen should be removed (e.g., by placement of chest tube or other large catheter through the ventral abdominal wall) before general anesthesia is induced to avoid further compromising respiration.

Urinary System Disorders in the Foal

Thomas J. Divers • Dominic R. Dawson-Soto • Lisa E. Fultz

Umbilical disorders of the neonatal foal, including patent urachus, urachal infections, and omphalitis, are discussed in detail in Chapter 17.

Uroperitoneum

BLADDER RUPTURE. The most common bladder disorder in otherwise healthy newborn foals is bladder rupture.[1-3] Foals aged less than 1 week are the most commonly affected, with an incidence of 0.2% to 2.5%.[4] There may be an increased incidence in colts, but some reports fail to support this.[4,5] In septic foals, bladder necrosis leading to leakage of urine may occur, possibly secondary to hematogenous spread of bacteria.[6] *E. coli* was the most common bacteria isolated from both peripheral blood and tissue sample in septic foals with ruptured bladders.[4] Focal necrotizing cystitis leading to tiny focal bladder perforations, uroperitoneum, and peritonitis has been reported in association with septic omphalitis in a 15-day-old foal, and *Clostridium perfringens* urachal infection was identified as a cause of uroperitoneum in two neonatal foals.[7,8] Clinical signs include stranguria and repeated posturing to urinate during the first few days of life. Urine accumulates in the abdomen, typically leading to depression and abdominal distention between days 2 to 4 of life. Repeated posturing and stranguria can easily be misinterpreted as tenesmus associated with meconium impaction. Further, affected foals may continue to void small volumes of urine, so establishing a diagnosis of ruptured bladder can initially be challenging until more obvious signs of uroperitoneum (e.g., decreased nursing, abdominal distention) develop.

Laboratory findings in foals with uroperitoneum include hyponatremia, hypochloremia, hyperkalemia, and azotemia.[1-3,9,10] Foals receiving continuous fluid therapy before the diagnosis may not exhibit typical electrolyte changes, and instead suspicion of uroperitoneum should be raised with other signs such as decreased urinary output, abdominal distention, weakness, or other changes in clinical condition. Occasionally, a foal may also develop intermittent fine muscle tremors or a cardiac arrhythmia resulting from these electrolyte alterations, especially hyperkalemia.[10] Transabdominal ultrasonographic examination usually reveals a large quantity of free fluid in the abdominal cavity, but occasionally the bladder can still appear fluid filled, depending on the size of the leak (Fig. 34.15, *A* and *B*). A peritoneal fluid creatinine–to–serum creatinine ratio >2 : 1 or the presence of calcium carbonate crystals in the abdominal fluid confirms uroperitoneum.[1-3,9]

FIG. 34.15 **A,** Ultrasonographic appearance of a normal bladder in a foal. **B,** Ultrasonographic image of a ruptured bladder in a foal. The increased free peritoneal fluid is outlining the bladder and a loop of small intestine. The creatinine within the fluid was greater than twice that of the serum, consistent with uroabdomen.

Treatment of bladder rupture includes surgical closure of the defect, supportive care, and broad-spectrum prophylactic antibiotics for 3 to 7 days postoperatively.[1,2,6,11] An emergency surgical procedure is usually not required, and in most cases, postponement of surgery for several hours until electrolyte abnormalities are partially corrected (most notably correction of hyperkalemia to a serum concentration <6.0 mEq/L) is recommended. This can usually be accomplished by IV administration of 1 to 3 L of a 0.9% NaCl/5% glucose solution. Treatment with insulin should be avoided unless hyperkalemia is causing significant electrocardiographic (ECG) abnormalities

and response to initial fluid therapy is poor. With marked hyperkalemia or abdominal distention causing respiratory embarrassment, slow drainage of urine from the abdomen (e.g., by chest tube or 10- to 14-gauge IV catheter) may be necessary before induction of anesthesia; IV fluid support should be provided during drainage. Despite significant azotemia in some affected foals, use of aminoglycoside antibiotics is generally safe because the azotemia is postrenal rather than reflecting intrinsic renal disease. In most cases, placement of a urinary catheter to maintain an empty bladder for the initial 2 postoperative days is unnecessary, but careful monitoring of urine output along with serial abdominal ultrasonography is recommended if a catheter is not placed. Postoperative bladder atony requiring bethanechol and an indwelling urinary catheter has been reported.[12] Uroperitoneum may recur after surgery in an occasional foal as a result of ongoing leakage from the bladder tear. When this complication occurs, it can usually be managed conservatively by placement of an indwelling bladder catheter (closed system) for 3 to 5 days. Rarely, a second celiotomy may be required. Nonsurgical management using an indwelling catheter and closed urinary-collection system has been successfully used in a critically ill foal, in which the bladder defect was sealed within 5 days.[13]

URACHAL URINE LEAKAGE. Uroperitoneum may also develop in foals with urachal infection or ischemia. Affected foals are often septicemic or hospitalized for treatment of prematurity, hypoxic-ischemic encephalopathy, or botulism, and uroperitoneum is recognized later (e.g., after 5 to 10 days of treatment).[4,11] Prolonged recumbency and bladder distention are likely risk factors. The urachus of many affected neonates appears normal during the first 2 days of life, but in some cases, particularly with septicemia, may subsequently become patent. Urine leakage through the umbilicus may or may not be accompanied by leakage into the abdominal cavity or subcutaneous tissues of the abdominal wall. In other affected foals the umbilicus remains normal, and all urine leakage accumulates into the abdominal cavity. When monitored, inappropriate weight gain (e.g., >2 kg in 24 hours) is another common finding in hospitalized neonates that develop uroperitoneum, along with decreased urinary output. Transabdominal ultrasonography can be useful in detecting inappropriate urachal patency and communication with the bladder (Fig. 34.16, *A* and *B*).

Laboratory abnormalities typical for uroperitoneum may be found in affected foals but are not consistently abnormal, because these patients are often being treated with IV fluids. Correction of the problem includes surgical removal of the diseased urachus, closure of the bladder apex, and continued supportive care for the primary disease. The prognosis for a successful outcome for these foals is not as favorable as for bladder rupture because they often have a degree of peritonitis (increasing risk for adhesions), and uroperitoneum is often only one of several complications of the underlying disease.[4,11]

In an occasional foal, the urachus may also rupture more distally than usual and lead to subcutaneous accumulation of urine, ventral abdominal swelling, stranguria, signs of colic, and distress.[14] The swelling may be differentiated clinically from a hematoma or septic omphalitis because it may enlarge quickly and often becomes cold. Ultrasonographic examination and/or local aspiration of fluid and measurement of creatinine (twofold or greater than in serum) confirm the diagnosis. Prompt surgical removal of the leaking urachus is indicated.

URETERAL DEFECTS. Ureteral defect(s) or disruption may also lead to development of uroperitoneum in both male and female foals.[1] Although rare in comparison with bladder rupture in foals, numerous case reports do exist, encompassing both traumatic and congenital ureteral abnormalities.[15-23] Stranguria is usually absent, and urine initially accumulates in the retroperitoneal space, but with time the retroperitoneal tissue ruptures, causing uroperitoneum. Affected foals may not be presented until 5 to 10 days of age or even older because urine accumulation is slower than with a ruptured bladder. Clinical signs include decreased nursing, depression, and mild colic, and in fillies an external bulging of the vagina may be observed. Laboratory findings are typical for uroperitoneum, and with significant hyperkalemia, intermittent muscle fasciculations may also be noted.

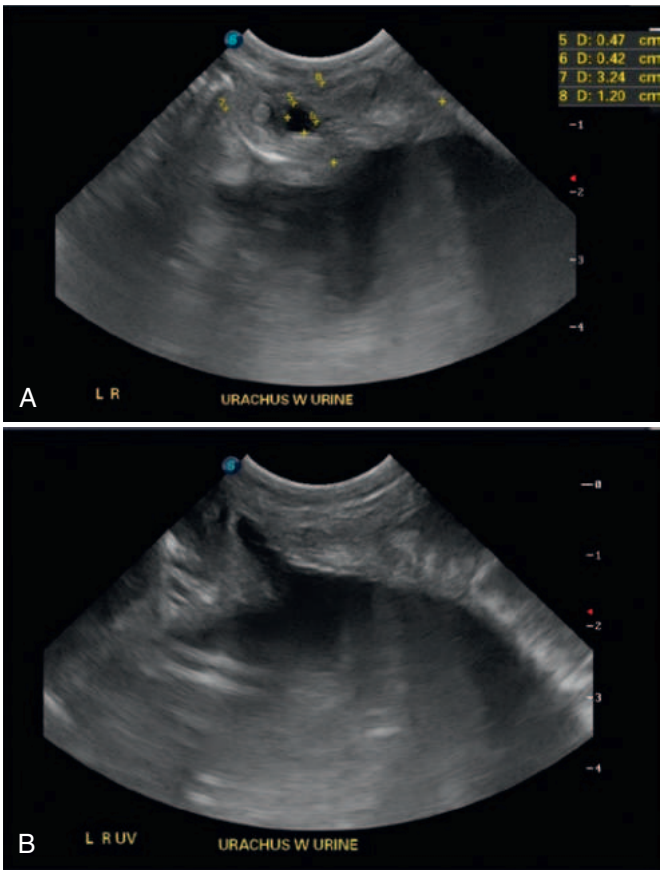

FIG. 34.16 **A,** Ultrasonographic image of hypoechoic fluid within a foal's urachal remnant, consistent with patent urachus. **B,** Ultrasonographic image of communication between the urachus and bladder in a foal, diagnostic of patent urachus.

If urine accumulation remains localized to the retroperitoneal space, ultrasonographic examination of the lower abdomen may be normal, but a large amount of retroperitoneal fluid will be detected around the kidney and upper flank (within retroperitoneal space) on the affected side(s). In addition, the renal pelvis may be mildly dilated.[24] If the peritoneal membrane is ruptured, physical and ultrasonographic examination findings are similar to those seen with a ruptured bladder, but careful ultrasonographic examination may also reveal a full bladder or concurrent retroperitoneal fluid accumulation. As with a ruptured bladder, the ratio of retroperitoneal or peritoneal fluid creatinine–to–serum creatinine is >2 : 1. In small foals (e.g., <50 to 75 kg), excretory urography (after IV administration of contrast agent) or pyelography (after percutaneous injection of contrast agent into renal pelvis with ultrasonographic guidance) may be useful for localizing the ureteral defect(s).[20] Computed tomography can also be useful in the diagnosis of ureteral abnormalities in foals.[21,22]

One or both ureters may be involved, and during surgical exploration, one or more defects can usually be found in the proximal half of the ureter, often near the renal pelvis. During

surgery the defect(s) can be localized by catheterizing the ureter through a cystotomy and then injecting dye (e.g., Evans blue, methylene blue). Successful correction of unilateral and bilateral defects can be accomplished by placing a stent in the affected ureter(s) for 7 to 26 days.[15,16,23] Surgical reimplantation of a ureter into the bladder (ureteroneocystostomy) has also been used to successfully correct a stenotic ureter in a 2-day-old foal.[23]

A report describing bilateral ureteral defects adjacent to the renal pelves provided histopathologic evidence that the lesions were traumatic in origin rather than developmental anomalies.[18] The foal in that report had previously been kicked by its dam. One of the authors (TJD) has seen three foals with similar ureteral defects, all of which also had multiple rib fractures. Ureteropelvic junction injuries and proximal ureteral tears are a recognized complication after blunt abdominal trauma in human patients.[25] These observations suggest that many ureteral defects in foals may more likely be traumatically induced at foaling rather than being developmental anomalies. However, there are several case reports of nontraumatic congenital ureteral defects in foals.[17,20,21,23]

Cystitis

Cystitis can develop in septic, recumbent, premature, or neonatal foals being treated with broad-spectrum antibiotics. Evidence indicates that bacterial infection of the urinary tract, whether primary or due to hematogenous spread, may contribute to the development of uroperitoneum.[5,6] When cystitis is suspected, the bladder should be catheterized and a urine sample submitted for urinalysis and quantitative culture. Urinary tract infections with *Candida* spp. are fairly common in recumbent neonates on broad-spectrum antibacterials. Specific antimicrobial therapy is not usually necessary for *Candida* cystitis as long as systemic antibiotics can be discontinued. However, fluconazole is an option for treatment because if antibiotic therapy continues, dissemination of the *Candida* infection can sometimes spread to other sites (e.g., joints).

Ruminant Renal System

Emily A. Barrell

Ulcerative Posthitis and Vulvitis

Stacey R. Byers

Ulcerative posthitis and vulvitis (enzootic balanoposthitis, pizzle rot, sheath rot) is an ulcerative bacterial infection of the mucous membrane and surrounding skin of the prepuce and vulva. It is most commonly observed in small ruminants but has been reported in dromedary camels.[1]

Clinical Signs and Differential Diagnoses

In male small ruminants, the infection begins as a moist ulcer, usually at or near the mucocutaneous junction of the prepuce. A thin, loose, brown to red, malodorous scab (Fig. 34.17) covers the ulcer. If the scabs are removed, little or no hemorrhage occurs. Focal swelling is often noticeable at the cranial aspect of the prepuce, and the area is painful on palpation.

If untreated, the infection spreads along the mucosal surface inside the prepuce, creating the more serious internal form of ulcerative posthitis. In such cases the entire prepuce may be swollen and elongated. Affected animals often show dysuria, and goats may vocalize during voiding. As the local inflammation progresses, ulceration may result in fibrous adhesions between the penis and prepuce. Severe inflammation of the glans penis can cause stricture of the urethral process (pizzle) and restrict urine egress, resulting in signs similar to those of obstructive urolithiasis. Impairment of breeding soundness may result from pain, blood or exudate in the ejaculate, penile adhesions, scarring of the preputial orifice, or suppurative urethritis. Weight loss may occur in chronic cases. Phimosis has been reported in affected camels.[1]

FIG. 34.17 Ulcerative posthitis in a Suffolk ram.

Ulcerative lesions of similar appearance can develop on the vulva and perineum of affected females. Gross vulvar enlargement may be noticed from a distance. Dysuria may result from involvement of the urethral orifice. The fibrosis and contracture that develop in chronic, severe cases may distort normal vulvar conformation to the point of impairing copulation or parturition.

Ulcerative dermatosis (lip and leg ulcer) in sheep is dermatitis caused by poxvirus related to the contagious ecthyma virus. Infection with this agent may manifest as balanoposthitis and vulvitis, and the crusted ulcers that develop closely resemble those induced by infection with *Corynebacterium renale*. Ulcerative dermatosis can be differentiated from ulcerative posthitis because lesions are also present on the face and legs with the former condition. The lesions readily bleed and often contain a nonodorous, purulent discharge.

Contagious ecthyma (orf) occasionally affects the genitalia and perineum, although lesions are more frequently found on the lips, face, and udder. These lesions are raised, appear proliferative, and are covered with a thick, durable scab. Secondary bacterial infections and necrosis can occur with concurrent *Fusobacterium necrophorum* infection.[2]

Urolithiasis must be strongly considered in the differential diagnosis of any dysuric male small ruminant. Preputial trauma, particularly if resulting from entrapped grass awns, can cause preputial swelling, pain, and exudation within the preputial cavity. External ulcerative lesions would not be expected in such cases.

Caprine herpesvirus 1 (CHV-1) and ovine herpesvirus 2 (OHV-2) infections have been documented to cause preputial,

penile, vulva, and vaginal lesions in goats and sheep, respectively. Ulcers tested positive by PCR for the herpesviruses.[3-6]

Corynebacterium pilosum, *Corynebacterium cystitidis*, *Mycoplasma mycoides* subsp. *mycoides* large colony type, *Actinobacillus seminis*, *Ureaplasma* spp., *Mycoplasma ovine-caprine* serogroup 11, and *Mycoplasma capricolum* subsp. *capricolum* have been implicated in posthitis and vulvitis in sheep.[7-9] A possible synergism between *Mycoplasma mycoides* subsp. *mycoides* large lolony type and *Trueperella pyogenes* has been demonstrated in Dorper sheep in South Africa.[8]

Pathophysiology

C. renale is the bacterium most commonly implicated in ulcerative posthitis. These are aerobic, gram-positive, pleomorphic, club-shaped bacteria that are normal inhabitants of the skin and external genitalia of small ruminants. The bacteria contain the enzyme urease. A high-protein diet results in increased ammonia production in the rumen, which is converted to urea in the liver. The urea is eliminated through the renal system. *C. renale* proliferates, and the urease hydrolyzes the urea back to ammonia, causing chemical irritation and ulceration of the prepuce and surrounding skin.

Epidemiology

The condition appears to be more common in males than females. Risk factors are associated with increased or excessive dietary protein concentration (usually >16%), such as alfalfa hay or lush legume or legume-grass pastures. However, diets with protein levels as low as 12% have been implicated.[7] Rams, pet wethers, club or show lambs or kids, wool and fiber production animals, and feedlot lambs are most predisposed to the disease. Increasing the plane of nutrition in intact males before breeding predisposes to development of this disease, and multiple animals can be affected simultaneously.[10,11] Breeds with dense wool or hair, such as Merino sheep and Angora goats, are also at risk owing to urine soaking the coat near the preputial orifice. Blowfly myiasis appears to increase the risk of ulcerative posthitis.[11]

Disease can occur in individual or multiple animals, since the organism can persist in wool, hair, and scabs for as long as 6 months and can survive freezing in scabs and exudative material. Venereal transmission of the disease has been documented; several months may pass between exposure of ewes to infected rams and development of vulvitis in the ewes. Production losses result from debilitation caused by pain, incapacitation of breeding animals, loss of breeding soundness, and deformation of external genitalia.

Treatment and Prognosis

Reduction of protein and nonprotein nitrogen intake is crucial for successful treatment of affected animals and prevention of additional cases. Dietary changes alone may result in satisfactory cure if the lesions are early in development. Incorporation of grass hay feeding into a program of legume pasture grazing may help limit protein intake.

Affected animals should be isolated to limit venereal or contact transmission. Fly control should be implemented. Wool or hair should be removed from the skin surrounding the prepuce or vulva, and a topical antibiotic may be applied. Caustic antiseptic solutions should not be used. Treatment with systemic antimicrobials is indicated for advanced cases or for outbreaks, in which handling of several animals for topical therapy is not feasible. *C. renale* is sensitive to penicillin, ampicillin, cephalosporins, and oxytetracycline. Treatment should continue until the lesions have dried and acute inflammation has subsided. Topical therapy of the preputial or vulvar mucosa includes application of mastitis treatment tubes, triple antibiotic ointment, or "petercillin." Petercillin is prepared by mixing 240 g anhydrous lanolin, 20 mL of procaine penicillin G (300,000 IU/mL), and 200 mg aqueous prednisolone. A small amount can be warmed up and injected into the prepuce using an AI infusion pipette or small feeding catheter. Oral or injectable NSAIDs can be used to decrease the inflammation and pain associated with the infection.

Surgical treatment of advanced cases is recommended for severe strictures. The ventral preputial tissue can be resected to allow for normal urine flow or be incised along part of its length.

Response to treatment is optimal early in the infection, before deformation of the prepuce or vulva secondary to fibrosis occurs. The chances for full recovery without recrudescence are poor if dietary protein intake is not reduced. Complete recovery of breeding soundness is unlikely in animals with internal ulcerative posthitis. In breeding males, the presence of ulcerative posthitis does not directly influence semen motility or morphology, but since pain is likely to suppress libido, proper treatment and documentation of lesion resolution are recommended in affected males before the breeding season.[12]

Prevention

Prevention primarily involves limiting both protein and nonprotein nitrogen intake. Breeding males should be body condition scored early enough before the breeding season so that any necessary weight gains can be made slowly rather than as a sudden onset immediately before the breeding season. Whenever possibly, weight gain should be induced by feedstuffs with a protein concentration of less than 12% on a dry matter basis. Separation of affected males will help decrease spread through contact with exudative materials. Shearing, especially at the time of highest protein intake, may be efficacious in reducing disease incidence.

Urolithiasis

Stacey R. Byers

Definition and Etiology

Urolithiasis is a common metabolic disease in all livestock species, but castrated small ruminants are particularly at risk. Uroliths cause disease through trauma to the urinary tract and obstruction of urinary outflow. Urolithiasis can occur in outbreaks, as an endemic problem in group-housed animals, or as an individual disorder.

The clinical signs of urolithiasis vary and are based on duration, extent (complete vs. partial), and location of the obstruction. Early clinical signs can be remarkably subtle and may include anorexia, depression, and mild bloat. A history of colic and straining to urinate or defecate may be provided, and novice owners often mistake stranguria for constipation or tenesmus. If investigating a sick, intact, or castrated male small ruminant, urolithiasis should be high on the differential list, regardless of the clinical signs.

Four common disorders can result from urolithiasis: acute urethral obstruction, chronic urethral obstruction, urethral rupture, and urinary bladder rupture. Less commonly seen are ureterolithiasis and hydronephritis.

Clinical Signs and Differential Diagnoses

Acute Urethral Obstruction

Impacted calculi lead to urethral trauma and progressive bladder distention, resulting in stranguria and abdominal pain. Affected

VetBooks.ir

animals may be restless, tread, swish their tails, and grind their teeth. Goats and camelids may vocalize. Tachycardia, tachypnea, and mild bloat secondary to ruminal stasis are common findings. Stranguria is manifested as repetitive bouts of stretching and contraction of the abdominal muscles. Straining may induce secondary rectal prolapse, so urethral obstruction should be investigated as the primary disease in cases of rectal prolapse. Rarely, affected calves develop a visible dilation of the urethra at the midline of the perineum proximal to the obstruction.[1] Anuria occurs if urethral obstruction is complete, whereas urine may dribble in cases of partial obstruction. Crystals or blood may be found on the hairs of the preputial tuft; in cases of anuria the hairs are dry. If a urine sample can be collected for dipstick analysis, proteinuria and occult hematuria are frequently detected.

Rectal palpation (digital rectal palpation in small ruminants and camelids) often reveals pulsation of the pelvic urethra. In cattle, bladder distention is palpable per rectum, although if bladder or urethral rupture has occurred, the bladder is typically not palpably enlarged.

Abdominal palpation may be useful in affected small ruminants, small camelids, and pot-bellied pigs. The examiner should place the fingertips of each hand into the ventral flank on each side of the abdomen. While slowly pressing the fingertips toward midline in the caudal abdomen, the examiner may encounter an orange- to grapefruit-sized, firm, spherical structure, which is the distended bladder. Severe bladder distention will not be palpated in cases of incomplete urethral obstruction or bladder rupture.

Common sites for urolith obstruction include the distal aspect of the sigmoid flexure, near the insertion of the retractor penis muscles in cattle, and the urethral process in sheep and goats. However, uroliths can be found along any length of the urethra.

Owing to the frequent lack of specific clinical signs, acute urethral obstruction can resemble a variety of diseases. Tachycardia, colic, bloat, and anorexia are characteristic of GI obstruction, but auscultation and percussion of the abdomen, abdominal succussion, rectal palpation, and transabdominal or transrectal ultrasonographic examination should differentiate this condition from acute urethral obstruction. Encephalopathies, salmonellosis, coccidiosis, and proctitis from rectal prolapse or trauma frequently cause tenesmus. Additional signs of primary neurologic or GI dysfunction should be evident with these diseases.

Although rare in male ruminants, primary UTIs may result in dysuria and pollakiuria. Bladder distention is uncommon with UTI, and large numbers of WBCs and bacteria are present in the urine sediment.

Occasionally, an animal with urolithiasis successfully voids the obstructing urolith(s). The resultant traumatic urethritis might cause dysuria, but the rate and ease of urination typically improve over time and with anti-inflammatory treatment.

Juvenile male camelids have been observed straining or posturing to urinate. On cystotomy, no uroliths have been discovered. Etiology has not been conclusively determined, but transrectal ultrasound has identified prostatitis in some individuals. It is suspected that hormonal influences or ascending UTIs may be contributing to prostatic or urethral inflammation.

In younger animals, it is important to consider congenital abnormalities (e.g., ectopic ureter(s), pelvic displacement of the urinary bladder, urethral duplication). Congenital abnormalities may manifest at birth or not until later, depending on the level of observation and whether the defect results in obstruction, partial obstruction, or constant urine dribbling.

Chronic Urethral Obstruction

Uncommonly, partial urethral obstruction causes chronic dysuria and stranguria if calculi impair but do not completely obstruct urine outflow.[2] If a chronic partial obstruction is present, the affected animal has a characteristic slow or intermittent urine flow during voiding. Lethargy, reduced appetite, and thin body condition are evident if renal failure has developed. On rectal palpation, the bladder may be small, and thickening of the bladder wall may be palpable.[2]

Urine dribbling may also occur in animals with neurologic disease, previous urethral trauma (stricture formation), congenital anomalies of the urogenital tract, infection, or neoplasia. Contrast urethrography may be used to identify the presence of strictures or anomalous structures. Small ruminants with the internal form of ulcerative posthitis may dribble urine. In such cases, characteristic preputial lesions are present. Tumors of the urinary tract, although rare compared with urolithiasis, may cause gradual obstruction in cattle, small ruminants, and camelids.

If there is a complete urethral obstruction for approximately 36 hours or more, the animal is at risk of developing bilateral hydroureter and hydronephrosis, and imaging studies of the kidneys and ureters are warranted.

Urethral Rupture

Urethral rupture is a common complication of urethral obstruction in ruminants and camelids. The wall of the obstructed urethra undergoes pressure necrosis, causing leakage of urine into the subcutaneous tissue of the perineum and ventral abdomen. Sequelae include cellulitis, penile adhesions (possibly creating phimosis), urethral fistula formation, and urethral stricture. Erection failure secondary to vascular obstruction of the corpus cavernosum of the penis has been reported as a sequela to urethral obstruction and rupture in a goat.[3]

Affected animals are frequently depressed and inappetent and have bilaterally symmetric, pitting edema in the ventral perineum, inguinal region, prepuce, and ventral abdomen (Fig. 34.18). Swelling of the abdominal wall may extend as far forward as the axillae. The affected areas are initially warm and painful on palpation. As necrosis progresses, the tissues become cool, dark, nonpainful, and potentially gangrenous. A fistula may develop to allow urine to escape. Fever may occur if tissue necrosis and sloughing are extensive. Transrectal palpation or ultrasound reveals a small bladder.

Ventral abdominal swelling is also found with umbilical or scrotal hernias and omphalophlebitis. These conditions can be differentiated from urethral rupture by careful palpation of affected tissues, aspiration of any fluid pockets for cytologic examination, and ultrasonography. In bulls, penile hematomas may cause localized swelling of the prepuce in the prescrotal

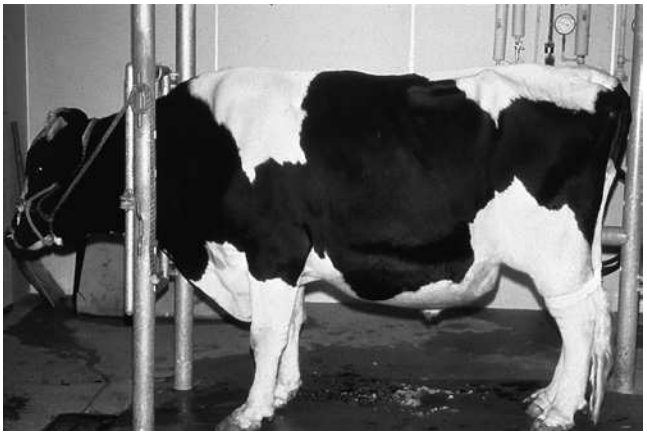

FIG. 34.18 Urethral rupture in a Holstein steer. Tissue swelling from urine accumulation may extend to the sternum and axillae.

region and caudal sheath, but the swelling does not involve the ventral abdominal wall. Aspiration of a suspected penile hematoma is not recommended because of the risk of iatrogenic infection.

Urinary Bladder Rupture

In all ruminants and camelids, prolonged bladder distention secondary to urethral obstruction may result in pinpoint perforations, tears, or necrosis of large areas of the bladder wall. In cows, bladder rupture may also occur as a rare complication of dystocia.[4] Rupture of an urachal remnant may also result in uroperitoneum.[5] The dorsum of the bladder fundus is the most common site for rupture, but bladder rupture can occur at any site.

Relief of bladder distention causes cessation of stranguria. Bilateral distention of the ventral abdomen develops within 1 to 2 days after rupture and is accompanied by worsening clinical signs of depression, anorexia, weakness, dehydration, and shock. Ballottement of the abdomen may elicit a fluid wave. Rectal temperature may be normal, but shock may result in hypothermia. The animal's breath may smell like ammonia. On transrectal or transabdominal palpation, the bladder is small or not palpable. Transabdominal ultrasonography reveals a large volume of free fluid and a collapsed or partially filled bladder. Abdominocentesis yields a large volume of blood-tinged fluid; the fluid may smell like urine when heated, although this is quite subjective. On occasion, urine will translocate into the thoracic cavity or scrotum through the inguinal canals. Uremia and dehydration result in debilitation and eventual death if medical and surgical treatments are not provided.

Seepage of urine across the bladder wall and into the abdominal cavity may occur in cases of severe bladder distention; in such cases, rupture is often imminent.

Differential diagnoses for bladder rupture include diffuse peritonitis, ileus, enteritis, vagal indigestion, ascites, caudal vena caval thrombosis, and hypoproteinemia. Marked peritoneal cavity effusion may be found in cases of mesothelioma or lymphoma. These conditions are differentiated from bladder rupture through transrectal palpation, ultrasonography, cytologic and chemical analysis of peritoneal fluid, evaluation of serum chemistry, and abdominal exploratory surgery.

Ureterolithiasis and Nephrolithiasis

Animals with acute ureteral obstruction may show severe colic with stretching, kyphosis, treading, collapse, and vocalization. Signs of distress may be less severe or even absent if obstruction is intermittent or incomplete.[6] Enlargement of the blocked ureter may be palpated transrectally, and if the left ureter is obstructed, enlargement of the left kidney may be appreciated. Transabdominal or transrectal ultrasound may aid in the diagnosis in small ruminants and camelids. Pyelonephritis can be the inciting cause of ureteral obstruction or renal calculosis. With ureteral or renal rupture, uroperitoneum or retroperitoneal accumulation of urine may occur.

Similar signs of abdominal pain or colic can result from GI or urinary tract obstruction in ruminants and camelids. Auscultation and percussion of the abdomen, rectal palpation findings, ultrasonography, or radiography may allow for differentiation of GI obstruction from ureteral or renal obstruction. Cases of ureteral or renal calculosis without colic may show nonspecific signs of illness, and serum chemistry, urinalysis, and ultrasound examination are needed for definitive diagnosis.

Ancillary Diagnostic Tests

Examination of the Urethral Process in Small Ruminants

Sedation or general anesthesia facilitates extrusion of the penis for examination. Because of its diuretic effect, xylazine may exacerbate bladder distention and is not recommended. Diazepam (0.1 to 0.2 mg/kg IV) and acepromazine (0.05 to 0.1 mg/kg IV or IM) have been used successfully, either as sole agents or in combination with butorphanol (0.05 to 0.1 mg/kg IV). Alternatively, isoflurane by mask can be used.

An adjunct or alternative to sedation is administration of epidural anesthesia, which provides greater patient comfort and eliminates muscular resistance to penile extrusion. One milliliter of 2% lidocaine per 15 kg (33 lb) of body weight is injected into the epidural space at the lumbosacral junction. Lower dosages may provide sufficient anesthesia. The total dose should not exceed 15 mL of 2% lidocaine in any small ruminant, regardless of size. If CSF is obtained, half of the epidural lidocaine dosage can be administered as a true spinal block. Hindlimb motor blockade is expected with either epidural or true spinal anesthesia at this site; the effects typically last 1 to 2 hours.

To exteriorize the penis, the sheep or goat is propped up on its rump and the hind legs are pulled up alongside the trunk. For larger sheep or goats, this can be aided by a person sitting (e.g., in a chair or on a bale of straw), with the animal propped up between his or her legs. It is critical that the animal be positioned such that its spine is perpendicular to the floor. Addition of lidocaine jelly or several milliliters of 2% lidocaine added to a water-based lubricant and squirted into the prepuce may decrease discomfort for exteriorizing the penis. The examiner can then exteriorize the penis by pushing the sigmoid flexure cranially from the base of the scrotum while pulling the sheath caudally. In some animals and overconditioned males, the preputial mucosa must be carefully grasped with small forceps or Allis tissue forceps to aid in extruding. The penis can then be grasped with a piece of gauze to keep it exteriorized. The urethral process can then be inspected and palpated for the presence of discrete uroliths or sandlike grit within the lumen. If the urethral process is obstructed, it can be amputated with a scalpel blade (see Surgical Treatment section later).

ULTRASONOGRAPHY AND RADIOGRAPHY. A presumptive diagnosis of urolithiasis can usually be made through historical and physical examination findings. Ultrasonographic and radiographic evaluation of the urinary tract is useful for confirming the diagnosis, locating obstruction sites, and aiding in determining prognosis.[7-11] In cases of prolonged urethral obstruction (≥48 hours) or urethral obstruction with severe azotemia, it is prudent to perform ultrasonographic examination of the kidneys before considering surgical treatment. Detection of severe hydronephrosis warrants a poor prognosis for recovery.

Ultrasonographic evaluation of the bladder of pot-bellied pigs, small ruminants, and camelids is most easily accomplished through transabdominal scanning directed caudodorsally from the inguinal area. Both kidneys of small ruminants and camelids and the bovine right kidney can be examined from the right paralumbar fossa. In cattle, transrectal examination of the pelvic urethra, bladder, ureters, and left kidney can be performed. Marked distention of the bladder, thickening of the bladder wall, and echogenic material within the bladder lumen may be seen with acute urethral obstruction. A large volume of free fluid in the abdomen is characteristic of uroperitoneum and is suggestive of existing or impending rupture.

Radiographic examination of the urinary tract is limited to pot-bellied pigs, camelids, small ruminants, and young cattle. Lateral views of the abdomen can be used to detect and locate radiopaque calculi in the bladder and urethra.[9] This is accomplished most easily with the animal in lateral recumbency with the hindlimbs pulled caudally. It is also essential to image the entire urethra to determine the presence and location of additional stones.

Intravenous, normograde or retrograde contrast urethrography can assist in the detection of radiolucent urethral calculi,

VetBooks.ir

urethral strictures, or urethral rupture. A contrast urethrogram can be performed in adult bucks and rams and some older castrated males by placing a catheter approximately 5 cm into the penile urethra and injecting 10 to 30 mL of water-soluble contrast media. The catheter should be completely filled with contrast material before insertion into the urethra to avoid accidental introduction of bubbles into the catheter. Injection should be performed slowly with minimal pressure to avoid iatrogenic urethral rupture. The technique may not be possible in juveniles and wethers as the penile frenulum limits exteriorization of the penis. Following tube cystostomy, contrast urethrography can be performed by injecting the contrast material into the bladder through the catheter. The catheter can then be clamped shut temporarily to detect stones, strictures, or urethral rupture.

Clinical Pathology

ACUTE AND CHRONIC URETHRAL OBSTRUCTION. Hematologic and serum chemistry findings may be unremarkable in ruminants with acute urethral obstruction uncomplicated by urethral or bladder rupture. Hyperglycemia and a stress leukogram may be present. With time, hemoconcentration and azotemia develop secondary to reduced water intake. Hematuria and proteinuria are consistent abnormalities, whereas crystalluria is a variable finding. With chronic urethral obstruction, hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and severe azotemia with isosthenuria suggest extensive nephron damage caused by hydronephrosis. Pyuria is present with traumatic urethritis, cystitis, or secondary bacterial infection.

BLADDER RUPTURE. Bladder rupture and accumulation of urine in the abdomen result in hematologic and serum biochemical parameter alterations that worsen over time. Urine osmolality is normally two to three times that of extracellular fluid (ECF), and urine contains higher concentrations of urea, creatinine, and potassium but lower concentrations of sodium and chloride than ECF. Therefore, movement of water, urea, and electrolytes occurs along diffusion gradients, resulting in hyponatremia, hypochloremia, hyperphosphatemia, uremia, and hemoconcentration.

Serum potassium concentration in ruminants with bladder rupture is more variable, depending on appetite and time before diagnosis. Although animals with uroperitoneum are at risk of hyperkalemia, serum potassium concentration tends to be normal or low in ruminants with bladder rupture, even if uroperitoneum exists for several days. Anorexia may contribute to hypokalemia or normokalemia in these cases, and aldosterone release secondary to volume depletion results in dramatic increases in salivary potassium excretion, providing an alternative route of potassium excretion in affected animals. Once in the GI tract, potassium absorption may be diminished by ileus and preferential absorption of sodium over potassium. Alkalosis, which occurs secondary to hypochloremia, may also serve to reduce ECF potassium concentration by encouraging movement of potassium intracellularly.

Although only a small fraction (<10%) of phosphorus excretion in the ruminant is via urine, hyperphosphatemia may occur secondary to uroabdomen. Potential mechanisms for hyperphosphatemia include phosphorus diffusion from the urine into the ECF, reduced glomerular filtration, and tissue hypoxia causing breakdown of organic phosphate compounds in cells. In addition, reduced salivary flow from anorexia may limit phosphorus excretion in the saliva, contributing to phosphorus retention. Anorexia, ileus, and a competitive effect of hyperphosphatemia may contribute to reduction in serum calcium concentration in cases of uroabdomen.

Measurement of creatinine in the peritoneal fluid can be used to confirm a diagnosis of uroperitoneum. Creatinine is a relatively large polar molecule that does not readily diffuse from the abdominal cavity into the ECF space. Therefore, peritoneal fluid creatinine can be compared to serum creatinine concentration, with a peritoneal fluid–to–serum creatinine ratio of greater than 2:1 indicative of uroperitoneum.

Uroperitoneum may induce a mild chemical peritonitis. WBC count and blood fibrinogen levels may increase in cases of ruptured bladder. There is a risk of coagulopathies due to azotemia and uremia affecting platelet aggregation and coagulation factor function.

URETHRAL RUPTURE. Leakage of urine into the subcutaneous space following urethral rupture produces hematologic and serum biochemical alterations that are similar but typically less severe than those seen with bladder rupture. Tissue necrosis and secondary infection may result in neutrophilia, leukocytosis, and hyperfibrinogenemia.

Ureterolithiasis and Nephrolithiasis

Azotemia and secondary hydronephrosis are most severe if the obstruction is bilateral. With chronic ureteral obstruction, hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and severe azotemia with isosthenuria suggest extensive nephron damage caused by hydronephrosis. Pyuria is present with traumatic urethritis, cystitis, or secondary bacterial infection.

Pathophysiology

Multiple factors influence the development of urinary calculi, but of primary importance is the development of high urinary concentrations of soluble ionized minerals (crystalloids) that aggregate to form insoluble crystals. Supersaturation of urine with a calculus-forming crystalloid is a prerequisite for urolith development, but supersaturation alone is not solely responsible for urolith initiation because normal urine is typically supersaturated with a variety of calculogenic ions.[12] Urine contains variable concentrations of mucopolysaccharides, ions, and organic acids that act as intrinsic inhibitors of crystallization. Through physical and electrochemical interactions, these compounds maintain calculogenic minerals in a colloidal suspension. Calculus formation is initiated if supersaturation of urine with appropriate crystalloids exceeds the protective capabilities of the crystallization inhibitors. The crystalloids are rendered insoluble and precipitate out of the aqueous phase of urine. Calculi enlarge as further mineral precipitation takes place on the crystal surfaces. Dietary, environmental, and management influences interact to determine the degree of supersaturation of urine with calculogenic minerals. Dehydration, with resultant concentration of urinary minerals, would appear to be a potential contributing factor in the development of all types of uroliths.

The solubility of some calculogenic crystalloids is influenced by urinary pH. Struvite (magnesium ammonium phosphate), calcium phosphate, and calcium carbonate uroliths are less soluble in alkaline urine, whereas calcium oxalate solubility is not affected by changes in urine pH within the physiologic range. The effect of urinary pH on silica calculi is debatable, but there is a trend toward reduction in formation under conditions of mild aciduria.[13]

Primary UTIs are considered an uncommon cause of ruminant urolithiasis. Purulent debris within the urinary tract may serve as a nidus for crystal development, and bacterial ureases may increase urinary pH, thereby reducing the solubility of certain crystalloids. Vitamin A deficiency has been incriminated as a contributory factor for urolith development by leading to metaplasia of urinary tract epithelium.[12] This may create nidi for calculogenesis through desquamation of cells or altered cell surface characteristics.

Feeding patterns may influence the risk for calculogenesis. Meal feeding exerts an osmotic draw of fluid into the rumen from the ECF. This leads to a release of antidiuretic hormone that results in a transient decline in urine output and an increase

in urine concentration. These changes in urine composition can be limited through ad libitum feeding.[14]

The influence of water hardness (dissolved mineral content), in particular in magnesium concentrations, has been implicated in the pathogenesis of this disease in ruminants.[15]

PHOSPHATIC CALCULI. Ruminants consuming rations high in phosphorus (grain-based rations) typically develop struvite (magnesium ammonium phosphate hexahydrate) or apatite (calcium phosphate) calculi.[12,16] Rations where the calcium/phosphorus ratio is less than 2:1 are particularly prone to cause outbreaks of urolithiasis.[12] However, the role of phosphorus in urolith formation is not clearly defined, and struvite urolith formation appears to be primarily affected by the magnesium and, to a lesser extent, other minerals in the diet.[12,17,18] Magnesium absorbed from the gut is excreted through the kidneys. High potassium in the diet alters the dietary cation-anion difference (DCAD) and increases the risk of urolith formation (see more about DCAD in Prevention section later).[19]

Ruminant saliva is rich in phosphorus, and the GI tract is the primary route of phosphorus excretion in ruminants. In theory, ruminants consuming pelleted rations produce less saliva, which would reduce GI phosphate losses and increase urinary phosphate excretion. Struvite uroliths are typically white or gray, usually smooth, radiopaque, and easily broken.[12] They can be found as a single stone or sandlike debris, which is more commonly seen in ruminants.

SILICA CALCULI. Silica urolithiasis is primarily a problem of ruminants grazing native rangeland grasses of western North America. A fraction of dietary silica, as unpolymerized silicic acid, is dissolved in the ruminal fluid of the grazing animal, absorbed, and excreted in the urine.[12] Water intake is usually intermittent in ruminants on rangeland. During periods of water deprivation, water and sodium resorption by the kidneys results in the formation of highly concentrated urine. Calculi can develop as the silicic acid concentrates and polymerizes to the less soluble form, polysilicic acid.

The incidence of silica urolithiasis can be increased by feeding sheep rations that have a high calcium–to–phosphorus ratio (≥ 2.8:1) and induce more alkaline urine.[13,20] It is important to note that a high calcium-to-phosphorus ratio in the diet can help to prevent one type of urolith (struvite) but may be a contributory factor for another (silica). This underscores the importance of both ration and urolith mineral analyses in the formulation of preventive measures for this disease.

Silica uroliths in ruminants are hard, smooth, white to brown, radiopaque, and often layered.[12] The uroliths are usually composed of about 20% mucoprotein, 75% silicon dioxide, and variable amounts of calcium oxalate and calcium carbonate.[12]

CALCIUM-BASED CALCULI. The two main types of calcium-based uroliths are calcium carbonate and calcium oxalate. Calcium carbonate uroliths are common in small ruminants grazing lush, rapidly growing clover pastures or being fed alfalfa hay.[21] Forages like these are rich in calcium and low in phosphorus and magnesium and have high oxalate content. In the gut, oxalate avidly binds calcium and makes it unavailable for absorption. With gradual introduction of oxalate-rich diets, ruminal bacteria efficiently metabolize oxalate to bicarbonate, so metabolism of oxalate in the rumen may increase the availability of dietary calcium. These factors may combine to increase urinary calcium excretion and alkalinize urine, thereby promoting calcium carbonate calculogenesis.

Oxalates in the diet, as well as low calcium and decreased water intake, may increase the risk of forming calcium oxalate stones. Given its low solubility, calcium oxalate crystals are often present in normal urine and may be incorporated into other uroliths as a trace component.[22]

Calcium carbonate uroliths have a characteristic round, smooth shape and copper color and are often present as multiple uroliths scattered throughout the lower urinary tract. Calcium oxalate uroliths are typically dense, hard, white to yellow, and either smooth or jagged.[12]

Epidemiology

GENDER. Obstructive urolithiasis in ruminants and camelids is almost exclusively a disease of males and castrated males. Urinary calculi appear to develop to a similar degree in female ruminants, but most calculi can pass through the relatively short, distensible urethra of the female, making urethral obstruction uncommon. The urethra of the male is long and surrounded by the less distensible corpus spongiosum and tunica albuginea.

Research indicates calculi form to a similar extent in the urinary tracts of intact and castrated male ruminants. The increased predisposition for urethral obstruction in steers and wethers may be due to the loss of testosterone on urethral diameter.[23,24] However, because many castrated small ruminants are kept as pets, factors such as diet, environment, and age are likely to differ compared with intact males. Specific gender risks in camelids and pot-bellied pigs are not well described; in commercial pigs, urolithiasis is generally associated with husbandry problems such as improper calcium/phosphorus ratio in the ration and inadequate water availability.[25]

SEASON. The incidence of urolithiasis increases in hot, arid months in warm climates and in late fall and winter in North America. Seasonal effects are likely due to limited water availability and decreased consumption with colder weather.

AGE. All ages of ruminants are at risk for developing obstructive urolithiasis. The tendency for this disease to be seen in younger ruminants may be the result of dietary influences because younger animals are more often fed concentrates for weight gain and eventual slaughter than are mature males kept for breeding. Because relatively fewer mature males are kept for breeding, the apparently increased prevalence of urolithiasis in younger animals may simply reflect the greater numbers of younger males and castrated males at risk.

OTHER. Inherent differences in an individual animal's mineral metabolism or urinary tract health may also play a role; some animals can ingest a calculogenic diet and remain unaffected, while others develop uroliths rapidly. Animals prone to develop uroliths may have ineffective protective capabilities within the urinary tract, such as a lack of crystallization inhibitors.

Certain breeds of ruminants appear to be predisposed to urolithiasis; for example, African pygmy and Nigerian dwarf goats appear to be prone to developing this disease. Again, because these goats are often kept as pets, it is possible they may be fed or managed in ways that increase their disease risk; further, they may be more likely to be seen by a veterinarian compared with ruminants intended for food or kept out on rangeland.

Necropsy Findings

When the entire length of urethra is opened along the sagittal plane, hemorrhage and necrosis of the urethral mucosa are evident at the site of obstruction. Attention should be paid to examination of the distal urethra in camelids, the urethral process in sheep and goats, and the sigmoid flexure in cattle. Calculi may be relatively large, discrete mineral aggregates or very fine and sandlike. Calculus material should be collected for analysis of mineral composition (Box 34.1). Occasionally, no calculi can be found in the urinary tract, but mucosal trauma and necrosis of the bladder or urethra persist.

Urethral rupture is characterized by the subcutaneous accumulation of urine in the inguinal area, prepuce, and ventral abdomen and hemorrhage at the site of the urethral defect.

In cases of bladder rupture, the abdominal cavity is filled with a large volume of blood-tinged fluid. Defects in the bladder wall vary in size and location, and necrosis of large areas of bladder wall may be present. In rare cases, the bladder wall is intact but obvious uroabdomen exists, suggesting transmural seepage of urine.

Hydronephrosis, hydroureter, and bladder wall hypertrophy may be present in animals with chronic urethral obstruction.[2]

Treatment and Prognosis

SALVAGE. Steers and feeder lambs may be sent for immediate slaughter if urethral obstruction is diagnosed before development of azotemia or urinary tract rupture.

MEDICAL TREATMENT. Medical treatment of urolithiasis is aimed at relief of the obstruction and correction of any fluid and electrolyte abnormalities. The antispasmodic effect of certain tranquilizers may facilitate passage of a urethral obstruction. These drugs may also aid in relaxation of the retractor penis muscle, which results in straightening of the sigmoid flexure to facilitate passage of calculi. In small ruminants, medical treatment with IV fluids, NSAIDs, or tranquilizers alone is usually unsuccessful, resulting in surgical intervention or euthanasia.

While stabilizing a patient before surgery or as an adjunct to medical treatment, the bladder can be drained with a percutaneous catheter inserted in the lower flank or ventral abdomen. Long IV catheters or a suprapubic catheter can be inserted, using ultrasonography as a guide, and temporarily left in place. Percutaneous infusion using Walpole solution has been used following cystocentesis in goats.[26] Urine was removed, and the solution infused into the bladder one to three times to decrease the urine pH to 4 to 5. This process was thought to promote chemical dissolution of uroliths in the bladder and urethra.

Ruminants and camelids with urinary tract obstruction, particularly those with uroperitoneum, often require preoperative stabilization of hypovolemia and correction of electrolyte abnormalities, especially if surgery is to be performed under general anesthesia or with the animal restrained in recumbency. Fluid therapy should be guided by analysis of serum electrolyte concentrations. An initial bolus of hypertonic (7%) saline followed by physiologic (0.9%) saline solution can be used to correct intravascular volume deficits, hyponatremia, and hypochloremia. Calcium salts can be added to the fluids if indicated.

Empirical supplementation of IV fluids with potassium should be avoided because the potential for hyperkalemia always exists. Hyperkalemia can induce bradycardia and fatal cardiac dysrhythmias, and this effect is augmented by concurrent hyponatremia. Administration of dextrose, sodium bicarbonate, and/or insulin (regular insulin at 0.25 to 0.4 U/kg) reduces serum potassium concentration by promoting movement of potassium from the extracellular to the intracellular space. Blood glucose should be closely monitored when insulin is administered. Uremic animals undergoing IV fluid therapy may develop pulmonary edema, so attention must be paid to respiratory rate, auscultatory findings, and respiratory effort during fluid therapy.

Slow drainage of urine from the abdominal cavity reduces pressure on the diaphragm and slows progression of metabolic derangements caused by uroperitoneum. This can be difficult to achieve as the omentum is prone to occluding the cannula. In long-standing cases of uroabdomen, urine may also be present in the thorax, further warranting close observation of respiratory function during anesthesia. Thoracocentesis to remove thoracic urine is indicated if respiratory function is compromised; otherwise, abdominal drainage usually induces resolution of thoracic urine accumulation.

Although bacterial infection is not considered to be a common primary cause of urolithiasis, secondary UTIs may develop after surgical intervention. Loss of the flushing effect of urination, urinary mucosal damage, impaired host cellular defenses secondary to uremia, and indwelling urinary catheter placement may contribute to the development of ascending UTI. Perioperative antibiotic therapy is therefore prudent, with due consideration of withdrawal times in animals intended for slaughter.

SURGICAL TREATMENT. There are multiple surgical options for urolithiasis, which are dictated by economic considerations, intended use of the animal, available facilities and equipment, types of stones, and status of the patient.[27] Removal or bypass of the obstruction and restoration of urine output are the goals of surgical treatment. The prognosis for both short- and long-term survival will vary according to the patient's status and the surgical procedure chosen. Acute renal failure is an occasional sequela to urinary tract obstruction and should be considered in the prognosis. Regardless of the surgical technique used, the client should be forewarned about the future risk of reobstruction.
