Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

This edition is dedicated to all students of veterinary medicine and to veterinary practitioners across the globe. Special thanks and recognition go to the authors of previous editions, including Dr. Gwendolyn Carroll, Dr. Cheryl Hedlund, Dr. Caroline Horn, Dr. Donald Hulse, Dr. Ann Johnson, and Dr. Howard Seim. Their expertise and hard work were fundamental in making this textbook the fundamental resource that it has become.

ABOUT THE AUTHORS

EDITOR-IN-CHIEF

Theresa W. Fossum, DVM, MS, PhD; Diplomate ACVS

Theresa (Terry) W. Fossum is a Professor of Surgery and holds the Tom and Joan Read Chair in Veterinary Surgery at Texas A&M University (TAMU). She is a world-renowned surgeon and serves as the Director for Cardiothoracic Surgery and Biomedical Devices in the Michael E. DeBakey Institute at TAMU. She was recently appointed Director of the new Texas A&M Institute for Preclinical Studies, a $60 million venture at TAMU, which will promote public-private partnerships to speed the development of medical devices and drugs. Dr. Fossum's leadership was integral in conceptualizing and funding this Institute.

Dr. Fossum graduated from Washington State University College of Veterinary Medicine in 1982. After completing an internship at Santa Cruz Veterinary Hospital the following year, she went on to do a surgery residency and master's degree at the Ohio State University. She received board certification in Surgery (ACVS) in 1987 and joined the faculty at TAMU later that year. In 1992, she completed a PhD in veterinary microbiology. Dr. Fossum's main interests are diseases of the respiratory and cardiovascular system, including cardiopulmonary bypass procedures. Dr. Fossum has authored numerous articles on chylothorax and other respiratory and surgical diseases. She is the principal investigator of numerous research projects, including evaluation of the DeBakey Ventricular Assist Device in a calf model, evaluation of angiogenic factors for the treatment of cardiac ischemia, and vascular adaptations to hypertension. Dr. Fossum sits on the Board of Directors of the National Space Biomedical Research Institute and is the Chairman of the Board of Governors for the Foundation for Biomedical Research. Dr. Fossum is a previous recipient of the Wiley Distinguished Professor of Veterinary Medicine Award and the Carl J. Norden Distinguished Teacher Award at TAMU. In 2004, she received the Texas Society for Biomedical Research Award in recognition and appreciation for her many years of dedicated service to the science, research, and medical communities in Texas. Dr. Fossum, along with Dr. Michael E. DeBakey, founded the CARE Foundation in 2004 to provide an infrastructure for veterinary medicine to perform research using animals with spontaneous disease. She serves as president of the organization.

EDITORS

Dr. Jane Cho, DVM, DACVO

Originally from New York, Dr. Cho received her BA from the University of Pennsylvania and her DVM from Cornell University. She did her internship at the Animal Medical Center in New York City and returned to Cornell for her residency in comparative ophthalmology. After having served on the American College of Veterinary Ophthalmologists (ACVO) Exam Committee as well as on the Editorial Board for the journal *Veterinary Ophthalmology*, she was elected to the ACVO Board of Regents in 2013, currently serves as Vice President of the ACVO, and is slated to become its President in 2017. She has worked in private ophthalmology practice in New Jersey and Arkansas and is co-founder of Veterinary Eye Specialists, a private ophthalmology practice in Thornwood, NY.

Curtis W. Dewey, DVM, MS, CVA, CVCH, DACVS, DACVIM (Neurology)

Dr. Dewey was a faculty neurologist at Texas A&M University (1995–2001) and a staff neurologist at Long Island Veterinary Specialists (2001–2006) prior to returning to his alma mater, Cornell University, in 2006 as Associate Professor of Neurology/Neurosurgery. He has authored or co-authored numerous peer-reviewed journal articles and many textbook chapters. He has recently published the third edition of his own comprehensive textbook, *Practical Guide to Canine and Feline Neurology*, with his co-editor, Dr. Ronaldo C. da Costa. His current textbook project is an illustrated guide to canine acupuncture, with co-author Dr. Huisheng Xie of the Chi Institute. He is a nationally and internationally recognized speaker and has served on the editorial board of a number of veterinary journals (*Veterinary Surgery, Journal of the American Animal Hospital Association, Compendium on Continuing Education for the Practicing Veterinarian*). He has also served as an ad hoc reviewer for many other journals. He has served on the American College of Veterinary Internal Medicine (ACVIM) (Neurology) Residency Training Committee (2005–2008; committee chair 2007–2008) and the ACVIM Taskforce on Neurosurgical Training of Neurology Residents (2004–2010; committee chair 2007–2010). He consults regularly with Long Island Veterinary Specialists and Veterinary Specialists and Emergency Service of Rochester. He has been a member of the Board of Directors of the New York Veterinary Foundation since 2008. Dr. Dewey is a member of the AVMA and Veterinary Emergency and Critical Care Society. His main areas of research include seizure control and surgical management of congenital brain disorders. Dr. Dewey was the recipient of the 2014 Hills American College of Veterinary Emergency and Critical Care Jack Mara Scientific Achievement Award.

Kei Hayashi, DVM, PhD, Diplomate ACVS
Dr. Hayashi graduated from the University of Tokyo with BVMS/DVM/PhD degrees (1986–1997), and then obtained MS and PhD degrees at the University of Wisconsin (1997). He completed a small animal surgery residency at the University of Wisconsin (2003) and became a Diplomate of the ACVS. He served as an assistant/associate professor of small animal orthopedic surgery at Michigan State University (2003–2005) and University of California–Davis (2005–2012). He is currently an Associate Professor, Department of Orthopedic Surgery, at the College of Veterinary Medicine at Cornell University. Dr. Hayashi's research focus is in the pathology of ligament/tendon injury and wound healing, evaluation of total joint replacement systems, molecular profiling of osteoarthritis, and comparative orthopedics and sports medicine. His clinical interests are in arthroscopy, total joint arthroplasty, biological approach to joint surgery, minimally invasive fracture treatment, and application of novel research discoveries to clinical patients.

Janice Lynne Huntingford, DVM, DACVSMR, CVA, CVPP, CCRT, CAVCA
Dr. Huntingford is a 1984 graduate of the Ontario Veterinary College, University of Guelph, in Guelph, Ontario. She is certified in chiropractic, acupuncture, rehabilitation, and pain management. She is the owner and medical director of the Essex Animal Hospital in Essex, Ontario. In 2015 she became a Diplomate of the American College of Veterinary Sports Medicine and Rehabilitation, a consultant for the Veterinary Information Network Rehab/Sports Medicine/Chronic Pain board, and a survivor of sled dog research at the Yukon Quest in –40°C temperatures. Dr. Huntingford has lectured nationally and internationally on rehabilitation and pain management to veterinarians and veterinary technicians. She has co-authored several textbook chapters on rehabilitation and published a number of peer-reviewed manuscripts on sporting dog nutrition and exercise physiology. When not practicing she enjoys spending time on her farm/winery with her chef husband, Harold, a menagerie of dogs, cats, and horses, and even a few adult children!

Catriona M. MacPhail, DVM, PhD, Diplomate ACVS
Dr. MacPhail received her undergraduate degree from Rice University and her veterinary degree from Texas A&M University. Dr. MacPhail completed her rotating internship, surgical residency, soft tissue/surgical oncology fellowship, and PhD all at Colorado State University (CSU). She is a Diplomate of the ACVS as well as an ACVS Founding Fellow in Surgical Oncology. Dr. MacPhail has been on faculty at CSU since 2004 and became the Small Animal Chief Medical Officer for CSU in 2014. Dr. MacPhail is a frequent speaker at national and international meetings and has authored numerous journal articles and book chapters. Dr. MacPhail is the surgical laboratories coordinator for the third-year veterinary students at CSU and is an active contributor to the overall curriculum. Her primary clinical and research interests include upper and lower respiratory surgery, gastrointestinal and urinary surgery, wound reconstruction, and minimally invasive surgery. She is an active member of ACVS, Society of Veterinary Soft Tissue Surgery, and Veterinary Society of Surgical Oncology.

Jane E. Quandt, DVM, MS, DACVAA, DACVECC
Dr. Quandt graduated with a DVM from Iowa State University in 1987. Her anesthesia residency was at the University of Minnesota, and she obtained her master's degree in anesthesia in 1991. She became a diplomate of the American College of Veterinary Anesthesia and Analgesia in 1993 and was on faculty at the University of Georgia College of Veterinary Medicine for 8 years. Feeling the need to improve her ability to manage the critical and emergency patient, she completed an emergency critical care residency at the University of California–Davis and University of Minnesota. Dr. Quandt became a diplomate of the American College of Veterinary Emergency & Critical Care, small animal, in 2007, and was a faculty member at the University of Minnesota College of Veterinary Medicine for 10 years, practicing anesthesia and emergency and critical care. She rejoined the University of Georgia College of Veterinary Medicine in 2011 as a tenured associate professor in anesthesia.

MaryAnn G. Radlinsky, DVM, MS, DACVS
Dr. Radlinsky was an academic surgeon for approximately 12 years at Kansas State University and the University of Georgia. She did her internship and residency at Texas A&M University and initially worked in private practice prior to her academic career. She published many articles in the area of minimally invasive surgery and recently became a founding fellow in the area. She has a particular interest in minimally invasive treatment of chylothorax and other diseases of the thorax. She has lectured across the United States, Europe, Asia, and South America on various topics related to soft tissue surgery. She has been an active member of the Veterinary Endoscopy Society and has been past secretary and president. She is currently a Founding Fellow, Minimally Invasive Surgery (Soft Tissue Surgery) and General Surgeon at VetMed in Phoenix, Arizona.

Kurt S. Schulz, DVM, MS, Diplomate ACVS
Dr. Schulz served on the veterinary faculty of Texas A&M University and was an associate professor at the University of California for 9 years, where he served as Chief of Small Animal Surgery from 1999 to 2003. He currently practices at Peak Veterinary Referral Center in Williston, Vermont. He has published over 50 peer-reviewed articles on veterinary surgical research and continues to teach arthroscopy and advanced orthopedic surgical techniques nationally and internationally. His other books include *Small Animal Arthroscopy* and the *Pet Lover's Guide to Canine Arthritis and Joint Problems*. He is an active member of the Veterinary Orthopedic Society, VA3, and the ACVS.

Michael D. Willard, DVM, MS, Diplomate ACVIM
Dr. Willard is an internist with a special emphasis on gastroenterology, endoscopy, pancreatology, and hepatology. Dr. Willard has received several awards for teaching excellence since 1987, among them the 1994 National Norden Award. In addition, he has numerous clinical presentations and has conducted some research in gastroenteric problems. Dr. Willard is a past secretary of the specialty of Internal Medicine and a past president of the Comparative Gastroenterology Society. He serves as a reviewer for several veterinary journals. He has contributed numerous journal articles and several monographs and book chapters. He is currently a professor in the Department of Small Animal Medicine and Surgery at the College of Veterinary Medicine at Texas A&M University.

Audrey Yu-Speight, DVM, MS, Diplomate ACVO
Dr. Yu-Speight earned her BS and MS at Stanford University and worked as a chemical engineer in the biotech industry for 4 years before attending veterinary school at Texas A&M University. She completed her internship and residency at Cornell University and served on the faculty. She has worked in private ophthalmology practice since 2003 and founded Veterinary Eye Center in Austin, Texas, in 2006. She consults on Veterinary Information Network and has worked on veterinary ophthalmology committees (Credentials, Grants, Maintenance of Certification). In 2016, she was awarded the annual Clinical Referral and Consultation Award from the Texas Academy of Veterinary Practice, an affiliate of the Texas Veterinary Medical Association.

PREFACE

This fifth edition of *Small Animal Surgery* (*SAS*) will quickly become your daily go-to surgery reference. We hope that busy practitioners and veterinary students alike will find it to be a practical, easy-to-use, and highly valuable resource. If you have perused previous editions of *SAS*, you will note that this edition has undergone a few significant changes. While we have put a substantial effort into providing videos as an important component to *SAS*, as detailed under the Expert Consult section below, we have taken care to maintain the well-loved and highly appreciated aspects of previous editions, including (1) a limited number of contributors, (2) an excellent art program, and (3) a consistent format that varies minimally between chapters. Because of the numerous online attributes of this edition, it is available as a print book as well as on the accompanying Expert Consult website. Thus, while providing a practical, traditional textbook, we also offer a dynamic way of learning. We are extremely proud of this fifth edition and think that it is our best yet. We hope you agree.

EXPERT CONSULT

Expert Consult is the platform for the online version of the fifth edition of *Small Animal Surgery.* The website offers online access to the complete book, plus videos and some additional features such as Aftercare Instruction sheets and content on some Rarely Performed Procedures. The website contains the complete text, with full search capabilities, as well as references that link to PubMed. See the inside front cover of the book for instructions on accessing the Expert Consult site.

In the Expert Consult version of this edition, we have included numerous videos that should assist with the understanding of surgical diseases, help you with making a diagnosis, and demonstrate the specific techniques for the surgical procedures that are described. The complexity of the videos ranges from the basics of opening a peel pouch and demonstration of a gait abnormality to the more intricate manipulations required during a surgical procedure. Recognizing the busy nature of veterinary practices and the need for concise, specific information, we strived to make these videos short and succinct. Thus the disease or procedure being demonstrated typically does not have voiceover or explanatory title cards. We will continue to add new videos throughout the life of this edition and welcome approved videos from our colleagues. *To provide a video for review and possible inclusion, please contact Dr. Fossum at terry.fossum@gmail.com.*

In addition to a fully searchable text, Expert Consult offers several user-friendly tools that enhance the user experience. You will find Rarely Performed Procedures as well as Aftercare Instruction templates. To maintain a reasonably sized textbook, some of the less commonly performed procedures detailed in previous editions were removed from the print book and are presented in a fully searchable format (Rarely Performed Procedures). These procedures may, in some cases, be a historical review of procedures that are no longer used in veterinary medicine, or they may be the intervention of choice for diseases or conditions where surgical intervention is uncommon. The Aftercare Instruction templates are meant to be a time-saving tool to assist veterinarians and their staff in providing customizable, detailed discharge instructions for their clients.

UPDATES AND AUTHORS

Throughout the text, you will find that we have updated procedures with new information and, in many cases, we have added descriptions of entirely new procedures that were either rarely used or not used when the previous editions were published. It was our goal to make sure that we produced the most state-of-the-art book possible. Although it has always been our desire to provide clinically useful information rather than a monologue of research on a given topic, we have addressed the need for a review of recent research by providing up-to-date references. To make room for newer references, we have removed most references that were more than 7 years old from this edition, unless (in rare circumstances) the reference was thought to be a "classic." On Expert Consult, the references are directly linked to the original article on PubMed for easy access by the reader.

As with previous editions, the bulk of this book was written by six surgeons (Drs. Curtis Dewey, Theresa Fossum, Kei Hayashi, Catriona MacPhail, MaryAnn Radlinksy, and Kurt Schulz) and an internist (Dr. Michael Willard). However, there are also major contributions from an anesthesiologist (Dr. Jane Quandt), a sports medicine expert (Dr. Janice Huntingford), and two ophthalmologists (Drs. Audrey Yu-Speight and Jane Cho). Part One, *General Surgical Principles,* has contributions from most of the team. To provide additional information on the increasingly important subjects of anesthesia and pain management, we have divided these topics into two chapters: "Principles of Anesthesia and Anesthetics" (Dr. Quandt) and "Pain Management" (Dr. Quandt and Dr. Dewey). "Pain Management" includes a new section on acupuncture. In addition, throughout the text readers will find extensive and comprehensive tables on anesthetic management of animals with particular diseases or conditions. These tables, originally provided by Dr. Caroline Horn and updated for this edition, provide detailed information on the preoperative, intraoperative, and postoperative management of surgical cases in an easy-to-read format, complete with drug doses. Practitioners will find these tables to be a very useful, quick reference. "Fundamentals of Physical Rehabilitation" (Chapter 11) has been extensively revised by Dr. Janice Huntingford, who is a Diplomate of Canine Rehabilitation and Sports Medicine. The topic of regenerative medicine has been updated by Dr. Schulz and is now included in the chapter "Principles of Orthopedic Surgery and Regenerative Medicine" (Chapter 31). Chapter 14, updated by Drs. Willard and Schulz, includes principles of minimally invasive surgery (MIS) and a practical guide to imaging of the surgical patient. Techniques of endoscopy and MIS for specific conditions and diseases can be found throughout the text.

Drs. Catriona MacPhail and MaryAnn Radlinsky were responsible for much of Part Two, *Soft Tissue Surgery.* Dr. Kurt Schulz, and a new addition to the *SAS* team, Dr. Kei Hayashi, provided the material encompassed in Part Three, *Orthopedics.* Dr. Curtis Dewey updated the neurology chapters in Part Four, *Neurosurgery*. Drs. Audrey Yu-Speight and Jane Cho, both board-certified ophthalmologists, extensively updated Chapter 16, "Surgery of the Eye." Lastly, Dr. Mike Willard reviewed and provided his perspective on many of the chapters so that we can provide the most up-to-date information on the medical management of surgical disease.

CONTENT

We have added a significant amount of new information to the text and have maintained the way we reorganized the coverage of minimally invasive procedures to make the text more user friendly. As with the fourth edition, we have a separate chapter on minimally invasive surgery that covers the basics of endoscopy, thoracoscopy, laparoscopy, and arthroscopy. However, we have also included the descriptions of minimally invasive procedures directly within the specific chapters where they are applicable. For example, when you read about surgical pericardiectomy, a description of thoracoscopic pericardiectomy directly follows.

As with previous editions, we believe that to be successful, surgeons must have detailed knowledge of the important issues regarding diagnosis, an awareness of potential differential diagnoses, and a thorough appreciation of preoperative concerns relative to the animal's disease or condition. These sections are each outlined in the text. In addition, anesthetic concerns, surgical anatomy, wound healing, postoperative concerns, and potential complications are detailed. The surgical technique itself is described in detail, which provides the reader with a comprehensive and thorough description of each procedure. The surgical procedure is discussed in *blue italicized type* to make it easy to distinguish from the rest of the text. While we did debate the practicality of including advanced procedures in this textbook, we decided that practitioners would benefit greatly from a better understanding of the procedures, even though they likely would choose to refer these cases to a specialist. With this in mind, we have marked some procedures as "advanced" to forewarn readers of the difficulty of the procedure. While the difficulty of any procedure lies primarily with the experience of the surgeon, the procedures denoted with the special icon AP are ones that the authors find particularly challenging and thus would recommend that they be performed by someone with advanced training or special expertise in that area.

GENERAL FORMAT

This book is composed of 44 chapters and is organized into four parts. The 14 chapters of Part One, *General Surgical Principles,* were written with veterinary medical students and practitioners in mind. The information contained in these chapters is what we teach our students in their introductory surgery courses. Found within these chapters is detailed information on the basics of sterile technique, surgical instrumentation, suturing, preoperative care, and rational antibiotic use. We have emphasized the use of scrubless and/or waterless surgeon prep solutions and new patient prep solutions in the chapters on patient and surgeon preparation. Although these solutions and techniques are not particularly new, studies suggest that they are not well known or frequently used by practicing veterinarians. Chapter 10 contains information on postoperative care, including new consideration on the nutritional management of surgical patients. Because nutrition affects many body systems and is an important adjunct to case management, we have included detailed information on techniques for hyperalimentation in this chapter. Chapter 11 details the basics of physical rehabilitation in veterinary patients. We believe that physical rehabilitation is underutilized in many veterinary practices. In addition to this basic chapter, specific recommendations for physical rehabilitation can be found throughout the orthopedic and neurologic chapters. Chapter 12 provides basic information on anesthesia techniques and drugs with important information for practitioners, and Chapter 13 details pain management. As previously noted, we have attempted to give an overview of anesthetic and analgesic techniques while providing detailed protocols for the management of specific diseases in the various chapters in Parts Two, Three, and Four. These anesthetic tables have been expanded in this edition to include preoperative and postoperative management suggestions for these cases and include recommendations for analgesia as well as suggestions for monitoring these cases.

Parts Two, Three, and Four contain information on soft tissue surgery, orthopedic surgery, and neurosurgery, respectively. These chapters are divided into a section detailing general principles and a section on specific diseases. The *General Principles and Techniques* portion begins with definitions of procedures and terms relevant to the organ system detailed. Next are sections detailing information on preoperative concerns and anesthetic considerations. This is followed by a discussion on antibiotic use (including recommendations for antibiotic prophylaxis) and a brief description of pertinent surgical anatomy. Anatomy is too often neglected in surgical textbooks or, because of formatting, is not well correlated with the techniques in a given chapter. We have circumvented this problem by including it as a separate and consistent heading under *General Principles and Techniques.* Surgical techniques that are broadly applicable to a number of diseases are also detailed in this section. However, if a surgical procedure is specific to a particular disease, the description of the technique is found instead with the specific disease description. Brief discussions on healing of the specific organ or tissue as well as suture material and special instruments follow the surgical techniques descriptions. The final headings in the *General Principles and Techniques* section are *Postoperative Care and Assessment, Complications,* and *Special Age Considerations.*

The *Specific Diseases* portion of each chapter begins with definitions and, when relevant, synonyms for the disease or techniques. Next, general considerations and clinically relevant pathophysiology are detailed. This information is meant to provide practical material for case management, rather than to serve as a supplemental text for pathophysiology. The discussions of diagnoses are detailed and include information on signalment and history, physical examination findings, diagnostic imaging, and pertinent laboratory abnormalities. Sections on differential diagnoses and medical management of affected animals are consistently provided. These are followed by a detailed description of the relevant surgical techniques. We have attempted to detail most commonly used techniques, although we may have noted our preference for a particular method. Information on positioning patients for a given procedure is provided as a separate heading. The remainder of the *Specific Diseases* section deals with postoperative care of the surgical patient, potential complications, and prognosis.

Although some of the procedures in this text are best performed only by surgeons with advanced training, we believe that practitioners referring these cases should be provided with adequate information regarding the surgery to talk with their clients in a detailed and knowledgeable fashion; thus we have elected to include some advanced procedures in this

textbook as well as procedures more commonly performed in general practice. As with all surgical procedures, the surgeon must exercise judgment as to what their qualifications and experience are in reference to performing a particular procedure.

CHAPTER FORMAT

I. General principles and techniques
   A. Definitions
   B. Preoperative management
   C. Anesthesia
   D. Antibiotics
   E. Surgical anatomy
   F. Surgical technique
   G. Wound healing
   H. Suture materials and special instruments
   I. Postoperative care and assessment
   J. Complications
   K. Special age considerations
II. Specific diseases
   A. Definitions
   B. General considerations and clinically relevant pathophysiology
   C. Diagnosis
   D. Differential diagnosis
   E. Medical management
   F. Surgical treatment
   G. Surgical technique
   H. Suture materials and special instruments
   I. Postoperative care and assessment
   J. Complications
   K. Prognosis

ANESTHESIA PROTOCOLS

For quick reference, recommendations for anesthetizing animals with a particular disease or disorder are found in the *Specific Diseases* section of each chapter. Dr. Jane Quandt served as our anesthesia consultant for this revision. The anesthesia protocol tables include recommended drug dosages and should be extremely useful to busy practitioners. Although we recognize that many veterinarians have established protocols that they prefer and with which they are comfortable, the protocols provided in this book have proved to be a handy resource for many practitioners.

SPECIAL FEATURES

As in past editions, we have included hundreds of tables and boxes that summarize key clinical information. It has always been our intent to make this book as user friendly as possible. For this reason, we have maintained the NOTE boxes interspersed throughout most chapters, which highlight important concerns, key concepts, and precautions. To facilitate ease of access and to promote comprehension, we have created unique tables and boxes with similar types of information. These tables and boxes are color coded and are marked with distinct icons for easy content identification, as follows:

Calculations

General Treatment

Analgesics/Postoperative Care/Pain Management

Diagnosis/Differential Diagnosis

Key Points

Anesthetics/Sedation

Clinical Signs

Antibiotics

Complications

Causes/Etiology

Classification of Disease

ART PROGRAM

We were extremely privileged to work with our original illustrator, Laura Pardi Duprey, on this fifth edition. In addition to being an incredibly skilled artist, she has an extremely broad-based and detailed knowledge of anatomy. You will find the illustrations in this text exceptionally clear and accurate. We have added many new images, and revised many more, in our attempt to make this book among the best illustrated textbooks in veterinary medicine.

We have added new artwork to existing procedures, and you will find that there are more color illustrations in this edition than in the last. In fact, nearly the majority of the illustrations in this edition are in full color.

INDEX

The index of *Small Animal Surgery* is thorough and exhaustive. We have avoided cross-referencing readers to separate entries in the index. Rather, we have opted to duplicate page sources each time a topic is listed because we believe that this is the most useful format for practitioners.

SUMMARY

Regardless of where you practice or when you graduated, it is the hope of the entire *Small Animal Surgery* team that you find this edition to be an extremely user-friendly, informative text that assists you in diagnosing and treating surgical conditions. We welcome your feedback and suggestions on what you appreciate about this textbook and what we might do to improve future editions. Please feel free to send your comments to terry.fossum@gmail.com.

ACKNOWLEDGMENTS

AUTHOR ACKNOWLEDGMENTS

I would like to once again thank my past and current authors on this book. I am blessed to have been able to work with some of the best and most dedicated veterinarians in the field. This edition was in many ways the most difficult edition that we have undertaken. After the print text was submitted, we began months of working on videos. Some videos had already been in authors' possession, but many others were specifically shot and edited for this edition. The time and effort that went into creating these videos were significant, and I thank those who made providing them a priority.

PERSONAL ACKNOWLEDGMENTS

A textbook of this nature takes the input and hard work of a great number of people to ensure that it is a quality reference. Special thanks to Rae Robertson, Content Development Specialist; Jennifer Flynn-Briggs, Senior Content Strategist; and all the others at Elsevier who worked on this project. We thank them for their enthusiasm, words of encouragement, and vision, and most of all for their belief in this book. Without them, this edition would not have been possible.

We would also like to thank our mentors and colleagues, who have instilled in us a love of surgery and a dedication to our profession. Without you, this book would not have become a reality. To all of you who purchased previous editions, we appreciate your input and recommendations. We particularly welcome your suggestions on how to improve future editions. We hope you find this edition a worthy effort.

Finally, I would like to acknowledge the support and encouragement of my wonderful family: my husband, Matt Miller; my sons, Chase and Kobe Miller; my mother, Marian Smith; and my mother-in-law, Diane Miller. I would also like to thank my colleagues in the extraordinary workplace that I now call home, Midwestern University. Particular thanks and recognition go to my boss and Midwestern's phenomenal leader, Dr. Kathleen Goeppinger.

CONTENTS

PART ONE General Surgical Principles

1 **Principles of Surgical Asepsis,** 1
Kurt S. Schulz and Terry W. Fossum
2 **Care and Handling of Surgical Equipment and Supplies,** 4
Terry W. Fossum and Kurt S. Schulz
3 **Surgical Facilities and Maintenance of the Surgical Environment,** 18
Terry W. Fossum
4 **Preoperative and Intraoperative Care of the Surgical Patient,** 26
Catriona MacPhail and Terry W. Fossum
5 **Preparation of the Operative Site,** 36
Terry W. Fossum
6 **Preparation of the Surgical Team,** 42
Terry W. Fossum
7 **Surgical Instrumentation,** 50
Catriona MacPhail and Terry W. Fossum
8 **Biomaterials, Suturing, and Hemostasis,** 60
Catriona MacPhail and Terry W. Fossum
9 **Surgical Infections and Antibiotic Selection,** 79
Michael D. Willard, Kurt S. Schulz, and Terry W. Fossum
10 **Nutritional Management of the Surgical Patient,** 90
Catriona MacPhail, Michael D. Willard, and Terry W. Fossum
11 **Fundamentals of Physical Rehabilitation,** 105
Janice Lynne Huntingford and Terry W. Fossum
12 **Principles of Anesthesia and Anesthetics,** 125
Jane Quandt and Terry W. Fossum
13 **Pain Management and Acupuncture,** 140
Jane Quandt, Curtis W. Dewey, and Terry W. Fossum
14 **Principles of Minimally Invasive Surgery and Imaging of the Surgical Patient,** 158
Michael D. Willard, Kurt S. Schulz, Kei Hayashi, and Terry W. Fossum

PART TWO Soft Tissue Surgery

15 **Surgery of the Integumentary System,** 179
Catriona MacPhail and Terry W. Fossum
16 **Surgery of the Eye,** 266
Audrey Yu-Speight, Jane Cho, and Terry W. Fossum
17 **Surgery of the Ear,** 302
Catriona MacPhail and Terry W. Fossum
18 **Surgery of the Digestive System,** 331
MaryAnn Radlinsky and Terry W. Fossum
19 **Surgery of the Abdominal Cavity,** 512
Terry W. Fossum
20 **Surgery of the Liver,** 540
MaryAnn Radlinsky and Terry W. Fossum
21 **Surgery of the Extrahepatic Biliary System,** 571
MaryAnn Radlinsky and Terry W. Fossum
22 **Surgery of the Endocrine System,** 586
Catriona MacPhail and Terry W. Fossum
23 **Surgery of the Hemolymphatic System,** 631
MaryAnn Radlinsky and Terry W. Fossum
24 **Surgery of the Kidney and Ureter,** 650
Catriona MacPhail and Terry W. Fossum
25 **Surgery of the Bladder and Urethra,** 678
Catriona MacPhail and Terry W. Fossum
26 **Surgery of the Reproductive and Genital Systems,** 720
Catriona MacPhail and Terry W. Fossum
27 **Surgery of the Cardiovascular System,** 788
Catriona MacPhail and Terry W. Fossum
28 **Surgery of the Upper Respiratory System,** 833
Catriona MacPhail and Terry W. Fossum
29 **Surgery of the Lower Respiratory System: Lungs and Thoracic Wall,** 884
Catriona MacPhail and Terry W. Fossum
30 **Surgery of the Lower Respiratory System: Pleural Cavity and Diaphragm,** 916
Terry W. Fossum

PART THREE Orthopedics

31 **Principles of Orthopedic Surgery and Regenerative Medicine,** 957
Kurt S. Schulz, Kei Hayashi, and Terry W. Fossum
32 **Principles of Fracture Diagnoses and Management,** 976
Kei Hayashi, Kurt S. Schulz, and Terry W. Fossum
33 **Management of Specific Fractures,** 1036
Kei Hayashi, Kurt S. Schulz, and Terry W. Fossum
34 **Diseases of the Joints,** 1134
Kurt S. Schulz, Kei Hayashi, and Terry W. Fossum
35 **Management of Muscle and Tendon Injury or Disease,** 1280
Kurt S. Schulz, Kei Hayashi, and Terry W. Fossum
36 **Other Diseases of Bones and Joints,** 1295
Kurt S. Schulz, Kei Hayashi, and Terry W. Fossum

PART FOUR Neurosurgery

37 **Neurodiagnostic Overview for the Small Animal Surgeon,** 1313
Curtis W. Dewey and Terry W. Fossum
38 **The Neurologic Examination and Relevant Neuroanatomy,** 1323
Curtis W. Dewey and Terry W. Fossum
39 **Surgery of the Brain,** 1338
Curtis W. Dewey and Terry W. Fossum
40 **Surgery of the Cervical Spine,** 1365
Curtis W. Dewey and Terry W. Fossum
41 **Surgery of the Thoracolumbar Spine,** 1404
Curtis W. Dewey and Terry W. Fossum
42 **Surgery of the Cauda Equina,** 1427
Curtis W. Dewey and Terry W. Fossum
43 **Nonsurgical Disorders of the Brain and Spine,** 1444
Curtis W. Dewey and Terry W. Fossum
44 **Peripheral Nervous System Disorders and Diagnostic Techniques,** 1460
Curtis W. Dewey and Terry W. Fossum

Index, 1465

Principles of Surgical Asepsis

Infection remains one of the most potentially devastating and challenging complications of surgery. Infection in a veterinary surgical practice may occur during surgery or any time during hospitalization. It is incumbent upon the veterinary practitioner and staff to ensure that all possible measures are taken to reduce the risk of iatrogenic infection.

ASEPSIS VERSUS STERILITY

The terms *aseptic technique* and *sterile technique* are used interchangeably by some authors (Box 1.1), but in strict terms, *asepsis* is defined as the absence of microorganisms that cause disease, whereas *sterile* is defined as being free of all living microorganisms. Therefore techniques to maintain sterility are more appropriate for the operating room (OR) setting, but aseptic principles should be applied to the entire hospital. Outside the OR, these techniques have been referred to as *medical asepsis* and are designed to protect both the patient and hospital staff.

The complete absence of microorganisms cannot be achieved in a hospital environment, but use of aseptic techniques substantially aids in the control of pathogens and decreases the risk of infection for patients and staff. When specific procedures are discussed in this text, *aseptic technique* has been referred to as *clean technique. Sterile technique* (see Box 1.1) applies to work performed in a sterile field. The higher level of protection in a sterile field is critical because the natural defenses of the patient are breached by surgical incision, puncture, or introduction of instruments into the vascular system. Studies in human surgical practice have attempted to determine when sterile technique versus aseptic technique is necessary for certain minor procedures. For example, arthrocentesis (see p. 1136) performed under sterile technique might require the use of sterile gloves, a sterile patient preparation kit, and a small drape, whereas the same procedure performed using clean or aseptic technique would require only nonsterile gloves and an alcohol wipe. The differences in time and cost involved for sterile technique versus clean technique can be substantial.

TRANSMISSION OF MICROORGANISMS

Numerous sources of microorganisms are found in veterinary hospitals, but as in human hospitals, the hospital staff is the most likely means of transmission. Other sources of transmission include contaminated instruments and the environment. The specific means of transmission from staff to patient include airborne, droplet, and contact. Airborne and droplet types of transmission of microorganisms are common in human hospitals but less common in veterinary hospitals because of the low incidence of reverse zoonosis (transmission of disease from human to nonhuman animals). Contact, in which pathogenic microorganisms are transferred to the patient from another patient or from an environmental source, is the most common method of microorganism transmission in veterinary hospitals. During surgery, contact may also be responsible for transmission of the patient's own microorganisms from the skin or nasopharynx to the surgical wound.

Sources of Contamination

Sources of contamination may be divided into animal sources and inanimate sources.

Animal Sources

Sources of microorganisms from patients include the skin, hair, nasopharynx, and other orifices such as the vulva or anus.

Inanimate Sources

The primary sources of microorganisms from inanimate objects are fomites and air. A *fomite* is any inanimate object capable of carrying infectious organisms. Fomites may include the hospital structure (walls, floors, etc.), furniture, equipment, implants, and cleaning equipment. Protocols must be established to maintain an aseptic environment by having scheduled cleansing of potential fomites and regular monitoring for possible hospital-borne infections (see Chapter 3).

Airborne Sources

One cubic foot of air contains thousands of particles, which can increase to more than 1 million particles during a lengthy surgical procedure. This increase is due to traffic into and out of the room and other air currents that develop. Particles in air are significant sources of microorganisms and may be responsible for 80% to 90% of microbial contamination of a surgical wound. Primary sources of microorganisms found in the air include the floor, the hospital staff, and the patient.

PRINCIPLES OF HOSPITAL ASEPSIS

Minimization of infection in a surgery practice involves applying principles of aseptic technique throughout the hospital. Goals are to minimize sources of contamination and to block transmission

ABSTRACT

Infection remains one of the most potentially devastating and challenging complications of surgery. Surgeons must understand the concepts of asepsis and sterility, how microorganisms are transmitted in the hospital, and how to prevent infection.

BOX 1.1 Glossary

Antisepsis Prevention of sepsis by exclusion, destruction, or inhibition of growth or multiplication of microorganisms from body tissues and fluids.

Antiseptics Inorganic chemical compounds that combat sepsis by inhibiting growth of microorganisms without necessarily killing them. Used primarily on skin to stop the growth of resident flora.

Asepsis Absence of microorganisms that cause disease.

Aseptic technique Method to prevent contamination by microorganisms.

Barrier A material used to reduce or inhibit the migration or transmission of microorganisms in the environment: personnel attire and gowns, furniture and patient drapes, equipment and supply packaging, and ventilating filters.

Contaminated Carrying or infected by microorganisms.

Cross-contamination Transmission of microorganisms from patient to patient or from inanimate object to patient.

Decontamination Cleaning and disinfecting or sterilizing processes carried out to make contaminated items safe to handle.

Disinfection Chemical or mechanical (friction) destruction of pathogens.

High-level disinfection Used for equipment/instruments that contact the skin or mucous membranes but do not penetrate the body (semicritical items; see Table 1.2) and where sterility is not required.

High-level sterilization Required when a surgical instrument or medical device enters beneath the skin or mucous membranes (critical items; see Table 1.2).

Irreducible minimum Microbial burden cannot get any lower; item is sterile to its highest degree.

Low-level disinfection Used for noncritical items (see Table 1.2) where the instrument or device contacts skin but does not penetrate the body or mucous membranes.

Spatial relationships Awareness of sterile, unsterile, clean, and contaminated areas, objects, and individuals and their proximity to each other.

Standard precautions Procedures followed to protect personnel from contact with the blood and body fluids of patients.

Sterile Free of living organisms.

Sterile field Area around the site of incision into tissue or the site of introduction of an instrument into a body orifice that has been prepared using sterile supplies and equipment.

Sterile technique Method by which contamination with microorganisms is prevented to maintain sterility throughout the surgical procedure.

Terminal sterilization and disinfection Procedures carried out for the destruction of pathogens at the end of the surgical procedure in the operating room after the patient has been removed.

Modified from Philips N. In: *Berry and Kohn's Operating Room Technique.* 13th ed. St. Louis: Elsevier; 2017.

of microorganisms. Some techniques that aid in reduction of the quantity of pathogenic microorganisms are listed in Box 1.2.

BOX 1.2 Techniques That Aid in Reduction of the Quantity of Pathogenic Microorganisms

- Regular hand washing by hospital staff
- Use of nonsterile or sterile gloves when handling likely sources of pathogens, including high-risk patients (e.g., patients with known infection or wounds), equipment (e.g., contaminated sponges), and hospital surfaces
- Cleaning or disposal of equipment between patients
- Containment of contaminated supplies and equipment
- Proper storage of equipment
- Regular equipment cleaning protocols
- Proper handling of soiled laundry
- Scheduled cleaning of hospital surfaces
- Proper maintenance of hospital heating, ventilation, and air conditioning systems
- Minimization of unnecessary traffic
- Isolation of patients with known pathogenic microorganisms

STERILE TECHNIQUE

All surgical procedures are ideally performed under sterile conditions. Sterile technique is designed to prevent the transmission of microorganisms into the body during surgery or other invasive procedures. General principles of aseptic technique should be familiar to all personnel working in and around the surgical environment (Table 1.1). These principles include the following: (1) use only sterile items within a sterile field; (2) sterile (scrubbed) personnel are gowned and gloved; (3) sterile personnel operate within a sterile field (sterile personnel touch only sterile items or areas, unsterile personnel touch only unsterile items or areas); (4) sterile drapes are used to create a sterile field; (5) all items used in a sterile field must be sterile; (6) all items introduced onto a sterile field should be opened, dispensed, and transferred by methods that maintain sterility and integrity; (7) a sterile field should be maintained and monitored constantly; and (8) surgical staff should be trained to recognize when they have broken technique and should know how to remedy the situation.

NOTE You must know what equipment and supplies are sterile and what are not sterile and keep the two apart. If contamination occurs, remedy the contamination immediately.

STERILIZATION AND DISINFECTION

Sterilization is the destruction of all microorganisms (bacteria, viruses, spores) on an item. It usually refers to objects (e.g., instruments, drapes, catheters, needles) that come in contact with tissue or enter the vascular system. Disinfection is the destruction of most pathogenic microorganisms on inanimate (nonliving) objects, whereas antisepsis is the destruction of most pathogenic microorganisms on animate (living) objects. Neither disinfection nor sterilization claims to kill or inactivate all microorganisms. The level of disinfection or sterilization needed depends on what the object (instrument or medical device) is being used for. Given that all invasive procedures involve contact with a patient's sterile tissue or mucous membranes, it is essential that appropriate techniques for disinfection and sterilization be utilized by veterinary surgeons. High-level sterilization is required when a surgical instrument or medical device enters beneath the skin or mucous membranes *(critical items;* Table 1.2). These instruments and implants must be handled using sterile technique. Equipment that contacts the skin or mucous membranes only for surgical purposes without penetrating the body must be cleaned and disinfected to reduce the level of microorganisms, but sterility is not required. High-level disinfection is generally used for such items (*semicritical items;* see Table 1.2); terminal sterilization is common with some of these instruments, but sterility is not maintained during the procedure. Low-level disinfection (*for noncritical items;* see Table 1.2) is needed when the instrument or device contacts skin but does not penetrate the body or mucous membranes.[1] Antiseptics are used to kill microorganisms during patient skin preparation and surgical scrubbing (see Chapters 5 and 6); however, the skin is not sterilized. Cleaning is generally restricted in meaning to the physical removal of surface contaminants, usually with detergents or soap and water, ultrasound, or other methods. Although cleaning does remove soils and bacteria, it does not kill or inactivate viruses or bacteria.

TABLE 1.1 General Rules of Aseptic Technique

Rule	Reason
Surgical team members remain within the sterile area.	Movement out of the sterile area may encourage cross-contamination.
Talking is kept to a minimum.	Talking releases moisture droplets laden with bacteria.
Movement in the operating room (OR) by all personnel is kept to a minimum; only necessary personnel should enter the OR.	Movement in the OR may encourage turbulent airflow, resulting in cross-contamination.
Nonscrubbed personnel do not reach over sterile fields.	Dust, lint, or other vehicles of bacterial contamination may fall on the sterile field.
Scrubbed team members face each other and the sterile field at all times.	A team member's back is not considered sterile even if wearing a wraparound gown.
Equipment used during surgery must be sterilized.	Unsterile instruments may be a source of cross-contamination.
Scrubbed personnel handle only sterile items; nonscrubbed personnel handle only nonsterile items.	Nonscrubbed personnel and nonsterile items may be sources of cross-contamination.
If the sterility of an item is questioned, it is considered contaminated.	Nonsterile, contaminated equipment may be a source of cross-contamination.
Sterile tables are sterile only at table height.	Items hanging over the table edge are considered nonsterile because they are out of the surgeon's vision.
Gowns are sterile from mid-chest to waist and from gloved hand to 2 inches above the elbow.	The back of the gown is not considered sterile even if it is a wraparound gown.
Drapes covering instrument tables or the patient should be moisture proof.	Moisture carries bacteria from a nonsterile surface to a sterile surface (strike-through contamination).
If a sterile object touches the sealing edge of the pouch that holds it during opening, it is considered contaminated.	Once opened, sealed edges of pouches are not sterile.
Sterile items within a damaged or wet wrapper are considered contaminated.	Contamination can occur from perforated wrappers or from strike-through from moisture transport.
Hands may not be folded into the axillary region; rather, they are clasped in front of the body above the waist.	The axillary region of the gown is not considered sterile.
If the surgical team begins the surgery seated, they should remain seated until the surgery has been completed.	The surgical field is sterile only from table height to the chest; movement from sitting to standing during surgery may promote cross-contamination.

TABLE 1.2 Levels of Sterility and Disinfection

Level of Sterility	Definition	Requirements for Sterilization, Cleaning, and Handling	Examples
Critical	Equipment or implants entering sterile tissue of the vascular system	Requires sterilization Handle with sterile technique	Implants Catheters Surgical instruments Laparoscopes Suture material Biopsy forceps Arthroscopes[a]
Semicritical	Equipment that does not penetrate the body; they contact the skin or mucous membranes only	Requires high-level disinfection Must be cleaned before disinfection Sterility generally not maintained during procedure	Vaginoscopes Colonoscopes Flexible endoscopes[a] Some dental instruments Endotracheal tubes
Noncritical	Instruments that contact the mucous membranes or intact skin not directly associated with surgery	Terminal cleaning recommended between patients Disinfection appropriate in some cases	Laryngoscopes Ultrasound probes not used in the body Blood pressure cuffs ECG leads Pulse oximeters Stethoscopes

[a]The incidence of infection associated with endoscope use is low, but infections have occurred; thus at a minimum they should be subjected to high-level disinfection after each use.
ECG, Electrocardiogram.

Care and Handling of Surgical Equipment and Supplies

Regardless of the sterilization technique used, instruments and linens (e.g., towels, gowns, drapes) must be cleaned of gross contamination. Instruments should be cleaned manually or with ultrasonic cleaning equipment and appropriate disinfectants as soon as possible after surgery, and linens should be laundered. Depending on use, surgical instruments and supplies must then be either sterilized or disinfected (see Chapter 1 and Table 1.2).

CLEANING

Cleaning should be done as soon as possible after use of the instrument to prevent drying and caking of blood and other debris on the item. It is a vital step as it removes organic material and inorganic salts that interfere with sterilization. Water with detergents or enzymatic cleaners are used, and it may be done mechanically (e.g., ultrasonic cleaner, dishwasher, utensil washer/sanitizer) or manually.

DISINFECTION

High-level disinfectants destroy all microorganisms with the exception of some bacterial spores[1] and may be accomplished via liquid immersion (see later) or pasteurization. Low-level disinfection destroys vegetative bacteria, as well as some viruses and fungi, but typically does not kill spores or mycobacteria. Disinfectants include peracetic acid–hydrogen peroxide, glutaraldehyde, hydrogen peroxide, improved hydrogen peroxide (2%), ortho-phthalaldehyde (OPA), peracetic acid, ethylene oxide (EtO), heavy metal ions, or dyes. Common disinfectants, their uses, and necessary precautions are listed in Tables 2.1 and 2.2.

STERILIZATION

The reliability of any sterilization method depends on the number, type, and inherent resistance of microorganisms on the items to be sterilized and whether other materials (e.g., soil, oil) that may shield against or inactivate the sterilizing agent are present on the items. Methods to sterilize equipment or supplies include (1) high temperature, (2) low temperature, or (3) liquid immersion. Advantages and disadvantages of commonly used sterilization technologies are summarized in Table 2.2. High-temperature (steam autoclave or dry heat) sterilization may be used for heat-tolerant critical and semicritical items; however, the high temperature and moisture of a steam autoclave make it unusable for many of today's devices. Likewise, dry-heat sterilization produces temperatures that cannot be tolerated by most devices and is seldom used. Low-temperature sterilization systems (e.g., EtO gas, hydrogen peroxide gas plasma, hydrogen peroxide and ozone, hydrogen peroxide vapor; see Table 2.2) are used for heat-sensitive critical and semicritical items (see also Table 1.2).

Liquid immersion includes chemical sterilants such as glutaraldehyde, glutaraldehyde with phenol, and various concentrations of hydrogen peroxide with peracetic acid (see Tables 2.1 and 2.2).[1] Devices cannot be wrapped when using liquid sterilants, and they typically need to be rinsed with water that often is not sterile, which limits their usefulness.

Steam Sterilization

Saturated steam under pressure is a practical and dependable agent for sterilization of heat-tolerant medical supplies and packaging. Steam rapidly destroys all known microorganisms by means of coagulation and cellular protein denaturation. To ensure the destruction of all living microorganisms, the correct relationship between temperature, pressure, and exposure time is critical. The unit used to create this high-temperature, pressurized steam is called an *autoclave*. Certain types of microorganisms have greater inherent heat resistance than do other organisms. Spores of thermophilic aerobes and anaerobes are the most resistant known forms of life to moist heat. Virus particles are more vulnerable to steam sterilization than are spores.

Types of Steam Sterilizers

Gravity Displacement Sterilization

The most commonly used steam sterilizer in veterinary practice is the gravity (or "downward") displacement sterilizer (Figs. 2.1 and 2.2). This sterilizer works on the principle that air is heavier than steam. Supplies to be sterilized are loaded into the inner chamber. A narrow, outer jacket-type chamber surrounds the inner chamber. Pressurized steam from the narrow, outer chamber enters the inner chamber and surrounds the supplies. Air in the inner chamber is pulled downward by gravity to the floor and exits through a temperature-sensitive valve. As steam accumulates and the temperature increases, the steam-release valve closes. Because the function of this sterilizer is based on the ability of air to move to the bottom of the autoclave, careful wrapping (see p. 12) and loading of supplies are critical. Table 2.3 shows the recommended sterilization times for commonly sterilized items. See Table 2.4 for minimum time and temperature standards for various types of steam sterilizers.

Prevacuum Sterilization

The prevacuum sterilizer relies on air being actively pulled out of the inner chamber, thereby creating a vacuum. Steam is injected into the chamber to replace the air. This method of sterilization provides greater steam penetration in a shorter time than the gravity displacement sterilizer (see Table 2.4).

Immediate-Use Steam Sterilization

Immediate-use, emergency, or "flash" sterilization is performed when an unwrapped, nonsterile item must be sterilized quickly.

ABSTRACT

Proper preparation and storage of surgical equipment and supplies are critical to minimizing the risk of surgical infections and maintaining the quality of surgical equipment. A thorough understanding of the concepts of sterilization and disinfection is critical. Surgeons and staff should be familiar with differing methods of sterilization and storage of equipment.

TABLE 2.1 Common Disinfectants/Sterilants Used in Veterinary Practice

Agent	Practical Use	Disinfectant Properties	Antiseptic Properties	Mechanisms of Action	Precautions
Alcohol: isopropyl alcohol (50%–70%); ethyl alcohol (70%)	Spot cleaning; injection site preparation	Good	Very good	Protein denaturation, metabolic interruption, and cell lysis	Corrosive to stainless steel; volatile; damage to shellac mountings of lensed instruments; hardens rubber and some plastic tubing after prolonged use; irritating to tissues
Chlorine compounds: hypochlorite	Cleaning floors and countertops	Good; available as liquid (sodium hypochlorite) or solid (calcium hypochlorite)	Fair	Release of free chlorine and oxygen	Inactivated by organic material; corrosive to metal; may cause skin irritation and esophageal burns if ingested; discolors fabric
Iodine compounds: iodophors (7.5%) scrub solution	Cleaning dark-colored floors and countertops	Good	Good	Iodination and oxidation of essential molecules	Stains fabric and tissue; do not use on silicone tubing
Glutaraldehyde: 2% alkaline solution	Disinfection of lenses and delicate instruments	Good; sterilizes	None	Protein and nucleic acid alkylation	Tissue reaction; odor; rinse instruments well before using; can be highly toxic
Hydrogen peroxide	Often used as an antiseptic; stabilized form used on environmental surfaces	Good	Very good, particularly against anaerobic bacteria	Formation of free hydroxyl radicals (OH), which oxidize thiol groups in enzymes and proteins	May be irritating to skin at high concentrations; irritating to eyes
Ortho-phthalaldehyde (OPA)	Chemical sterilant similar to glutaraldehyde but not irritating to eyes and nasal passages	Good; sterilizes; fast acting	None	Aldehyde binds to the outer cell wall of the organism (similar to glutaraldehyde)	Doesn't smell but wear personal protective equipment when handling; provide good ventilation; rinse equipment thoroughly
Peracetic acid	Used in automated machines to chemically sterilize instruments	Good; effective in presence of organic material; very rapid kill; no harmful residue	None	Denatures proteins, disrupts cell wall permeability, and oxidizes sulfhydryl and sulfur bonds in proteins, enzymes, and other metabolites	Unstable; quickly loses activity, particularly when diluted; corrosive; irritating to eyes, skin, and respiratory system; can corrode copper, brass, bronze, and galvanized iron

A gravity displacement sterilizer is used for this purpose. The item is placed unwrapped in a perforated metal tray and is sterilized according to the manufacturer's time and temperature recommendations (see Table 2.4). With detachable handles, sterilized items are transported to the operating room (OR) in the metal tray. It is difficult to deliver these devices aseptically; the tray is hot, wet, and unwrapped, which means it collects dust, debris, and microorganisms more readily than dry, cool trays with biobarrier protection. This type of sterilization should be used only in emergencies when no alternative is available. Immediate-use sterilization generally is not recommended for implantable medical devices or power equipment unless specifically approved by the manufacturer. If an implant must be flashed, a "rapid read" biological spore test is used and can be read in 1 hour for a flash cycle. In flash sterilization, it is important to minimize the risk of contamination during transportation. The sterilizer should be located in the restricted area of the surgical suite or treatment site. It is advised to use rigid sterilization container systems (that are validated for use in immediate-use sterilization; Fig. 2.3) and the single-wrapper technique.

Chemical (Gas) Sterilization

Ethylene Oxide

EtO is a flammable, explosive gas that kills microorganisms by altering their normal cellular metabolism and replication through alkylation of proteins, deoxyribonucleic acid (DNA), and ribonucleic acid (RNA). Advantages and disadvantages of EtO are given in Table 2.2. Flexible endoscopes typically require special EtO caps that prevent rupture of the outer plastic layer. The time required for sterilization depends on the concentration of EtO, the humidity level, the temperature, and the volume, density, and types of materials to be sterilized. Most items are sterilized at 54.4°C (130°F) for approximately 2.5 hours; heat-sensitive items are sterilized at 37.8°C (100°F) for approximately 5 hours. The manufacturer's recommendations for EtO exposure time must be followed. Compact, tabletop units (Fig. 2.4) are available that have combinations of ventilation and purge systems (e.g., Anprolene, Anderson Products). The most common veterinary units run on 12- and 24-hour cycles and operate at room temperature.

Items should be clean and dry before EtO sterilization; moisture and organic material bond with EtO and leave a toxic residue. If an item cannot be disassembled and all surfaces cleaned, it cannot be sterilized. Items are packed and loaded loosely in the sterilizer to allow gas circulation. Complex items (e.g., power equipment) are disassembled before processing (see p. 13). Items that cannot be sterilized with EtO include acrylics, some pharmaceutical items, and solutions.

The effectiveness of EtO sterilization may be changed by lumen length, lumen diameter, inorganic salts, and organic materials.

TABLE 2.2 Methods to Sterilize or Disinfect Surgical Instruments, Implants, and Devices

Classification of Items	Level of Germicidal Action	Type of Sterilization/Disinfection	Advantages	Disadvantages
Critical (surgical instruments, implants, cardiac catheters)	Kills all microorganisms, including spores	Sterilization • Steam (autoclave)	• Nontoxic • Easy to use • Inexpensive • Rapid acting • Penetrates packing and lumens	• Deleterious for heat-labile items • Must be used carefully to avoid burns
		• Hydrogen peroxide gas plasma	• Safe to use; no toxic residues • Fast cycle time; aeration not needed • Process temp 50°C (122°F); safe for heat- and moisture-sensitive items • Simple to operate	• Cannot process cellulose (paper), linens, or liquids • Requires synthetic (polypropylene) packaging and special container trays • Cannot process large or bulky items because chamber is small
		• Ethylene oxide	• Effective • Penetrates medical packaging • Easy to monitor and control	• Potential hazard to staff • Long aeration times required
		• Vaporized hydrogen peroxide	• Safe to use; no toxic residues • Fast cycle time; aeration not needed • Safe for heat- and moisture-sensitive items	• Cannot process large or bulky items because chamber is small • Cannot use for liquid, linens, powders, or cellulose materials • Requires synthetic (polypropylene) packaging and special container trays
Semicritical (endoscopes, anesthesia equipment)	Kills all microorganisms except high numbers of bacterial spores; high-level disinfectant	• Glutaraldehyde (Glu); ≥2.0% • Ortho-phthalaldehyde; 0.55% • Hydrogen peroxide; 7.5% • Hydrogen peroxide + peracetic acid 1.0%/0.08% • Hydrogen peroxide + peracetic acid 7.5%/0.23% • Hypochlorite (free chlorine); 650–675 ppm • Accelerated hydrogen peroxide; 2% • Peracetic acid; 0.2% • Glu + isopropanol; 3.4%/26.0% • Glu + phenol/phenate; 1.21%/1.93%	• See Table 2.1	• See Table 2.1
Noncritical (walls, floors, ECG leads)	Kills vegetative bacteria, fungi, and some viruses; low-level disinfectant	• Ethyl or isopropyl alcohol; 70%–90%	• See Table 2.1	• See Table 2.1
		• Chlorine; 100 ppm (1:500 dilution)	• See Table 2.1	• See Table 2.1
		• Phenolic; use per manufacturer recommendation	• Active ingredient in Lysol, Pine Sol • Active against bacteria and some viruses • Maintain activity in presence of organic material	• Not active against nonenveloped viruses and spores • May cause tissue irritation • May be toxic to neonates
		• Iodophor; use per manufacturer recommendation	• See Table 2.1	• See Table 2.1
		• Quaternary ammonium; use per manufacturer recommendation	• Good cleaning agents but poorly effective as antiseptics • Less effective against gram-negative bacteria than gram-positive bacteria	• Not effective against nonenveloped viruses, fungi and bacterial spores

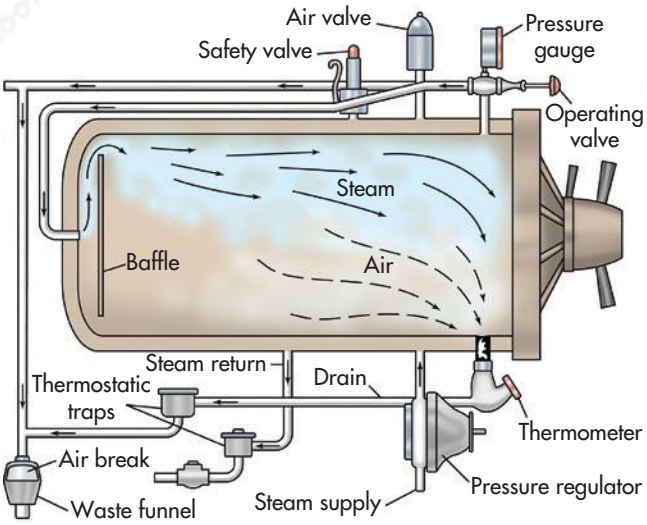

FIG. 2.1 Diagram of a gravity displacement autoclave.

FIG. 2.2 Getinge steam autoclave. (Courtesy Getinge, Gothenburg, Sweden.)

Several studies have shown failure of EtO in inactivating contaminating spores in endoscope channels or lumen test units and residual EtO levels averaging 66.2 ppm even after the standard degassing time. It is recommended that dental handpieces be steam sterilized. Environmental and safety hazards associated with EtO are numerous and severe, and the manufacturer's guidelines for equipment use should be followed carefully to prevent injury to the patient or hospital personnel. The Environmental Protection Agency has classified EtO as a Group B1, probable human carcinogen.

TABLE 2.3 Exposure Periods for Sterilization in Gravity Displacement Sterilizers

Item	Minimum Time Required (min), 121°C–123°C (250°F–254°F)
Scrub brushes (in dispensers, cans, individually wrapped)	30
Dressings (wrapped in muslin or paper)	30
Glassware (empty, inverted)	15
Instruments (wrapped in double-thickness muslin)	30
Instruments combined with suture, tubing, porous materials (wrapped in muslin or paper)	30
Metal instruments only (unwrapped)	15
Linen: maximum size 30 × 30 × 50 cm (12 × 12 × 20 in) (6 kg wrapped)	30
Needles (individually packaged in glass vials or paper, lumens moist)	30
Needles (unwrapped, lumens moist)	15
Rubber catheters, drains, tubing (wrapped in muslin or paper, lumens moist)	30
Rubber catheters, drains, tubing (unwrapped, lumens moist)	20
Utensils (wrapped in muslin or paper, on edge)	20
Utensils (unwrapped, on edge)	15
Syringes (unassembled, individually packaged in muslin or paper)	30
Syringes (unassembled, unwrapped)	15
Suture: silk, cotton, nylon (wrapped in paper or muslin)	30
Solutions:	
75–250 mL	20 (slow exhaust)
500–1000 mL	30 (slow exhaust)
1500–2000 mL	40 (slow exhaust)

Plasma Sterilization

Plasma sterilization (see Table 2.2) is a low-temperature sterilization technique that has become a method of choice for sterilizing heat-sensitive items. This process inactivates microorganisms primarily through the combined use of hydrogen peroxide gas and the generation of free radicals (hydroxyl and hydroperoxyl free radicals) during the plasma phase of the cycle. Conventional sterilization techniques (e.g., autoclaves, ovens, chemicals such as EtO) rely on irreversible metabolic inactivation or on breakdown of vital structural components of the microorganism. Plasma sterilization operates differently because it uses ultraviolet (UV) photons and free radicals. An advantage of the plasma method is the possibility of sterilizing at relatively low temperatures (50°C [122°F]), preserving the integrity of polymer-based

instruments, which cannot be subjected to autoclaves and ovens. Furthermore, plasma sterilization is safe, both for the operator and for the patient, in contrast to EtO.

Vapor phase hydrogen peroxide sterilization is a form of plasma sterilization that uses hydrogen peroxide to process instruments quickly and efficiently (Fig. 2.5). Instruments can be sterilized at low temperatures (i.e., <50°C [122°F]) and short time intervals (i.e., 45 minutes), and they are immediately available because aeration is not required. Items for sterilization must be wrapped in nonwoven polypropylene fabric or plastic (Tyvek/Mylar) pouches (Table 2.5). Items that can be sterilized through this process include stainless steel, aluminum, brass, silicone, Teflon, latex, ethyl vinyl acetate, Kraton, polycarbonate, polyethylene (high and low density), polyolefin, polyurethane, polypropylene, polyvinyl chloride, and polymethylmethacrylate. Some plastics, electrical devices, and corrosion-susceptible metal alloys can be sterilized by hydrogen peroxide gas plasma. An important shortcoming of plasma sterilization is its dependence on the actual "thickness" of the microorganisms to be inactivated because UV photons need to reach the DNA. Any material covering the microorganisms (e.g., packaging) will slow down the process. Items that cannot be sterilized safely include linen, gauze sponges, wood products (including paper), endoscopes, some plastics, liquids, items that cannot be disassembled, items that cannot be

completely dried, items with copper or silver solder or that use bisphenol epoxy, tubes and catheters longer than 30 cm (12 inches), and tubes and catheters smaller than 1 to 3 mm in diameter. Special adapters (H_2O_2 boosters) are required for use with devices with lumens to ensure that the sterilant gains access to these areas.

TABLE 2.5 Types and Use of Sterilization Packaging Materials Based on Sterilization Method

Sterilization Method	Packaging Material Requirements	Acceptable Materials
Steam autoclave	Should allow steam to penetrate	Paper Plastic Cloth Paper peel packages Wrapped perforated cassettes Sterile container systems
Ethylene oxide	Must allow ethylene oxide to penetrate Do not use nylon, polyvinyl chloride, polyvinyl alcohol, cellophane, or aluminum foil	Cloth nonwoven fabric (polyethylene) Peel packs and pouches
Hydrogen peroxide plasma	Plasma or vapor must penetrate the wrapping Metal trays block radiofrequency waves and cannot be used Cellulose is not compatible, so paper and woven materials with cotton fibers cannot be used	Nonwoven polypropylene Tyvek

Peracetic Acid Sterilization

Peracetic acid is a highly biocidal oxidizer that maintains its efficacy in the presence of organic material. It denatures proteins, disrupts cell wall permeability, and oxidizes sulfhydryl and sulfur bonds in proteins and enzymes. The sterilant, 35% peracetic acid, and an anticorrosive agent are supplied in a single-dose container. The container is punctured at the time of use, immediately before the lid is closed and the cycle is initiated. The concentrated peracetic acid is diluted to 0.2% with filtered water (0.2 µm) at a temperature of approximately 50°C (122°F). Diluted peracetic acid is circulated within the chamber of the machine. This automated machine is used in the United States to chemically sterilize medical and surgical instruments (e.g., flexible endoscopes). Lumenated endoscopes must be connected to an appropriate channel connector to ensure that the sterilant has direct contact with the contaminated lumen. Bronchoscopy-related infections have occurred when bronchoscopes were processed using the wrong connector.[2]

Ionizing Radiation

Most equipment available prepackaged from the manufacturer has been sterilized by ionizing radiation (i.e., cobalt 60 gamma rays or electron accelerators). This low-temperature sterilization process is restricted to commercial use because of its expense. No ionizing radiation processes have been cleared by the US Food and Drug Administration (FDA) for use in health care facilities. Items commonly used in the OR that are sterilized with ionizing radiation include suture material, sponges, disposable items (e.g., gowns, drapes, table covers), powders, and petroleum goods. Resterilization by other means may not be

possible for prepackaged sterilized items that have been opened but not used, because an alternate technique could damage the item and create a health hazard.

Cold Chemical Sterilization

Chemicals used for sterilization must be noncorrosive to the items being sterilized. Glutaraldehyde is a saturated dialdehyde that has gained wide acceptance as a high-level disinfectant and chemical sterilant. It is noncorrosive to metals, rubbers, and plastics and provides a means of sterilizing delicate lensed instruments (e.g., endoscopes, cystoscopes, bronchoscopes). The biocidal activity of glutaraldehyde is a consequence of its alkylation of sulfhydryl, hydroxyl, carboxyl, and amino groups, which alters RNA, DNA, and protein synthesis within microorganisms. Most equipment that is safe for immersion in water is safe for immersion in 2% glutaraldehyde. Glutaraldehyde products are marketed under a variety of brand names and are available in a variety of concentrations, with and without surfactants. For high-level disinfection of endoscopes, a 2% glutaraldehyde solution without surfactant is recommended.

Items for sterilization should be clean and dry; organic matter (e.g., blood, saliva) may prevent penetration into crevices or joints. Residual water causes chemical dilution. Complex instruments should be disassembled before immersion. Immersion times suggested by the manufacturer should be adhered to closely (e.g., 2% glutaraldehyde: 10 hours at 20°C–25°C [68°F–77°F] for sterilization; 10 minutes at the same temperature for disinfection). After the appropriate immersion period, instruments should be rinsed thoroughly with sterile water and dried with sterile towels to prevent damage to the patient's tissues. The major problem associated with glutaraldehyde is that it is a known respiratory and dermal irritant and sensitizer, and adverse health effects may occur in exposed workers. Failure to rinse disinfected equipment thoroughly, leaving residual glutaraldehyde on the endoscope, has led to serious conditions, including chemical colitis, pancreatitis, and mucosal damage in human patients. OPA is a new alkylating agent that contains 0.55% 1,2-benzenedicarboxaldehyde. It has shown superior mycobactericidal activity compared with glutaraldehyde with less contact time required (see Table 2.2).

STERILIZATION INDICATORS

Simply placing an item in a sterilizer and initiating the process does not ensure sterility. Failure to achieve sterility may be the result of improper cleaning (if an item cannot be disassembled and all surfaces cleaned, it cannot be sterilized), mechanical failure of the system used, improper use of equipment, improper wrapping, poor loading technique, or failure to understand the concepts of sterilization processes.

Sterilization indicators allow monitoring of the effectiveness of sterilization. Indicators may undergo a chemical or biological change in response to some combination of time and temperature. Chemical indicators, which are available for steam, gas, and plasma sterilization, generally consist of paper strips or tape impregnated with a material that changes color when a certain temperature is reached (Figs. 2.6 to 2.8). The chemical responds to conditions such as extreme heat, pressure, or humidity, but the response does not reflect the duration of exposure, which is critical to the sterilization process. Therefore it is important to remember that chemical indicators do not indicate sterility, only that certain conditions for sterility have been met. The indicators are placed in the center of each pack and on the outside of the item to be sterilized.

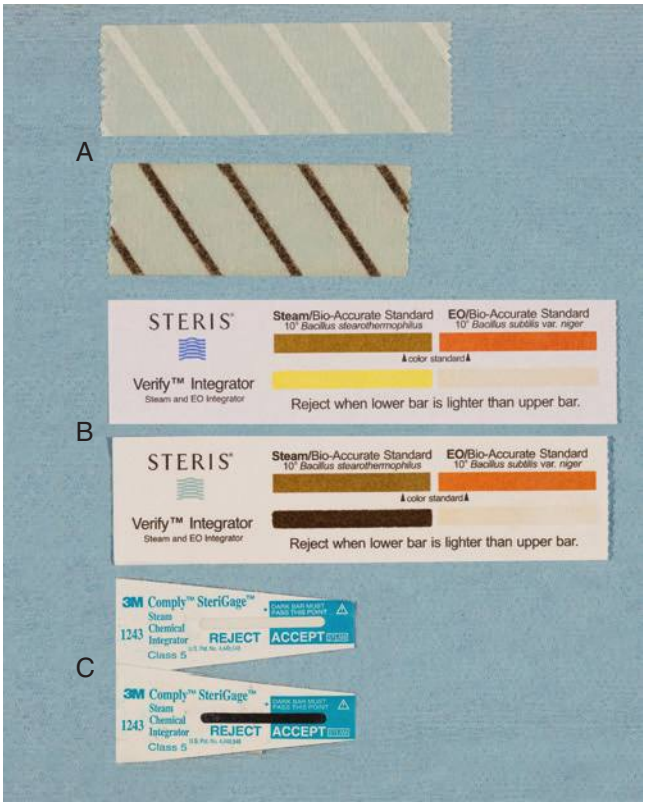

FIG. 2.6 Tape and indicator strips for steam sterilization. (A) The diagonal stripes on the tape *(top)* turn from tan to black. (B) The yellow steam strip *(top)* turns dark brown and must be darker than the line above it. (C) The clear line in the center *(top)* turns black *(bottom)*.

Some autoclaves have a temperature-time graph on the control panel. This indicator method is reliable for measuring the temperature reached and the length of time that each load is exposed to that temperature. A written record can be kept of each processed load.

Use of a biological indicator is the surest way to determine sterility. A strain of highly resistant, nonpathogenic, spore-forming bacteria (*Bacillus stearothermophilus* for steam, *Bacillus subtilis* for gas), which is contained in a glass vial or a strip of paper, is placed in the load of goods to be sterilized. After the sterilization cycle is complete, the vial or strip is recovered and cultured; growth of the organism documents inadequate sterilization. Biological indicators should be used at least weekly to test the effectiveness of the sterilization process.

Sterilization indicators should not be relied on heavily because of the problems mentioned previously. There is no substitute for close supervision of personnel, a general understanding of sterilization processes, and maintenance of high standards for preparing, packing, and loading supplies.

Pack Preparation

The procedure for wrapping items is based on enhancing the ease of sterilization and preserving the sterility of the item, not on convenience or personal preference.

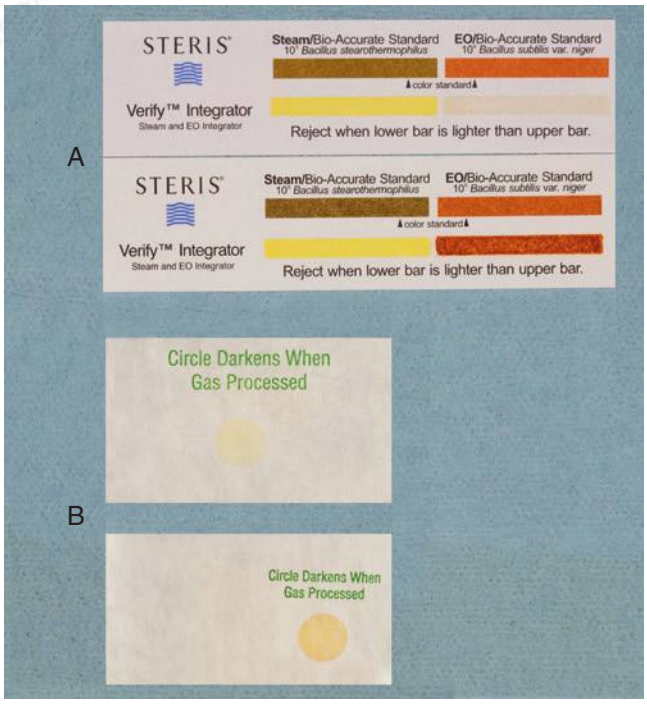

FIG. 2.7 Indicator strips and bag indicators for ethylene oxide (EtO) sterilization. (A) Gas indicator bar on strip turns from tan *(top)* to dark brown *(bottom)*. The bottom bar has to be darker than the top bar. (B) EtO bag indicators turn from a light color *(top)* to a darker shade *(bottom)*. *Note:* Color changes may vary depending on the manufacturer.

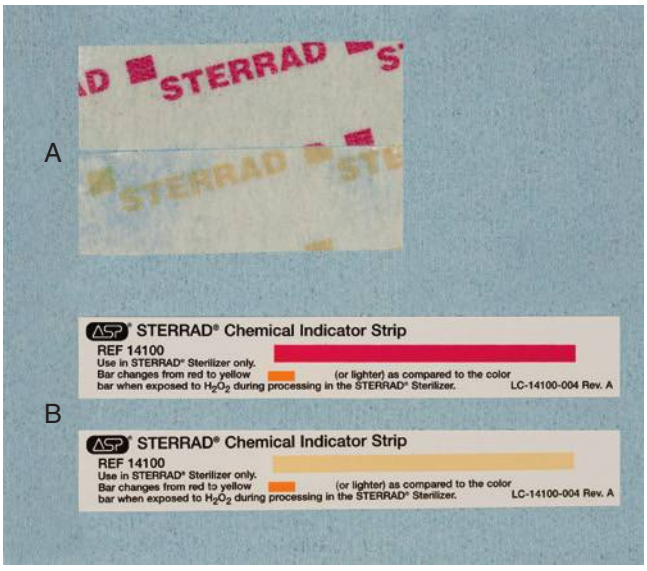

FIG. 2.8 Tape and indicator strips for plasma sterilization. (A) Red writing on tape *(top)* turns to yellow *(bottom)*. (B) Red stripe on the indicator strip *(top)* turns to yellow *(bottom)*. *Note:* Color changes may vary depending on the manufacturer.

Packaging materials (e.g., wrapped or container systems) allow penetration of the sterilization agent and maintenance of sterility after sterilization. Materials for maintaining sterility of instruments during transport and storage include wrapped, perforated instrument cassettes, peel pouches of plastic or paper, sterile container systems, and sterilization wraps (which can be woven or nonwoven). Packaging materials should be designed for the type of sterilization process being used (see Table 2.5). Items sterilized by pressurized steam or other methods (e.g., EtO, plasma) must be wrapped in a specific manner (see p. 12). Packaging materials should also be appropriate for the items being sterilized (Table 2.6). For example, nonpaper materials should be used to package sharp instruments, which can easily puncture paper packaging. Metal closures (e.g., staples, paper clips) that might puncture packaging materials should not be used.

NOTE Do not place paper-plastic pouches within wrapped sets or containment devices because they cannot be positioned to ensure adequate contact with the sterilant, air removal, or drying.[3]

Sterile container systems are typically rigid, boxlike devices made from heat-resistant and steam-sterilizable high-performance plastic or other materials in which instruments can be placed and sterilized (see Fig. 2.3). Rigid containers were first developed in Germany in the mid-1980s. The main function of these early containers was to transport sterile instruments and dressings. In that era, it was not unusual for sterile supplies to be kept in a few containers for an entire day's operating schedule. At the Association of Operating Room Nurses Congress in 1980, the concept of "rigid packaging for sterilization" was introduced in the United States. With time, sterilization containers have gained the confidence of hospital professionals. They are both durable and cost-effective, aid in pack organization, and tend to protect instruments better than wraps. Sterile container systems are the most environmentally friendly because they do not require disposable packaging or laundered cloth. Unlike cloth or paper wrapping, sterile container systems cannot be torn or easily damaged and provide superior protection for surgical equipment. They stack conveniently and can be processed much more rapidly than paper- or cloth-wrapped trays. Closed container systems require filters (in the lid only or in both the lid and the bottom of the container) and latches, seals, and/or tamper-resistant seals. Rigid containers may be a good choice if the sterilization chamber is large enough to accommodate them, and if current storage space is sufficient to accommodate the new configuration. Dozens of different container sizes and shapes are used to accommodate most commonly used instruments, including scopes, drills, and cameras.

NOTE The Association of periOperative Registered Nurses (AORN) recommends a maximum weight limit of 11 kg (25 lb) for instrument sets to avoid insufficient steam contact and a problem with drying that may result in wet packs.[3]

The original sterilization wraps were 140 thread count muslin cloth. Advantages of these cloths included that they were soft, reusable, inexpensive, absorbent, and could easily be draped over trays. However, because they were woven, bacteria could penetrate the pack. Most hospitals double-wrap packs when using cloth to reduce contamination of surgical instruments. In the 1960s, nonwoven materials were introduced that provided a more effective microbial barrier that was also water resistant. The

TABLE 2.6 Packaging Materials Based on Device Type

Medical Device	Sterilization Method	Suggested Packaging Material
Stainless steel instrument(s) Instrument set(s)	Steam	140 count muslin SMS Woven cotton/polyester-blend fabrics Pouches Sterile container systems

EtO, Ethylene oxide.

material used for these wraps was derived from cellulose and was not particularly strong. Hence, sequential (double) wrapping was still necessary. The introduction of polypropylene allowed the development of wraps possessing strength, barrier, and repellent properties. Currently, the most preferred nonwoven technologies used in the medical market are spunlaced and SMS (spunbond, meltblown, spunbond). Spunlaced nonwovens are made by entangling polyester fibers with a layer of wood pulp, whereas SMS materials feature a composite of three layers—spunlace, meltblown, and spunbonded—normally using a polypropylene resin and then stacked together. These products provide excellent protection from microbial contamination. However, despite the fact that the barrier efficacy of a single sheet of wrap has improved over the years, using multiple wrap layers is common practice because of the rigors of handling packs and the consequences of bacterial contamination.

Before packing, instruments are separated and placed in order of their intended use. If steam or gas sterilization is used, the selected wrap should be penetrable by steam or gas, impermeable to microbes, durable, and flexible. Commonly used wrapping materials, the advantages and disadvantages of each, and the sterilization techniques with which each is compatible are listed in Table 2.7.

To ensure maximum penetration, specific guidelines should be followed when packs are prepared for steam and gas sterilization (see Table 2.4). Presterilization wraps for steam sterilization comprise two thicknesses of two-layer muslin or nonwoven (i.e., paper) barrier materials. The poststerilization wrap (i.e., the wrap used after sterilization and the proper cool down period) is a waterproof, heat-sealable plastic dust cover; this wrap is not necessary if the item is to be used within 24 hours of sterilization. Small items may be wrapped, sterilized, and stored in heat-sealable paper or plastic peel pouches (Video 2.1). When sterile container systems are used, the instruments are placed in the inner basket, the filter(s) are replaced, and the unit is sealed with tape or plastic locks. There are no additional storage requirements poststerilization.

Items to be gas sterilized are wrapped in heat-sealable plastic peel pouches or tubing or muslin wrap. When plasma sterilization is used, items should be wrapped in heat-sealable Tyvek-Mylar pouches or polypropylene wraps.

For steam and gas sterilization, instruments should be organized on a lint-free (huck) towel placed on the bottom of

a perforated metal instrument tray. Instruments with boxlocks should be open when autoclaved. A 3- to 5-mm space between instruments is recommended for proper steam or gas circulation. Complex instruments should be disassembled when possible, and power equipment should be lubricated before sterilization. If the item has a lumen, a small amount of water should be flushed through it immediately before steam sterilization because water vaporizes and forces air out of the lumen; conversely, moisture left in tubing placed in a gas sterilizer may reduce the action of the gas below the lethal point. Containers (e.g., saline bowl) should be placed with the open end facing up or horizontal; containers with lids should have the lid slightly ajar. Multiple basins should be stacked with a towel between them. A standard count of radio-opaque surgical sponges should be included in each pack.

A sterilization indicator (see p. 10) (chemical indicators) should be placed in the geometric center (not on top) or in the area considered least accessible to sterilant penetration of each pack before it is wrapped.

Solutions should be steam sterilized separately from instruments, using the slow exhaust phase (see Table 2.3).

NOTE Complex instruments may require longer sterilization times to adequately penetrate the instruments or multiple tray levels (e.g., total hip replacement equipment). These extended sterilization cycle times should be described in the manufacturer's instruction for use (IFU) documentation.

Immersing instruments for long periods of time in any solution can prove damaging. Never leave instruments in any solution for longer than 20 minutes. Do not immerse instruments with tungsten carbide inserts (gold handles) in solutions containing benzyl ammonium chloride (BAC) because this chemical is known to loosen the tungsten carbide.

Linens may be steam sterilized. The maximum size and weight of linen packs that can be steam sterilized effectively are $30 \times 30 \times 50$ cm ($12 \times 12 \times 20$ in) and 6 kg, respectively. Closely woven table drapes should be packed separately. Layers of linen are alternated in their orientation to permit steam penetration. As with instruments, a sterilization indicator (see p. 10) should be placed in the center of each pack.

NOTE Manufacturers of reusable medical devices and surgical instruments for human use are required by the FDA to provide detailed and validated instructions for the disassembly, lubrication, cleaning, disinfecting, packaging, and sterilization of their products. These instructions are provided in IFU documents. IFUs are available for most veterinary surgical and medical products as well.

Wrapping Instrument Packs

Instrument packs should be wrapped so they can be easily unwrapped without breaking sterile technique (Fig. 2.9 and Video 2.2).

Folding and Wrapping Gowns

Gowns must be folded so they can be easily donned without breaking sterile technique (Fig. 2.10).

FOLDING AND WRAPPING DRAPES

Drapes should be folded so that the fenestration can be properly positioned over the surgical site without contaminating the drape (Fig. 2.11).

HANDLING AND STORAGE OF STERILIZED INSTRUMENTS AND EQUIPMENT

After removal from the autoclave, packs are allowed to cool and dry individually on racks. Placing the packs on top of each other during cooling may promote condensation of moisture, resulting in strike-through contamination. Strike-through contamination occurs when moisture carries bacteria from a nonsterile surface to a sterile surface. When wrapped sterile packs are completely dry, they should be stored in waterproof dust covers in closed cabinets (rather than uncovered on open shelves) to protect them from moisture or exposure to particulate matter (i.e., dust-borne bacteria). Sterile container systems can be stacked without additional covers. Excessive handling of sterile supplies should be avoided, especially if the items are pointed or have sharp edges. Sterile items should be handled gently and should be protected from bending, crushing, or compression forces that could break a seal or puncture the package. Sterile packs should be stored away from ventilation ducts, sprinklers, and heat-producing light. Ideal environmental conditions are characterized by low humidity, low air turbulence, and a constant, controllable room temperature.

Sterile Shelf Life

The use of published expiration dates for sterilized items in various types of wrappers is controversial. Events, not time, contaminate products. It was recently shown that if items are packaged, sterilized, and handled properly, they remain sterile unless the package is opened, gets wet, is torn, has a broken seal, or is damaged in some other way (i.e., event-related expiration). The length of time an item is considered sterile depends on a number of factors: (1) the type and configuration of the packaging materials; (2) the number of times a package is handled before use; (3) the number of personnel who may have handled the package; (4) whether the package was stored on open or closed shelves; (5) the condition of the storage area (e.g., cleanliness, temperature, humidity); and (6) the method of sealing and whether dust covers were used.[5] For an event-related expiration system to be used effectively, appropriate protocols must be adopted for sterilizing and handling items.

Handling Sterilized Items

Sterile packs should be labeled with the date on which the item was sterilized and a control lot number for tracing a nonsterile item. Heat-sealed, waterproof dust covers should be placed on items not routinely used. Items should be stored in a manner that does not compromise packaging and sterility, and they need to be rotated in such a way that the item processed first is used first.

If a sterile pack is damaged, it should not be used. Damage is defined as wraps that have moisture present; packs that have been placed in a dusty environment or stored near the source of an air current; items that have been dropped, bent, crushed, compressed, torn, or punctured; or packs that have a broken seal. Education of surgery personnel must include training in

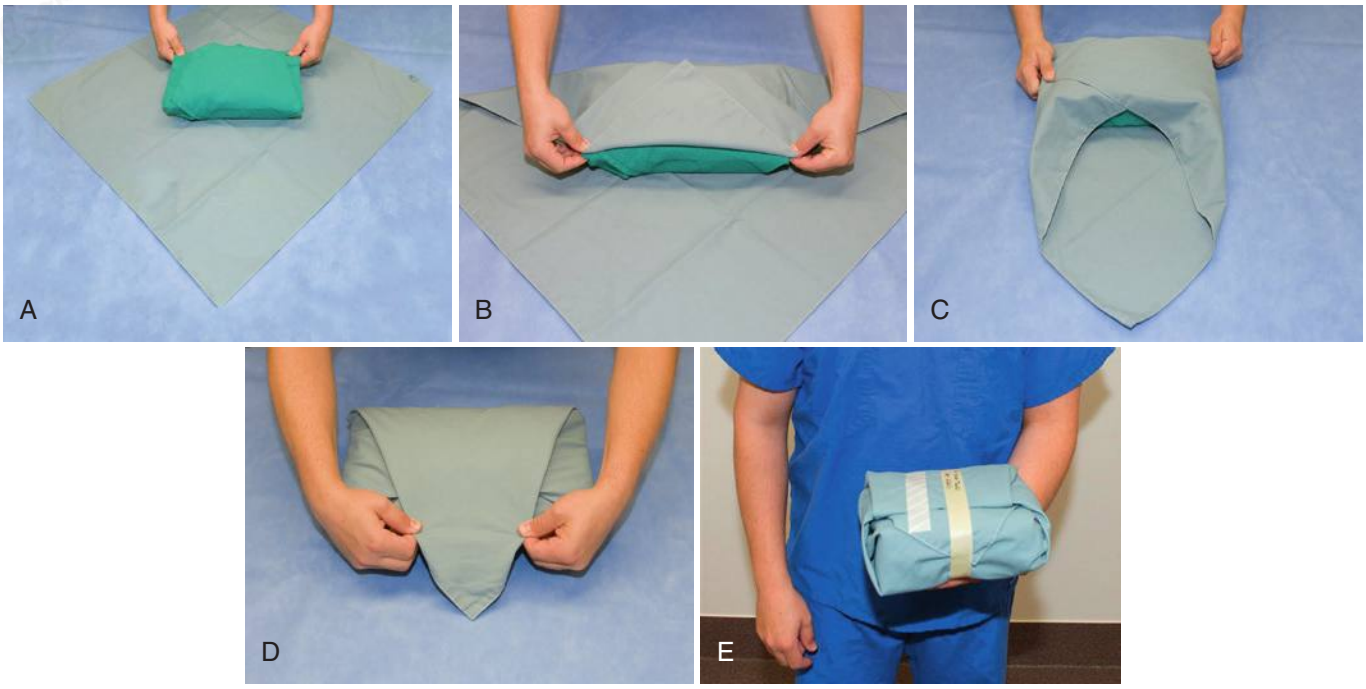

FIG. 2.9 Wrapping an instrument pack. (A) Wrap the instrument pack in a clean huck towel. Place a large, unfolded wrap in front of you and position the instrument tray in the center of the wrap so that an imaginary line drawn from one corner of the wrap to the opposite corner is perpendicular to the long axis of the instrument tray. (B) Fold the corner of the wrap that is closest to you over the instrument tray and to its far edge. Fold the tip of the wrap over so it is exposed for easy unwrapping. (C) Fold the right corner over the pack. Fold the left corner similarly. (D) Turn the pack around and fold the final corner of the wrap over the tray, tucking it tightly under the previous two folds. (E) Wrap the pack in a second layer of cloth or paper in a similar manner. Secure the last corner of the outer wrap with masking tape and a piece of heat-sensitive indicator tape.

ways to protect sterile items from events that cause loss of sterility. The integrity of sterilized items must be carefully assessed to identify damaged goods, and plastic dust covers must be removed or wiped clean before reaching the surgical area.

Wet Packs

Wet packs are sterilized containers that have interior moisture in the form of dampness, droplets, or puddles of water after the sterilization and cool down process. The American National Standards Institute and Association for the Advancement of Medical Instrumentation recommend considering such packs as contaminated as there are no scientific studies to prove otherwise.[4] Wet packs may be due to improper or excessive autoclave loading or inadequate cool down times.

Unwrapping and Opening Sterile Items

Sterile items are wrapped in a manner that allows OR personnel to unwrap the items without contaminating them. Three popular methods are used to distribute wrapped sterile items.

Unwrapping Large Sterile Linen/Paper/Polypropylene Packs That Cannot Be Held During Distribution (Video 2.3)

If the pack is too large, cumbersome, or heavy to be held during distribution, it may be opened onto a Mayo stand or back table. *Place the pack on the center of the Mayo stand or back table, and open each folded layer by pulling it toward you (this prevents your hand and arm from extending over the sterile area). Handle only the edge and underside of the wrap. Follow the same procedure for each fold. When the pack is open, have a sterile team member place it on the sterile table.*

There is disagreement over the correct way to open double-wrapped sterile packs (i.e., outer layer only or both layers), and evidence supports both techniques. The rationale for opening the outer layer only is that this technique eliminates the risk of microbial shedding from the circulating nurse's hands and arms onto the contents of the sterile package. The rationale for opening both wrappers is that when the outer surface of the inner wrapper is opened, it may become contaminated by dust particles and debris from the outer wrapper. If the circulating nurse opens this inner wrapper, the possibility of contamination is reduced. The decision of which technique to use must be based on the technical expertise of personnel and on barrier quality.

Unwrapping Sterile Linen/Paper Packages That Can Be Held During Distribution

These packs may be opened and placed on a sterile table as described in Fig. 2.12, or after opening, they may be grasped by a sterile team member.

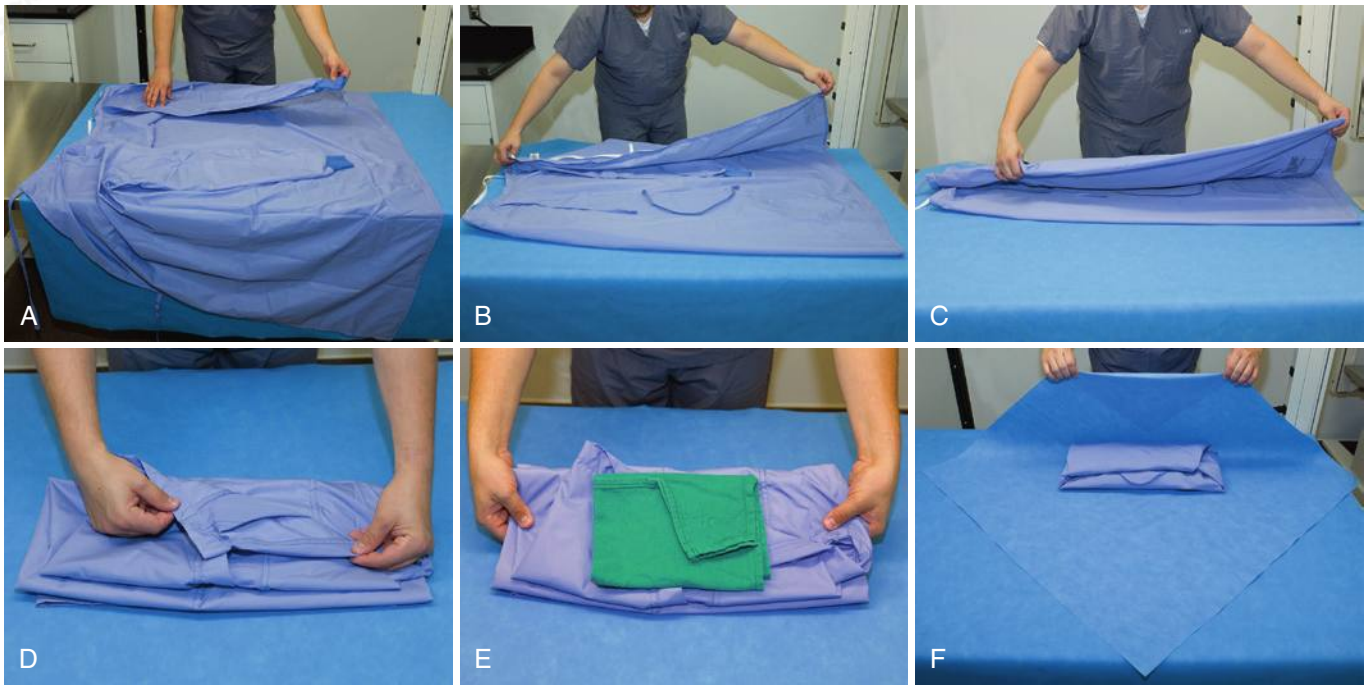

FIG. 2.10 Folding and wrapping surgical gowns. (A) Place the gown on a clean, flat surface with the front of the gown facing up. Fold the sleeves neatly toward the center of the gown with the cuffs of the sleeves facing the bottom hem. (B) Fold the sides to the center so the side seams are aligned with the sleeve seams. (C) Fold the gown in half longitudinally (the sleeves will be inside the gown). (D) Starting with the bottom hem, fanfold the gown toward the neck. (E) Fold a hand towel in half horizontally, and fanfold it into about four folds. Place it on top of the folded gown, leaving one corner turned back so that it can be easily grasped. (F) Wrap the gown and towel in two layers of paper or cloth wrap as described in Fig. 2.9.

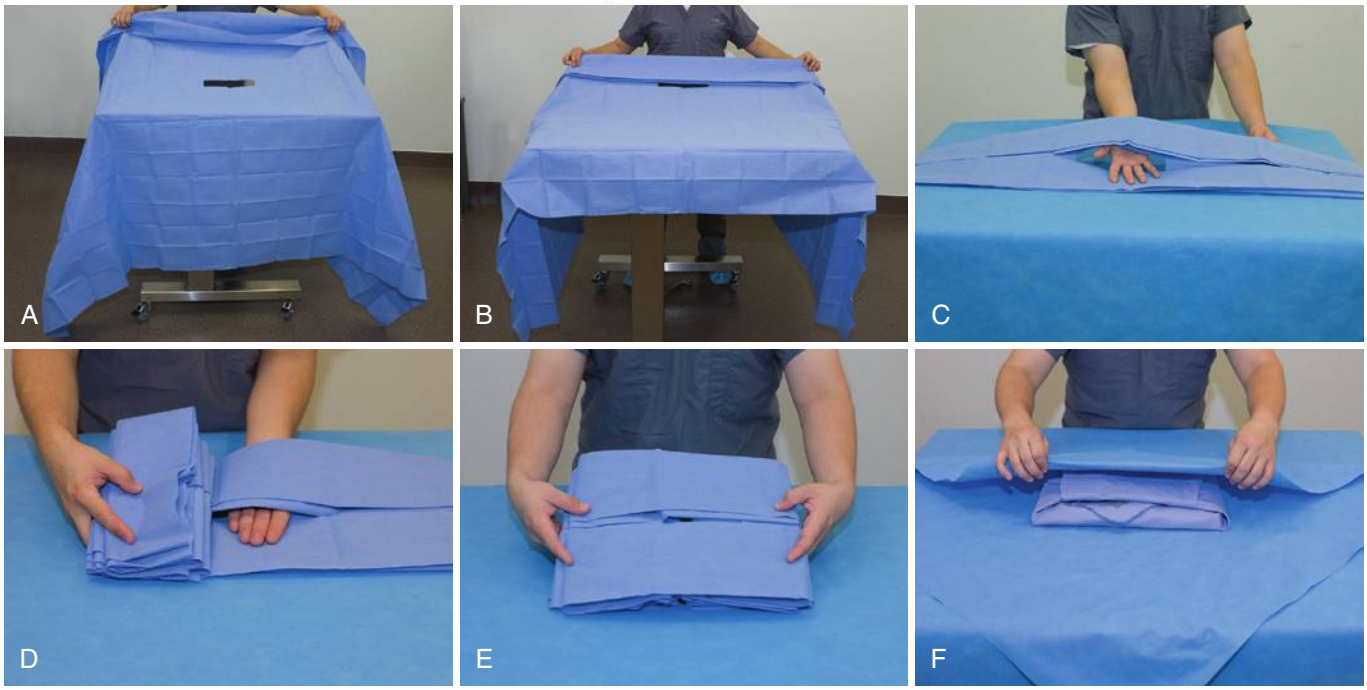

FIG. 2.11 Folding and wrapping drapes. (A) Lay the drape flat with the ends of the fenestration perpendicular to you and the sides of the fenestration parallel to you. (B) Grasp the edges of the drape nearest you and fanfold the drape to the center. The edge of the drape should be exposed (dorsal) so it can be easily grasped during unfolding. (C) Turn the drape around and fanfold the other half the same way. (D) Fanfold one end of the drape to the center (the fingers are through the fenestration); repeat with the other end. (E) If the drape has been folded properly, the fenestration is on the ventral outermost aspect. (F) Fold the drape in half, and wrap it in two layers of paper or cloth wrap as described in Fig. 2.9.

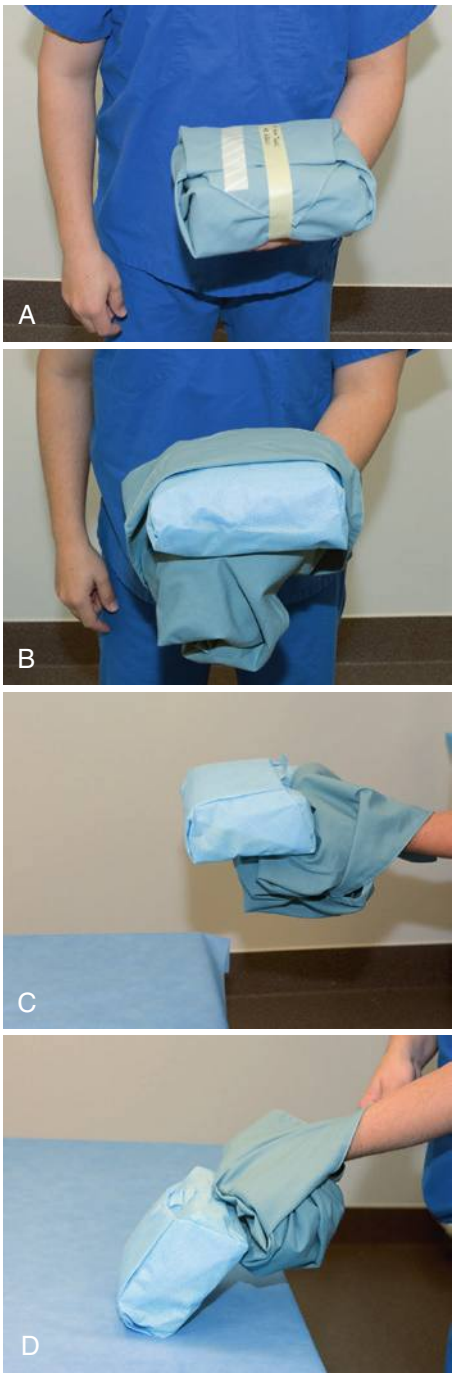

FIG. 2.12 (A) To unwrap a sterile linen pack that can be held during distribution, hold the pack in your left hand if you are right-handed (and vice versa). (B) Using your right hand, unfold one corner of the wrap at a time, being careful to secure each corner in the palm of your left hand to prevent corners from recoiling and contaminating the contents. (C) Hold the final corner with your right hand; your hand should be completely covered by the wrap. (D) When the pack is fully exposed and all corners of the wrap have been secured, gently set the pack on the sterile field, being careful not to allow your hand and arm to reach across or over the sterile field.

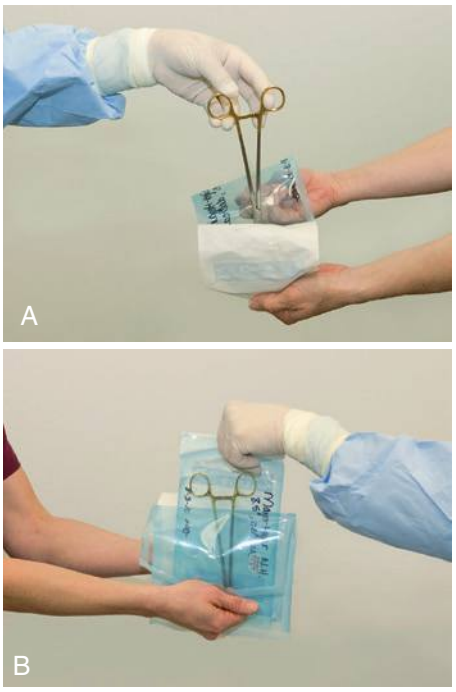

FIG. 2.13 Opening (A) single-wrapped and (B) double-wrapped peel-back pouches.

Unwrapping Sterile Items in Paper/Plastic or Plastic Peel-Back Pouches (Video 2.4)

Identify the edges of the peel-back wrapper, and carefully separate them (Fig. 2.13). Peel the edges of the wrapper back slowly and symmetrically to ensure that the sterile item does not come in contact with the torn edge of the wrapper (the torn edge of a peel-back wrapper is unsterile). If the item is small, place it on the sterile area as described earlier, being careful not to lean across the sterile table. If the item is long or cumbersome, have a sterile team member grasp it and gently pull it from the peel-back wrapper, taking care not to brush the item against the peeled edge of the wrapper. Scalpel blades and suture materials are opened in a similar manner.

Opening Sterile Container Systems (Video 2.5)

Place the container on a nonsterile surface and pop the latches by breaking the tape or plastic locks (Fig. 2.14). Remove the cover and place to the side. A sterile individual reaches in to retrieve the inner basket containing the surgical equipment.

POURING SOLUTIONS INTO BASINS

Solutions (i.e., sterile saline and antiseptics) are poured into basins. The basin should be held away from the surgical table by a sterile team member to prevent the nonsterile assistant's hand and arm from extending over the sterile area. The solution is poured without splashing, taking care to prevent it from dripping down the container onto the sterile person's hand. The solution container should not touch the sterile basin.

FIG. 2.14 Opening a sterile container system. (A) The container is placed on a nonsterile counter. The latches are opened by breaking the tape or plastic locks, and the cover is removed. (B) A sterile individual reaches in and retrieves the inner basket containing the sterile equipment. (C) The entire basket or just its contents may be placed on the sterile instrument table. Surgical Facilities and Maintenance of the Surgical Environment

A variety of physical layouts are suitable for modern operating rooms (ORs) and surgical areas, but the goals of all designs should be patient safety and work efficiency. Designing an efficient workspace requires more than knowing the appropriate number of air exchanges an OR should have to reduce airborne contaminants or how many rooms are necessary to facilitate an efficient workflow. It also requires careful attention to traffic patterns, the space required for storage of supplies to be sufficient to meet the needs of the caseload, adequate space for staff and surgeons to allow them to function efficiently, and ample room for the provisions for sterile processing nearby. The surgical area should be in close proximity to the anesthesia and surgical preparation areas, critical care, radiology, and central supply. However, it should be isolated from general traffic flow (e.g., examination rooms, offices, reception area, wards). In large facilities, such as universities and surgical referral centers, anesthesia and surgical preparation areas should be a separate working unit that is isolated from general hospital traffic.

STRUCTURE AND DESIGN OF THE SURGICAL AREA

Because of the constant danger of contamination to surgical patients, the surgical area should be delineated into "restricted," "semirestricted," and "unrestricted" areas. Restricted areas include ORs, sterile supply rooms, and the scrub sink area. Scrub suits, hair coverings, and masks are required whenever anyone enters these areas (even for cleaning). The semirestricted areas include the peripheral support areas of the surgical suite, including hallways between the ORs and nurses' stations, instrument and supply processing areas, storage areas, and utility rooms. Personnel are required to wear surgical attire and cover all head and facial hair when entering these areas. Unrestricted areas include a central control point that is established to monitor the entrance of patients, personnel, and materials into the restricted areas. The anesthesia and surgical preparation rooms, dressing rooms, lounges, and offices are also in the unrestricted zone. A commonly used floor plan is one in which the surgical suites are arranged around a central workstation for OR nurses. Easy access to each OR from the workstation ensures efficient traffic flow, which reduces cross-contamination between areas. The goal is to create realistic traffic and commerce of patients, personnel, and supplies, with careful attention to restricted and semirestricted work areas.

Individuals entering a restricted area from an unrestricted area must don proper surgical attire (see Chapter 6); the ideal location for moving from an unrestricted area to a restricted one (or vice versa) is through a locker room. Surgical personnel who leave a restricted area and enter an unrestricted area must cover their clothing with a closed knee-length lab coat before they leave and discard these items when they return to the restricted area. Doors between restricted and unrestricted areas should be kept closed at all times. **Food and drink are permitted only in unrestricted areas.** Movement of clean and sterile supplies and equipment should be separated as much as possible from movement of contaminated supplies and equipment by space, time, and traffic patterns. Soiled linen and trash should be kept in an unrestricted area, and patients should be clipped and vacuumed in an unrestricted area before transport to a restricted area (e.g., the OR).

> **NOTE** To prevent contaminating the surgical suite, clip the patient and perform the initial surgical preparation in a separate (unrestricted) area. Never clip patients in the OR.

TRAFFIC PATTERNS

Because airborne contaminants can cause or aggravate infection, it is best to create traffic patterns that minimize traffic into and out of rooms. This restricts the movement of airborne contaminants, such as organisms carried and shed by people and objects. Entry into the OR and other restricted areas should be limited to essential equipment and personnel. A study presented at the 2016 American College of Surgeons National Surgical Quality Improvement Program Conference suggested that minimizing OR traffic could lower rates of surgical site infections (SSIs).[1] After review of their infection rates, a Canadian hospital determined that they had an excessively high rate of wound infections from orthopedic operations such as knee and hip joint replacements; they decided to implement practices to reduce traffic movement into the OR. Reasons for entering and exiting the OR during operations included retrieving charts, instruments, or equipment and taking a break. Over a 2-year period they were able to reduce OR traffic from between 42 and 70 door openings per case to 3.2 door openings per case. They reported that this intervention may have contributed to a decrease in orthopedic SSIs from 2.8% to 2.1%. Logically, opening the doors to the OR decreases the effectiveness of the ventilation system in effectively clearing potential contaminants from the OR outward.

Guidelines useful for limiting movement from the outside into the operating suite are provided in Box 3.1.

Most particles and bacteria found in OR air are shed from skin and hair by personnel in an OR. Although no one has established a direct relationship between the number of people in an OR and the development of postoperative infection, some studies suggest that as the number of personnel in the OR increases, so does the incidence of SSIs. Whether this has to do with the people themselves or the greater amount of traffic into and around the room is not clear.

ABSTRACT

Patient safety and work efficiency are the most important goals of designing a surgical suite and prep area. Proper care and cleaning of the areas are critical to reduce infection.

BOX 3.1 Guidelines Useful for Limiting Movement into the Operating Room (OR)

1. Allow only those people who are essential to the procedure into the OR while operations are being performed.
2. Limit movement of personnel within the OR.
3. Keep the doors of ORs closed during surgeries/procedures.
4. Ensure that anyone entering the OR is properly trained in infection control practices and sterile technique.

DESCRIPTION AND FUNCTION OF ROOMS IN THE SURGICAL AREA

Dressing Room

The dressing room is used by surgical personnel for changing into proper surgical attire. It should have closed cabinets for storing scrub suits, shoe covers, masks, and caps and a separate area for hanging street clothes. A hamper for dirty laundry should be available to minimize carrying of contaminated linen through the hospital.

Anesthesia and Surgical Preparation Areas

The anesthesia induction and surgical preparation area should be adjacent to the surgical area yet out of major hospital traffic patterns. This room should be supplied with equipment and medications that may be necessary in an emergency (e.g., defibrillator, endotracheal tubes, suction, oxygen, crash cart). It also should have anesthetic equipment (machines and drugs), laryngoscopes, clippers (mounted on the wall or hanging from the ceiling), vacuums (large canister or central), skin preparation materials (antiseptic soaps, alcohol, sterile gauze sponges), sharps containers, needles and syringes, and monitoring equipment, all of which should be readily available to ensure efficient anesthesia and preoperative patient preparation.

NOTE Drugs and equipment necessary for an emergency can be stored in a mobile crash cart; this facilitates movement from the anesthesia preparation room to the OR and to recovery.

NOTE Clipper blades may be a source of infection between patients. Clean and disinfect them regularly by soaking them in alcohol or chlorhexidine or spraying them with an ethanol/o-phenol/phenol product.[2]

Preparation counters and surfaces should be impervious and easily cleaned and disinfected (Table 3.1). Stainless steel preparation tables with built-in sinks are ideal. Gas scavenger systems should be present at each anesthesia preparation table. General lighting is supplied by main overhead fluorescent lights, which are supplemented by a spotlight directed at each preparation table. A sink designated for cleaning anesthetic hoses, endotracheal tubes, and rebreathing bags, plus a plastic rack for draining and drying rebreathing bags and hoses, should be available. An erasable anesthesia-surgery scheduling board, easily visible to anesthesia and surgical personnel, should list the day's procedures.

Temperature in the preparation room should be kept between 17°C and 20°C (62°F and 68°F) and humidity at 50% or less to reduce microbial growth. Gurney surfaces should be padded, and circulating water and/or warm air blankets should be used to prevent hypothermia. Well-constructed gurneys (i.e., made of stainless steel or other easily cleaned materials, with relatively large wheels with bearings that can be easily lubricated, and rubber bumpers mounted on the corners to prevent damage to doors and walls) should be available for patient transportation. An adhesive microfilm dust pad should be placed at the doorway between the anesthesia preparation room and the surgical area to collect dust, hair, and other particulates on gurney rollers, shoes, and anesthetic equipment.

Anesthesia Supply Room

The anesthesia supply room should be adjacent to the anesthesia and surgical preparation room. Equipment necessary to keep anesthesia machines working properly, extra endotracheal tubes, anesthetic monitoring equipment, oxygen "E" tanks, hoses, catheters, and airway connectors are stored here. This room may also have a cabinet for storing nongaseous anesthetic agents, and it may be a convenient location for storing large oxygen tanks that supply oxygen to each anesthesia preparation table and to the OR.

Nurses' Workstation

The nurses' workstation should be centrally located in the surgical area (i.e., the restricted area). An autoclave (for flash sterilization), an incubator and/or blanket warmer (for irrigation fluids and for towels to wrap patients after surgery), a refrigerator (for medications and solutions), and formalin containers are kept in this area. A daily surgery log, OR protocols, and a telephone are also kept at the workstation. Soiled instruments may be sent to a central supply area or may be decontaminated, washed, lubricated, and wrapped or packaged here for resterilization. This area should be divided into two separate areas to prevent cross-contamination of clean supplies if it is used for decontaminating and wrapping instruments.

Sterile Instrument Room

The sterile instrument room is a restricted area that houses all sterilized and packaged instruments and supplies. It is commonly near the nurses' workstation. Surgery personnel assemble items necessary for a particular case from supplies in this room. Items should be logically arranged on shelves (e.g., alphabetical order) and routinely checked for "outdates" (i.e., time-related expiration; see p. 13) and package integrity (i.e., event-related expiration; see p. 13).

Sterile supplies should be transported into ORs in closed sterile containers. Inadequate sterilization of surgical instruments has been implicated in outbreaks of SSI. For this reason, indicators documenting adequate sterilization must be included in all sterile instrument sets (see Chapter 2).

Equipment Room

As a general rule, unless a piece of equipment is mostly or exclusively used in a given OR, it should be stored elsewhere. Large pieces of equipment, such as anesthesia machines, lasers, monitoring equipment, operating microscopes, and portable surgery lights, can be stored in an equipment room. Equipment should be kept free of dust and cleaned routinely using the protocol described for OR disinfection (see p. 21). The equipment room is a valuable area because it eliminates storage of large, expensive pieces of equipment in hallways, where they could be damaged or create a hazard.

Most equipment should be kept in an equipment storage area in the semirestricted area adjacent to the OR. For specialty rooms

TABLE 3.1 Common Disinfectants

Product	Main Ingredient(s)	Use Instructions	Contact Time	Effective Against
Ultra Clorox	Sodium hypochlorite 6%, other ingredients 94%	Dilute at 3/4 cup/gallon of water	In kitchen or bathroom 5 minutes; for toilet bowl 10 minutes; for mildew 15 minutes	Parvovirus, gram-positive and gram-negative bacteria
Roccal D Plus	Didecyl dimethyl ammonium chloride, alkyl dimethyl benzyl ammonium chloride, alkyl dimethyl benzyl ammonium chloride, bis-*n*-tributyltin oxide, inert ingredients	Hard surfaces, 3.75 g/L (1/2 oz/gallon) of water; boot bath, 7.5 g/L (1 oz/gallon) of water; badly soiled areas, 11.23 g/L (1.5 oz/gallon) of water	10 minutes	Gram-positive and gram-negative bacteria, *Aspergillus fumigatus, Trichophyton mentagrophytes, Candida albicans,* parvovirus, parainfluenza
Clorox Clean-Up	Sodium hypochlorite 1.84%, other ingredients 98.16%	Mop floors with 34 g/L (1 cup/gallon) of water	5 minutes	*Escherichia coli, Salmonella choleraesuis, Staphylococcus aureus, Streptococcus pyogenes*
Nolvasan Solution	Chlorhexidine diacetate 2%, other ingredients 98%	7.5 g/L (1 oz/gallon) of water; for rabies, 3 oz/gallon of water	10 minutes	Gram-positive and gram-negative bacteria, canine distemper virus, feline rhinotracheitis virus, canine coronavirus
Snap 'n' Go #6 (Neutral Disinfectant, purple)	Octyl decyl ammonium chloride 6.51%, dioctyl dimethyl ammonium chloride 3.25%, alkyl benzyl ammonium chloride 8.68%, inert ingredients	3.75 g/L (1/2 oz/gallon) water or full strength	10 minutes	Gram-positive and gram-negative bacteria; use this dilution for feline leukemia virus, canine distemper virus
Snap 'n' Go #14 (Veterinary Disinfectant, green)	*n*-Alkyl dimethyl ethylbenzyl ammonium chloride 4.5%, dimethyl ethylbenzyl ammonium chloride, inert ingredients	7.5 g/L (1 oz/gallon) water or 30 g/L (4 oz/gallon) water	10 minutes	Gram-positive and gram-negative bacteria, canine distemper virus, feline calicivirus; use this dilution for canine parvovirus, adenovirus, coronavirus, and parainfluenza viruses and for feline panleukopenia, coronavirus, and picornavirus
Virkon *S*	Potassium peroxymonosulfate 20.4%, sodium chloride 1.5%, other ingredients 78.1%	For 1% solution, add one (1) tablet to 120 g (16 fl oz) of water; solution stable for 7 days	10 minutes	Gram-positive and gram-negative bacteria; *Aspergillus fumigatus, Candida albicans, Microsporum canis;* canine parvovirus and distemper; feline parvovirus, herpes, and calicivirus; and *Leptospira canicola*

(cardiology, neurology), an adjacent space in the restricted area near the OR should be designated as storage. The tendency to favor additional OR space, at the expense of storage space, when designing an OR suite results in cluttered corridors and ORs, which can become safety hazards.

Other storage spaces are designated for clean supplies and packaged reusable items and should be in a separate space from the soiled workroom. Carts and gurneys must not be stored where they obstruct corridors.

Housekeeping Supply Room

Supplies used to decontaminate and clean surgical suites may be stored in the supply room or closet. Cleaning equipment and supplies stored here must be restricted to use in the OR to prevent cross-contamination from other hospital areas.

Scrub Sink Area

Scrub sink areas should be centrally located for the OR suites. Antiseptic soap in an appropriate dispenser (i.e., foot activated or motion sensitive), scrub brushes (i.e., sterilized reusable brushes or a disposable polyurethane brush-sponge combination, unless brushless scrub solutions are used [see Chapter 6]), and fingernail cleaners should be kept within easy reach at each scrubbing station. Deep stainless steel sinks equipped with knee-, elbow-, or foot-operated or motion-sensitive water activators are ideal. Electronic sensory activated scrub sinks as shown in Fig. 3.1 allow "no touch" activation. With reusable brushes, the dispensing container and clean brushes must be detached and autoclaved regularly. The scrub sink area must be located away from wrapped sterile supplies because of possible contamination by water droplets and spray from the sinks. Scrub sinks should never be used to clean equipment or instruments or to dispose of body fluids.

FIG. 3.1 Motion-sensitive water-activated scrub sink. (Courtesy Texas A&M Institute for Preclinical Studies.)

Gowning and Gloving Area

Gowning and gloving can be done outside or inside the OR. Controversy continues over which location results in the least cross-contamination, but no evidence supports one location over another.

NOTE If the OR is small, or if several people are scrubbing in, gowning and gloving in a separate area may help prevent contamination of personnel, sterile supplies, or the prepped surgical site.

Operating Room

ORs are individual rooms where surgeries are performed. The room should be large enough to allow personnel to move around sterile equipment without contaminating it and to accommodate the large pieces of equipment necessary for some procedures.

Guidelines from the American Institute of Architects recommend that newly constructed general ORs should have a minimum clear floor area of 37 m_2 (400 square feet) exclusive of fixed or wall-mounted cabinets and built-in shelves, with a minimum of 6 m (20 feet) clear dimension between fixed cabinets and built-in shelves.[3] These guidelines also state that rooms for cardiovascular, neurologic, orthopedic, and other special procedures that require additional personnel or large equipment should have a minimum clear floor area of 55.7 m_2 (600 square feet) and a minimum of 6 m (20 feet) clear dimension exclusive of fixed or wall-mounted cabinets and built-in shelves.

For renovations, the minimum clear floor area for general purpose rooms and orthopedic rooms should be 33.4 m_2 (360 square feet). Cardiovascular, neurologic, and other special purpose rooms should be 37 m_2 (400 square feet). Windows should have coved or sloped edges and should be without ledges that can collect dust. They should be well sealed and should not be allowed to be opened. Studies have shown that natural light enhances staff morale.

Some suppliers that offer lights and tables (e.g., Skytron, Berchtold Corp.) also supply voice and touch screen activation systems, video monitors, cameras, power booms, and more for an integrated OR that is efficient and multifunctional. Integrated OR suites can be custom-configured to be minimal or extravagant and may be built from scratch or retrofitted.

The OR should be uncluttered and simple so that no areas trap dust or are difficult to clean. Floors, ceilings, walls, and other surfaces should be smooth, nonporous, and constructed of fireproof materials. Smooth surfaces can be thoroughly cleaned and disinfected (see Table 3.1), which helps prevent trapping of biological material that could cross-contaminate. Surface materials should be able to withstand frequent washing and cleaning with strong disinfectants.

Uniform ceilings are recommended for ORs. Most ceilings are made of plaster; however, moisture-resistant gypsum wallboard systems with special epoxy-based coatings may be less costly. Ceiling-mounted lights or fixtures should be sealed so that dust and contaminants cannot enter through openings and so that there is no compromise to the ventilation system. In semirestricted and unrestricted areas (e.g., recovery and holding areas), lay-in ceilings with clips that ensure that dust and other contaminants do not enter the room may be used[4]; however, they are not permitted in ORs.

Proper air handling is the single most important environmental factor in the prevention of SSI. Operating suites are ideally maintained at positive pressure so that air flows from the cleanest areas to the least clean areas. Air should flow from the OR toward corridors and adjacent areas. Current requirements for airflow conditions in hospital ORs are regulated by the international technical society organized to advance the arts and sciences of heating, ventilation, air-conditioning and refrigeration (ASHRAE Standard 170-2008). Although this standard contains airflow requirements such as the number of exchanges and the temperature and humidity of the air, it does not address airborne contaminant levels. At least 15 air changes per minute should be maintained, and at least 3 air changes per minute should be made up of fresh air. ORs are designed to introduce air at the ceiling with exhaust near the floor (plenum system). Rooms may be engineered for horizontal laminar flow, in which particle-free air is moved over the operative field at a uniform velocity, picking up particles in its path and passing them through a high-efficiency particulate air (HEPA) filter. Although the benefit of laminar flow systems is questionable, HEPA filters do appear to provide the best environment for reducing microbial contaminants in the air of the OR. Regularly scheduled surveillance and maintenance of the air handling system is crucial. This involves checking for moisture in walls, ceilings, and other potentially porous materials; ensuring the integrity of air ducts; and checking fan settings and filters. Scavenging systems that pull anesthetic gases out of the OR air should be installed in each room.

General lighting in the OR is supplied by main overhead fluorescent lights, which are supplemented by one or preferably two halogen spotlights. Surgery lights are designed to emit a soft white light that is of high intensity, low heat, and true color and that reduces shadows without glare. Options include single, double, and triple light-head configurations in wall, ceiling, and stand mounts. Surgical lights are generally ceiling mounted. Track lighting should be avoided because dust and bacteria may become trapped in the tracks. Rotation capabilities are important; most lights rotate 360 degrees at the light-head axis, but some are even more flexible. Many lights can incorporate cameras. Fiberoptic headlamps worn by many surgeons are now available in comfortable, lightweight models that virtually eliminate shadowing of the surgical site (Fig. 3.2).

Stainless steel operating tables should be fully adjustable for height (hydraulic mechanism) and degree of tilt (Fig. 3.3). Tabletops should include a flat, one-piece surface or should have V-trough capabilities. Tables vary not only in terms of the types of procedures that can be performed on them, but also in imaging

FIG. 3.2 Fiberoptic headlamp.

FIG. 3.3 Operating room table with remote control to allow tipping of the table in any direction during the surgical procedure. (Courtesy Texas A&M Institute for Preclinical Studies.)

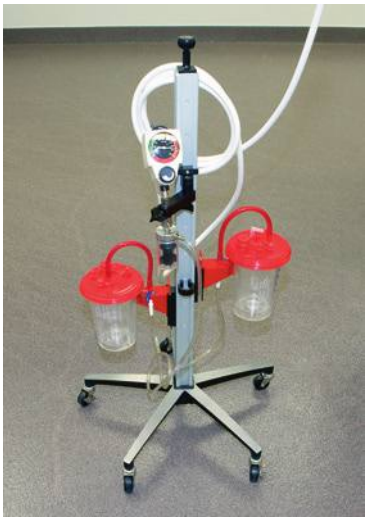

FIG. 3.4 Portable suction unit. (Courtesy Texas A&M Institute for Preclinical Studies.)

capabilities, mobility, and availability of accessory options. Tables that provide full-function tilt, Trendelenburg, reverse Trendelenburg, and other positioning capabilities are particularly useful. Tables with removable leg sections are convenient for orthopedic procedures. Specialized tables are available for intraoperative imaging when 100% of the tabletop is radiolucent. Portable V-troughs and insulating table pads should be available. Special tabletop attachments that allow the anesthesiologist to see the patient's head should be provided so the patient can be monitored without contamination of the surgical field.

An instrument table (e.g., Mayo stand) or a back table should be available. The table should be large enough to accommodate all instrumentation required for the surgical procedure. Instrument tables should be made of stainless steel and be adjustable in height. A kick bucket is used by surgical team members to discard soiled sponges during surgery. The bucket frame should have wheels so it can be moved easily (i.e., kicked) about the OR. Plastic bag liners for kick bucket containers facilitate cleanup.

Suction (portable or piped in; Fig. 3.4) should be available in each OR. Suction units with disposable containers are reliable, easily cleaned, and cost-efficient. Suction hoses should not be reused unless they are sterilized because they are a common source of surgical wound contamination. Other accessory equipment, such as physiologic monitors, the anesthesia supply cart, intravenous stands, and sitting stools, should be available. Each OR should be provided with a method to view radiographs (radiographic view box preferably flush-mounted to facilitate cleaning, or a digital screen). Portable imaging devices are optimal for evaluating placement of orthopedic implants. The OR should have a wall clock to determine elapsed time, particularly when vascular occlusion is necessary. Supply cabinets with tight-fitting doors (to minimize dust accumulation) may be located in each OR for storing suture material, dressings, sponges, scalpel blades, and frequently used instruments. Doors to the OR should be kept closed to reduce the mixing of OR air with corridor air.

Patient body temperature must be maintained during surgery, especially if the animal weighs less than 10 kg, or if the surgical procedure is prolonged. Hypothermia has numerous deleterious effects on the patient, including decreased cerebral blood flow, vasodilation, increased cardiac irritability, and decreased cardiac output.[5] Importantly, heat loss is significant after the animal has been premedicated; thus attempts should be made to prevent the deleterious effects of hypothermia as early as possible, but certainly as soon after anesthetic induction as is feasible. In a 2015 study, prewarming dogs weighing less than 10 kg in an incubator prior to inhalation anesthesia did not improve or maintain their body temperature during inhalation anesthesia with isoflurane in oxygen.[6] Warming inhaled gases (e.g., Darvall's anesthesia breathing circuits) might be more effective than warming blankets or devices, including providing warmed intravenous fluids. Different types of patient warming devices are available in veterinary medicine, including warm-air circulating devices (e.g., Bair Hugger, Hot Dog Patient Warming System, Darvall Vet Cocoon), water circulating systems, and electric warming pads. The ChillBuster Vet Surgical System (ThermoGear) consists of a surgical warming blanket, warming cage mat, and disposable covers to keep the surgical and recovery areas free of contamination. Some systems now come with a HEPA filter that is built into the unit so that dirt and debris are not recirculated (e.g., SurgiVet Equator Convective Warming System, Smiths Medical). These units may also have a thermostat that is located at the blanket itself, rather than at the heating unit, which may prevent overheating and burning of the patient. Electric-style pads are increasing in popularity because the temperature is fixed (38.9°C [102°F]), they can be cleaned and sanitized, and unlike water circulating pads, they cannot be punctured. Triple lumen fluid warmers (e.g., SurgiVet Hotline fluid warmer [Smiths Medical]) that deliver fluids and blood products to the patient at a consistent temperature may be of some value during surgery and postoperative care of surgical patients.

Room "Turnover"

Standard practice is to routinely clean rooms after each operation to provide a clean environment for the next one. Centers for Disease Control and Prevention guidelines specify use of a one-step process and a hospital detergent registered with the Environmental Protection Agency (EPA) and designed for general housekeeping purposes when blood or body fluid contamination of surfaces may occur. Likewise, the Occupational Safety and Health Administration requires that any equipment or surfaces contaminated with blood or potentially infectious agents should be cleaned and decontaminated. If single-use, disposable mops and cloths are not utilized, mop heads and cloths should be

cleaned after each use and allowed to dry before reuse. After the last surgical procedure of the day or night, OR floors should be wet mopped with a single-use mop and an EPA-registered hospital disinfectant (see Table 3.1). Tacky surfaces and mats should not be used at the entrances of ORs. Ultraviolet lights also should not be used. Despite the practice of closing ORs or following special procedures to clean rooms after contaminated or dirty operations, no data support such practices.[4]

Postoperative Recovery Area

The postoperative recovery area should be adjacent to the surgical area, yet separate from other hospitalized patients. Patients should be placed in individual, heated cages and carefully monitored until recovery is complete. Patients that require intensive care should be taken directly to the critical care facility. Temperature in the recovery room should be warmer than in the OR (i.e., 21°C–25°C [70°F–77°F]). Warming cabinets with a supply of warm fluids and blankets should be available. Analgesic medications and any equipment or medications that may be necessary in an emergency (e.g., defibrillator, laryngoscopes, endotracheal tubes, suction, oxygen, the crash cart) should be available.

Minor Procedures Surgery Room

A separate room adjacent to the anesthesia preparation area should be designated for minor contaminated surgical procedures (e.g., lacerations, biopsies, wound management, dental procedures, endoscopy). The room should be equipped with an operating table, spotlight, gas and suction lines for anesthesia equipment, suture material, antiseptic preparation materials, and instrument packs for minor surgery. Because of the nature of surgical procedures performed in this room, it should be properly cleaned and disinfected after each surgical procedure and at the end of each surgery day.

PERSONNEL

Responsibilities and functions of every member of the surgical team should be clearly defined in writing. This is done to clarify the job description and establish the accountability of each employee. These policies must be carefully followed and strictly enforced to ensure safe and efficient operation of the surgical area. All staff members should be evaluated periodically. Provision should be made for training programs, educational self-improvement, and information dissemination, and current books, periodicals, and audiovisual tapes of new procedures and techniques should be available.

The surgeon's role is to guide the flow and scope of what happens in the OR during surgery. Surgical assistance is often provided by a veterinary technician or nurse. Surgical assistants carry out functions that assist the surgeon in performing a safe operation, including developing a working knowledge of the procedure being performed, providing retraction and hemostasis, and manipulating instrumentation and tissues into proper position to complete the surgical task. A knowledgeable surgical assistant is invaluable. Both veterinary technicians and assistants must practice the hospital policy and procedures, involving a unified approach to aseptic technique.

An anesthesiologist is responsible for meticulous monitoring and adjustment of the patient's physiologic status during surgery. Anesthesiologists are trained to render immediate care in a physiologic crisis. Occasionally, the surgeon and the anesthesiologist must work together to carefully time surgical maneuvers, as in cardiothoracic surgery. A properly trained anesthesiologist allows the surgeon to concentrate on the surgical procedure.

Operating Room Supervisor and Surgical Technician

In large facilities, the OR supervisor oversees technicians working in the surgical area. This individual is responsible for organizing work schedules, training new staff, setting policies for the surgical area, implementing and enforcing policies, and developing educational programs and seminars. The OR supervisor also participates in the day-to-day technical aspects of running a surgical area (i.e., circulates, opens surgical packs, and retrieves special instruments).

In a small facility (i.e., one that has only one or two ORs), the OR supervisor assumes all the tasks of the surgical technician already mentioned. The supervisor may also have other technical tasks to perform as a veterinary technician, such as administering anesthetics, providing restraint, and serving as receptionist. Qualifications of a well-educated technician include graduation from an approved veterinary technician/nurse program and 1 to 2 years of basic training in a veterinary practice or veterinary teaching hospital.

REPAIRS AND RENOVATIONS

In human hospitals, nosocomial infections ranging from *Aspergillus* and mold in ceilings to *Legionella* in wet areas prompted support of mandatory proactive infection control risk assessments (ICRAs) by the Joint Commission for the Accreditation of Hospitals, the American Society of Hospital Epidemiologists, and the American Institute of Architects. ICRAs should be initiated in the earliest stages of the design or development phase of a project to identify potential infectious risks to the patient population, any risks associated with the mechanical systems of the building, and areas that will be influenced by the project. Goals include defining necessary containment measures (e.g., traffic diversion, waste removal, and work disruption) during construction and anticipating any safety hazards that can result from the construction.[4]

Care and Maintenance of the Surgical Environment

Surgery puts patients at risk for nosocomial (hospital-acquired) infection unless strict environmental, equipment care, and maintenance standards are established and followed. Because most surgical infections develop from bacteria entering the incision site during surgery, proper preparation of the surgical environment is crucial in reducing the likelihood of infection.

The OR is considered a restricted area, and appropriate attire must be worn by all personnel entering or leaving it (see Chapter 6). To keep the surgical environment as free of microorganisms as possible, routine cleaning and disinfection should be performed. The term **cleaning** refers to removal of soil (i.e., blood, serum, urine, or pus); the term **disinfection** refers to treatment of surfaces, materials, and equipment with chemicals to reduce bacterial numbers (see also Chapter 2). Cleaning and disinfection are usually performed simultaneously, except when large quantities of organic material or other body fluids are present.

DAILY CLEANING ROUTINES

Operating Room

At the beginning of each surgery day, all horizontal surfaces, lights, OR equipment, and furniture should be damp dusted

BOX 3.2 Daily Care and Maintenance of the Operating Room

At the Beginning of Each Day

- Wipe flat surfaces of furnishings and lights with a cloth dampened with a disinfectant solution.

After Each Surgical Procedure

- Collect used instruments and place them in a cool water and detergent or enzymatic solution.
- Collect waste materials and soiled linens and place them in the proper containers.
- Wipe instrument and surgical tables, stands, kick buckets, and heating pads with a disinfectant.
- If necessary, clean the floor (move the surgical table and clean under it if body fluids have collected there).

After the Last Surgical Procedure of the Day

- Clean and disinfect kick buckets.
- Check ceilings, walls, cabinet doors, counter surfaces, and all furniture, and clean as necessary.
- Clean and care for individual items (e.g., monitoring devices, anesthesia equipment, surgical lights) according to the manufacturer's instructions.
- Wipe counter surfaces and cabinet doors with a disinfectant solution.
- Wipe instrument and surgical tables, stands, heating pads, and light fixtures with a disinfectant solution. Disassemble the surgical table if necessary to clean it thoroughly.
- Check supplies and restock as necessary.
- Roll wheeled equipment (e.g., surgical table, monitoring devices) through a small amount of disinfectant solution placed on the floor.
- Wet vacuum or damp mop the floor.

BOX 3.3 Daily Care and Maintenance of the Scrub Room and Sinks

Between Scrubbing Sessions

- Dispose of wrappings from packs.
- Dispose of debris in sinks.

After the Last Surgical Procedure of the Day

- Remove waste and clean waste receptacles with a disinfectant. Line waste receptacles with a plastic bag.
- Check supplies and restock.
- Clean and refill soap dispensers.
- Wipe counter surfaces, cabinet doors, walls adjacent to sink, and switch plates.
- Scrub and disinfect sinks.
- Wet vacuum or damp mop the floor.

BOX 3.4 Daily Care and Maintenance of the Patient Preparation Area

Between Patient Preparations

- Discard waste material (e.g., feces).
- Properly dispose of urine and clean the sink.
- Remove hair from clipper blades and lubricate according to manufacturer's instructions.
- Check walls, counters, and cabinet doors and clean with a disinfectant if necessary.
- Vacuum and clean the floor as necessary to remove hair clippings.

At the End of the Day

- Remove waste and clean waste receptacles with a disinfectant. Line waste receptacles with a plastic bag.
- Wipe light fixtures and supply lines with a disinfectant.
- Clean clippers according to manufacturer's instructions.
- Vacuum the floor to remove hair clippings. Change the filter in the vacuum. Wipe the outside of the vacuum, the hose, and the nozzle with a disinfectant.
- Check the walls and ceiling, and clean as necessary.
- Check supplies and restock.
- Wipe counter surfaces, cabinet doors, walls adjacent to sink, and switch plates with a disinfectant.
- Scrub and disinfect sinks.
- Wet vacuum or damp mop the floor.

with a lint-free cloth and hospital-grade disinfectant (Box 3.2). After each surgical procedure, areas contaminated by organic debris (e.g., floors, doors, counters, equipment, operating table) should be cleaned and disinfected. If biohazards (i.e., infectious diseases or chemotherapeutic agents) are encountered during surgery, special precautions (i.e., specific disinfectant, cleaning time, and disinfectant contact time) should be taken during cleaning and disinfection.

At the close of each day, operating tables, counters, lights, equipment, floors, windows, cabinets, and doors should be cleaned and disinfected in preparation for the next day's activities. Linen and waste bags should be collected, the linen laundered, and waste disposed of properly. Kick buckets should be disinfected and lined with new plastic bags. Surgical lights and monitoring and anesthetic equipment are cleaned and disinfected according to manufacturers' specifications. Wheels and coasters of all movable equipment and gurneys are cleaned and disinfected. The OR should be restocked with commonly used instruments, suture material, gauze sponges, needles, and syringes, and the floor should be wet vacuumed or damp mopped. Wet vacuuming is preferred because wet mops support heavy bacterial growth and can be a major source of contamination and infection. If mops are used, mop heads should be laundered and dried daily. They should be rinsed between uses and soaked in disinfectant.

Scrub Sinks

Scrub sink areas need special attention during the day because water is frequently splashed on floors and walls, and blood and other organic debris can be tracked from the scrub sink area to the surgical suite (Box 3.3). Water and soap splashed on the floor should be routinely removed to avoid slips, falls, and other accidents by surgical personnel. This area should be cleaned as needed throughout the day, with used scrub brushes and fingernail cleaners removed, soap dispensers cleaned, and sinks and walls washed. This area should be disinfected at the end of the day.

Anesthesia and Patient Preparation Room

Sinks, vacuum canisters, trash buckets, gurneys, and anesthesia preparation tables should be kept clean of organic debris and disinfected as necessary throughout the day (Box 3.4). Hair removed during patient preparation should be vacuumed from surgical tables and floors. Blood, urine, feces, tissue, serum, and purulent material should be contained and discarded. Needles and other sharp instruments should be disposed of in appropriate containers. Discarded biohazard materials should be disposed of in color-coded bags or should be clearly marked as a biohazard.

Plumbing fixtures, floors, cabinets, anesthetic equipment, utility rooms, furniture, and other equipment should be cleaned and disinfected daily. At the end of the day, the sink in the preparation area should be disinfected and a cup of disinfectant solution poured down the drain. The inner surface of garbage containers should be disinfected. Bags and filters of portable vacuums should be removed and replaced as necessary; the outside surfaces of the vacuum (including the hose and nozzle) should be wiped clean and disinfected. Clippers should be cleaned according to manufacturer's instructions. Floors should be wet vacuumed or damp mopped and supplies restocked. If a mop is used, the mop bucket should be emptied and cleaned, and all cleaning equipment and supplies should be returned to a designated storage closet.

Recovery Room

Cages, sinks, trash buckets, and gurneys should be cleaned of organic debris and disinfected as needed throughout the day. Plumbing fixtures, floors, cabinets, anesthetic equipment, utility rooms, furniture, and other equipment should be cleaned and disinfected daily as described in the previous section.

After a surgical patient has vacated a recovery room cage, it must be carefully disinfected before it is used by the next patient. Before the cage is disinfected, padding, paper, and organic matter should be removed. Disinfectant should be sprayed on all surfaces of the cage, including the door. Dry organic matter should be scrubbed with a brush until it is released. Lastly, the area in front of the cage should be cleaned and disinfected. Linen (e.g., pads, blankets, and heating blanket covers) should be laundered before reuse. Plastic circulating-water heating blankets should be cleaned and disinfected. This protocol helps maintain a consistently low level of microbes in the surgical recovery area, which reduces the incidence of nosocomial infection. However, some infectious diseases (e.g., parvovirus) require special precautions.

WEEKLY AND MONTHLY CLEANING ROUTINES

Surgical suites should be emptied of movable equipment and thoroughly cleaned once a week. Shelves of supply cabinets, walls, windows, windowsills, ceilings, light fixtures, surgical tables, utility and supply carts (and castors), utility rooms, equipment storage areas, and infrequently used equipment also should be cleaned and disinfected. OR floors should be wet vacuumed at least weekly, and the grills of ventilation ducts vacuumed. Walls, floors, and ceilings should be mopped once a month, and wheels and other movable parts of equipment and gurneys should be lubricated.

Preoperative and Intraoperative Care of the Surgical Patient

The selection and preparation of surgical patients require attention to a number of details. The patient should always receive a complete physical examination, followed by the appropriate laboratory workup. A thorough history helps determine the extent of the physical and laboratory examinations. Obtaining preoperative information also allows comparison of the animal's status before and after surgery (e.g., ability to micturate before and after spinal surgery). General assessment and stabilization of the surgical patient are discussed in this chapter; preoperative considerations for specific diseases are provided throughout the text.

HISTORY TAKING

A thorough history from the owner or caregiver aids in evaluation of the underlying disease process and identification of other abnormalities that might affect the surgical outcome. Although in emergencies an abbreviated history is often necessary, eventually a thorough history should always be obtained. The history should include the signalment, diet, exercise, environment, past medical problems, recent treatments (especially antiinflammatory, antimicrobial, and potentially nephrotoxic or hepatotoxic therapy), and any evidence of infection. Before embarking upon a detailed chronology of endless detail, the presenting complaint should be defined, specifically: (1) When did the current problem start? (2) What did the problem look like when it first began? and (3) Has the problem gotten better or worse, and if so, how? After the chief complaint has been defined, then one has a framework in which the details will make more sense.

Questions should be framed to avoid vague responses and to obtain specific information. For example, "When was your dog last vaccinated?" is a better question than "Is your dog current on his vaccinations?" Vomiting, diarrhea, altered appetite, exposure to toxins or foreign bodies, coughing, exercise intolerance, and other abnormalities should be noted. Animals with a history of previous drug reactions or seizures must be identified so that certain drugs can be avoided.

PHYSICAL EXAMINATION

The animal should be systematically evaluated during a physical examination, in which all body systems are evaluated. The animal's general condition (body condition, attitude, and mental status) should be noted. If indicated, animals should have a neurologic examination (see Chapter 38) and an orthopedic examination (see Chapter 31) in addition to evaluation of the respiratory, gastrointestinal, cardiovascular, and urinary systems. Emergencies may allow only a cursory examination until the animal has been stabilized. Evaluation of the preanesthetic physical status (Table 4.1) is a good determinant of the likelihood of cardiopulmonary emergencies during or after surgery; the more deteriorated the physical status, the higher the risk of anesthetic and surgical complications.

LABORATORY DATA

The animal's physical status and the procedure to be performed dictate the extensiveness of the laboratory workup. Determination of the hematocrit, total protein (TP), blood urea nitrogen or preferably serum creatinine concentration, and urine specific gravity may suffice for young, healthy animals undergoing elective procedures (e.g., ovariohysterectomy and declawing) and in healthy animals with localized disease (e.g., patellar luxation). If the animal is older than 5 to 7 years, even with a physical status of I or II (see Table 4.1), or has systemic signs (e.g., dyspnea, heart murmur, anemia, ruptured bladder, gastric dilation-volvulus, shock, and hemorrhage), and/or if the anticipated surgery time is longer than 1 to 2 hours, a complete blood count, serum biochemistry profile, and urinalysis should be done. Venous blood gas analysis could also be considered to determine the animal's acid-base status.

The necessity for additional laboratory data is dictated by the animal's presenting signs and underlying disease (Table 4.2). Identification of associated or underlying disease influences preoperative management, the surgical procedure performed, the prognosis, and postoperative care. Animals with neoplasia should be evaluated for metastasis (e.g., thoracic radiographs, abdominal ultrasound, and/or lymph node aspiration). Those with cardiac disease should have thoracic radiographs, cardiac ultrasound scans, and/or electrocardiograms (see Chapter 27). In endemic areas, the patient's heartworm status should be checked before surgery. Traumatized animals should have thoracic radiographs so that the diaphragm, pleural space, and lungs can be evaluated for conditions such as pulmonary contusion, pneumothorax, pleural effusion, or diaphragmatic hernia. Full-body sedated computed tomography (CT) exams can also be considered for traumatized animals to assess for unidentified injuries. Although economic considerations are important, a thorough preoperative examination is cost-effective because it often prevents or predicts costly complications.

NOTE Remember that there are age-related differences in hematologic and serum biochemical values in dogs. Growth and maturation of puppies influences some of these values such that they diverge greatly from those for adults (e.g., white blood cell count, red blood cell count, hematocrit, alkaline phosphatase activity, hemoglobin, calcium, phosphorus, protein, and globulin concentrations).

ABSTRACT

The surgical patient requires a thorough assessment before sedation, anesthesia, or surgical intervention in order to rate the physical status of the animal and determine surgical risk. The patient's history, clinical signs, physical examination findings, laboratory test results, and cursory diagnostic imaging findings are all critical for complete evaluation. If indicated and if possible, the patient should receive stabilization measures before surgery, including but not limited to oxygen therapy, fluid therapy, and correction of acid-base and electrolyte abnormalities.

KEYWORDS

patient assessment
stabilization
oxygen therapy
fluid therapy
checklists

TABLE 4.1 Rating of Physical Status in Surgical Patients

Physical Status	Animal's Condition	Examples
I	Healthy with no discernible disease	Patient is undergoing an elective procedure (e.g., ovariohysterectomy, declaw, castration)
II	Healthy with localized disease or mild systemic disease	Patellar luxation, skin tumor, cleft palate without aspiration pneumonia
III	Severe systemic disease	Pneumonia, fever, dehydration, heart murmur, anemia
IV	Severe systemic disease that is life threatening	Heart failure, renal failure, hepatic failure, severe hypovolemia, severe hemorrhage
V	Moribund; patient not expected to live longer than 24 hours with or without surgery	Endotoxic shock, multiorgan failure, severe trauma

DETERMINATION OF SURGICAL RISK

Once the history, physical examination, and laboratory tests have been completed, the surgical risk can be estimated and a prognosis given (Table 4.3). An *excellent prognosis* should be given if the potential for complications is minimal and there is a high probability that the patient will return to normal after surgery. If there is a high probability of a good outcome but some potential for complications, a *good prognosis* is warranted. If serious complications are possible but uncommon, if recovery may be prolonged, or if the animal may not return to its presurgical function, a *fair prognosis* is warranted. If the underlying disease or the surgical procedure is associated with many or severe complications (or both), if recovery is expected to be prolonged, if the likelihood of death during or after the procedure is high, or if the animal is unlikely to return to its presurgical function, a *poor prognosis* should be given. A *guarded prognosis* is often given when the outcome is highly variable or unknown.

Occasionally the risk of the surgical procedure may outweigh its potential benefits. For example, removal of an apparently benign skin mass may not be warranted in an animal with hepatic or renal dysfunction. Likewise, patients with thoracic metastases may not benefit from removal of the primary tumor. Quality of life must be considered for veterinary patients; those with severe, debilitating, untreatable disease may not benefit from surgery. However, for some patients surgery may improve the quality of life even if length of life is limited.

CLIENT COMMUNICATION

Communication with the client is extremely important to ensure the owner's satisfaction after surgery. Owners should be informed before surgery of the diagnosis, surgical or nonsurgical options, potential complications, postoperative care, prognosis, and cost. Although cost cannot always be predicted because of unanticipated complications, owners should be kept apprised of the animal's status and of procedures that may affect the initial cost estimate. If the disease is hereditary, neutering should be recommended. A waiver signed by the owner, authorizing surgery and accepting anesthetic and surgical risks, is mandatory and should be part of the medical record.

PATIENT STABILIZATION

Patients should be stabilized as thoroughly as possible before surgery. Occasionally, stabilization is impossible, and surgical intervention must be done rapidly; however, replacing fluid deficits and correcting acid-base and electrolyte abnormalities before induction of anesthesia usually are justified. Intravenous (IV) fluids are indicated for all animals undergoing general anesthesia and surgery, including healthy animals having elective procedures. The need for perioperative antibiotics is dictated by the animal's disease and the procedure being performed. Recommendations for antibiotic prophylaxis and therapy are given with discussions of specific diseases throughout this text. Perioperative antibiotic use is discussed in Chapter 9.

The patient history, clinical signs, physical examination findings, electrolytes, and total carbon dioxide (CO_2) are helpful in identifying significant acid-base abnormalities. The blood pH, arterial oxygen partial pressure (PaO_2), arterial carbon dioxide partial pressure ($PaCO_2$), and bicarbonate concentration may be measured to determine the extent of such abnormalities. If the animal is notably acidemic (arterial pH <7.2), efforts to optimize ventilation and capillary perfusion should be instituted. As a result of production and retention of CO_2 in the tissues, correcting base deficits with sodium bicarbonate without concurrent ventilatory and hemodynamic support may be detrimental; most acidotic patients do not require bicarbonate administration. The amount of bicarbonate necessary to give for a given base deficit can be calculated using the formula in Box 4.1.

The patient's nutritional state is often critical in chronically diseased animals. Preoperative parenteral or enteral hyperalimentation (see Chapter 10) is sometimes recommended to

BOX 4.1 Calculation of Volumes Needed for Blood Transfusion or Bicarbonate Therapy

Blood Transfusion

Blood needed (mL) = Recipient's weight (kg) × Desired PCV − Recipient PCV Donor's PCV × 70 (cat) or 90 (dog)[a]

Note: A rough estimate is 2.2 mL of blood/kg of body weight increases the recipient's PCV by 1%.

Bicarbonate Therapy

Bicarbonate needed (mEq) = 0.3 × Base deficit[b] (mEq) × Body weight (kg)

Give one half intravenously (IV) over 10 to 15 minutes and reevaluate; give remainder over 4 to 6 hours if necessary *or* give 1–2 mEq/kg IV; repeat only if indicated based on assessment of acid-base balance and potassium concentration.

Note: Because carbon dioxide is an end product of bicarbonate administration, ensure adequate ventilation.

[a]Total blood volume is estimated at 90 mL/kg for dogs and 70 mL/kg for cats.
[b]Some calculate the base deficit as the difference between the desired bicarbonate and the actual bicarbonate (rather than the normal bicarbonate and the actual bicarbonate). Animals that are acidotic enough to require bicarbonate therapy need continual monitoring.
PCV, Packed cell volume.

TABLE 4.2 Brief Considerations for Selected Clinical Pathologic Findings

Laboratory Abnormality	Comments	Major Differential Diagnoses
High BUN	Obtain urine specific gravity before initiating fluid therapy; measure serum creatinine concentration	Prerenal azotemia, primary renal disease, postrenal azotemia
Low BUN		Hepatic insufficiency (e.g., portosystemic shunt, cirrhosis), severe polyuria-polydipsia, low-protein diet
High ALT	ALT may be normal in some animals with severe hepatic disease	Hepatic disease: the magnitude of the increase in ALT is neither diagnostic for any particular disease nor prognostic; severe muscle disease can cause increases in ALT
Low albumin	Substantial inconsistencies between laboratories, methodology used to measure albumin in people can severely underestimate canine albumin concentration	Hepatic disease, loss from kidneys or gastrointestinal tract, severe exudative cutaneous lesion (e.g., burn); lack of nutrition is not the sole cause for a serum albumin <2.0 g/dL
High SAP	Commonly elevated in young growing animals or caused by steroids or anticonvulsants; falsely elevated with severe lipemia or severe bilirubinemia (>8 g/dL)	Hepatic disease, steroid therapy, extrahepatic biliary obstruction, some neoplasms; many dogs with increased SAP as the only biochemical abnormality do not have clinically significant hepatobiliary tract disease
High bilirubin	Exposure to fluorescent light may degrade bilirubin	Hepatocellular disease, extrahepatic biliary obstruction, intrahepatic cholestasis, hemolytic anemia, severe sepsis
High calcium	It is probably best to measure ionized serum calcium because serum albumin concentrations can have a substantial effect on total serum calcium concentrations, masking hypercalcemia	Paraneoplastic syndrome (lymphosarcoma, anal sac adenocarcinoma), primary hyperparathyroidism, calciferol-containing rodenticides, hypervitaminosis D, hypoadrenocorticism, granulomatous disease, chronic renal failure
Low calcium	Artificially low in animals with low albumin	Renal disease (especially acute), pregnancy (eclampsia), hypovitaminosis D, hypoparathyroidism
High phosphorus	Normal in young, growing dogs	Renal failure (acute and more severe chronic)
Low phosphorus		Refeeding syndrome, excessive insulin—especially in ketoacidotic cats (can cause hemolysis)
High creatinine	Emaciated animals have a falsely reduced serum creatinine	Renal disease, prerenal azotemia, uroabdomen, muscle trauma (very minor elevations)
High glucose	Stress may increase glucose to 200–400 mg/dL in cats	Diabetes mellitus
Low glucose	Delayed separation of RBCs falsely lowers glucose	Hepatic disease, insulinoma, hypoadrenocorticism, extrahepatic neoplasms, septicemia or toxemia, starvation of neonates
High sodium	Primarily caused by loss of free water	Vomiting, diarrhea, renal failure, diabetes insipidus, inappropriate fluid therapy, adipsia for any reason, free water loss for any reason
High potassium	Thrombocytosis may falsely elevate potassium; hemolysis increases potassium in selected breeds	Hypoadrenocorticism, severe renal failure, uroabdomen, selected drugs
Low potassium		Vomiting, diarrhea, diuretic therapy, chronic renal failure (especially in cats), inappropriate fluid therapy, refeeding syndrome
High total CO_2		Usually means metabolic alkalosis due to vomiting gastric contents, excessive diuretic administration, sodium bicarbonate administration, inappropriate fluid therapy. Can also mean a compensated respiratory acidosis (exceedingly rare)
Low total CO_2		Usually means metabolic acidosis from any of a number of causes, rarely means compensated respiratory alkalosis
High eosinophils		Parasitism (heartworm), eosinophilic diseases, mast cell tumor, hypersensitivities
High basophils		Parasitism (heartworm), mast cell tumors
High lymphocytes	Can be found in young animals	± Lymphosarcoma, ± feline leukemia virus, chronic lymphocytic leukemia, some dogs with ehrlichiosis
Low lymphocytes		Severe stress, lymphangiectasia, chylothorax, acute viral diseases
High RBCs	Some breeds (e.g., greyhounds) normally have higher packed cell volume (e.g., 55%) than other breeds	Dehydration, polycythemia, hypoxia (right to left shunts)

ALT, Alanine aminotransferase; *BUN,* blood urea nitrogen; *RBC,* red blood cells; *SAP,* serum alkaline phosphatase.

improve nutritional status before surgery. For example, in patients with cleft palate, cleaning particulate matter from the nasal cavity, administering the appropriate antibiotics, and providing enteral hyperalimentation for several weeks before surgery may reduce infection and improve wound healing.

Traumatized patients must be evaluated swiftly to detect life-threatening abnormalities. The cardiovascular and respiratory systems should be assessed by evaluating the pulse quality and rate, respiratory rate and effort, mucous membrane color, and capillary refill time (Videos 4.1 and 4.2). The heart should be

TABLE 4.3 Guidelines for Determining Surgical Prognosis

Prognosis	Criteria
Excellent	Potential for complications is minimal High probability that patient will return to normal after surgery
Good	Some potential for complications High probability of a good outcome
Fair	Serious complications are possible, but uncommon Recovery may be prolonged Animal may not return to its presurgical function
Poor	Underlying disease or surgical procedure is associated with many or severe complications Recovery is expected to be prolonged Likelihood of death during or after the procedure is high The animal is unlikely to return to its presurgical function
Guarded	Outcome is unknown or uncertain

BOX 4.2 Abdominal Focused Assessment With Sonography for Trauma (AFAST) Protocol to Detect Free Abdominal Fluid in Dogs (see Fig. 4.1)

The AFAST examination consists of two ultrasonographic views (transverse and longitudinal) in each of the following four areas:
1. Diaphragmaticohepatic (DH) view: probe placed subxiphoid
2. Splenorenal (SR) view: probe placed at left flank
3. Hepatorenal (HR) view: probe placed at right flank
4. Cystocolic (CC) view: probe placed at midline over urinary bladder

At each area, the ultrasound probe (5- or 7.5-MHz curvilinear probe) is fanned through an angle of 45 degrees from the long- and short-axis positions and is moved 2 to 3 cm (1 in) in each of four directions (i.e., cranial, caudal, left, and right) from the starting point until target organs are located.

auscultated for evidence of murmurs or an arrhythmia, and the lungs should be evaluated for crackles or wheezes. Diminished heart or lung sounds suggesting the presence of space-occupying pleural disease or a diaphragmatic hernia should be noted. Oxygen therapy should be given to animals that appear to be in respiratory distress or have other signs of oxygen deprivation. Thoracic radiographs or thoracic CT should be considered in traumatized patients regardless of the lack of obvious respiratory distress.

The use of ultrasound as a point-of-care test for animals presenting with emergent conditions has been gaining wide acceptance.[1] Abdominal and thoracic focused assessment with sonography for trauma (AFAST and TFAST) allow for detection of peritoneal, pleural, and pericardial fluid, in addition to rapidly identifying pneumothorax. The AFAST examination is a four-quadrant protocol (Box 4.2; Fig. 4.1) that is performed with the animal in right or left recumbency. An abdominal fluid score is recorded, ranging from 0 (no fluid in any quadrant) to 4 (peritoneal fluid in all quadrants). Serial AFAST examinations performed every 2 to 4 hours allow detection of delayed accumulation of peritoneal fluid. The TFAST examination is a five-point scan that evaluates the animal in both right and left lateral recumbencies (Box 4.3; Fig. 4.2).

OXYGEN THERAPY

Clinical signs of hypoxia include dyspnea, cyanosis, tachycardia, tachypnea, postural changes, anxiety, and/or central nervous

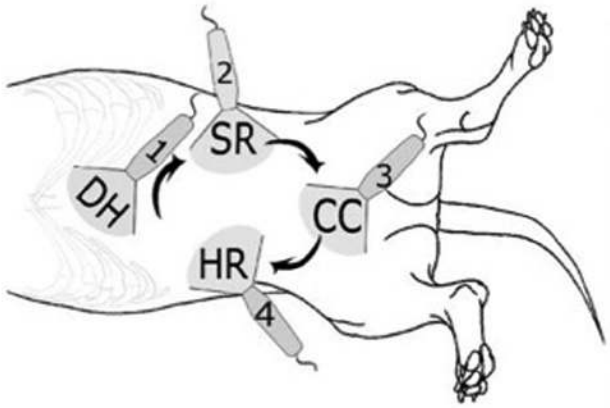

FIG. 4.1 Four views of the abdominal focused assessment with sonography for trauma (AFAST) examination: (1) diaphragmaticohepatic *(DH)*, (2) splenorenal *(SR)*, (3) cystocolic *(CC)*, and (4) hepatorenal *(HR)*. (From Boysen SR, Lisciandro GR. The use of ultrasound for dogs and cats in the emergency room. *Vet Clin North Am Small Anim Pract.* 2013;43[4]:773–797.)

BOX 4.3 Thoracic Focused Assessment With Sonography for Trauma (TFAST) Protocol to Detect Pleural Fluid, Pericardial Fluid, and Pneumothorax in Dogs (see Fig. 4.2)

The TFAST examination consists of examination of five areas:
1. Left and right chest tube site (CTS): probe placed at the seventh to ninth dorsolateral intercostal space
2. Left and right pericardial sac (PCS) view: probe placed at the fifth to sixth ventrolateral intercostal space
3. Diaphragmaticohepatic (DH) view: probe placed subxiphoid

system depression. If clinical signs, arterial blood gases, pulse oximetry, or the patient's disease suggest hypoxia, supplemental oxygen may be administered via mask, flow-by, or nasal catheter, or the animal may be placed in an oxygen cage or tent.

NOTE Remember that patients can be hypoxic without showing signs of cyanosis because greater than 5 g/dL of deoxygenated hemoglobin must be present in the circulation before cyanosis can be detected. The patient must have a PCV of approximately 15% to have 5 g hemoglobin/dL.

Flow-by oxygen may be the easiest way to provide supplemental oxygen in an emergency situation (Fig. 4.3; Table 4.4). The oxygen line is placed within 1 to 3 cm of the patient's nose and mouth, which creates a small area where the fraction of inspired oxygen (F_iO_2) is increased. However, because it requires a care provider to be present to hold the oxygen line and to ensure that the patient does not move away from it, and because a high oxygen flow rate is required, it is not always practical or the best choice. Furthermore, it is not nearly as effective as the other methods described below.

Face mask delivery of oxygen is a useful short-term method to provide supplemental oxygen. With an oxygen flow rate of 6

TABLE 4.4 Methods for Supplementing Oxygen

Mode of Oxygen Delivery	Indication	Oxygen Flow Rate	Fraction of Inspired Oxygen
Face mask	Short-term emergency stabilization	6–10 L/min (be sure face mask fits well)	35%–55%
Flow-by	Short-term emergency stabilization; face mask not tolerated	6–8 L/min	25%–45%
Tent or Elizabethan collar canopy	Nasal catheter not tolerated; oxygen cage not available	0.75–1 L/min	30%–40%
Nasal catheter	Postoperative oxygen delivery; prolonged delivery	1–6 L/min; 50–100 mL/kg/min	30%–50%
Nasotracheal tube	Upper airway obstruction; nasal catheter not tolerated	50 mL/kg/min	40%–60%
Oxygen cage	Prolonged delivery of oxygen; limited access to patient		40%–50%

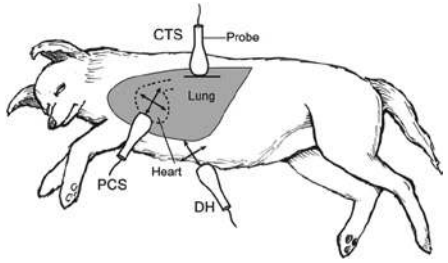

FIG. 4.2 Five views of the thoracic focused assessment with sonography for trauma (TFAST) examination: (1) right and left chest tube site *(CTS)*, (2) right and left pericardial sac *(PCS)*, (3) midline diaphragmaticohepatic *(DH)*. (From Boysen SR, Lisciandro GR. The use of ultrasound for dogs and cats in the emergency room. *Vet Clin North Am Small Anim Pract.* 2013;43[4]: 773–797.)

FIG. 4.3 A 12-year-old large mixed-breed dog receiving flow-by oxygen supplementation.

FIG. 4.4 Makeshift oxygen tent.

to 10 L/min and a well-fitted mask, an F_iO_2 of 0.35 to 0.55 may be achieved (see Table 4.4). Be aware that face masks may not be tolerated (especially in severely dyspneic animals) and are often difficult to fit well to the faces of cats and brachycephalic dogs. An alternative is to use an Elizabethan collar covered with plastic wrap to create an oxygen-enriched environment. The end of the oxygen tube should be fed up through the collar and secured (Fig. 4.4). To allow elimination of CO_2, make a small hole in the plastic wrap.

Nasal catheters may be used when more prolonged oxygen delivery is desired than can be achieved with flow-by or face mask techniques (Box 4.4). Other advantages of nasal catheter delivery of oxygen are that it permits access to the patient without loss of the oxygen-rich environment (versus an oxygen cage), and it is well tolerated in most patients. When necessary, bilateral catheters can be placed. The appropriate oxygen flow rate is based upon assessment of the degree of respiratory distress, the patient's respiratory rate and pattern, and the patient's size. The recommended initial therapeutic dose for unilateral nasal oxygen supplementation is approximately 50 to 100 mL/kg per minute. These flow rates can achieve a tracheal F_iO_2 of approximately 50%. Although high gas flow rates can be administered through a single nasal catheter, these high flow rates are associated with patient discomfort, nasal turbinate desiccation, and airway constriction. In such cases, administering oxygen through bilateral nasal catheters can improve patient comfort. Nasotracheal tubes

BOX 4.4 Nasal Oxygen Insufflation

1. Select a small, red rubber feeding tube (3.5–5 Fr for cats, 5–8 Fr for dogs) to serve as a catheter and lubricate the tip with lidocaine gel.
2. Place one or two drops of local anesthetic (e.g., 2% lidocaine or proparacaine) in the nostril.
3. Premeasure the catheter to the medial canthus of the eye or the caudal ramus of the mandible.
4. Elevate the dorsal aspect of the nose and feed the lubricated catheter into the nostril the predetermined distance.
5. Suture or glue (e.g., VetBond) the catheter to the external naris and muzzle, and over the frontal sinus or along the jaw. With cats, do not allow the tube to touch the whiskers.
6. Place an Elizabethan collar on the animal.
7. Attach the tube to an oxygen source and administer humidified oxygen to maintain oxygen saturation at greater than 90%; typically start at 50 mL/kg/min and adjust as necessary.[a]

[a]Gastric distention may occur if the flow rate is too high.

FIG. 4.5 A 5-year-old English Bulldog with nasotracheal intubation to facilitate postoperative recovery.

can be used in animals, particularly brachycephalic breeds, which will not tolerate an intranasal catheter (Fig. 4.5; see Table 4.4).

An oxygen cage provides a sealed environment in which the F_iO_2, ambient temperature, and humidity can be controlled. An ambient temperature of 70°F and a relative humidity of 40% to 50% is desired. The major disadvantage of an oxygen cage is that it isolates the patient from the clinician because each time the oxygen cage door is opened there is a loss of the oxygen-rich environment.

FLUID THERAPY

Fluid therapy should be initiated if hemorrhage or shock is suspected (Table 4.5). The normal blood volume of dogs is approximately 90 mL/kg and that of cats is approximately 60 to 70 mL/kg. Treatment of acute hypovolemia is intended to establish a circulating blood volume that allows adequate tissue perfusion. Generally, hypovolemic patients can be given polyionic isotonic fluid intravenously in the first hour (60–90 mL/kg in dogs, 45–60 mL/kg in cats) without adverse effects; however, patients with pulmonary, cardiovascular, or severe renal disease may be less tolerant of rapid fluid administration. Commonly, one-quarter to one-half the calculated shock dose is administered over 15 to 30 minutes, and the patient is carefully reassessed for changes in vital signs. If hemodilution is not a concern, balanced electrolyte solutions (e.g., lactated Ringer's solution, Normosol-R) may be given. The duration of action of infused crystalloids is short, with only approximately 10% of the solution remaining in the intravascular space at 1 hour.

Limited-volume fluid resuscitation (LVFR) is an alternate means for animals presenting with hemorrhagic shock. The smallest fluid volume required to restore intravascular volume is used, thereby minimizing extravasation of fluid into the interstitium and decreasing the risk of blood clot disruption. LVFR protocols typically use hypertonic saline or colloids instead of crystalloid solutions.

Hypertonic saline solutions are beneficial for reducing total fluid requirements, limiting edema, and increasing cardiac output. Adding a colloid (e.g., hetastarch, plasma) to hypertonic saline prolongs the effect of the volume expansion. However, animals with protein-losing nephropathy or enteropathy quickly lose the albumin they receive from plasma, making this an expensive and poorly effective therapy. Synthetic colloids are a better option in these patients. Colloids could also be considered for animals that are hypoproteinemic (i.e., total solids less than 4.5 g/dL). Fresh-frozen plasma (FFP) is beneficial for patients in need of coagulation factors because of consumption or dilution (e.g., when large doses of synthetic colloids have been given). The major preoperative concern in anemic patients is maintaining oxygen-carrying capacity; therefore transfusions (i.e., whole blood or packed red cells) may be necessary in anemic patients. Animals with a preoperative packed cell volume (PCV) less than or equal to 20% usually benefit from transfusions. The amount of donor blood necessary can be estimated by the formula presented in Box 4.1.

Crystalloid Solutions

Crystalloids are solutions containing electrolyte and nonelectrolyte solutes capable of entering all body fluid compartments. Advantages of crystalloid fluid therapy include replacement of interstitial and intravascular fluid losses, minimal impairment of coagulation, and no risk for allergic reaction, as well as low cost and wide availability. The main disadvantage is the limited duration of IV volume expansion when using crystalloid therapy alone. Large volume of crystalloid administration can contribute to decreased colloid oncotic pressure, resulting in tissue edema and other serious consequences.

Examples of crystalloid solutions include **Normosol-R, lactated Ringer's solution**, **5% dextrose**, **Plasma-lyte A**, and **normal saline (0.9%)**. Supplementation of these fluids with potassium chloride (KCl) is indicated if the patient is hypokalemic or likely to become so (e.g., from vomiting). A sliding scale for potassium addition to parenterally administered fluids is provided in Table 4.6. Thorough mixing of the crystalloid solution following addition of KCl should be performed to avoid potentially life-threatening infusion of potassium.

The choice of fluid to administer depends on the nature of the disease process and the composition of the body fluid losses. Patients vomiting gastric contents may become hypokalemic or hypochloremic. They can develop metabolic alkalosis (see p. 398), in which case 0.9% NaCl with 20 to 30 mEq KCl per liter is a reasonable choice, or they can become acidotic. The acid-base status cannot be accurately predicted. If the vomitus is not primarily stomach contents, lactated Ringer's may be used initially while awaiting laboratory results.

TABLE 4.5 Blood and Fluid Products: Indications for Use and Doses

Product	Indications	Infusion Rate
Isotonic crystalloid solutions[a]	Shock Dehydration Maintenance	*Dogs:* Up to 90 mL/kg (to effect) *Cats:* Up to 60 mL/kg (to effect) Maintenance rate is approximately 66 mL/kg/day for a 10-kg dog; larger dogs need less (e.g., 44 mL/kg/day for a 40-kg dog) and smaller dogs need more (e.g., 81 mL/kg/day for a 5-kg dog)
Hetastarch	Shock Hypoalbuminemia	*Dogs:* 10–20 mL/kg/h (shock) *Cats:* 10–15 mL/kg/h over 10–15 min (shock) 5–10 mL/kg (can repeat) *or* constant-rate infusion (1–2 mL/kg/h) up to 20 mL/kg/day (hypoalbuminemia)
Pentastarch	Shock Hypoalbuminemia	*Dogs:* 10–20 mL/kg/h (shock) *Cats:* 10–15 mL/kg/h (shock) 5–10 mL/kg (can repeat) *or* constant-rate infusion (1–2 mL/kg/h) up to 20 mL/kg/day (hypoalbuminemia)
25% Human serum albumin	Shock Hypoalbuminemia	5–25 mL/kg; maximal volume 2–4 mL/kg (bolus or slow push) 0.1–1.7 mL/kg/h as a constant-rate infusion[b]
7% Hypertonic saline[c]	Shock Hypoalbuminemia	4 mL/kg over 5 min, then isotonic crystalloids (10–20 mL/kg/h) to effect
Fresh whole blood	Anemia Hemorrhage Coagulopathy Shock	10–22 mL/kg (see also Box 4.1); in general, 2 mL/kg will raise the PCV by 1% For shock: 22 mL/kg/h maximum
Stored whole blood	Anemia Hemorrhage	10–22 mL/kg (see also Box 4.1); in general, 2 mL/kg will raise the PCV by 1%
Packed red blood cells	Anemia Hemorrhage	6–10 mL/kg and then reassess PCV to determine if more is necessary; in general, 1 mL/kg will raise the PCV by 1%
Platelet-rich plasma	Thrombocytopenia Coagulopathy	1 unit/3–10 kg
Fresh-frozen plasma	Coagulopathy Hypoproteinemia DIC	10–20 mL/kg; then reassess serum albumin or AT III concentration to determine if more is necessary
Cryoprecipitate	Von Willebrand disease Hemophilia	1 unit/5–15 kg
Oxyglobin	Anemia Shock	*Dogs:* 15–30 mL/kg at a maximum rate of 10 mL/kg/h *Cats:* 5–10 mL/kg at a maximum rate of 5 mL/kg/h

TABLE 4.6 Sliding Scale for Potassium Supplementation

Serum Potassium (mEq/L)	mEq KCl to Add to 250 mL Fluid	Maximal Fluid Infusion Rate[a] (mL/kg/h)
<2.0	20	6
2.1–2.5	15	8
2.6–3.0	10	12
3.1–3.5	7	16

[a]Do not exceed 0.5 mEq/kg/h.

Hypertonic saline (7.2%) can be used for restoration of intravascular volume in patients with severe hypovolemic shock or head trauma. Its use requires preexisting normal hydration, and thus hypertonic saline is primarily useful in dogs or cats with sudden development of hypovolemia rather than hypovolemia from untreated dehydration. If it is given as a rapid bolus, hypotension may occur and can be fatal. Lower doses should be used in patients with cardiac disease, and central venous pressure should be monitored during administration. Hypertonic saline should be avoided in patients with severe dehydration and hyperosmolar conditions. It is given as an IV infusion (1 mL/kg per minute) at a dose of 4 to 6 mL/kg, or can be used for low-volume fluid resuscitation.

Colloid Solutions

Colloids are large-molecular-weight substances (e.g., plasma, dextrans, and hetastarch) that are restricted to the plasma compartment because of their size. These solutions are often used in animals in shock or that are severely hypoalbuminemic (i.e., serum albumin <1.5 g/dL); however, colloids should be used with caution due to the potential for adverse outcomes (see Note on next page). Factors that influence the duration and volume of intravascular expansion associated with artificial colloids are the species of animal, dose, specific colloid

formulation, preinfusion intravascular volume status, and microvascular permeability. After administration, albumin rapidly disappears from the intravascular space; however, synthetic colloids contain molecules that vary in molecular weight. Smaller molecules are rapidly excreted, whereas the larger molecules remain in the circulation and are gradually hydrolyzed or removed by the reticuloendothelial system. The benefits of colloid therapy include rapid volume expansion with low volume administration as compared with crystalloids. The calculated volume of required crystalloid therapy can be reduced by 40% to 60% when administered concurrently with synthetic or natural colloid to achieve the same anticipated outcomes. Disadvantages of colloid solutions include possible allergic reactions, possible renal impairment, interference with coagulation, and increased expense.

The artificial colloids used most frequently in the United States are **hetastarch** and **dextran 70**. The recommended dosage for both is 20 mL/kg per day (see Table 4.5). All the commonly used artificial colloids can cause abnormal coagulation when large doses are given, when they are given repeatedly, or when there is reduced intravascular degradation. These coagulopathies may be associated with a reduction in factor VIII and von Willebrand factor. The low-molecular-weight dextrans (e.g., dextran 40) may be associated with acute renal failure and should not be used.

NOTE Use colloids judiciously as studies have suggested that their use may be associated with increased risk of acute kidney injury or death.[2]

Albumin has a molecular weight of approximately 69,000 Daltons and is most commonly given to small animal patients as stored plasma or FFP, stored whole blood, or fresh whole blood. Because it equilibrates with the interstitial space rapidly, relatively large volumes must be given to achieve a sustained rise in plasma colloid osmotic pressure (COP). Plasma can be administered at a rate of 4 to 6 mL/min in an acute hypovolemic crisis, whereas in normovolemic patients, plasma can be administered at 6 to 22 mL/kg over a 24-hour period.

Human serum albumin (HSA) can be used for volume expansion but is more often utilized for treatment of severe hypoalbuminemia. Hypoalbuminemia is often a consequence of critical illness and is associated with increases in morbidity and mortality in both humans and dogs (Box 4.5). HSA has been shown to effectively increase serum albumin, total solids, and COP in critically ill dogs. However, administration of HSA is controversial as it has (rarely) been associated with serious adverse reactions, including death. There are variable data in the veterinary literature regarding the incidence of complications with HSA use, with a low number of mild adverse reactions reported in some studies and several serious complications potentially attributable to HSA administration in others.[3] In addition, HSA has been shown to be highly antigenic in both ill and normal dogs, and presents a significant risk if administered more than once. Goals for HSA administration in dogs are to increase serum albumin to 2.0 to 2.5 g/dL and COP to 14 to 20 mmHg (Box 4.6).

Blood Products

Whole blood is the blood product most commonly transfused into dogs and cats. It contains donor blood plus anticoagulant. Although no standards have been established for the volume of blood that constitutes 1 unit, a human collection system generally contains approximately 450 mL of blood and 63 mL of anticoagulant and is designated as 1 unit. Whole blood contains red blood cells, clotting factors, proteins, and platelets. The initial dose is 10 to 22 mL/kg (see Table 4.5).

Packed red cells are the red cells and a small amount of plasma that remains after most of the plasma has been removed. Approximately 200 mL of packed red cells is obtained from 450 mL of whole blood. Because packed red cells do not contain clotting factors or platelets, they are typically used to treat anemia. The initial dose is 6 to 10 mL/kg (see Table 4.5). **FFP** is the plasma obtained from a unit of whole blood plus the anticoagulant. If frozen at −30°C (−22°F), clotting factors contained in FFP remain viable for approximately 1 year, whereas albumin is preserved for 5 years. The dose of plasma that is required to increase the albumin concentration of blood by 1 g/dL is approximately 45 mL/kg, which makes its use in most hypoproteinemic animals cost-prohibitive. It is typically used to treat coagulopathies that arise from a congenital deficiency of clotting factors (e.g., von Willebrand disease or hemophilia). The dose is 10 to 20 mL/kg. **Platelet-rich plasma** and platelet concentrates are prepared from fresh whole blood by slow centrifugation. The platelets are then suspended in plasma for transfusion. Transfused platelets may be rapidly destroyed in patients with immune-mediated thrombocytopenia. **Cryoprecipitate** is a concentrated source of von Willebrand factor, factors XIII and VIII, and fibrinogen. It is primarily used to treat the corresponding clotting disorders (i.e., von Willebrand disease and hemophilia).

Whole blood transfusions are readily available in many practices. Whole blood should be serotyped to avoid allergic reactions in dogs and cats. Typing sera are available for six blood types in dogs (dog erythrocyte antigen [DEA] 1.1, 1.2, 3, 4, 5, 7) and three in cats (A, B, AB). The most antigenic canine blood type appears to be DEA 1.1. A DEA 1.1-negative dog that has been previously sensitized with DEA 1.1-positive blood will

develop an acute hemolytic transfusion reaction after repeated transfusions of type DEA 1.1-positive blood, thus blood typing of blood donor and patient before the first transfusion is recommended, or at least before a second transfusion if only DEA 1.1-negative blood donors are used.

There is wide breed and geographic variation in the proportion of type B cats. It is thought that more than 99% of domestic cats in the United States are type A, but this number may be decreasing. The frequency of type B cats is markedly higher in Australia, Asia, and Europe. Cats develop naturally occurring antibodies against foreign blood types that result in premature destruction of transfused red cells, clinically severe transfusion reactions, and neonatal isoerythrolysis. Type B cats that are given type A blood typically develop a rapid, potentially fatal transfusion reaction following even a single transfusion of a small volume of blood. Type A cats given type B blood may develop a mild transfusion reaction that is often not clinically apparent; however, the PCV typically falls to pretransfusion levels within a few days of the transfusion. Type A and type AB kittens born to a type B queen receiving anti-A alloantibodies through the colostrum are at risk for developing isoerythrolysis during the first few days of life. Type AB is extremely rare in domestic cats, and blood from a type A donor is adequate. Cross-matching should be performed to detect antibodies in the plasma of the recipient or donor.

In a massive hemorrhage, blood may be given as rapidly as possible. In stable patients, starting with a low dose (i.e., 0.25 mL/kg) to ascertain whether a transfusion reaction is likely is wise (see Table 4.5). If no adverse reaction is noted, the rate can be increased. A dosage of 4 mL/kg per hour has been recommended as the upper limit in patients with heart disease. The volume of whole blood or packed red blood cells necessary to elevate the patient's PCV to the desired level (generally 25%–30% in dogs and 20% in cats) can be calculated using the formula in Box 4.1. Transfusion reactions may be acute or chronic. The incidence of transfusion reactions in dogs and cats has been reported as high as 15%, and this risk increases in untyped or unmatched recipient animals. Dogs with immune-mediated disease appear to be at increased risk. Transfusion reactions are classified as immunologic or nonimmunologic, and acute or delayed. Acute immunologic reactions include immune-mediated hemolysis, febrile nonhemolytic reactions, and hypersensitivity reactions. Nonimmunologic acute reactions include nonimmune-mediated hemolysis, volume overload, hypocalcemia, air embolism, and bacterial contamination leading to sepsis. Delayed transfusion reaction is typically manifested as immune-mediated hemolysis 3 to 5 days posttransfusion. Premedication prior to blood transfusion with antihistamines or corticosteroids does not appear to reduce the risk of transfusion reactions.

If an acute reaction is suspected, the transfusion should immediately be discontinued. For mild reactions (fever, urticaria), the transfusion can often be continued at a slower rate. Short-acting glucocorticoids (methylprednisolone succinate, 30 mg/kg IV once; or dexamethasone sodium phosphate, 0.5–1 mg/kg IV once) and antihistamines (diphenhydramine, 2 mg/kg IV) can also be administered. Antihistamines are also often given prior to administration of blood or plasma products to help prevent mild reactions. More severe reactions should receive IV fluid therapy and be closely monitored and treated for signs of shock, disseminated intravascular coagulation, renal failure, and sepsis.

NOTE Hemoglobin-based, oxygen-carrying fluid or blood substitutes have been approved for use in dogs; however, the availability of such products has been inconsistent and unreliable for several years.

Intraoperative Fluid Therapy

Intraoperative fluid therapy must take into consideration the effects of anesthesia and surgery on fluid hemodynamics. A dosage rate of 10 to 15 mL/kg per hour of crystalloid fluids during surgery is generally recommended to offset hypotension and maintain perfusion during anesthesia. Lower rates (5 mL/kg per hour) may be adequate for healthy patients undergoing elective procedures. Prewarming fluids, especially for young or small patients, is recommended.

If blood losses exceed 10% of the blood volume in an animal with a normal PCV and TP, blood replacement during surgery is indicated. Although an awake animal may tolerate acute blood loss of up to 25% of their total blood volume, anesthetized animals are less tolerant of rapid blood loss. Blood loss during surgery should be calculated by counting blood-saturated sponges and cotton-tipped applicators and monitoring blood suctioned from the field. As a general rule of thumb, a blood-soaked sponge (4 × 4) will contain 5 to 10 mL of blood, whereas a premoistened (with sterile saline) blood-soaked laparotomy sponge will contain up to 50 mL of blood. To estimate the amount of blood lost in aspirated fluids, the PCV of the aspirated fluid can be multiplied by the volume of fluid aspirated and this figure divided by the PCV of the patient.

SURGICAL SAFETY CHECKLISTS

In human medicine, a significant reduction in postoperative complications and mortality has been associated with the use of surgical safety checklists. Implementation of the use of checklists should be considered for veterinary hospitals as well, as one recent study found a significant decrease in the frequency and severity of postoperative complications. Fig. 4.6 is an example of a surgical checklist used at an academic veterinary teaching hospital.

Preparation of the Operative Site

Endogenous microbial flora (especially *Staphylococcus pseudintermedius)* are the most common source of **surgical site infection** (SSI) in dogs.[1] The term *SSI* is more appropriate than "surgical wound contaminant" because it includes infection that directly results from surgical procedures that involve other areas of the body, such as organs or internal spaces that are manipulated during the operation (see Box 9.1). **Antisepsis** is the prevention of sepsis by preventing or inhibiting the growth of resident and transient microbes.

Normal or resident organisms live in the skin's superficial cornified layers and outer hair follicles. *S. pseudintermedius* can be cultured from the skin of most normal dogs and is the principal bacterial skin pathogen in this species. Staphylococci can cause a wide range of infections when the immune system becomes compromised or select comorbidities are present (i.e., renal failure, congestive heart failure, diabetes). Other transient pathogens in canine skin include *Enterococcus* spp., *Klebsiella* spp., *Pasteurella* spp., and *Streptococcus* spp. Reducing or eliminating exposure to this flora is extremely important during surgery. Although it is impossible to sterilize skin without impairing its natural protective function and interfering with wound healing, appropriate preoperative preparation reduces the number of bacteria and the likelihood of infection.

The prevalence of SSI is a major concern because of the associated increased incidence of morbidity and mortality, length of hospitalization, and cost of care for postoperative patients. Although similar data are not available for veterinary hospitals, in 2007 it was estimated that direct medical costs to US hospitals of all hospital-acquired infections among hospital patients was between $28.4 and $45 billion.[2] Preventive preoperative measures that can reduce the risk of SSI include administration of antimicrobial prophylaxis (see Chapter 9) and proper utilization of skin antiseptic agents for the surgical team (see Chapter 6) and the patient. Among human patients with SSI who die in the postoperative period, death was directly related to SSI in over 75% of cases[3]; thus it is imperative that veterinarians and their staff be proactive in preventing infection during surgery by using proper techniques and solutions to prepare the skin for surgery.

DIETARY RESTRICTIONS

In adult animals, food intake is generally restricted 8 to 12 hours before induction of anesthesia to avoid intraoperative or postoperative emesis and aspiration pneumonia. Shorter periods may be recommended in some small breed dogs to prevent hypoglycemia. Access to water generally is not generally curtailed. Operations of the large intestine (see Chapter 18) often require specialized preparations (e.g., dietary restriction for 48 hours) and/or enteric antibiotics (e.g., oral kanamycin, neomycin, penicillin G, metronidazole). Food should not be withheld from young animals for longer than 4 to 6 hours because hypoglycemia may occur.

EXCRETIONS

The animal should be allowed to defecate and urinate shortly before induction of anesthesia. Colonic surgery may require enemas (see Chapter 18). An empty urinary bladder often facilitates abdominal procedures. If urine is not evacuated naturally, the bladder may be manually expressed with the animal under general anesthesia, or a sterile urethral catheter may be passed into the bladder.

TREATMENT OF HAIR

Before a patient is prepared for surgery, the patient's identity, surgical procedure to be performed, and surgical site should be verified (see preoperative checklist; Fig. 4.6). In some cases, bathing the animal the day before surgery to remove loose hair, debris, and external parasites may be warranted. Whenever possible, infection remote to the surgical site should be identified and treated before an elective operation is performed. Elective procedures should be postponed until the infection has resolved.

Hair should be removed as close to the time of surgery as possible, and hair removal should always occur outside the room where the surgical procedure will be performed (e.g., in the prep room). **Removal of hair the night before surgery is associated with a significantly higher superficial skin infection rate than removing the hair immediately before surgery.** The surgical site should be identified, and hair should be liberally clipped around the proposed incision site so that the incision can be extended within a sterile field (Fig. 5.1). The prepared area should be large enough to accommodate extension of the incision, additional incisions (if needed), and all possible drain sites. It must also be large enough that inadvertent wound contamination is avoided if the drapes move during the procedure. A general guideline is to clip at least 20 cm on each side of the incision. The hair can be removed most effectively with an electric clipper and a No. 40 clipper blade. Patients with dense hair coats may be clipped first with a coarser blade (No. 10); the higher the blade number, the shorter the remaining hair. Clippers should be held in a "pencil grip," and initial clipping should be done with the hair growth pattern. Subsequent clipping should be against the pattern of hair growth to obtain a closer clip. Depilatory creams are less traumatic than other hair removal methods, but they induce a mild dermal lymphocytic reaction. They are most useful in irregular areas where adequate hair removal is difficult. Razors are occasionally used for hair removal (e.g., around the eye) but can cause microlacerations in skin that may

ABSTRACT

Proper preparation of the surgical patient is vital to reduce the incidence of surgical site infections. One-step alcohol-based solutions may be more cost effective than using surgical sponges once all costs, including pack preparation, are considered. Chlorhexidine solutions appear to be more effective than povidone-iodine solutions when used for surgical skin preparation.

FIG. 5.1 Liberally clip hair around the proposed incision site so the incision can be extended within a sterile field. In male dogs, be sure to clip the prepuce.

FIG. 5.2 For limb procedures that do not require exposure of the paw, exclude the paw from the surgical area by placing a latex glove over the distal extremity and securing it to the limb with tape. Wrap the glove with tape or Vetrap.

increase irritation and promote infection. After hair removal is complete, loose hair is removed with a vacuum.

For limb procedures in which exposure of the paw is unnecessary, the paw can be excluded from the surgical area by placing a latex glove over the distal extremity and securing it to the limb with tape (Fig. 5.2). The glove should be covered with tape or self-adherent bandaging tape (e.g., Vetrap, COHERE, Coban). The foot is then "draped out" of the sterile field (see later). To enhance manipulation of limbs during surgery, a hanging-leg preparation may be done. The limb is circumferentially clipped and then is hung from an intravenous (IV) pole during prepping to allow all sides to be scrubbed.

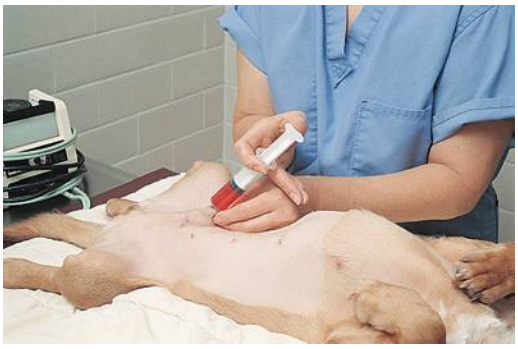

FIG. 5.3 Flush the prepuce of male dogs with antiseptic solution before performing the sterile preparation.

Before the animal is transported to the surgical suite, the incision site is given a general cleansing scrub, and ophthalmic antibiotic ointments or lubricants are placed on the cornea and conjunctiva. Studies suggest that using *clean,* rather than sterile, supplies for this initial cleansing prep does not influence the infection rate if the skin is intact. Lesions, eruptions, abrasions, irritations, rashes, dermatitis, burns, denuded or traumatized areas, or other similar medical conditions that could provide a portal of entry for a pathogen should not be present. In male dogs undergoing abdominal procedures, the prepuce should be flushed with an antiseptic solution (Fig. 5.3). The skin is scrubbed with germicidal soaps to remove debris and reduce bacterial populations. The area is lathered well until all dirt and oils have been removed. This is a generous scrub that often encompasses the hair surrounding the operation site to remove unattached hairs and dander that may be disturbed during draping.

Commonly used scrubbing solutions include iodophors, chlorhexidine gluconate (CHG), alcohols, hexachlorophene, and quaternary ammonium salts. Alcohol is not effective against spores but produces a fast kill of bacteria and acts as a defatting agent. Using alcohol by itself is not recommended, but it is commonly used in conjunction with CHG or povidone-iodine (PVI; see later). Hexachlorophene and quaternary ammonium salts are less effective than other available agents and are no longer recommended for preoperative skin preparation. It is important to avoid abrading the skin by excessive scrubbing with gauze sponges.

POSITIONING

Before sterile application of the epidermal germicide, the animal is moved to the operating room, positioned so the operative site is accessible to the surgeon, and secured with ropes, sandbags, troughs, tape, or vacuum-activated positioning devices. When these restraints are applied, interference with respiratory function and peripheral circulation, as well as the musculature and its innervation, must be avoided. Monitoring devices should be connected or the connections rechecked after the patient is positioned. Warm-air circulating devices (e.g., Bair Hugger, Hot Dog Patient Warming System, Darvall Vet Cocoon), water circulating systems, or electric warming pads (see Chapter 3) are placed adjacent to or over the patient, depending on the site of the surgical incision. If electrocautery is to be used, the ground plate should be positioned under the patient. If a hanging-leg preparation is to be done, the limb should be carefully suspended with tape from an IV pole.

STERILE SKIN PREPARATION

The purposes of the preoperative skin preparation are to (1) remove soil and transient microorganisms from the skin, (2) reduce the resident microbial count to subpathogenic levels in a short time and with the least amount of tissue irritation, and (3) inhibit rapid rebound growth of microorganisms. "Sterile" preparation begins after positioning of the animal has been completed. For some solutions, gauze sponges are sterilized in a pack, along with bowls into which the germicides can be poured. Newer solutions that are prepackaged with an applicator do not require sponges and may be more economical (see later). *Handle sponges with sterile sponge forceps or a gloved hand using aseptic technique. Use your dominant hand to perform the sterile preparation and your less dominant hand to retrieve sponges from the preparation bowl.* Transferring sterile sponges to the dominant hand before scrubbing the animal helps ensure that the hand picking up the sponges is not contaminated during the procedure. *Begin scrubbing at the incision site, usually near the center of the clipped area. Use a linear or circular scrubbing motion, moving from the center to the periphery. Do not return sponges from the periphery to the center because bacteria could be transferred onto the incision site; discard sponges after reaching the periphery.*

NOTE Using concentric circles, rather than a horizontal or linear preparation, has not been shown to reduce surgical site infection.[4]

Characteristics of an ideal preoperative antiseptic are provided in Box 5.1. Alcohol-based solutions that require shorter prep times than aqueous-based solutions (e.g., PVI, CHG) are now commonly used in human medicine, and their use is increasing in veterinary medicine. These newer solutions, which typically combine alcohol with PVI, CHG, or zinc pyrithione, appear to have better antimicrobial activity than PVI, CHG, or alcohol alone and provide a more persistent reduction in the baseline number of bacteria (Table 5.1). **In humans, evidence suggests that CHG is a more effective skin preparation agent than PVI.**[4–6] A meta-analysis conducted to verify whether recent evidence supports the hypothesis that CHG is more efficient than other antiseptics in reducing SSI rates was published in 2016.[6] The authors conducted a systematic review from 2000–14 in all languages. The primary end point was SSI incidence and secondary skin bacterial colonization. The authors concluded that there is moderate-quality evidence supporting the use of CHG for preoperative skin antisepsis and high-quality evidence that the use of CHG is associated with fewer positive skin cultures. CHG-alcohol is also recommended by the Centers for Disease Control and Prevention as the antiseptic of choice to reduce vascular catheter–associated bloodstream infection. If CHG (see Table 5.1) is the preparation solution, it remains in contact with the skin at the end of the preparation procedure or may be rinsed with saline. Because CHG binds to keratin, contact time is less critical than with PVI. Two 30-second applications have been advocated as adequate for antimicrobial activity.

When PVI (see Table 5.1) and alcohol are used, the site is typically scrubbed alternately with each solution three times to allow 5 minutes of contact time; however, using alcohol (isopropyl alcohol) between PVI scrubs reduces the contact time of PVI with skin and may diminish its efficacy; thus this is not recommended. Excess solution on the table or in body "pockets" should be blotted with a sterile towel or sponges. When the final PVI scrub is finished, a 10% PVI solution should be sprayed or painted on the operative site (Fig. 5.4).

One-Step Alcohol-Based Solutions

Using one-step alcohol-based solution (e.g., ACTIPREP, ChloraPrep, DuraPrep), apply the solution with a sterile applicator, working

BOX 5.1 Characteristics of an Ideal Preoperative Antiseptic

- Kill all bacteria, fungi, viruses, protozoa, tubercle bacilli, and spores
- Be hypoallergenic
- Be nontoxic
- Have residual activity
- Not be absorbed
- Be nontoxic and be able to be used repeatedly safely
- Be safe to use on all parts of the body and in all body systems

TABLE 5.1 Properties of Antiseptics Used for Preoperative Skin Preparation

Antiseptic	Mode of Action	Activity	Examples
Iodine/iodophors (PVI)	Penetration of the cell wall and oxidation and replacement of intracellular molecules with free iodine. *Iodophors* are solutions of iodine with a surfactant or stabilizing agent that liberates free iodine	Wide range of bacteria, tubercle bacilli, and some spores (e.g., *Clostridia*); activity is greatly reduced by the presence of organic material (pus and exudates)	10% PVI: Betadine
Alcohol (IPA)	Rapidly denatures bacterial cell wall proteins and biomolecules (DNA, RNA, lipids)	Wide range of bacteria, tubercle bacilli, and many fungi and viruses	70% isopropyl alcohol
CHG	Disrupts cell membrane and precipitates cellular contents	Wide range of bacteria; more effective against gram-positive bacteria than gram-negative bacteria; minimal activity against tubercle bacteria, *Mycobacterium* spp., and fungi	4% CHG: Hibiclens, Betasept 2% CHG: Nolvasan
Alcohol-based solutions	Combination of previously listed modes of action	Broad spectrum of activity due to the combination of several antiseptics with different modes of action	2% CHG + 70% IPA: ChloraPrep 83% ethanol + zinc pyrithione: Actiprep PVI (0.7% available iodine) + 74% IPA: DuraPrep

CHG, Chlorhexidine gluconate; *IPA,* isopropyl alcohol; *PVI,* povidone-iodine.

from the center outward (Fig. 5.5). Once a uniform application has been applied, allow the surgical site to dry for approximately 2 to 3 minutes before draping or using an electrosurgical unit.

NOTE One-step alcohol-based solutions such as ChloraPrep are more effective than PVI, CHG, or alcohol alone. They may be cheaper to use when all costs (e.g., prep pack sterilization) are taken into consideration.

NOTE Prevent pooling of alcohol or alcohol-based solutions, particularly if electrocautery is being used, as these solutions are flammable. Do not drape until the solution is thoroughly dried.

DRAPING

Once the patient has been positioned and the skin prepared, the animal is ready to be draped. If electrocautery is to be used, sufficient time should elapse between skin preparation and the application of drapes to permit complete evaporation of flammable substances (e.g., alcohol, defatting agents) from the skin. If an abdominal incision extends to the pubis in male dogs, the prepuce should be clamped to one side with a sterile towel clamp (Fig. 5.6). The purpose of drapes is to create and maintain a sterile field around the operative site. Draping is performed by a gowned and gloved surgical team member and begins with placement of field drapes (quarter drapes) to isolate the unprepared portion of the animal. These towels should be placed one at a time at the periphery of the prepared area. Field drapes may be huck towels or disposable, nonabsorbent towels. Drapes should not be flipped, fanned, or shaken because rapid movement of drapes creates air currents on which dust, lint, and droplet nuclei can migrate. Drapes, supplies, and equipment that extend over or drop below table level should be considered nonsterile because they are not within the visual field of the surgeon and their sterility cannot be verified.

Once the towels have been placed, they should not be readjusted toward the incision site because this carries bacteria onto the prepared skin. Towels are secured at the corners with sterile Backhaus towel clamps (Fig. 5.7). The tips of the towel clamps, once placed through the skin, are considered nonsterile and should be handled appropriately. Generally, field towels do not

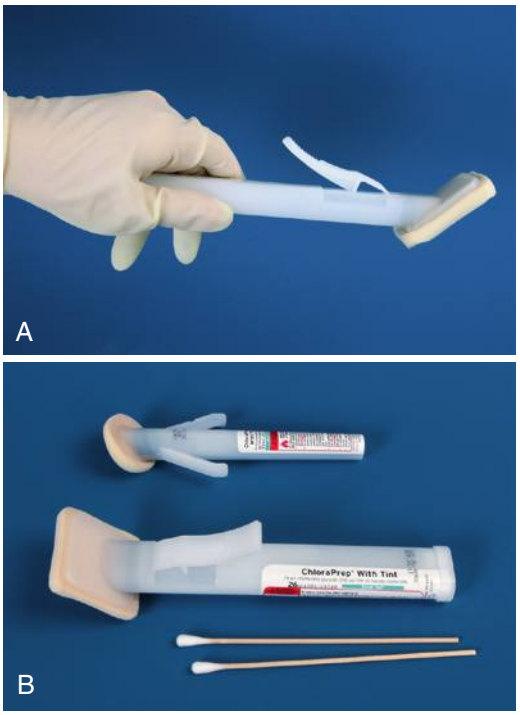

FIG. 5.5 (A) A one-step alcohol-based solution such as ChloraPrep is applied with a sterile applicator, working from the center outward. Once a uniform application has been applied, the surgical site is allowed to dry for approximately 2 to 3 minutes before draping or use of an electrosurgical unit. Rinsing and repeated applications are not necessary. (B) The solution comes in 10.5 and 26 mL applicators for skin preparation.

FIG. 5.6 If an abdominal incision extends to the pubis in male dogs, clamp the prepuce to one side with a sterile towel clamp.

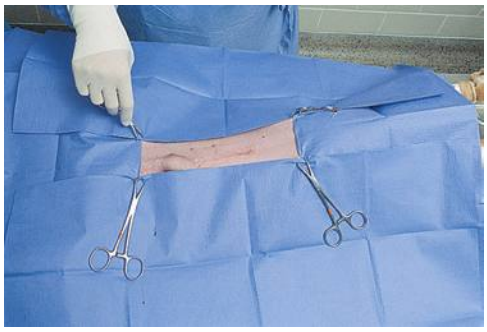

FIG. 5.7 Secure field drapes at the corners with sterile Backhaus towel clamps. The tips of the towel clamps are considered nonsterile once they have been placed through the skin and should be handled appropriately.

FIG. 5.8 If the drape does not have a fenestration, cut one to the appropriate size. The edges of the drape can be secured to the field drapes with Allis tissue forceps (not towel clamps). Do not put holes through the outer drape.

FIG. 5.9 When performing a hanging-leg preparation, place field drapes around the limb and secure them with towel clamps.

FIG. 5.10 The limb is placed through a fenestration of a lap or fanfold drape, and the drape is secured. A plastic adhesive drape has been applied to the skin and surrounding drapes.

cover the edges of the table, and care should be taken not to brush a sterile gown against this nonsterile field. Once the animal and the incision site are protected by field drapes, final draping can be performed (Fig. 5.8). A large drape is placed over the animal and the entire surgical table to provide a continuous sterile field. Cloth drapes should have an opening of appropriate size and position that can be placed over the incision site while the drape covers the remaining surfaces.

To drape a limb, field drapes should be placed and secured as described previously to isolate the surgical site or the proximal aspect of the limb if the leg is hung (Fig. 5.9 and Video 5.1). The unprepared area of the limb is held by a nonsterile member of the surgical team, and the tape holding the elevated limb is cut. The limb is presented to the sterile surgical member, so it may be taken with a hand in a sterile stockinette or towel. The limb should not be turned loose until it is securely held by the sterile surgical team member. If a stockinette is used, it should be carefully unrolled down the limb and secured with towel clamps. If a sterile towel is used, the limb should be carefully wrapped with the towel before it is secured to the skin with a towel clamp. Water-impermeable (disposable) towels (plus the towel clamp) should then be covered with sterile Kling. If a cloth towel is used, it (and the towel clamp) should be covered with sterile Vetrap. The limb is now ready to be placed through a fenestration of a lap or fanfold drape and the drape secured (Fig. 5.10). The end of the stockinette is wrapped with a self-adherent cohesive bandage material (e.g., Vetrap, COHERE, Coban).

The World Health Organization (WHO) Global Guidelines for the Prevention of Surgical Site Infection recently suggested that antimicrobial sealants, such as plastic adhesive drapes with or without antimicrobial properties, *not* be recommended for the purpose of preventing SSI.[5] To reduce skin exposure and subsequent contamination during surgery, additional skin draping, or "toweling-in," is sometimes performed after the skin incision has been made, but its value is debatable. Wound protector devices consist of a semirigid plastic ring placed into the abdomen through the laparotomy wound to which an impervious drape is circumferentially attached. This plastic drape comes up and out of the wound on to the skin surface, thus protecting the cut edges of the wound. Wound protection devices may be of benefit in clean-contaminated, contaminated, and dirty abdominal surgical procedures for the purpose of reducing the rate of SSI, but their value has not been established and is controversial.[5,7]

After the animal and nearby nonsterile surfaces have been covered with sterile drapes, the instrument tray can be arranged, and surgery can begin.

OTHER CONSIDERATIONS TO REDUCE THE INCIDENCE OF SURGICAL SITE INFECTION

Additional recommendations made in the latest report of the WHO guidelines for the prevention of SSI include (1) providing enhanced nutritional support (oral or enteral multiple nutrient–enhanced nutritional formulas) in underweight patients who

undergo major surgical operations (see Chapter 10), (2) perioperative oxygenation (see later and Chapter 4), (3) maintenance of normal body temperature (see Chapter 3), (4) use of protocols for intensive perioperative blood glucose control in both diabetic and nondiabetic patients, and (5) maintenance of adequate circulating volume control/normovolemia (see Chapter 12).[5] They noted that a moderate quality of evidence shows that providing a high fraction of inspired oxygen (FiO_2; 80%) is beneficial in patients undergoing procedures under general anesthesia with endotracheal intubation and results in a significant decrease of the risk of SSI compared with 30% to 35% FiO_2. As a result, the panel unanimously agreed to recommend that patients undergoing surgical procedures under general anesthesia should receive 80% FiO_2 intraoperatively and in the immediate postoperative period for 2 to 6 hours, if feasible. The panel unanimously agreed that warming devices should be used to avoid patient hypothermia in the operating room and during the surgical procedure to reduce the risk of SSI and, more importantly, other complications associated with surgery such as a decrease in myocardial events, blood loss, and transfusion requirements. The panel suggested that immunosuppressive agents *not* be discontinued perioperatively for the purpose of reducing SSI.

Preparation of the Surgical Team

Although most surgical site infections (SSIs) are caused by the patient's endogenous flora, operating room (OR) personnel are also an important source of bacterial contamination.[1] Although careful preparation of the surgical team and nonsterile personnel is important to reduce the number of bacteria in the surgical suite, it does not eliminate them. It is estimated that individuals shed approximately 1 million microorganisms from their bodies each day,[2] and a correlation has been noted between the number of people, their movements, and the number of airborne bacteria in a surgical suite. Therefore surgical room personnel should be reduced to only those essential for anesthesia or surgical support. To minimize contamination during surgery, strict guidelines should be followed regarding surgical attire for all surgical room personnel, including observers, and guidelines for performing surgical scrubs and preps (see Chapter 5) should be closely followed.

SURGICAL ATTIRE

Although there have been drastic improvements in the arena of SSI prevention over the last century, evidence supporting many current wardrobe and aseptic environment practices in the OR continues to be limited. Nonetheless, current recommendations suggest that all those entering the OR suite should be appropriately clothed, regardless of whether surgery is in progress or not. Surgical attire includes scrub suits, hair coverings, masks, footwear and shoe covers, gowns, and gloves.

Scrub Suits, Jackets, and Laboratory Coats

To minimize microbial contamination from OR personnel, scrub suits rather than street clothes should be worn in the operating suite. With two-piece pant suits, loose-fitting tops should be tucked into the trousers. Tunic tops that fit close to the body may be worn outside the trousers. The sleeves of the top should be short enough to allow the hands and arms to be scrubbed. Pants should have an elastic waist or drawstring closure. Scrub clothes should be laundered between wearings and changed if they become visibly soiled or wet to prevent transfer of microorganisms to the surgical environment. Wearing scrub clothes outside the surgical environment increases microbial contamination. In human hospitals, evidence does not support wearing cover apparel (e.g., laboratory coats) to protect scrub attire from contamination; in fact, there is evidence that in these settings laboratory coats worn as cover apparel can be contaminated with large numbers of pathogenic microorganisms, leading to contamination of scrub suits.[3] However, the large amount of loose hair present in veterinary hospitals makes cover attire more likely to be beneficial rather than detrimental, as long as it is laundered daily.

Nonscrubbed personnel should wear long-sleeved jackets over their scrub clothes because opening sterile supplies onto the sterile field without wearing a long-sleeved jacket may allow skin squames from the perioperative team member's bare arms to drop onto the sterile field and increase the risk for an SSI.[3] Jackets should be worn buttoned or snapped closed to minimize risk of the edges inadvertently contaminating sterile surfaces.

Hair Coverings

Hair is a significant carrier of bacteria and, when left uncovered, may act as a filter and collect bacteria. Although the evidence for wearing a head covering is weak, complete coverage of the hair is recommended. Caps should completely cover all hair, and sideburns and beards require hoods for complete coverage (Fig. 6.1). Skullcaps that do not cover the side hair above the ears and the hair at the nape of the neck are inappropriate.

Footwear and Shoe Covers

Any footwear that is comfortable can be worn in the surgery area. Using dedicated shoes in the operating theatre is a sensible practice that may reduce spreading hair and other contaminants from the prep room to the OR. If dedicated shoes are not used, shoe covers should be provided. Shoe covers are generally made of disposable materials that are water repellent and tear resistant. Although the value of shoe covers is debatable in human ORs, most veterinary facilities recommend that they be donned when first entering the surgical area and worn when leaving it to keep shoes clean. **New shoe covers should be donned upon returning to the surgical area.** Because of the abundance of animal hair in veterinary hospitals, changing shoe covers immediately before entry into the surgical theater may decrease the amount of hair tracked into the OR by surgical room personnel.

Masks

Masks constructed from lint-free material containing a hydrophilic filter web sandwiched between two outer layers should be worn whenever entering a sterile area. Their major function is to filter and contain droplets of microorganisms expelled from the mouth and nasopharynx during talking, sneezing, and coughing. Masks must be fitted over the mouth and nose and must be secured in a manner that prevents venting. The dorsal aspect of the mask is secured by shaping the reinforcing top edge tightly around the nose.

Surgical Gowns

Factors to consider when purchasing surgical gowns and drape products are that they must provide a barrier to contamination and should be resistant to tears, punctures, and abrasions. The barrier properties of the critical zone of the gown or drape are

ABSTRACT

The most important advances in surgical hand asepsis in the past decade include no longer using scrub brushes, the introduction of alchohol rubs, and a reduction in the duration of the prep. These advances have been slow to be adopted by veterinary practitioners, but doing so will save both time and money and should reduce the number of surgical site infections seen in veterinary patients.

labeled by the manufacturer as level 1, 2, 3, or 4, with 4 being the most protective. The critical zone is the area where direct contact with blood, body fluids, or other potentially infectious materials is most likely to occur. The type of procedure (entering a body cavity vs. a superficial mass removal), duration of the procedure, potential for splash or soaking of the gown, and how likely contamination is to occur based on the individual's role in the surgery (surgeon, anesthetist, etc.) should also be considered when choosing gowns and drapes.

Surgical gowns may be reusable and made of woven materials (usually cotton), or they may be disposable. Which to use is largely due to individual choice because there is little consensus on which is better. Primary considerations include environmental concerns and cost.[4] One study found that the number of microorganisms isolated from the surgical environment was lower when disposable, nonwoven materials were used, resulting in lower rates of contamination in the OR.[5] These authors recommended that disposable paper gowns be used for all surgical cases, especially those involving implants, because of the heightened risk of infection with reusable gowns.

Reusable gowns are made by a number of companies and, depending on the manufacturer, may be of variable thickness and may have extra paneling added to the abdominal and arm regions for added protection. These different gowns have different levels of performance (level 1 to 4; see earlier) depending on the type of surgery for which they will be used. The more expensive gowns often can be laundered more frequently than those that are less expensive, without impairing the barrier function.

Disposable gowns are meant to be used during one surgery and then thrown away. They are nonwoven and are made by a nonwoven technique from fibers such as polypropylene and polyester.[6] Most manufacturers of disposable gowns and drapes (e.g., Medline Industries, 3M, Precision Fabrics Group, Kimberly Clark) use a technique known as SMS, which stands for spunbond, meltblown, spunbond.[7–9] In some cases the SMS process can include more than one meltblown layer between the outer spunbond layers. The purpose of the spunbond layer closest to the skin is primarily to keep the surgeon cool and maintain a highly breathable environment. The outer layer of spunbonded material is to give the gown tensile strength to prevent ripping or tearing.[6]

Surgical Gloves

Relying on gloves alone (without a surgical scrub) to prevent microbial contamination is not recommended because many surgical gloves have holes at the completion of surgery, and punctured gloves may increase the risk of SSIs, particularly when prophylactic antibiotics have not been administered (see Chapter 9). In human surgeries it has been noted that approximately 20% of gloves have tiny punctures after surgery, the majority of which go unnoticed by the surgeon. Although few studies have been done in veterinary medicine, one prospective study in small animal surgical procedures found that of 78 gloves sampled at the end of surgery from 39 procedures, bacterial contamination was present in 21% of gloves from 31% of the surgeries.[10] This study found no difference related to the left- or right-hand glove, surgical time, dominant hand, surgery type (orthopedic, soft tissue, neurologic), or surgical wound classification on the incidence of contamination. A prospective, randomized controlled trial designed to determine whether use of colored indicator gloves affects perforation detection rate and to identify risk factors for glove perforation during veterinary orthopedic surgery was recently reported.[11] In this study of 574 double pairs of gloves worn during 300 orthopedic surgical procedures (2296 gloves), perforations occurred during 43% of surgeries, with a mean of 2.3 holes per surgery. Inner gloves were intact in 63% of glove pairs where an outer perforation occurred. Intraoperative perforation detection was improved when colored indicator gloves were worn (83% sensitivity) versus standard gloves (34% sensitivity). Independent risk factors for perforation were placement of plates and/or screws, placement of an external skeletal fixator, use of orthopedic wire, and primary surgeon being board certified. However, the cost benefit of wearing an indicator glove versus double gloving is questionable.

NOTE Given the high rate of glove defects, you may wish to double glove and periodically change the outer glove or remove it during key points such as handling of an implant (e.g., in total hip replacement surgeries) or during laparotomies in animals at high risk of infection (i.e., immunocompromised, diabetic, or cushingoid animals).

SURGICAL SCRUB

All sterile surgical team members should perform a hand and arm scrub before entering the surgical suite. In 1840, a Hungarian obstetrician, Ignaz Philipp Semmelweis, discovered that antiseptic hand washing could reduce patient deaths from pathogens transmitted by hands. He reduced the maternal mortality rate from puerperal fever by approximately 90% over a 3-year period by initiating hand washing before touching hospital patients. Hand antisepsis was further advocated by Joseph Lister, Professor of Surgery at the Glasgow Royal Infirmary, in 1860 to promote asepsis and reduce SSI. Lister initiated the first known disinfection program in which the clinical environment and all equipment were cleaned with carbolic acid. Additionally, the surgical team was asked to wash their hands in a solution of 5% carbolic acid before undertaking surgery.

The objectives of a surgical scrub include mechanical removal of dirt and oil, reduction of the transient bacterial population (i.e., bacteria deposited from the environment), and residual depression of the skin's resident bacterial population (i.e., bacteria persistently isolated from the skin) during the procedure. Rapid multiplication of skin bacteria occurs under surgical gloves if hands are washed with a nonantimicrobial soap, whereas it occurs more slowly following preoperative scrubbing with a medicated soap.

Scrub Technique

Three main developments in surgical hand antisepsis have occurred in the past decade. These include (1) no longer using scrub brushes (rubbing vs. scrubbing) (Fig. 6.2), (2) the introduction of alcohol rubs (Box 6.1), and (3) a reduction in the duration of the prep. In veterinary schools, instructions for surgical hand antisepsis have, until recently, included scrubbing the hands and arms with a brush. This practice is no longer recommended because studies have determined that scrubbing with a brush results in skin damage and increased bacterial counts. Scrubbing with a brush has been demonstrated to remove epidermal layers, increase shedding of bacterial squamous cells, increase (not decrease) microbial counts, and change microbial flora. T**hus most experts agree that the time-honored convention of vigorously scrubbing off the uppermost layers of skin with a brush is not only unnecessary, but also unwise.** A recent review of eight peer-reviewed, randomized controlled trials and two nonrandomized controlled trials from 1990 to 2015 compared traditional hand scrubbing with chlorhexidine gluconate or povidone-iodine against alcohol-based hand rubbing, scrubbing with a brush versus without a brush, and detergent-based antiseptics alone versus antiseptics incorporating alcohol solutions.[12] Evidence showed that hand rubbing techniques are as effective as traditional scrubbing and seem to be better tolerated. Hand rubbing appears to cause less skin damage than traditional scrub protocols, and scrub personnel tolerated brushless techniques better than scrubbing with a brush. Despite such evidence, veterinarians have been slow to adopt these practices.[13]

Before scrubbing, all items of jewelry (including watches) should be removed from the hands and forearms because they are reservoirs for bacteria. Fingernails should be kept short, clean, natural, and healthy. Studies have shown no increase in microbial growth related to wearing freshly applied nail polish; however, nail polish that is obviously chipped or has been worn longer than 4 days is associated with the presence of greater numbers of bacteria and has been associated with infection. Artificial nails (e.g., bondings, tips, wrappings, tapes) should not be worn. A higher number of gram-negative microorganisms have been cultured from the fingertips of personnel wearing artificial nails than from personnel with natural nails, both before and after hand washing. Fungal growth between artificial nails and the natural nail has also been reported and can contaminate the surgical wound. Hands and forearms should be free of open lesions and breaks in skin integrity because skin infection may contaminate surgical wounds.

Once the scrub has been started, nonsterile items cannot be handled. If the hands or arms are inadvertently touched by a nonsterile object (including surgical personnel), the scrub should be repeated. During and after scrubbing procedures, the hands should be kept higher than the elbows. This allows water and soap to flow from the cleanest area (hands) to a less clean area (elbows).

When the scrub has been completed, the hands and arms should be dried with a sterile towel. *Pick up the sterile towel from the table, taking care not to drip water on the gown beneath it, and step back from the sterile table. Hold the towel lengthwise and, using a blotting motion, dry one hand and arm, working from hand to elbow with one end of the towel (Fig. 6.3). Bend over at the waist when drying the arms so that the end of the towel does not brush against your scrub suit. Once the hand and arm are dry, bring the dry hand to the opposite end of the towel. Dry the other hand and arm in a similar manner. Drop the towel into the proper receptacle or onto the floor if a receptacle has not been provided. Do not lower your hands below waist level.*

Scrub Solutions

Antimicrobial soaps and detergents used for scrubbing should be rapid acting, broad spectrum, and nonirritating and should inhibit rapid rebound microbial growth. Some hand scrubs can bind with the stratum corneum, resulting in residual activity. Because bacteria proliferate under gloves, particularly if the gloves are damaged during surgery, persistent chemical activity is desirable. Aqueous scrubs and alcohol rubs are the two most common forms of hand antisepsis. The former are water-based solutions that contain antiseptic agents such as chlorhexidine or povidone-iodine. Scrubbing involves wetting the hands and arms and then using either a brush or a sponge following a specific protocol (i.e., either timed or anatomic; see later). The most commonly used surgical scrub solutions in veterinary medicine are alcohol, chlorhexidine gluconate (Hibiclens, Betasept), povidone-iodine (Betadine), and hexachlorophene (Phisohex) (Table 6.1). Alcohol solutions, on the other hand, contain active ingredients (typically alcohol plus chlorhexidine, povidone-iodine, or other antiseptic agents) and are rubbed on the hands and forearms without using a brush or sponge (Video 6.1).

Alcohol rubs, which do not require rinsing, were first introduced around the late 1990s as an alternative to traditional aqueous-based antiseptic solutions. Alcohol-based solutions may be categorized as *alcohol-based waterless* (ABWL) or *alcohol-based water-aided* (ABWA). ABWL are often preferred over other products because they are easy to use and have few side effects. The new brushless solutions generally have a very rapid killing effect and require a shortened contact time compared with traditional povidone-iodine or chlorhexidine solutions (see later).

BOX 6.1 Surgical Hand Antisepsis/ Hand Rub With an Alcohol-Based Surgical Hand Rub[a]

A standardized protocol for alcohol-based surgical hand rubs should follow the manufacturer's written instructions and should include, but may not be limited to, the following:

1. Wash hands and forearms with soap and water if they are visibly soiled or contaminated with blood or saliva. Dry thoroughly.
2. Dispense the manufacturer-recommended amount of the surgical hand rub product. Apply the product to the hands and forearms, following the manufacturer's written instructions. Some manufacturers may require the use of water as part of the process.
3. Rub thoroughly until dry if using a waterless solution.
4. Repeat the product application process if indicated in the manufacturer's written instructions.

[a]Data from Recommended practices for surgical hand antisepsis/hand scrubs. In: *Standards, Recommended Practices, and Guidelines.* Denver: AORN; 2009.

FIG. 6.2 Use of a brushless surgical scrub solution. (A) If desired, clean under your fingernails with a nail pick. (*Note:* Nail picks have not been found to decrease bacterial numbers.) (B) Wet your hands and arms. (C) Dispense the appropriate amount of solution (e.g., Triseptin, 1/4 oz) into the palm of your hand by depressing the foot pump. (D) Insert and twist the fingertips of your opposite hand into the solution for several seconds. Transfer the solution to your opposite hand and repeat this step with the fingers of your other hand. (E) Rub your hands together, moving up the forearms to slightly past the elbows. (F) Add water throughout the wash to create additional lather. (G) Rinse thoroughly and repeat steps B through F. Stop below the elbows on the second application. Total scrub time: 2 to 7 minutes.

TABLE 6.1 Common Antimicrobial Soaps Available for Surgical Scrubs

Antimicrobial Soap	Mechanism of Action	Properties
Chlorhexidine gluconate	Disruption of cell wall and precipitation of cell proteins	• Broad spectrum (more effective against gram-positive than gram-negative bacteria or fungi) • Good virucide • Residual activity because it binds to keratin • Not inactivated by organic material • May be less irritating to skin than iodophors
Hexachlorophene	Disruption of cell wall and precipitation of cell proteins	• Bacteriostatic for gram-positive cocci • Minimal activity against gram-negative bacteria, fungi, or viruses • Not inactivated by organic material • Cumulative (nullified by alcohol) • May be neurotoxic
Iodophors (e.g., povidone-iodine)	Cell wall penetration, oxidation; replaces microbial contents with free iodine	• Broad spectrum (gram-negative and gram-positive bacteria, fungi, and viruses) • Some activity against spores • Inactivated by organic material • Requires minimum of 2 minutes of skin contact
Parachlorometaxylenol	Disruption of cell wall and enzyme inactivation	• Broad spectrum (more effective against gram-positive than gram-negative bacteria, fungi, or viruses) • Slow onset of action
Triclosan	Disruption of cell wall	• Broad spectrum (ineffective against many *Pseudomonas* spp.) • Minimally affected by organic material
Alcohol-based solutions	Combination of above	• Broad spectrum (gram-negative and gram-positive bacteria, fungi, and viruses)

FIG. 6.3 When drying your hands and arms, use one end of the towel to dry one hand and arm (work from hand to elbow). Then bring the dry hand to the opposite end of the towel and dry the other hand and arm in a similar manner.

Examples of brushless solutions on the market include Triseptin (Healthpoint Ltd.), Avagard (3M), Sterillium Rub (Bode Chemic), Purell Waterless Surgical Scrub (GOJO Healthcare), and Endure 450 (Ecolab Inc.).

NOTE A simple hand wash with nonmedicated soap and water before entering the operating theatre area is highly recommended to eliminate any risk of colonization with bacterial spores. Between surgeries, repeating hand rubbing, **without prior hand wash or scrub,** is recommended.

A recent meta-analysis of 14 studies compared a range of methods for performing surgical hand antisepsis.[14] Outcomes were the number of cases of SSIs in patients and the number of viable bacteria or fungal cells (colony-forming units [CFUs]) on the hand of the person operating, before and after surgery. Most of the studies were determined to be too small or sufficiently flawed to determine whether the method of hand antisepsis influenced the risks of SSI. There was some evidence that hand antisepsis with chlorhexidine may reduce the number of bacteria on the hands of health professionals compared with povidone-iodine. There was also some evidence that alcohol rubs with additional antiseptic agents may reduce CFUs compared with aqueous scrubs.

Scrub Duration

The third development within hand antisepsis has been the move toward shorter scrub duration. Over the past 3 decades, scrubs have gradually been reduced from 10 minutes to 2 minutes. In the aforementioned meta-analysis,[14] evidence for the effectiveness of different scrub durations varied. Four studies compared the effect of different durations of scrubs and rubs on the number of CFUs on hands. There was evidence that a 3-minute scrub reduced the number of CFUs compared with a 2-minute scrub; however, the evidence was considered low quality and was downgraded for imprecision and indirectness of outcome. Contact time between the antimicrobial soap or detergent and the skin should be based on documentation of a product's efficacy in the scientific literature and the manufacturer's guidelines. A 5- to 7-minute scrub for the first case of the day, followed by a 2- to 3-minute scrub between subsequent operations, generally is adequate. If the hands and arms are grossly soiled, scrub time should be extended or brush counts increased; however, skin irritation or abrasion should be avoided because this causes bacteria that reside in deeper tissues (e.g., around the base of hair follicles) to become more superficial, increasing the number of potentially infective organisms on the skin surface.

GOWNING (VIDEO 6.2)

Gowns serve as a barrier between the skin of the surgical team member and the patient. They should be constructed of a material that eliminates the passage of microorganisms between sterile

FIG. 6.4 (A) Have an assistant pull the gown up and over your shoulders and secure it by closing the neck fasteners and tying the inside waist tie. (B) If a sterile-back gown is used, do not secure the front tie until you have donned sterile gloves.

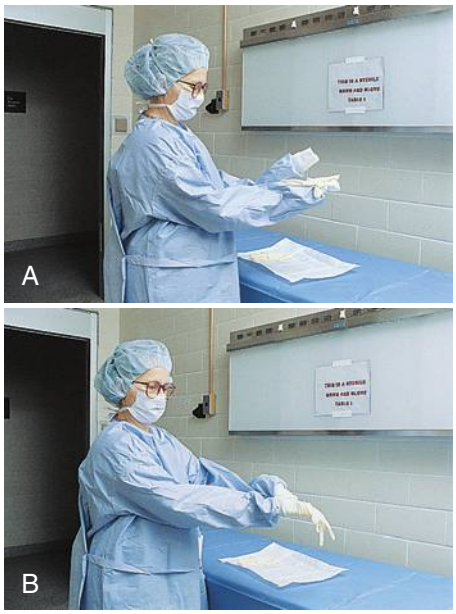

FIG. 6.5 Closed gloving. (A) Working through the gown sleeve, pick up one glove from the wrapper. Lay the glove palm down over the cuff of the gown with the thumb and fingers of the glove facing toward your elbow. (B) Grasp the cuff of the glove with your index finger and thumb. With the index finger and thumb of the other hand (within the cuff), take hold of the opposite side of the edge of the glove. Lift the cuff on the glove up and over the gown cuff and hand. Turn loose and come to the palm side of the glove and take hold of the gown and glove, pulling them toward the elbow while pushing the hand through the cuff and into the glove. Proceed with the opposite hand using the same technique.

and nonsterile areas and should be resistant to fluid, linting, stretch, pressure, and friction (especially in the forearm, elbow, and abdominal areas; see earlier). They should also be comfortable, economical, and fire resistant.

The technique of gowning is described here and is illustrated in Fig. 6.4. Gowning and gloving should be done from a surface separate from other sterile supplies (the surgical table) and from the surgical patient to avoid dripping water onto the sterile field and contaminating it. Gowns are folded so that the inside of the gown faces outward. *Grasp the gown firmly and gently lift it away from the table. Step back from the sterile table to allow room for gowning. Hold the gown at the shoulders and allow it to gently unfold. Do not shake the gown because this increases the risk of contamination. Once the gown is open, identify the armholes and guide each arm through the sleeves. Keep your hands within the cuffs of the gown. Have an assistant pull the gown up over your shoulders and secure it by closing the neck fasteners and tying the inside waist tie (see Fig. 6.4A). If a sterile-back gown is used, do not secure the front tie until you have donned sterile gloves (see Fig. 6.4B).*

GLOVING

Latex rubber gloves serve as barriers between the surgical team member and the patient; however, they are not a substitute for proper scrubbing methods. Lubricating agents for latex gloves such as magnesium silicate (talcum) or low cross-linked cornstarch allow gloves to slide more easily onto the hand. However, these agents can cause considerable irritation to various tissues, even if gloves are vigorously rinsed in sterile saline before surgery. Therefore the surgeon should use gloves in which the inner surfaces have been lubricated with an adherent coating of hydrogel. Potentially pathogenic gram-positive bacteria may be cultured from water droplets collected from surgeons after scrubbing. It is thought that these organisms are derived from scrub room tap water. It has also been demonstrated that gram-positive bacteria strike through the glove wrappings within 2 minutes of wetting the paper. **Optimally, gloves should not be dropped onto the opened gown pack before scrubbing and should not be placed onto a sterile field until the surgeon's arms have been dried.**

Gloving can be performed by three separate methods: (1) gloving yourself using a closed method; (2) gloving yourself using an open method; and (3) assisted gloving.

Closed Gloving

The closed method of gloving ensures that the hand never comes in contact with the outside of the gown or glove (Fig. 6.5 and Video 6.3).

Open Gloving

The open method of gloving is used when only the hands need to be covered (as for urinary catheterization, bone marrow biopsy, or sterile patient preparation) and during surgery when one glove becomes contaminated and must be changed. This method should not be used routinely for gowning and gloving (Fig. 6.6). The procedure used when both gloves are donned is shown in Fig. 6.7 and Video 6.4.

Assisted Gloving

The steps involved in assisted gloving are shown in Fig. 6.8 and Video 6.5. Both open and closed gloving are frequently associated with gown contamination, especially at the cuff. Scrub staff–assisted gloving, although uncommonly performed

FIG. 6.6 Open gloving when one hand is sterile. (A) Open the glove wrapper and pick up the correct glove at the folded edge with your sterile hand. Gently put your hand into the glove until your fingers are in the fingers of the glove. Place your thumb inside or near the thumb of the glove and hook the cuff of the glove over your thumb. Let go of the glove. (B) Place the finger of your sterile hand under the cuff at the palm of the glove. (C) Bend the wrist of the hand being gloved 90 degrees. (D) Gently walk your fingers around the cuff until they are at the front of the cuff and, at the same time, pull the cuff up and over your gown.

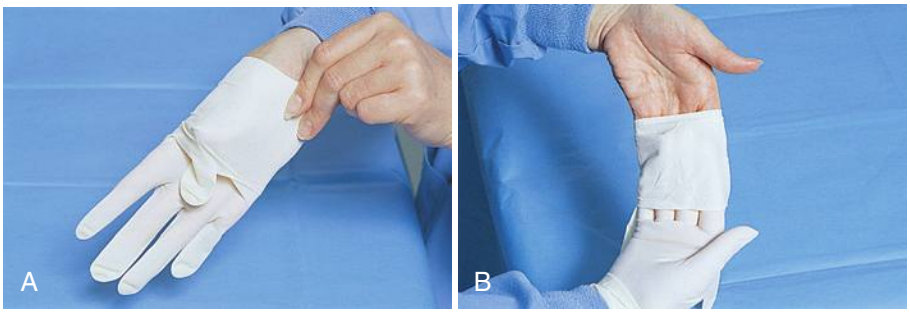

FIG. 6.7 Open gloving when neither hand is sterile. (A) Pick up one glove by its inner cuff with the opposite hand. Slide the glove onto the opposite hand; leave the cuff down. (B) Using the partially gloved hand, slide your fingers into the outer side of the opposite glove cuff. Slide your hand into the glove and unfold the cuff; do not touch your bare arm as the cuff is unfolded. With the gloved hand, slide your fingers under the outside edge of the opposite cuff and unfold it.

in veterinary medicine, may minimize the possibility of gown contamination.

Removing Gloves Aseptically

The procedure for removing gloves in an aseptic manner is described in Fig. 6.9.

MAINTAINING STERILITY DURING SURGERY

The techniques described in this chapter for gowning and gloving minimize the risk that the operative team may contaminate the surgical field. However, vigilance is necessary to prevent contamination of gowns or gloves. Once gowned, surgical team

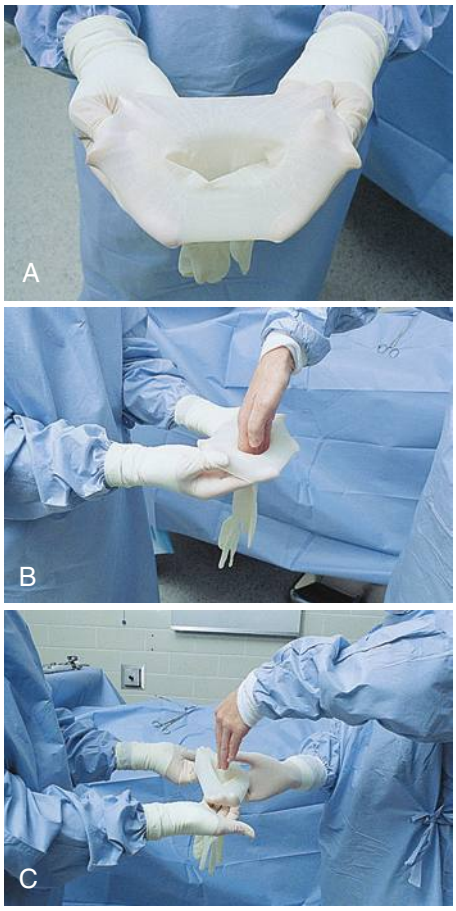

FIG. 6.8 Assisted gloving. (A) Have the assistant pick up one glove and place his or her fingers and thumb under the cuff of the glove. (B) With the thumb of the glove facing you, slip your hand into the glove; then have the assistant bring the cuff of the glove up and over the cuff of your gown and gently let it go. (C) Have the assistant pick up the other glove. Assist by holding the cuff of the glove open with the fingers of your sterile hand while putting your ungloved hand into the open glove. The assistant's thumbs are kept under the cuff while you thrust your hand into it.

members should always face the sterile field and should not touch or lean over a nonsterile area. The arms and hands should remain above waist level and below shoulder level. The arms should not be folded; they should be clasped in front of the body, above the waist. Scrubbed personnel should avoid changing position levels; they should be seated only if the entire surgical procedure will be performed at this level.

The front of the gown should be considered sterile from the chest to the level of the sterile field; the back of the gown is not considered sterile (even if a sterile-back or wraparound gown is used) because it cannot be seen by the scrubbed individual. The sleeves should be considered sterile from 2 inches above the elbow to the stockinette cuff. Because the stockinette cuff collects moisture (making it an ineffective microbial barrier), it is considered nonsterile and should be covered by sterile gloves at all times. The neckline, the shoulders, and the area under the arms should be considered nonsterile because they may be contaminated by perspiration or by rubbing together of collar and shoulder surfaces during head and neck movement.

FIG. 6.9 To remove gloves aseptically, the nonsterile assistant grasps the glove near the cuff (being careful not to touch the gown) and pulls it gently from the fingertips. Regloving should be performed using the assisted gloving technique described in Fig. 6.8.

Surgical Instrumentation

INSTRUMENT CATEGORIES

Each type of surgical instrument is designed for a particular use and should be used only for that purpose. Using instruments for procedures for which they are not designed (e.g., using Metzenbaum scissors to cut suture or tissue forceps to hold bone) may dull or break them. Specialized instruments for ophthalmologic surgery are discussed in Chapter 16.

Scalpels

Scalpels are the primary cutting instruments used to incise tissue (Fig. 7.1). Reusable scalpel handles (No. 3 and 4) with detachable blades are most commonly used in veterinary medicine; however, disposable handles and blades are available. Disposable scalpels with a locking retractable shield are designed to minimize the risk of surgical blade injuries while passing blades between procedural steps and during disposal. Blades are available in various sizes and shapes, depending on the intended task. A No. 10 blade is most commonly used in small animal surgery for incision and excision of tissues. A No. 15 blade is a smaller version of a No. 10 and is used for precise incisions in smaller tissues. A No. 11 blade is ideal for stab incisions into fluid-filled structures or organs. The curved angle of the No. 12 blade limits its applicability, but it is most often used in cats for elective dissection onychectomy (declawing).

Scalpels are usually used in a slide-cutting fashion, which means that the direction of pressure applied to the knife blade is at a right angle to the direction of scalpel pressure. When incising skin, the scalpel blade should be kept perpendicular to the skin surface. Scalpels can be held with a pencil grip, a fingertip grip, or a palmed grip. The pencil grip allows shorter, finer, and more precise incisions than the other grips because the scalpel is at a 30- to 40-degree greater angle to the tissue (Fig. 7.2). However, this angle reduces cutting edge contact, making this grip less useful for long incisions. The fingertip grip offers the best accuracy and stability for long incisions. The palmed grip is the strongest hold on the scalpel and allows exertion of great pressure on the tissue, but this is often unnecessary in surgical situations.

Scissors

Scissors come in a variety of shapes, sizes, and weights and generally are classified according to the type of point (e.g., blunt-blunt, sharp-sharp, sharp-blunt), blade shape (e.g., straight, curved), or cutting edge (e.g., plain, serrated) (Fig. 7.3). Curved scissors offer greater maneuverability and visibility, whereas straight scissors provide the greatest mechanical advantage when cutting tough or thick tissue. Metzenbaum (also called Metz, Nelson, delicate, or tissue scissors) or Mayo scissors are most commonly used in small animal surgery. Metzenbaum scissors are more delicate than Mayo scissors and are designed for sharp and blunt dissection or incision of finer tissues; Mayo scissors are used for cutting dense, heavy tissue, such as fascia. Heavy scissors are used to cut sutures, but these are separate instruments from those used to cut tissue. Suture scissors used in the operating room are different from suture removal scissors. The latter have a concavity on one blade to gently hook the suture away from the skin and facilitate easy removal. Delicate scissors (e.g., tenotomy scissors, iris scissors) are often used in ophthalmic procedures and other meticulous surgeries, such as perineal urethrostomy, that require fine, precise cuts. Bandage scissors have a blunt tip, which reduces the risk of cutting skin when the scissors are introduced under the bandage. Scissors should be utilized only for their specific purpose and should be regularly maintained to keep them sharp.

Scissors may be used for sharp cutting or blunt dissection. They are held with the tips of the thumb and ring finger through the finger rings and with the index finger resting on the shanks near the fulcrum. The ring finger or thumb should not be allowed to "fall through" the handle; the rings should be kept near the distal finger joint. This is referred to as a *wide-based tripod grip.* Most scissors are designed for use with a right-handed grip, so the natural pushing of the thumb and pulling of the fingers in a gripping motion apply maximal shear and torque to the blades. When used in the left hand, loss of shear and torque forces results in less precision and increased tissue trauma. Therefore left-handed surgeons should learn to cut with scissors with their right hand or should invest in specifically designed left-handed scissors.

Direction, control, and accuracy in cutting depend on the stability of the tissue between the blades of the scissors and the stability of the scissors in the operator's grip. The larger the angle between the blades when cutting, the less the scissors stabilize the tissue and the less accurate the cut. Using the end of the blade stabilizes tissue more securely and allows a more precise cut. Scissors should not be completely closed if the incision is to be continued because the result is a ragged incision; scissors should be nearly closed, advanced, and nearly closed again. Blunt dissection (i.e., separation of tissue by inserting the points and opening the handle) may be used to separate loosely bound tissues, such as muscle or fat, or to undermine skin edges for wound closure. Blunt dissection should not be used in tougher tissue or where precise cuts are possible.

Needle Holders

Needle holders grasp and manipulate curved needles (Fig. 7.4). Size and type of needle holder are determined by characteristics of the needle to be held and location of tissue to be sutured. Larger needles require wider, heavier jawed needle holders. If needle holders are used to hold suture, the jaws should be finely

ABSTRACT

General surgical instrumentation is designed to cut, grasp, manipulate, or retract tissue. The choice of instrument for a particular surgical task should be based on minimizing the amount of tissue trauma, which also relies on using that instrument properly. Tissue trauma can also be limited by appropriate care and maintenance of surgical instrumentation.

FIG. 7.1 Scalpel handles (*left,* No. 3; *right,* No. 4) and blades *(top to bottom)*: No. 10, 11, 12, 15, and 20.

FIG. 7.2 Scalpels are generally held with a pencil grip because this allows short, fine, precise incisions.

FIG. 7.3 Scissors. *Left to right:* stitch (suture removal), sharp-blunt, Metzenbaum, Mayo, wire, and tenotomy.

FIG. 7.4 Needle holders. *Left to right:* Mayo-Hegar, Olsen-Hegar, Mathieu, and Castroviejo.

serrated or smooth to prevent damaging the suture by fraying or cutting it. Long needle holders facilitate working in deep wounds. High-quality needle holders are made of noncorrosive, high-strength alloy and have a glare-free finish. The tips are hardened by coating them with a diamond surface or by fusing tungsten carbide to the face. Tungsten carbide inserts may be replaced when they become damaged or fail to hold suture adequately.

Most needle holders (e.g., Mayo-Hegar, Olsen-Hegar types) have a ratchet lock just distal to the thumb, but some (e.g., Castroviejo type) have a spring and latch mechanism for locking. Mayo-Hegar needle holders are commonly used in veterinary medicine for manipulating medium to coarse needles. Olsen-Hegar needle holders are used similarly but have scissor blades that allow suture to be tied and cut with the same instrument. The disadvantage of Olsen-Hegar needle holders is that expertise is required to prevent cutting the suture during knot tying. Mathieu needle holders have a ratchet lock at the proximal end of the handles of the needle holder, which permits locking and unlocking simply by progressively squeezing the handles together.

Needles generally should be placed perpendicular to the needle holder, which allows greatest maneuverability. When needles are placed at an angle, the handles must move through a wide arc during suturing. A needle is generally grasped near its center to allow it to be advanced through tissue with greater force and less risk of breakage. When the needle is grasped near the eye or swage, maximum needle length is available for suturing and risk of needle slippage is reduced; however, the needle is more likely to bend or break unless delicate tissue is being sutured. Conversely, holding the needle near the pointed end allows the greatest driving force when suturing tough tissue, but extracting the needle is difficult.

Needle holders may be held using a *palmed grip* (no fingers are placed in the rings, and the upper ring rests against the ball of the thumb [Fig. 7.5]), a *thenar grip* (the upper ring rests on the ball of the thumb, and the ring finger is inserted through the lower ring [Fig. 7.6]), a *thumb-ring finger grip* (thumb is placed through the upper ring and the ring finger through the lower ring [Fig. 7.7]), or a *pencil grip* (index finger and thumb rest on the shafts of the needle holder [Fig. 7.8]), which is used with Castroviejo needle holders. The palmed grip is most advantageous for suturing tough tissue that requires a strong needle-driving force; however, the needle cannot be easily released and regrasped after a stitch without changing to another grip, making suturing less precise.

NOTE Left-handed surgeons cannot palm right-handed instruments because the boxlock closes rather than opens with pressure.

FIG. 7.5 A palmed grip provides a strong driving force but less precision.

The thenar grip allows the needle to be released and regrasped for extraction without changing grips. Although it allows mobility, releasing the needle holder by exerting pressure on the upper ring with the ball of the thumb causes the needle holder handles to "pop" apart, and some needle movement occurs during this process. The greatest advantage of a thumb-ring finger grip is that it allows precision when releasing a needle. Although slower than the palmed or thenar grip, it is preferred when tissue is delicate or when precise suturing is required.

Tissue Forceps

Tissue (thumb) forceps are tweezer-like, nonlocking instruments used to grasp tissue (Fig. 7.9). The proximal ends are bonded together to allow the grasping ends to spring open or be squeezed shut. They are available in various shapes and sizes; tips (grasping ends) may be pointed, flat, round, smooth, or serrated with small or large teeth. Tissue forceps with large teeth should not

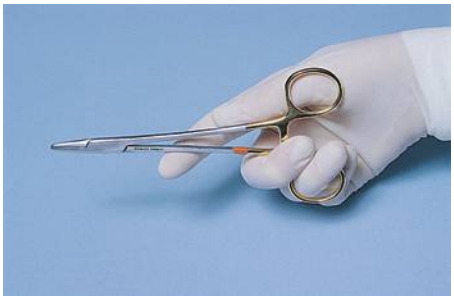

FIG. 7.6 A thenar grip provides good mobility, but releasing the needle holder by applying pressure with the ball of the thumb to the upper ring causes the handles to "pop" apart. This causes some movement of the needle in the tissue being sutured.

FIG. 7.7 The thumb-ring finger grip allows for the best precision of all grips and is preferable when suturing delicate tissue.

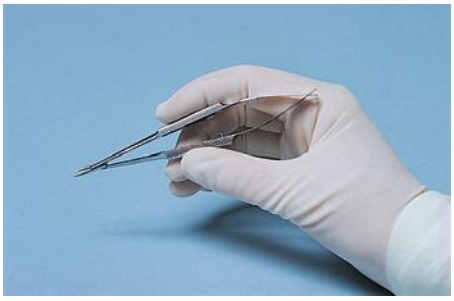

FIG. 7.8 A pencil grip is used with Castroviejo needle holders.

FIG. 7.9 Tissue forceps. *Left to right:* Bishop-Harmon (smooth tip), Bishop-Harmon (toothed), Brown-Adson, 132 tissue, serrated, and DeBakey.

FIG. 7.10 Holding tissue forceps with a pencil grip provides greater maneuverability than is attained with other grips.

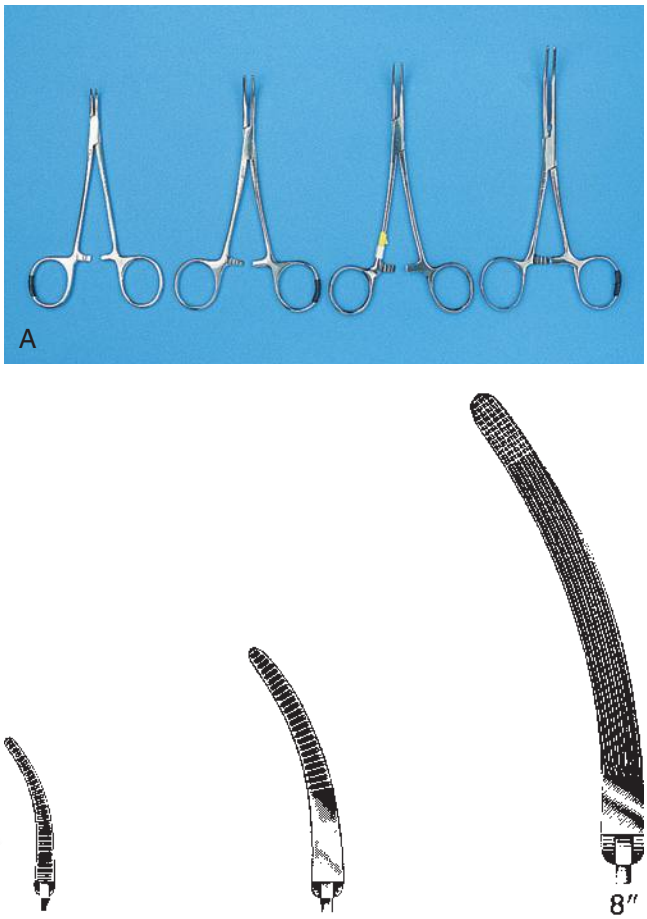

FIG. 7.11 (A) Hemostat forceps. *Left to right*: mosquito, Kelly, Crile, and Rochester-Carmalt. (B) Jaw detail of hemostatic forceps. *Left to right:* mosquito, Kelly, and Rochester-Carmalt.

be used to handle tissue that is easily traumatized. Tissue forceps with smooth tips, such as DeBakey forceps, are recommended for manipulation of delicate tissue, such as viscera or blood vessels. The most commonly used tissue forceps (i.e., Brown-Adson forceps) have small serrations on the tips that minimize trauma but facilitate holding tissue securely.

Tissue forceps are generally used in the nondominant hand. They should be held so that one blade functions as an extension of the thumb and the other blade functions as an extension of the opposing fingers (i.e., pencil position [Fig. 7.10]). Holding the shanks in the palm greatly limits maneuverability. When forceps are not in use, they can be palmed and held with the ring and little fingers, leaving the index and middle fingers free.

Tissue forceps are used to stabilize tissue and/or expose tissue layers during suturing. During suturing, tissue forceps are used on the far side of the wound to grasp the layer above the one being sutured. This layer is retracted upward and outward with the forceps, exposing the layer to be sutured. The needle point can then be placed at the desired level. Before the needle is driven completely through the tissue, the forceps should be moved from the superficial layer to grasp the layer being sutured. This layer can then be lifted to expose the needle's exit as it is passed through the tissue. The tissue layer on the near side being sutured is grasped and lifted to expose the desired needle entrance site. After the needle point has been placed at the desired site, the tissue forceps are moved and are used to retract the more superficial layer, thereby exposing the exit site. When needles are grasped with forceps during suturing, they should be grasped perpendicular to the shaft.

Hemostat Forceps

Hemostat forceps are crushing instruments used to clamp blood vessels (Fig. 7.11). They are available with straight or curved tips and vary in size from smaller (7.6 cm [3 in]) Mosquito hemostats with transverse jaw serrations to larger (22.9 cm [9 in]) angiotribes. Serrations on the jaws of larger hemostat forceps may be transverse, longitudinal, diagonal, or a combination of these. Longitudinal serrations are generally gentler to tissue than cross-serrations. Serrations usually extend from the tips of the jaws to the boxlocks, but in Kelly forceps, transverse (i.e., horizontal) serrations extend only over the distal portion of the jaws. Similarly sized Crile forceps have transverse serrations that extend the entire length of the jaw. Kelly and Crile forceps are used on larger vessels. Rochester-Carmalt forceps are larger crushing forceps often used to control large tissue bundles, such as during an ovariohysterectomy. They have longitudinal grooves with cross-grooves at the tip ends to prevent tissue slippage. Specialized

cardiovascular forceps (e.g., Satinsky forceps) allow occlusion of only a portion of the vessel. Serrations of cardiovascular clamps provide tissue compression without cutting delicate vessel walls. Large teeth at the tip ends of some forceps (i.e., Ochsner) help prevent tissue slippage within forceps.

Curved hemostats should be placed on tissue with the curve facing up. As little tissue as possible should be grasped to minimize trauma, and the smallest hemostat forceps that can accomplish the job should be used. To prevent having fingers momentarily trapped in the rings of hemostats, fingertips should be placed on the finger rings, or fingers should be inserted into the rings only as far as the first joint.

Tissue Forceps

Tissue forceps are used to grasp or clamp tissue, varying the degree of tissue trauma that is created. Allis tissue forceps have interlocking sharp teeth; this instrument is used to firmly grasp tissue that is going to be removed from the body. Babcock tissue forceps have broad, flared, and blunt grasping tips that are more delicate than Allis tissue forceps and can be used carefully on tissue remaining in the body. Doyen intestinal forceps are noncrushing, occluding forceps with shallow longitudinal striations that are used to temporarily occlude the lumen of the bowel.

Retractors

Handheld retractors (Fig. 7.12) and self-retaining retractors (Fig. 7.13) are used to retract tissue and improve visualization. The ends of handheld retractors may be hooked, curved, spatula-shaped (i.e., Hohmann), or toothed. Some handheld retractors (e.g., malleable or ribbon retractors) may be bent by the surgeon to conform to the structure or area of the body being retracted. Senn (rake) retractors are small, double-ended retractors with three small, fingerlike projections on one end and a flat, curved blade on the other. Army-Navy retractors are larger with blunt, broad blades on each end for retraction of large amounts of tissue. Self-retaining retractors (e.g., Gelpi, Weitlaner) maintain tension on tissue and are held open with a boxlock or another device (e.g., a set-screw, such as in Balfour and Finochietto retractors [Fig. 7.14]). Balfour retractors generally are used to retract the abdominal wall, and Finochietto retractors are commonly used during thoracotomies.

Miscellaneous Instruments

Instruments are available to suction fluid (Fig. 7.15), clamp drapes or other inanimate objects (Fig. 7.16), cut and remove pieces of bone (rongeurs [Figs. 7.17 and 7.18]), hold bones during fracture repair (Fig. 7.19), scrape surfaces of dense tissue (curettes), remove periosteum (periosteal elevators [Fig. 7.20]), cut or shape bone and cartilage (osteotomes and chisels [Fig. 7.21]), and bore holes in bone (trephines). Magnifying loupes are useful when precise cutting or suturing of tissue is necessary (e.g., cardiovascular or

neurologic surgery), and when relatively small tissues are handled (e.g., ureteral anastomoses). Numerous other specialized instruments have been developed to facilitate specific surgical procedures, particularly for minimally invasive surgery. Instrumentation for laparoscopy and thoracoscopy are described in Chapter 14. Some instruments used in orthopedic and neurologic procedures are shown in Figs. 7.22 to 7.24. Other orthopedic instruments are described in Chapter 32.

INSTRUMENT CARE AND MAINTENANCE

Good surgical instruments are valuable investments. They must be used properly and must receive routine care and maintenance to prevent corrosion, pitting, and discoloration and to prolong the life of the instruments (Table 7.1). Instruments should be rinsed in warm water immediately after the surgical procedure to prevent blood, tissue, saline, or other foreign matter from drying on them. If instruments cannot be immediately cleaned, they should be kept moist under a wet towel. Key takeaways from the Association of periOperative Registered Nurses (AORN) *Guideline for Cleaning and Care of Surgical Instruments* are listed in Box 7.1.[1]

Many manufacturers recommend that instruments be rinsed, cleaned, and sterilized in distilled or deionized water because tap water contains varying degrees of minerals that may discolor

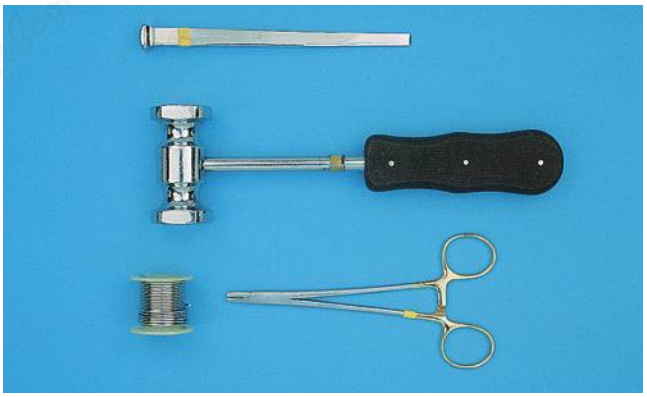

FIG. 7.21 Orthopedic equipment. *Top to bottom:* chisel, mallet, orthopedic wire, and wire twisters.

FIG. 7.23 Hall air drill and assorted bits.

and stain the instruments. If tap water is used for rinsing, instruments should be dried thoroughly to prevent staining and spotting. Instruments with several components should be disassembled before cleaning. Delicate instruments should be cleaned and sterilized separately.

BOX 7.1 Key Takeaways From 2014 AORN Guidelines for Cleaning and Care of Surgical Instruments[a]

- Clean and decontaminate instruments as soon as possible after use because this helps prevent biofilm formation. To reduce biofilm formation:
  - Remove gross soil at the point of use as dried blood and other organic material can be corrosive to instrument surfaces.
  - Do not allow blood or other bioburden to dry as this could make it more difficult to remove them and could compromise the effectiveness of the subsequent disinfection or sterilization.
  - Periodically irrigate the instruments with lumens to remove gross soil and reduce the risk of biofilm formation.
  - Keep the instruments moist by placing a towel moistened with sterile water over the instruments. DO NOT USE SALINE, which may cause pitting of the instruments.
- Laryngoscope blades may be a source of contamination to other patients because they come in contact with mucous membranes. To prevent this:
  - Clean blades and high-level disinfect or sterilize them after each use.
  - Handles are classified as a noncritical device; thus they require only cleaning and low-level disinfection. However, the rough surface of the laryngoscope handle can accumulate bioburden and occasional sterilization is warranted.
- Ophthalmic instruments have been associated with a syndrome of acute inflammation of the anterior segment of the eye in humans. To prevent this:
  - Ensure instruments are rinsed well and that no detergent residues remain.
  - Ensure that dried debris and residues of ophthalmic viscoelastic material have been cleaned from the instruments.
  - Rinse lumens and expel fluid from the lumen into the drain to prevent recontamination of the rinse water with debris from inside the lumen.
  - Use sterile, deionized water to rinse the instruments because untreated water may contain endotoxins or may cause stains, deposits, or corrosion of the instrument surface.
  - Dry lumens thoroughly with compressed air to eliminate moisture that could foster microbial growth.
  - Use cleaning products recommended by the manufacturer.

AORN, Association of periOperative Registered Nurses.

Cleaning

For instrument cleaning, use detergents with neutral or near-neutral pH (between 7 and 8); low-pH detergents corrode the protective surface of stainless steel if not fully rinsed off, whereas high-pH detergents corrode or cause "browning" of instruments and may impair function. Stains should be distinguished from rust (Table 7.2). Stains can be removed, whereas rust causes permanent damage. Enzymatic solutions containing proteases, lipases, and amylases are often added to neutral pH detergents to effectively and efficiently remove organic material from general surgical instruments and endoscopic equipment; these solutions must be thoroughly rinsed from instrumentation to avoid adverse reactions. Studies differ with regard to effectiveness of enzymatic versus nonenzymatic cleaners.

NOTE Do not use Betadine solution, dish soap, laundry soap, or hand scrubbing solutions to clean instruments because spotting and corrosion will occur.

TABLE 7.1 Causes of Instrument Corrosion, Pitting, or Discoloration

Type and Cause of Damage	Solution
Corrosion	
• Excessive moisture left on the surface of the instrument or in the instrument pack	• Preheat the autoclave; allow instruments to cool slowly; check autoclave valves for leaks
• Rinsing with tap water; deposition of alkali earth on walls of autoclave, which deposits on instruments	• Use distilled or deionized water during sterilization; periodically clean autoclave with acetic acid
• Prolonged exposure to enzymatic cleaning solutions	• Do not expose carbon steel instruments to enzymatic cleaners for longer than 5 minutes
Pitting	
• Exposing instruments to saline or foreign materials	• Rinse instruments with distilled water immediately after the procedure
• Detergent residue on instruments during autoclaving	• Avoid detergents with a chloride base, which form hydrochloric acid when combined with steam
• Use of alkaline detergents that remove the chromium oxide coat	• Use detergents that have a pH near 7
• Simultaneous cleaning of metals of dissimilar composition in an ultrasound cleaner	• During cleaning, separate instruments made from dissimilar metals
Rust Deposition	
• Deposition of iron on instrument from tap water	• Use distilled or deionized water during cleaning, rinsing, and sterilization
• Deposition and oxidation of carbon particles on stainless steel instruments when they are sterilized with chrome-plated instruments that have exposed metal	• Separate the two types of steel during sterilization; replace plated instruments that are peeling or imperfect
Spotting	
• Condensation and slow evaporation of water droplets containing sodium, calcium, and/or magnesium on instruments	• Follow instructions for autoclave use; open door after steam has been exhausted; check valves or gaskets; use distilled or deionized water

Ultrasonic cleaning can be used to follow manual cleaning of surgical instruments. This method removes small or microscopic organic material by cavitation and implosion in which waves of acoustic energy are propagated in aqueous solutions to disrupt the bonds that hold particulate matter to surfaces. Dissimilar metals (e.g., chrome and stainless steel) should not be mixed in the same ultrasonic cycle. All instruments should be placed in the ultrasonic cleaner with ratchets and boxlocks open and should not be piled on top of each other because delicate instruments could be damaged. Instruments should be

TABLE 7.2 Troubleshooting Stain Guide for Surgical Instruments[a]

Stain Color	Cause
Brown/orange	High-pH detergents, chlorhexidine, or improper soaking of instruments. May also be caused by soaking in tap water.
Dark brown	Low-pH instrument solutions. The brownish-colored film may also be caused by a malfunctioning sterilizer. Similar localized stain spots may be a result of baked-on blood.
Bluish black	Reverse plating, when instruments of different metals (e.g., chrome, stainless steel) are ultrasonically processed together. Additionally, exposure to saline, blood, or potassium chloride will cause this.
Multicolor	Excessive heat by a localized hot spot in the sterilizer. The rainbow-colored stain can be removed.
Light- and dark-colored spots	Water droplets drying on the instruments. Slow evaporation leaves sodium, calcium, and magnesium deposits.
Bluish gray	Liquid (cold) sterilization solutions are being used beyond manufacturer's recommendations.
Black	Contact was made with ammonia or a solution containing ammonia.
Gray	A liquid rust remover is being used in excess of manufacturer's recommendations.
Rust	Dried blood that has become baked on the serrated or hinged areas of surgical instruments. This organic material, once baked on, may appear dark in color. Rust also can be caused by soaking in tap water.

[a]Modified from Spectrum surgical instruments, repairs, instrument accessories; Spectrum Surgical Instruments Corp. http://www.spectrumsurgical.com.

removed from the cleaner and rinsed and dried at completion of the cycle.

If ultrasonic cleaning is unavailable, instruments should be cleaned as thoroughly as possible. Use an instrument cleaning brush to remove debris from the jaw serrations, teeth, and hinged areas. Various specialized instrument brushes are available (e.g., Frazier suction tube brushes, laparoscopic brushes, bone reamer brushes, endoscopic brushes), along with general instrument cleaning brushes. A soft nylon brush or toothbrush may also be used; rasps and serrated areas may require a wire brush. Dry surgical instruments on a clean paper towel. Place the fine tips of surgical hemostats face up on towels to prevent damage.

Lubricating and Autoclaving

Instruments with boxlocks, hinges, and power equipment should be lubricated before autoclaving. Only surgical lubricants should be used because they are steam penetrable; industrial oils interfere with steam sterilization and should not be used. Lubricant sprays are preferred over submersion in lubricant milk due to the potential for bacterial contamination from previously dipped instruments.

Surgical instruments are generally grouped into packs or kits according to their use (Tables 7.3 and 7.4). Before autoclaving, instruments should be wrapped in cloth or placed on a cloth inside a fenestrated pan to absorb moisture. Instruments should be sterilized with boxlocks or hinges open.

NOTE Never lock an instrument during autoclaving; this prevents steam from reaching and sterilizing overlapping metal surfaces. Hinge areas of forceps and hemostats can expand and crack when exposed to heat during autoclaving if they are locked.

The chamber should not be overloaded, and stacking of instruments should be avoided to prevent damage to delicate instruments. Kits should be double-wrapped (see p. 11) and sealed with autoclave tape. A sterilization monitor (e.g., OK sterilization indicators [Propper Manufacturing Company], Sterrad chemical indicator strips [Johnson & Johnson]) should be added before autoclaving (see p. 10). Rapid cooling of instruments should be avoided to prevent condensation. Additional information on autoclaving and other methods of sterilization can be found in Chapter 2.

TABLE 7.3 Suggestions for a Basic Soft Tissue Pack[a]

Instrument	Quantity
Halsted-mosquito hemostats, curved, 5 inch (12.5 cm)	2
Halsted-mosquito hemostats, straight, 5 inch (12.5 cm)	2
Kelly hemostats, curved, 5.5 inch (14 cm)	2
Crile forceps, straight, 5.5 inch (14 cm)	2
Rochester-Carmalt hemostats, curved, 7.25 inch (18.5 cm)	4
Mayo-Hegar or Olsen-Hegar needle holders, 7 inch (18 cm)	1
Brown-Adson tissue forceps	1
Allis tissue forceps, 5 × 6 teeth, 6 inch	4
Backhaus towel clamps, 5.25 inch (13 cm)	4
Metzenbaum scissors, curved, 8 inch (20 cm)	1
Mayo scissors, curved, 8 inch (20 cm)	1
Suture scissors, sharp-blunt, straight, 5 inch (12.5 cm)	1

Kirschner wires	2 each size
Intramedullary pins	2 each size

[a]Augmented with a general pack (see Table 7.3).

Cold Sterilization

Cold sterilization is used for some instruments but does not guarantee sterility. Instruments that cannot be autoclaved are best sterilized using alternate means (e.g., ethylene oxide or plasma sterilization; see pp. 5–8). Solutions that contain benzyl ammonium chloride (BAC) should not be used with instruments that have tungsten carbide inserts because BAC dissolves tungsten.

DRAPING AND ORGANIZING THE INSTRUMENT TABLE

Instrument tables should be height adjustable to allow them to be positioned within reach of surgical personnel. The instrument table should not be opened until the animal has been positioned on the surgical table and draped. Large, water-impermeable table drapes should cover the entire instrument table. To open these drapes, the drape and outer wrap are positioned on the instrument table and the exposed underneath surface of the drape is gently grasped. The ends and then the sides are unfolded. Once the drape has been opened, nonsterile personnel should not reach over it. Mayo stands often are used in procedures that require additional instruments, such as bone plating; specially designed stand covers are available for these tables. After the instrument pack has been opened (see p. 14), instruments should be positioned so that they can be readily retrieved. The layout is generally determined by the surgeon's preference, but grouping of similar instruments (e.g., scissors, retractors) facilitates their use. Whenever a body cavity is opened, sponges should be counted at the beginning of the procedure (before the incision is made) and again before closure to ensure that none have been inadvertently left in the cavity. Contaminated instruments and soiled sponges should not be placed back on the instrument table.

Biomaterials, Suturing, and Hemostasis

SUTURES AND SUTURE SELECTION

Suture plays an important role in wound repair by providing hemostasis and support for healing tissue. Tissues have different requirements for suture support, depending on the type of tissue and anticipated duration of healing. Some tissues need support for only a few days (e.g., muscle, subcutaneous tissue, skin), whereas others require weeks (fascia) or months (tendon) to heal. Individual patient variation further affects suture choice. Healing of wounds may be delayed by infection, obesity, malnutrition, neoplasia, drugs (e.g., steroids), and collagen disorders. In rapidly healing tissue, a suture that will lose its tensile strength at a similar rate that the tissue gains strength, and that will be absorbed by the tissue so that no foreign material remains in the wound, is ideal. Minimally invasive surgical techniques (see Chapter 14) put additional demands on the performance of surgical sutures. Not only must good knot security be maintained, but also the surface lubricant must ensure ease of manipulation, minimal tissue drag, and good biocompatibility with minimal inflammatory responses. Subjective preferences, such as familiarity with the material and availability, need also be taken into consideration when choosing a suture material.

Suture Characteristics

The ideal suture is easy to handle, reacts minimally in tissue, inhibits bacterial growth, holds securely when knotted, resists shrinking in tissue, absorbs with minimal reaction after the tissue has healed, and is noncapillary, nonallergenic, noncarcinogenic, and nonferromagnetic; however, such a material does not exist. Therefore surgeons must choose a suture that most closely approximates the ideal for a given procedure and tissue to be sutured. A wide variety of suture and needle combinations are available.

Suture Size

The smallest diameter suture that will adequately secure wounded tissue should be used to minimize trauma as the suture is passed through the tissue, and to reduce the amount of foreign material left in the wound. There is no advantage to using a suture that is stronger than the tissue to be sutured. The most commonly used standard for suture size is the United States Pharmacopeia (USP), which denotes dimensions from fine to coarse (with diameters in inches) according to a numeric scale, with 12-0 being the smallest and 7 the largest. The USP uses different standards for surgical gut and other materials (Table 8.1). The smaller the suture size, the less tensile strength it has. Stainless steel wire is sized according to the metric or USP scale or by the Brown and Sharpe (B and S) wire gauge (see Table 8.1).

Flexibility

The flexibility of a suture is determined by its torsional stiffness and diameter, which influence its handling and use. Flexible sutures are indicated for ligating vessels or performing continuous suture patterns. Less flexible sutures (e.g., wire) cannot be used to ligate small bleeders. Nylon and surgical gut are relatively stiff compared with silk suture; braided polyester sutures have intermediate stiffness.

Surface Characteristics and Coating

The surface characteristics of a suture influence the ease with which it is pulled through tissue (i.e., the amount of friction or "drag") and the amount of trauma caused. Rough sutures cause more injury than smooth sutures. Smooth surfaces are particularly important in delicate tissues, such as the eye. However, sutures with smooth surfaces also require greater tension to ensure good apposition of tissues, and have less knot security. Braided materials have more drag than monofilament sutures. Braided materials are often coated to reduce capillarity (see later discussion), but this also provides a smooth surface. Teflon, silicone, wax, paraffin-wax, and calcium stearate are used for coating sutures.

Capillarity

Capillarity is the process by which fluid and bacteria are carried into the interstices of multifilament fibers. Because neutrophils and macrophages are too large to enter the interstices of the fiber, infection may persist, particularly in nonabsorbable sutures. All braided materials (e.g., polyglycolic acid, silk) have degrees of capillarity, whereas monofilament sutures are considered noncapillary. Coating reduces the capillarity of some sutures, but regardless, capillary suture materials should not be used in contaminated or infected sites.

Knot Tensile Strength

Knot tensile strength is measured by the force in pounds that the suture strand can withstand before it breaks when knotted (Box 8.1). Sutures should be as strong as the normal tissue through which they are being placed; however, the tensile strength of the suture should not greatly exceed the tensile strength of the tissue.

Relative Knot Security

Relative knot security is the holding capacity of a suture expressed as a percentage of its tensile strength. The knot-holding capacity of a suture material is the strength required to untie or break a defined knot by loading the part of the suture that forms the loop; the suture material's tensile strength is the strength required to break an untied fiber with a force applied in the direction of its length (see Box 8.1).

ABSTRACT

When choosing a suture material, the surgeon must be knowledgeable about the healing properties of the particular tissue, the wound healing capability of the patient, and the characteristics of suitable suture materials (particularly tissue reactivity, tensile strength, knot security, and rate of absorption). The type of suture to be used depends on the procedure being performed and the tissue in which it will be placed. The suture material chosen must retain its strength until the wound heals sufficiently. Other methods for hemostasis and tissue apposition include, but are not limited to, energy-based devices and tissue adhesives (e.g., cyanoacrylates).

BOX 8.1 Terminology Used to Describe Suture Characteristics

- *Absorbability.* Progressive loss of mass and/or volume of suture material; does not correlate with initial tensile strength.
- *Breaking strength.* Limit of tensile strength at which suture failure occurs.
- *Capillarity.* Extent to which absorbed fluid is transferred along the suture.
- *Elasticity.* Measure of the ability of the material to regain its original form and length after deformation.
- *Fluid absorption.* Ability to take up fluid after immersion.
- *Knot-pull tensile strength.* Breaking strength of knotted suture material (10%–40% weaker after deformation by knot placement).
- *Knot strength.* Amount of force necessary to cause a knot to slip (related to the coefficient of static friction and plasticity of a given material).
- *Memory.* Inherent capability of suture to return to or maintain its original gross shape (related to elasticity, plasticity, and diameter).
- *Plasticity.* Measure of the ability to deform without breaking and to maintain a new form after relief of the deforming force.
- *Pliability.* Ease of handling of suture material; ability to adjust knot tension and to secure knots (related to suture material, filament type, and diameter).
- *Straight-pull tensile strength.* Linear breaking strength of suture material.
- *Suture pullout value.* The application of force to a loop of suture located where tissue failure occurs, which measures the strength of a particular tissue; variable depending on anatomic site and histologic composition (fat, 0.2 kg; muscle, 1.27 kg; skin, 1.82 kg; fascia, 3.77 kg).
- *Tensile strength.* Measure of the ability of a material or tissue to resist deformation and breakage.
- *Wound breaking strength.* Limit of tensile strength of a healing wound at which separation of the wound edges occurs.

From Lai SY, Becker DG. Sutures and needles, e-medicine. *Topic.* 2004;38.

Specific Suturing Materials

Suture materials may be classified according to their behavior in tissue (absorbable or nonabsorbable), their structure (monofilament or multifilament), or their origin (synthetic, organic, or metallic) (Fig. 8.1 and Table 8.2). Two major mechanisms of absorption result in the degradation of absorbable sutures. Sutures of organic origin, such as surgical gut, are gradually digested by tissue enzymes and phagocytized, whereas sutures manufactured from synthetic polymers are principally broken down by hydrolysis. Nonabsorbable sutures are ultimately encapsulated or walled off by fibrous tissue.

Monofilament sutures are made of a single strand of material and therefore have less tissue drag than multifilament sutures and do not have interstices that may harbor bacteria or fluid. Care should be used in handling monofilament sutures because nicking or damaging the material with forceps or needle holders may weaken the suture and predispose it to breakage. Multifilament sutures consist of several strands of suture that are twisted or braided together. Multifilament sutures generally are more pliable and flexible than monofilament sutures. They may be coated to reduce tissue drag and enhance handling characteristics (see previous discussion).

Absorbable Suture Materials

Absorbable suture materials lose most of their tensile strength within 60 days and eventually disappear from the tissue implantation site because they have been phagocytized or hydrolyzed (see Fig. 8.1 and Table 8.2). The time to loss of strength and for complete absorption varies among suture materials.

Organic absorbable materials. Catgut (surgical gut) is the most common nonsynthetic absorbable suture material. The word *catgut* is derived from the term *kitgut* or *kitstring* (the string used on a kit, or fiddle). Misinterpretation of the word *kit* as referring to a young cat led to the use of the term catgut. Surgical gut is made from the submucosa of sheep intestine or the serosa of bovine intestine, and is approximately 90% collagen. It is broken down by phagocytosis and, in contrast with other suture materials, elicits a notable inflammatory reaction. Plain surgical gut loses strength rapidly after tissue implantation. "Tanning" (cross-linking of collagen fibers), which occurs by exposure to chrome or aldehyde, slows absorption. Surgical gut is available as plain, medium chromic, or chromic; increased tanning generally implies prolonged strength and reduced tissue reaction. Surgical gut is rapidly removed from infected sites or areas where it is exposed to digestive enzymes, and is quickly degraded in catabolic patients. The knots may loosen when wet.

Synthetic absorbable materials. Synthetic absorbable materials (see Table 8.2) are generally broken down by hydrolysis and cause minimal tissue reaction. The time to loss of strength and to absorption is fairly constant in different tissue. Infection or exposure to digestive enzymes does not significantly influence the rate of absorption of most synthetic absorbable sutures. Polyglactin 910 and polyglycolic acid are more rapidly hydrolyzed in alkaline environments but are relatively stable in contaminated wounds. Polyglycolic acid, polyglactin 910, and poliglecaprone 25 may be rapidly degraded in infected urine; polydioxanone, polyglyconate, and glycomer 631 are acceptable for use in sterile bladders and those infected with *E. coli*. However, use of any suture that is degraded via hydrolysis may be at risk for accelerated degradation when the bladder is infected with *Proteus* spp. (see also p. 696) as all common monofilament absorbable sutures have been shown to degrade within 7 days in *P. mirabilis*-inoculated urine.

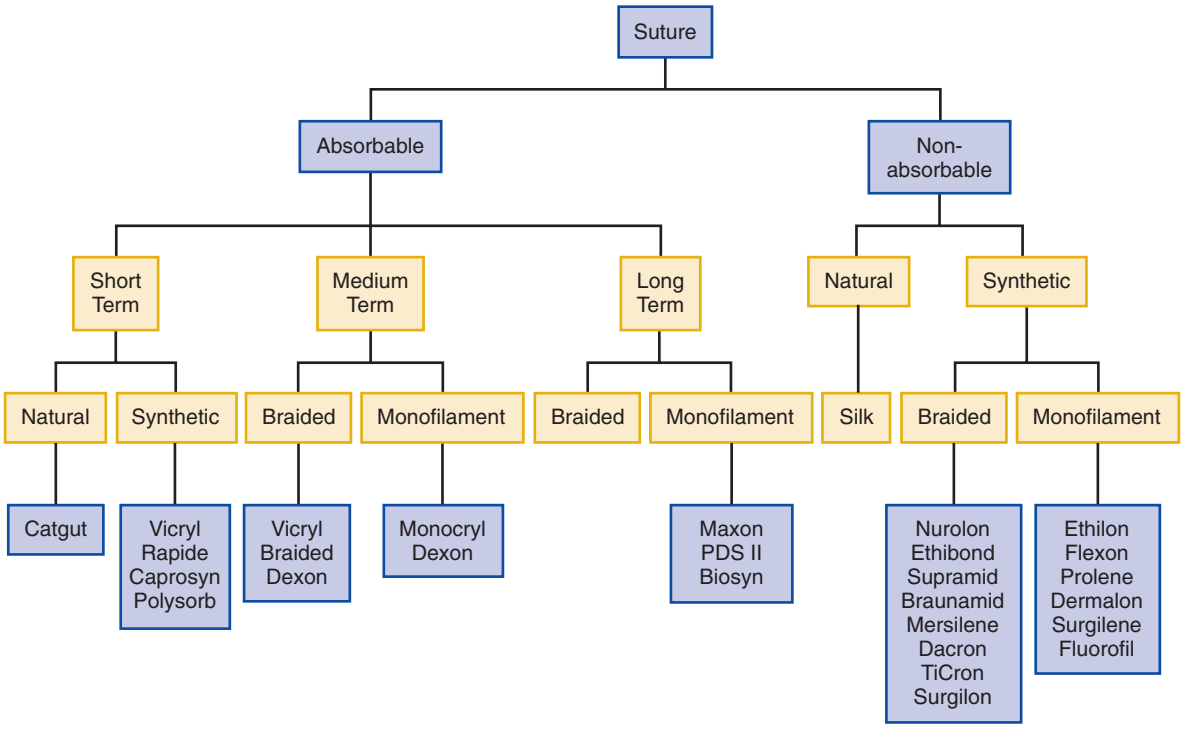

FIG. 8.1 Characteristics of sutures used in veterinary medicine.

Monofilament absorbable materials. Polydioxanone (PDS II) and polyglyconate (Maxon) are classic monofilament sutures that retain their tensile strength longer than multifilament sutures, with complete absorption occurring in 6 months. Poliglecaprone 25 (Monocryl) and Glycomer 631 (Biosyn) are monofilament rapidly absorbable synthetic materials that are pliable, lack stiffness, and have good handling characteristics. These sutures have good initial tensile strength that deteriorates in 2 to 3 weeks following implantation, and are completely absorbed by 120 days.

Polyglytone 6211 (Caprosyn) is a relatively new, rapidly absorbable monofilament suture. It is a synthetic polyester of glycolide, caprolactone, trimethylene carbonate, and lactide. Absorption of this material is essentially complete in 56 days, which is thought to lead to less wound complications and tissue reactions. This suture retains up to 30% knot strength at 10 days postimplantation and has excellent handling characteristics; however, its rapid absorption also limits its application.

Multifilament absorbable materials. Polyglycolic acid (Dexon) is braided from filaments extracted from glycolic acid and is available in both coated and uncoated forms. Polyglactin 910 (Vicryl) is a multifilament suture made of a copolymer of lactide and glycolide with polyglactin 370. It is coated with calcium stearate, and its rate of loss of tensile strength is similar to that of polyglycolic acid. Vicryl Rapide is a rapidly absorbed, synthetic braided suture that has an initial strength that is comparable to nylon and gut. However, the tensile strength declines to 50% in 5 to 6 days, and it is completely absorbed in 42 days. This suture is indicated for superficial closure of mucosa, gingival closure, and periocular skin closure.

Polysorb sutures are composed of Lactomer glycolide/lactide copolymer, which is a synthetic polyester composed of glycolide and lactide (derived from glycolic and lactic acids). Polysorb maintains 80% of its tensile strength at 2 weeks and 30% at 3 weeks, with absorption ranging from 56 to 70 days. Velosorb Fast sutures are composed of absorbable synthetic polyester comprised of glycolide and lactide. This suture is indicated for use in soft tissue approximation of the skin and mucosa, when only 7 to 10 days of wound support is required, as it retains the majority of its tensile strength until approximately 5 days. Complete absorption of Velosorb takes 40 to 50 days.

Nonabsorbable Suture Materials

Organic nonabsorbable materials. Silk is the most common organic nonabsorbable suture material used. It is a braided multifilament suture made by a special type of silkworm, and is marketed as uncoated or coated. Silk has excellent handling characteristics and is often used in cardiovascular procedures; however, it does not maintain significant tensile strength after 6 months and is therefore contraindicated for use in vascular grafts. It should also be avoided in contaminated sites; one silk suture may reduce the number of bacteria required to induce infection in a wound from 10^6 to 10^3.

Synthetic nonabsorbable materials. Synthetic nonabsorbable suture materials (see Table 8.2) are marketed as braided multifilament threads (e.g., polyester or coated caprolactam) or monofilament threads (e.g., polypropylene, polyamide, or polybutester). These sutures are typically strong and induce minimal tissue reaction. Nonabsorbable suture materials with an inner core and an outer sheath (e.g., Supramid) should not be buried in tissue because it may predispose to infection and fistulation. The outer sheath frequently is broken, which allows bacteria to reside underneath it.

NOTE Nylon cable ties are not recommended to be implanted in the body (e.g., used to ligate ovarian pedicles), as toxic substances are released during degradation, and may result in abscess or tumor formation.

TABLE 8.2 Characteristics of Suture Materials Commonly Used in Veterinary Medicine

Generic Name	Trade Name	Manufacturer	Suture Characteristics	Reduction in Tensile Strength[a]	Complete Absorption (Days)	Relative Knot Security[b]	Tissue Reaction[c]
Chromic surgical gut (catgut)	—	—	Absorbable Multifilament	33% at 7 days	60	— (wet)	+++
Polyglactin 910	Vicryl and Vicryl Plus	Ethicon	Absorbable Multifilament	25% at 14 days 50% at 21 days	56–70	++ ++	+ +

[a]Values given are approximate. Actual loss of tensile strength may vary depending on suture and tissue.
[b](–), Poor (<60%); (+), fair (60%–70%); (++), good (70%–85%); (+++), excellent (>85%).
[c](–), Minimal to none; (+), mild; (++), moderate; (+++), severe.

Metallic sutures. Stainless steel is the metallic suture most commonly used and is available as a monofilament or multifilament twisted wire. Surgical steel is strong and inert with minimal tissue reaction, but knot ends evoke an inflammatory reaction. Stainless steel has a tendency to cut tissue and may fragment and migrate. It is stable in contaminated wounds and is the standard for judging knot security and tissue reaction to suture materials.

Antimicrobial-coated sutures. Triclosan-impregnated suture is available in certain monofilament (PDS Plus, Monocryl Plus) and multifilament (Vicryl Plus) absorbable sutures. These sutures create an in vitro zone of inhibition against *Staphylococcus aureus*,

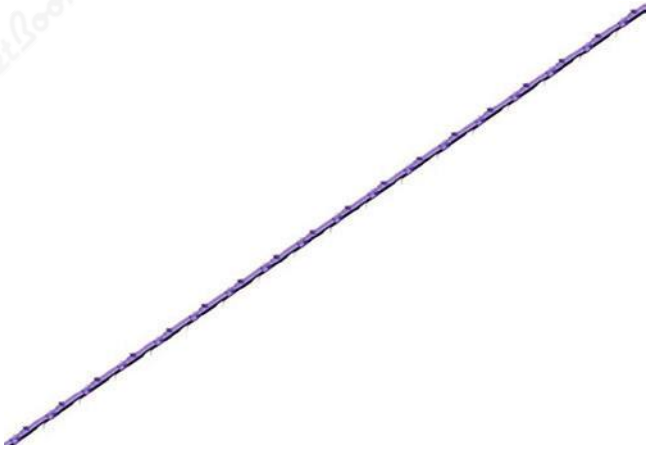

FIG. 8.2 Barbed suture material with unidirectional barbs notched into the strand.

Staphylococcus epidermidis, and *Escherichia coli* and are used to decrease rates of surgical site infection. Systematic reviews and meta-analyses in the human literature have failed to find evidence demonstrating the protective effect of triclosan-impregnated sutures on the occurrence of surgical site infections.[1,2] In the veterinary literature, a retrospective cohort study did not find additional benefit for using triclosan-impregnated suture for wound closure following tibial plateau leveling osteotomy in dogs.[3] However, in vitro comparison of impregnated versus nonimpregnated suture for adherence of methicillin-resistant *Staphylococcus pseudointermedius* found PDS Plus to have significantly less adherence than PDS II, Monocryl, Vicryl, and Stratafix Spiral PDO.[4]

Knotless barbed suture. Barbed suture material (e.g., V-Loc, Stratafix, Quill) has unidirectional barbs placed in a helical fashion around the suture strand (Fig. 8.2). These barbs allow the suture to become lodged in the tissue, creating multiple anchor points to distribute tension along the suture line. These sutures are also knotless as there is a preconstructed loop on the end to allow initial anchor of the suture line. Due to the unidirectional movement and anchoring of the suture through the tissue, there is no need for an end knot. Bidirectional barbs with double-swaged needles are also available on certain knotless suture materials (i.e., Quill, Statafix). Multiple experimental biomechanical studies have demonstrated similar tensile strength to standard monofilament suture material in a variety of tissues and procedures.[5–7] However, for tendon repair, smooth monofilament sutures were consistently stronger and were associated with less gap formation than knotless barbed suture.[8,9] Barbed monofilament suture (Stratofix Spiral PDO) has also been shown to have a comparable bacterial adherence profile of methicillin-resistant *S. pseudintermedius* to nonbarbed monofilament suture.[4]

Surgical Needles

A variety of needle shapes and sizes are available; selection of a needle depends on the type of tissue to be sutured (e.g., penetrability, density, elasticity, and thickness), topography of the wound (e.g., deep or narrow), and characteristics of the needle (i.e., type of eye, length, and diameter). Needle strength, ductility, and sharpness are important factors in determining the handling characteristics and use of a needle. The amount of angular deformation a needle can withstand before becoming permanently deformed is called *surgical yield*. Ductility is the needle's resistance to breaking under a specified amount of bending. The sharpness of a needle is related to the angle of the point (see p. 65) and the taper ratio of the needle. The sharpest needles have a long, thin, tapered point with smooth cutting edges. Most surgical needles are made from stainless steel wire because it is strong, corrosion free, and does not harbor bacteria.

The three basic components of a needle are the attachment end (i.e., swaged or eyed end), the body, and the point (Fig. 8.3A). Eyed needles must be threaded, and because a double strand of suture is pulled through the tissue, a larger hole is created than when swaged suture material is used. Eyed needles may be closed (i.e., round, oblong, or square) or French (i.e., with a slit from the inside of the eye to the end of the needle for ease of threading) (see Fig. 8.3B). Eyed needles are threaded from the inside curvature and are uncommonly used in surgical practice. With swaged sutures, the needle and suture are a continuous unit, which minimizes tissue trauma and increases ease of use.

The needle body comes in a variety of shapes (see Fig. 8.3C); the tissue type and depth and the size of the wound determine the appropriate needle shape. Straight (Keith) needles are generally used in accessible places where the needle can be manipulated directly with the fingers (e.g., placement of purse-string sutures in the anus). Curved needles are manipulated with needle holders. The depth and diameter of a wound are important when selecting the most appropriate curved needle. One-fourth circle needles are primarily used in ophthalmic procedures. Three-eighths and one-half circle needles are the most commonly used surgical needles in veterinary medicine. Three-eighths circle needles are more easily manipulated than one-half circle needles because they require less pronation and supination of the wrist. However, because of the larger arc of manipulation required, they are awkward to use in deep or inaccessible locations. A one-half circle or five-eighths circle needle, despite requiring more pronation and supination of the wrist, is easier to use in confined locations.

The needle point (i.e., cutting, taper, reverse cutting, or side cutting) (see Fig. 8.3D) affects the sharpness of a needle and the type of tissue in which the needle can be used. Cutting needles generally have two or three opposing cutting edges and are designed for use in tissues that are difficult to penetrate, such as skin. With conventional *cutting needles*, the third cutting edge is on the inside (i.e., concave) curvature of the needle. The location of the inside cutting edge may promote more "cut out" of tissue because it cuts toward the edges of the wound or incision. Reverse cutting needles have a third cutting edge on the outer (i.e., convex) curvature of the needle; this makes them stronger than similarly sized conventional cutting needles and reduces the amount of tissue cut out. Side cutting needles (i.e., spatula needles) are flat on the top and bottom and are generally used for ophthalmic procedures. Taper needles (i.e., round needles) have a sharp tip that pierces and spreads tissues without cutting them. They are generally used in easily penetrated tissues, such as the intestine, subcutaneous tissue, or fascia. Tapercut needles, which are a combination of a reverse cutting edge tip and a taperpoint body, are generally used for suturing dense, tough fibrous tissue, such as a tendon, and for some cardiovascular procedures, such as vascular grafts. Bluntpoint needles have a rounded, blunt point that can dissect through friable tissue without cutting. They are occasionally used for suturing soft, parenchymal organs, such as the liver or kidney.

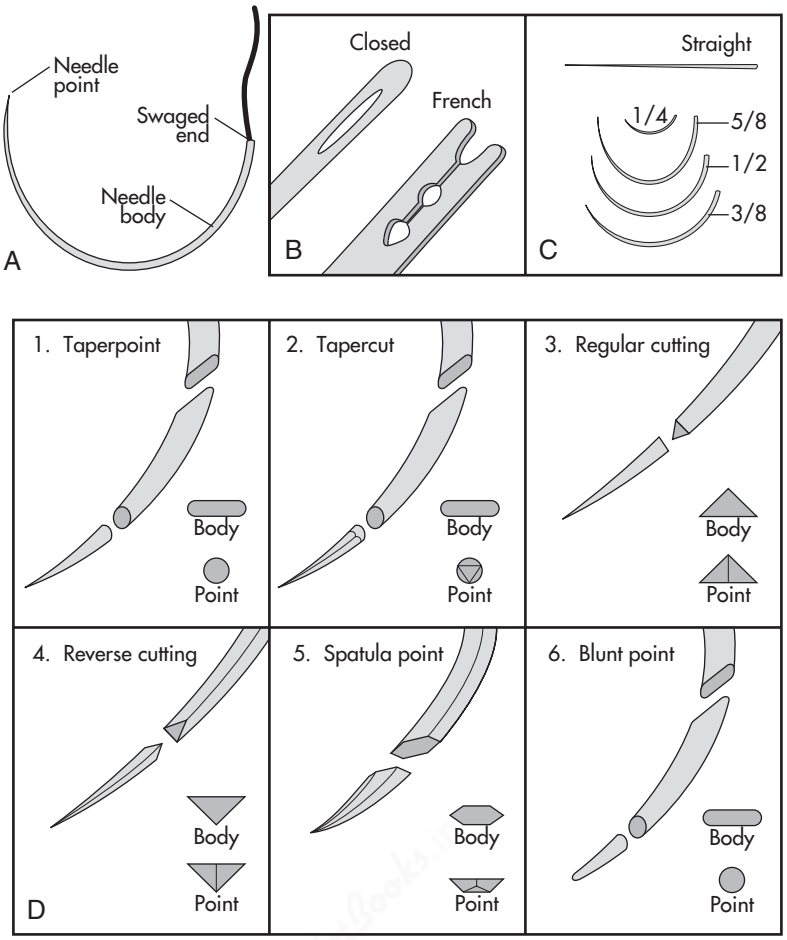

FIG. 8.3 (A) Basic components of a needle. (B) Types of eyed needles. (C) Shapes and sizes of needle bodies. (D) Detail of needle points.

Suture Selection for Different Tissue Types

Considerations for suture selection include the length of time the suture will be required to help strengthen the wound or tissue, the risk of infection, the effect of the suture material on wound healing, and the dimension and strength of the suture required.

Skin

Monofilament sutures should be used in skin to prevent wicking or capillary transport of bacteria to deeper tissue. Synthetic monofilament nonabsorbable sutures (e.g., nylon, polypropylene) generally have good relative knot security and are relatively noncapillary. Polymerized caprolactam (Supramid, Vetafil) has good handling characteristics, but it is braided and should not be buried in deeper tissue. Absorbable sutures (e.g., polydioxanone, polyconate) may be used in skin, but they should ultimately be removed because absorption requires contact with body fluids. Subcutaneous sutures are used to obliterate dead space and reduce tension on skin edges; multifilament or monofilament absorbable suture material is preferred.

Abdominal Closure

The rectus fascia may be closed with either an interrupted or a continuous suture pattern; however, most surgeons routinely close the rectus fascia with a simple continuous suture pattern. When using an interrupted pattern, numerous suture materials are adequate; however, suture that is rapidly removed (e.g., surgical gut) should be avoided in catabolic (i.e., hypoalbuminemic and malnourished) patients. When a continuous suture pattern is used, a standard absorbable or nonabsorbable monofilament suture with good knot security should be used (e.g., polypropylene, polybutester, polydioxanone, polyglyconate). One size larger suture than would normally be used is preferred for a continuous suture pattern. The knots should be tied carefully, and three or four square knots (six or eight throws) should be placed. Standard absorbable suture (e.g., polydioxanone or polyglyconate) may be preferable to prevent large amounts of foreign material from remaining permanently in the incision.

Muscle and Tendon

Muscle has poor holding power and is difficult to suture. Absorbable or nonabsorbable suture material may be used. Sutures placed parallel to the muscle fibers are likely to pull out, so consideration should be given to the type of suture pattern chosen (see p. 68). Suture material used for tendon repair should be strong, nonabsorbable, and minimally reactive. Suturing with a taper or taper-cut needle is generally less traumatic to these tissues. The largest suture that will pass without trauma through the tendon should be used.

Parenchymal Organs

Parenchymal organs, such as the liver, spleen, and kidneys, are generally sutured with absorbable monofilament sutures, as multifilament sutures tend to cut through this type of tissue because of the increased drag.

Hollow Viscus Organs

Absorbable monofilament sutures are generally recommended in hollow viscus organs, such as the trachea, gastrointestinal tract, or bladder, to prevent tissue retention of foreign material once the wound is healed. In addition, nonabsorbable suture may be calculogenic when placed in the urinary bladder or gallbladder and may be extruded into the lumen when implanted in intestine. Polyglycolic acid suture rapidly dissolves when incubated in sterile urine (6 days) or infected urine (3 days).

Infected or Contaminated Wounds

If possible, sutures should be avoided in highly contaminated or infected wounds because even the least-reactive nonabsorbable sutures elicit some degree of infection in tissue contaminated with either *Escherichia coli* or *Staphylococcus aureus*. Multifilament nonabsorbable sutures (e.g., silk or polyester) should not be used in infected tissue because they potentiate infection and may fistulate. Absorbable suture material is preferred; however, surgical gut should be avoided because its absorption in infected tissue is unpredictable. Synthetic monofilament nylon and polypropylene sutures may elicit less infection in contaminated tissue than metallic sutures.

Vessels and Vascular Anastomoses

Vessels should be ligated with absorbable suture material. Vascular anastomoses are typically performed with monofilament nonabsorbable suture material such as polypropylene. Nonabsorbable suture should also be used for vascular grafts. Arterial anastomoses may be performed in an end-end (Fig. 8.4A) or end-side fashion (see Fig. 8.4B). Arteriotomies may be closed using a vertical (Fig. 8.5A) or transverse (see Fig. 8.5B) method.

Reduction of blood loss from a vascular anastomosis (e.g., when a polytetrafluoroethylene graft is used) can be affected by suture choice, even when a technically perfect anastomosis has been performed, as bleeding may occur from the needle holes. Sutures having a needle-to-suture ratio of 2:1 or 3:1 are associated with more bleeding than when the needle-to-suture diameter ratio is 1:1, which allows the suture to completely fill the graft needle hole.

OTHER BIOMATERIALS

Tissue Adhesives

Cyanoacrylates (e.g., N-butyl and isobutyl-2-cyanoacrylate; Vetbond, LiquiVet, GLUture) are commonly used for tissue

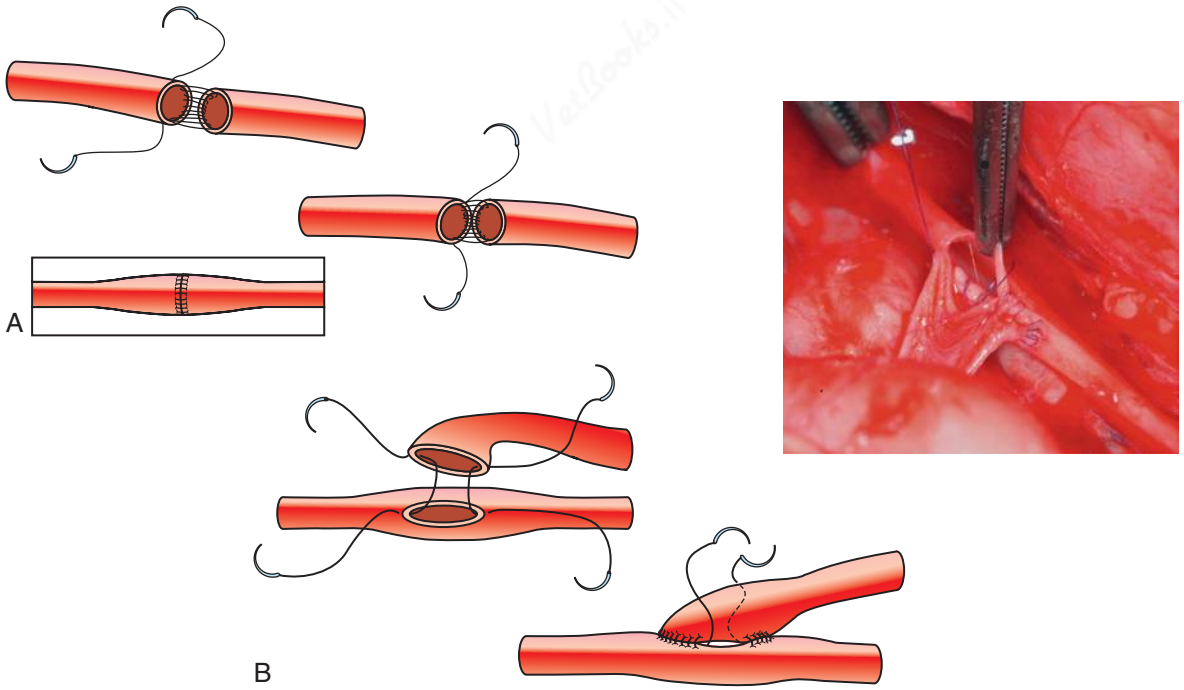

FIG. 8.4 (A) To perform an end-end arterial anastomosis, approximate the vessel ends and place two stay sutures at equidistant points (usually at the corners) between the ends. Use these sutures to hold the vessel steady and rotate the vessel if required while the anastomosis is being performed. Place continuous sutures at 2-mm intervals, 2 mm from the edge of the vessel beginning at the posterior wall (away from the surgeon) and continuing to the anterior wall. If stenosis is a concern, spatulate the ends. (B) For an end-side anastomosis, place sutures initially at the cranial (head) and caudal aspect (toe) of the two ends. Perform the anastomosis circumferentially, beginning with the posterior wall first and progressing to the anterior wall. *Inset:* End-side anastomosis of external jugular vein to carotid artery in a pig to create an experimental aneurysm.

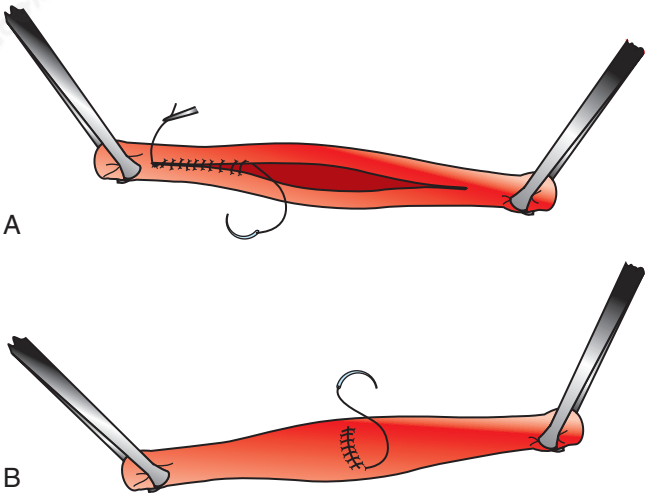

FIG. 8.5 An arteriotomy may be closed (A) vertically or (B) transversely.

adhesion in certain procedures, such as declawing, tail docking, and small (<5 cm) skin lacerations. These adhesives rapidly polymerize in the presence of moisture and produce a strong, flexible bond. Adhesion of the contact tissue generally takes less than a minute, but may be prolonged with excessive hemorrhage. Persistence of the glue in the dermis may result in granuloma formation or dehiscence, and placement in an infected site may be associated with fistulation. Heat generated during the procedure may cause tissue burns. Cyanoacrylate adhesives also cause an intense inflammatory reaction within subcutaneous tissue and should never be applied within deep wounds.

Dermabond (2-octylcyanoacrylate) is an adhesive to which special plasticizers have been added to provide flexibility. It reaches maximum bonding strength within 2.5 minutes and is equivalent in strength to healed tissue at 7 days after repair. It is marketed for humans as a replacement for sutures that are 4-0 to 5-0 or smaller in diameter for incisional or laceration repair.

Adhesives should not be used on bite wounds, severely contaminated wounds, ulcers, puncture wounds, mucous membranes, near the eye, or in areas of high moisture content. Adhesives are most useful when used on wounds that may close spontaneously, have clean or sharp edges, and are located on clean, nonmobile areas. Wounds in which the edges are separated more than 5 mm by the underlying skin tension are unlikely to stay closed with tissue adhesives alone and should be supported with subcutaneous sutures. Reliable closure of lacerations longer than 5 cm is also uncertain when tissue adhesives alone are used.

To apply tissue adhesives, clean the wound and control bleeding. Hold the wound together manually or with tissue forceps, with the edges slightly everted. Apply the adhesive by lightly wiping the applicator tip over the area in the direction of the long axis of the wound, at least 5 mm beyond the skin edges. Apply three to four thin layers successively; avoid a droplet or a single thick layer. Hold the wound edges together for 30 to 60 seconds after the last adhesive application to ensure that the adhesive has time to set fully. Remove adhesive applied to unwanted areas by using petroleum jelly or acetone. Do not cover with ointment, bandage, or a dressing. After 24 hours, gently wash the area with plain water, but do not scrub, soak, or expose it to moisture for any length of time. The adhesive will spontaneously slough off in 5 to 10 days.

Fibrin glue (e.g., Tisseel) is a relatively new generation of tissue adhesive. The product is composed of two separate solutions of concentrated human fibrinogen and bovine thrombin that, when combined, replicate the final stage of the coagulation cascade. A fibrin clot is generated in 10 to 60 seconds. Autologous fibrin glue (e.g., Vivostat) is made from the patient's blood before surgery, combining a biologic adhesive made of fibrinogen, factor XIII, fibronectin, thrombin, aprotinin, and calcium chloride. In humans, uses of the glue include fixation of skin grafts (i.e., without sutures) and stabilization of gastrointestinal and nerve anastomoses. It has also been used as a preclot material on vascular grafts and as a seal for sutured vascular anastomoses. However, there is limited experience with the use of fibrin glue in small animals.

Bioglue is a relatively new two-component surgical adhesive comprised of purified bovine serum albumin and glutaraldehyde. The two components are dispensed from a double-chamber syringe at the time of application. The amine proteins within the bovine albumin are bridged to the extracellular protein matrix within the tissue by the glutaraldehyde, creating a strong covalent bond. Complete polymerization takes 2 to 3 minutes. Bioglue is most commonly utilized in cardiovascular procedures because the glue also adheres to synthetic graft materials.

Ligating Clips

Clips (e.g., hemoclips or ligaclips) may be used for vessel ligation and are particularly useful when the vessel is difficult to reach or when multiple small vessels must be ligated. However, ligating clips are not recommended for use on vessels larger than 11 mm in diameter. The vessel should be dissected free of surrounding tissue before the clip is applied, and 2 to 3 mm of vessel should extend beyond the clip to prevent slippage. The vessel should be one-third to two-thirds the size of the clip.

Skin Staples

Rapid and precise wound closure can be achieved through the use of skin staplers. Numerous models are available (e.g., Precise Vista, Proximate Plus, Appose ULC), but most consist of a disposable hand-held unit that dispenses a single rectangular staple. Although there are slight variations between manufacturers, a standard skin staple is made of 316 L stainless steel and has a diameter of 0.5 mm, a span of 6 to 10 mm, and a leg length of 3.5 mm. Several staplers come with wide staples that span from 7 to 13 mm and have a leg length of 4.0 mm. Most staples penetrate the skin first and are then formed to the final configuration. This allows for good skin closure and a degree of tissue eversion that is favorable for wound healing. Other beneficial characteristics of the skin stapler include an angled head to allow visualization of staple deployment, a rotating head to facilitate precise staple placement, and an ergonomic, lightweight design to minimize hand and arm fatigue. A special staple remover facilitates clip removal after healing.

When placing staples, hold the wound edges together with tissue forceps. Place the stapling device gently (not firmly or with pressure) against the skin surface and slowly squeeze the trigger.

Absorbable skin staples (e.g., Insorb) have been developed to provide a rapid and cosmetic skin closure and eliminate the

need for staple removal. These staples are placed in the subcutaneous tissue to securely approximate wound edges. Absorbable subcuticular staples are made of synthetic polymers composed of polyglycolic and polylactic acids and are gradually absorbed by the body over a period of months.

Synthetic Surgical Mesh

Surgical mesh may be used to repair hernias (e.g., perineal hernias) or reinforce traumatized or devitalized tissue (abdominal hernias). It is also used to reconstruct large tissue defects following resection of devitalized, traumatized, or neoplastic tissue (see p. 913). Surgical mesh is available in nonabsorbable forms (e.g., polyester [Mersilene] fiber mesh and polypropylene [Prolene] mesh) or absorbable forms (e.g., polyglactin 910 [Vicryl] and polyglycolic acid [Dexon]) and in woven and knitted forms. Surgical mesh has been developed that has a thin, bioresorbable fabric layer (Proceed Mesh) that effectively separates the strong, supportive mesh from underlying tissue; it is being advocated for use in the abdominal cavity.

Although surgical mesh is generally elastic, it does not stretch significantly as the patient grows and thus should be used cautiously in immature patients. Fibrous tissue grows through the mesh interstices. Nonabsorbable mesh placed in contaminated wounds may extrude or fistulate and should be removed when the tissue has healed and the mesh is no longer required for support. Polypropylene mesh has been shown to facilitate the reconstruction of large tissue defects in small animals without serious complications.

Biologic Tissue Grafts

Animal tissue biomaterials are becoming more commonly considered as soft tissue replacements for hernia repair or reconstruction of tissue defects. Autologous free fascia lata grafts have been described for various orthopedic procedures and isolated clinical case reports for soft tissue reconstruction, as well as described experimentally for repair of diaphragmatic hernias, urethral defects, cranial cruciate ligament injury, and Achilles tendon rupture. If there is concern regarding donor site morbidity, canine allogenic fascia lata grafts are available.

Porcine small intestinal submucosa (Vet BioSISt) can be used as a surgical patch for soft tissue reconstruction or reinforcement. It is an absorbable, biocompatible material that acts as scaffold for tissue ingrowth. It is best used for enhancement of wound healing but should be used with caution in areas of tension, as degree of mechanical support is limited. In those situations, a multilaminate four-layer product is available that may provide adequate strength in low-strain areas.

COMMON SUTURE TECHNIQUES

Suture Patterns

Suture patterns can be classified as interrupted or continuous by the way they appose tissue (e.g., appositional, everting, or inverting) or by which tissues they primarily appose (e.g., subcutaneous or subcuticular). Appositional sutures (e.g., simple interrupted sutures) bring the tissue in close approximation; everting sutures (e.g., continuous mattress sutures) turn the tissue edges outward, away from the patient and toward the surgeon. Inverting sutures (e.g., Lembert, Connell, and Cushing sutures) turn tissue away from the surgeon, or toward the lumen of a hollow viscus organ.

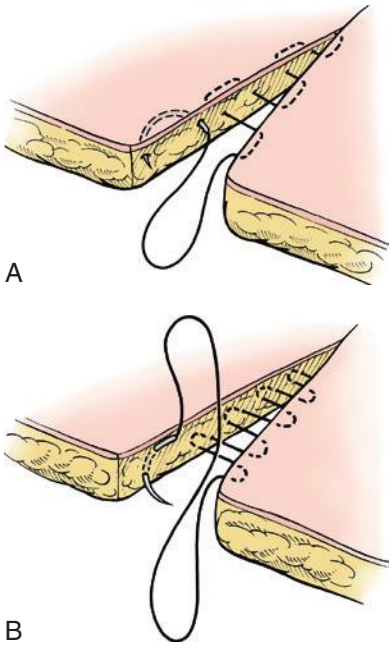

FIG. 8.6 Suture patterns. (A) Subcutaneous. (B) Subcuticular.

Subcutaneous and Subcuticular Patterns (Video 8.1)

Subcutaneous sutures are placed to eliminate dead space and provide some apposition of skin so that less tension is placed on skin sutures (Fig. 8.6A). Subcutaneous sutures are generally placed in a simple continuous manner; however, in some instances, such as when drainage might be necessary, simple interrupted sutures are preferable. Subcuticular or intradermal closures may be used in place of skin sutures to reduce scarring or eliminate the need for suture removal (e.g., fractious patient). The suture line is begun by burying the knot in the dermis (see p. 74). The suture is advanced in the dermal tissue, but, in contrast to a continuous subcutaneous line, the bites are parallel to the long axis of the incision (see Fig. 8.6B). The suture line is completed with a buried knot. Absorbable suture materials with a cutting needle are preferred for this suture pattern.

Interrupted Suture Patterns

Simple Interrupted Pattern

A simple interrupted suture is made by inserting the needle through tissue on one side of an incision or wound, passing it to the opposite side, and tying (Fig. 8.7A). The knot is offset so that it does not rest on top of the incision, and the ends of the suture are cut (for skin sutures, the ends are left long enough to allow them to be grasped during removal). The sutures should be placed approximately 2 to 3 mm away from the skin edge. Right-handed surgeons place sutures from right to left in a horizontal fashion; left-handed surgeons perform the opposite.

Simple interrupted sutures are easy and quick to place. They are appositional unless excessive tension is applied, then inversion may occur. Inversion of skin results in poor healing; therefore care should be taken to ensure that skin sutures are loose and the edges are apposed. The primary advantage of simple interrupted sutures is that disruption of a single suture does not cause the entire suture line to fail. However, simple interrupted

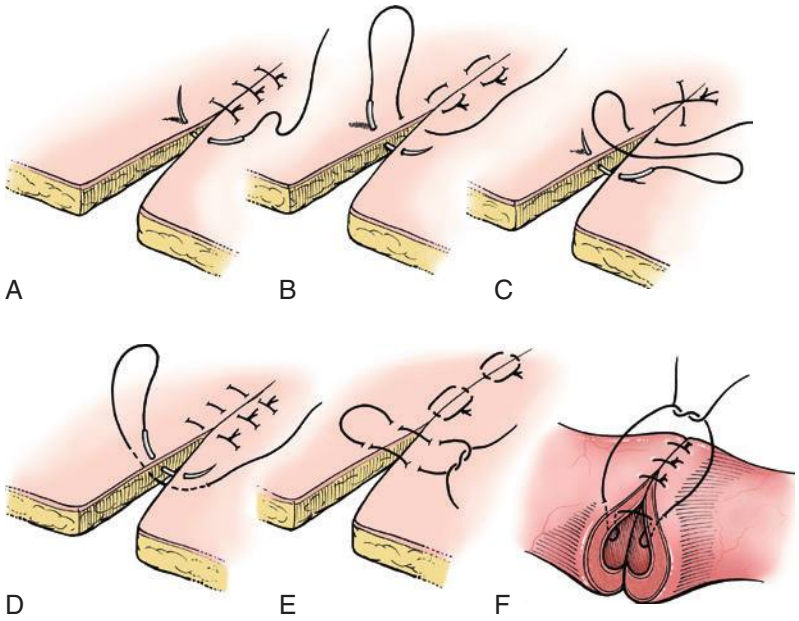

FIG. 8.7 Interrupted suture patterns. (A) Simple interrupted. (B) Horizontal mattress. (C) Cruciate. (D) Vertical mattress. (E) Halsted. (F) Gambee.

sutures take more time than continuous patterns and result in more foreign material (knots) in the wound.

Cruciate Pattern

When two simple interrupted sutures are placed parallel to each other and then tied across the incision to create an "X," a cruciate pattern is formed (see Fig. 8.7C). Cruciate sutures are appositional and can relieve low to moderate tension across an incision. Less suture material is used to close a skin incision with cruciate sutures than simple interrupted, yet cruciate sutures still afford the security of an interrupted pattern.

Horizontal Mattress Pattern

Horizontal mattress sutures are placed by inserting the needle on the far side of the incision, passing it across the incision, and exiting it on the near side, as described for a simple interrupted suture (see Fig. 8.7B). The needle is then advanced 6 to 8 mm along the incision and reintroduced through the skin on the near side. It then crosses the incision, exiting from the skin on the far side, and the knot is tied. Horizontal mattress sutures are generally separated by 4 to 5 mm. They are used primarily in areas of tension and can be placed rapidly; however, they often cause tissue eversion. Care should be exercised to appose, rather than evert, tissue margins, and the suture should be angled through the tissue so that it passes just below the dermis.

Vertical Mattress Pattern

To place a vertical mattress suture, the needle is introduced approximately 8 to 10 mm from the incision edge on one side, passed across the incision line, and exited at an equal distance on the opposite side (see Fig. 8.7D). The needle is reversed and inserted through skin on the same side and exited on the far side, each bite approximately 4 mm from the skin edge, and the knot is tied. Vertical mattress sutures are stronger than horizontal mattress sutures when used in areas of tension, and are preferred when addressing tension in skin closure, as there is less disruption to the blood supply of the wound edges. Placement of vertical mattress sutures is relatively time-consuming, but eversion of the skin margins is less of a problem than with horizontal mattress sutures. Both horizontal and vertical mattress pattern can be bolstered using rubber stents and buttons.

Halstead Pattern

A Halstead suture is another interrupted mattress pattern that is a modification of a continuous Lembert pattern (p. 70). It is an infrequent technique used in veterinary medicine, but does provide exact skin approximation. The needle enters and exits perpendicular to and on the same side of the incision. The needle then crosses over the wound and is passed in and out of the skin in a similar fashion. The needle is advanced down the incision, and this pattern is repeated in reverse, back across the incision, and the knot is tied (see Fig. 8.7E).

Gambee Pattern

A Gambee suture is an interrupted pattern used in intestinal surgery to reduce mucosal eversion. The suture is introduced the same as a simple interrupted suture from the serosa through the muscularis and mucosa to the lumen (Fig. 8.7F). The needle is then returned from the lumen through the mucosa to the muscularis before it crosses the incision. After crossing the incision, it is introduced in the muscularis and is continued through the mucosa to the lumen. The needle is then reintroduced through the mucosa and muscularis to exit from the serosal surface, and the suture is tied. Gambee sutures reduce mucosal inversion and may reduce wicking of material from the intestinal lumen to the exterior.

Continuous Suture Patterns

Simple Continuous Pattern

A simple continuous suture consists of a series of simple interrupted sutures with a knot on either end; the suture is continuous

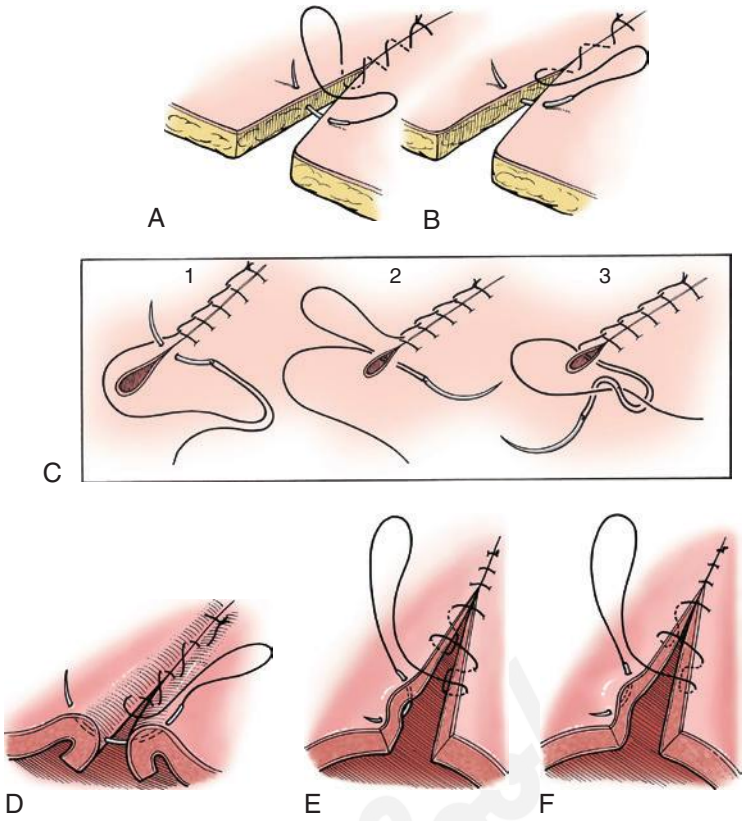

FIG. 8.8 Continuous suture patterns. (A) Simple continuous. (B) Running. (C) Ford interlocking (*C2* and *C3* illustrate how to end the suture line). (D) Lembert. (E) Connell. (F) Cushing.

between the knots (Fig. 8.8A). To begin a simple continuous suture line, a simple interrupted suture is placed and knotted, but only the end that is not attached to the needle is cut. The needle is then passed through the tissue from one side to the other, perpendicular to the incision. The suture is advanced above the incision line at a diagonal. A running suture is created if the suture is advanced above and below the incision line, but this is not as secure as less tissue is purchased (see Fig. 8.8B). To end a continuous suture, the needle end of the suture is tied to the last loop of suture that is exterior to the tissue.

Simple continuous suture lines provide maximum tissue apposition and are relatively air and fluid tight compared with a series of simple interrupted sutures. Simple continuous suture lines are frequently used to close the linea alba and subcutaneous tissue. Care should be taken when placing continuous suture lines in areas where tightening of the suture may result in a purse-stringlike effect, such as with an intestinal anastomosis.

Ford Interlocking Pattern

This pattern is a modification of a simple continuous pattern in which each passage through the tissue is partly locked (see Fig. 8.8C1). Each pass through the tissue is linked to the previous passage as the suture exits the tissue through a created loop of material. To terminate this suture pattern, the needle is reversed and introduced in the opposite direction from that used previously. The loop of the suture formed on the opposite side is tied to the single end (see Fig. 8.8C2 and C3). Locked suture patterns may be placed quickly and may appose tissue better than a simple interrupted pattern. This pattern also provides greater stability than a simple continuous pattern in the event of a partial break along the line. However, a larger amount of suture material is used, and sutures may be more difficult to remove.

Lembert Pattern

A Lembert pattern is a variation of a vertical mattress pattern applied in a continuous fashion. It is an inverting pattern that is often used to close hollow viscera. The needle penetrates the serosa and muscularis approximately 8 to 10 mm from the incision edge and exits near the wound margin on the same side. After passing over the incision, the needle penetrates approximately 3 to 4 mm from the wound margin and exits 8 to 10 mm away from the incision. This pattern is repeated along the length of the incision (see Fig. 8.8D).

Connell and Cushing Patterns

These are inverting patterns that are used to close hollow organs. A watertight seal is created by the inversion; however, appositional patterns are advocated for visceral closure in small animals, as this facilitates rapid intestinal healing. The Connell and Cushing patterns are similar, except that a Connell pattern enters the lumen, whereas a Cushing pattern extends only to the submucosal layer (see Fig. 8.8E and F). It was previously thought that a Cushing pattern would be preferable to a Connell for cystotomy closure because suture material in the lumen might be calculogenic; however, the use of rapidly absorbed monofilament sutures negate this concern.

The suture line is begun with a simple interrupted or vertical mattress suture. The needle is advanced parallel to the incision and introduced into the serosa, passing through the muscular and submucosal surfaces. From the deep surface (the lumen with a Connell suture), the needle is advanced parallel along the incision and returned through the tissue to the serosal surface.

Once outside the viscera, the needle and suture are passed across the incision and introduced at a point that corresponds to the exit point on the contralateral side. The suture is then repeated. The suture should cross the incision perpendicularly. When the suture is tightened, the incision inverts.

A Parker-Kerr suture is a modification of the Cushing and Lembert patterns that has been described for closing the stump of hollow viscera. It is seldom used because it causes excessive tissue inversion.

Tendon Sutures

Specific suture configurations are used to approximate severed ends of a tendon or to secure one end of a tendon to bone or muscle; these include Kessler locking-loop, Bunnel-Mayer, Krackow, and three-loop pulley suture patterns, among others. Select pattern descriptions are listed and more information can be found on p. 1283.

Three-Loop Pulley Suture

The three-loop pulley pattern is made with three loops oriented approximately 120 degrees to each other. The initial loop is placed perpendicular to the long axis of the tendon ends in a near-far fashion (Fig. 8.9). The second loop is placed in a plane 120 degrees from the first, at a point midway between the near and far positions. The final loop is placed in a far-near pattern 120 degrees from the first two sutures. This pattern is considered to be biomechanically superior to other tendon patterns, as it is more resistant to gap formation during tensile loading.

Bunnell Suture

A modified Bunnell suture pattern may be used to appose severed tendons. The needle is passed from one side of the proximal end of the severed tendon and crossed diagonally across the tendon to the opposite side, where it exits (see Fig. 8.9). The suture is reintroduced approximately 1 mm distal to the exit site and crossed diagonally to the other side of the tendon, where it exits from the severed end. It is introduced into the distal portion of the severed tendon from the cut end, and two cruciate sutures are placed. The suture exits at the severed end of the distal portion of the tendon and is reintroduced into the proximal tendon. The pattern is repeated in this portion of the tendon, with the suture exiting near the original entrance site. The tendon ends are apposed and the suture tightened.

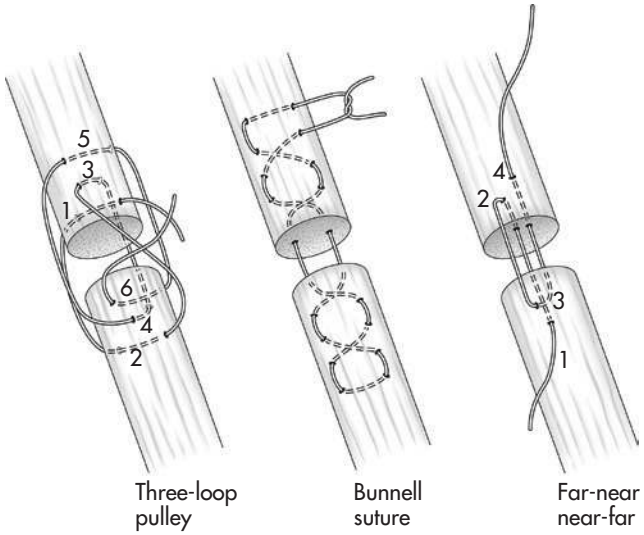

FIG. 8.9 Tendon sutures.

This pattern is not commonly used because it is difficult to place and may damage the tendon's microcirculation. Ischemia resulting from the suture may cause the suture to pull out or may result in death of the tendon ends. The resultant gap must then be filled with fibrous tissue.

Far-Near-Near-Far Suture

A far-near-near-far suture may be used in flat tendons. The needle is passed through the tendon perpendicular to and 5 mm from the severed tendon end (see Fig. 8.9). The needle then enters the distal section of the severed tendon in the same vertical plane 2 mm from the tendon edge. It is looped back to the proximal section of tendon, where it enters 2 mm from the severed edge. The suture is again looped back to the distal section of the tendon to enter 5 mm from the severed tendon edge. The suture ends are pulled taut and tied with a surgeon's knot. This pattern minimally disrupts blood flow and provides good resistance to tension because all suture passes are in the same vertical plane.

Knot Tying

The knot is the weakest point of a suture. A knot consists of at least two throws laid on top of each other and tightened. The throws can be joined parallel, as in a square knot, or crosswise, as in a granny knot (Fig. 8.10). Correct knot-tying technique is important because incorrectly tied knots (e.g., tumbled knots, half-hitches, or granny knots) may lead to dehiscence. Factors that influence knot security are the type of material, the length of the cut ends, the structural configuration of the knot, the number of throws used in knot construction, and surgeon experience.[10]

The most reliable configuration for a knot is superimposition of squared knots. A surgeon's (friction) knot involves passage of suture material twice on the first throw (see Fig. 8.10). Due to the extra suture material, this knot cannot be easily tightened and can withstand only a slight strain on the suture loop. Although it is often used in areas of tension, it is generally not recommended for use with coated or monofilament materials, and should be avoided unless tissue tension is such that use of the standard square knot would result in poor tissue apposition. A surgeon's knot is not recommended for vessel ligation. A surgeon's throw

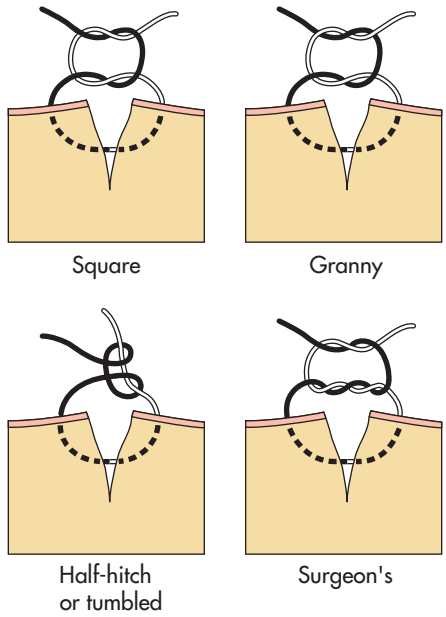

FIG. 8.10 Types of knots.

was recently shown to be less reliable in a vascular pedicle ligation model when compared to five other friction knots.[11] The Miller's knot, constrictor knot, and strangle knot were considered to be the most reliable when used as a first throw for vessel ligation. All three of these configurations have an overriding turn, which is a section of suture that passes on top of another section of suture, often perpendicular or at an angle to the underlying section (Fig. 8.11). Tension is maintained by providing compression on the underlying turns of suture.

Multifilament sutures generally have better knot-holding properties than monofilament materials; however, coating the suture to decrease tissue drag reduces knot security. To prevent strangulating tissue, excessive tension should be avoided when tying knots (except when ligatures are applied for hemostasis). Excessively tight skin sutures cause the patient discomfort and increase the likelihood that the animal will remove the sutures prematurely.

Instrument Ties

In veterinary medicine, instrument ties (Fig. 8.12) are more commonly used than hand ties because it is thought there is less waste of the suture. The first loop is made as shown in Fig. 8.12, after which the suture should not be lifted or have uneven pressure applied to either end, or the throw will loosen. If one end is pulled with greater tension than the other, a half-hitch will form (see Fig. 8.10). Opposing suture ends should be pulled perpendicular to the long axis of the incision. Lifting one hand causes the suture to tumble, forming a sliding two half-hitch knot. Failure to correctly cross the hands results in a granny knot.

Hand Ties

Hand ties are particularly useful in confined or hard to reach areas or when sutures have been preplaced, as in a thoracotomy closure. Hand ties generally require that suture ends be left longer than for an instrument tie, but can be placed much faster and more securely than instrument ties. A one-handed or two-handed technique may be used. The two-handed technique generally allows better control and accuracy; however, the one-handed technique is more useful in confined areas. Techniques for tying one-handed and two-handed knots are shown in Figs. 8.13 and 8.14.

FIG. 8.11 Strangle knot.

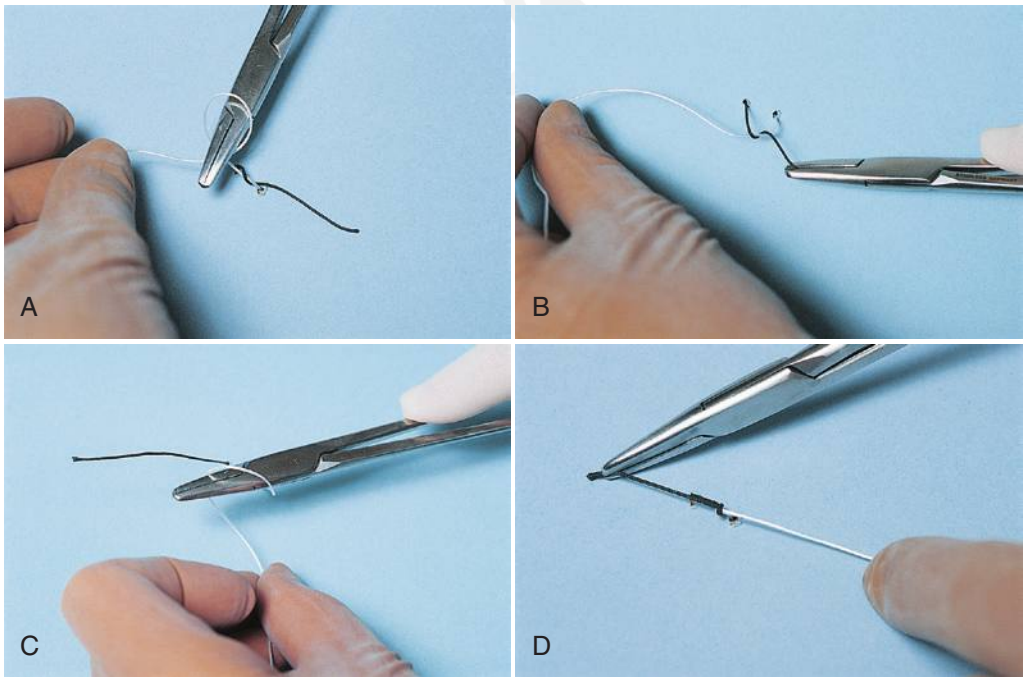

FIG. 8.12 Instrument tie. (A) Place the tips of the needle holders between the two strands of suture. Wrap the strand nearest you (*white*, or long end) around the needle holders to form a loop and grasp the end of the far piece of suture (*black,* or short end) in your needle holders. (B) Bring the short end toward you (through the loop) by reversing your hands, and tighten the suture gently. (C) For the second throw, wrap the strand farthest from you (*white,* or long end) over the needle holders to form a loop, grasp the end of the suture nearest you (*black,* or short end), and (D) pull it through the loop, snugly laying the knot down to prevent tightening the suture excessively. Keep your hands low and parallel when tightening the suture to prevent causing the knot to tumble.

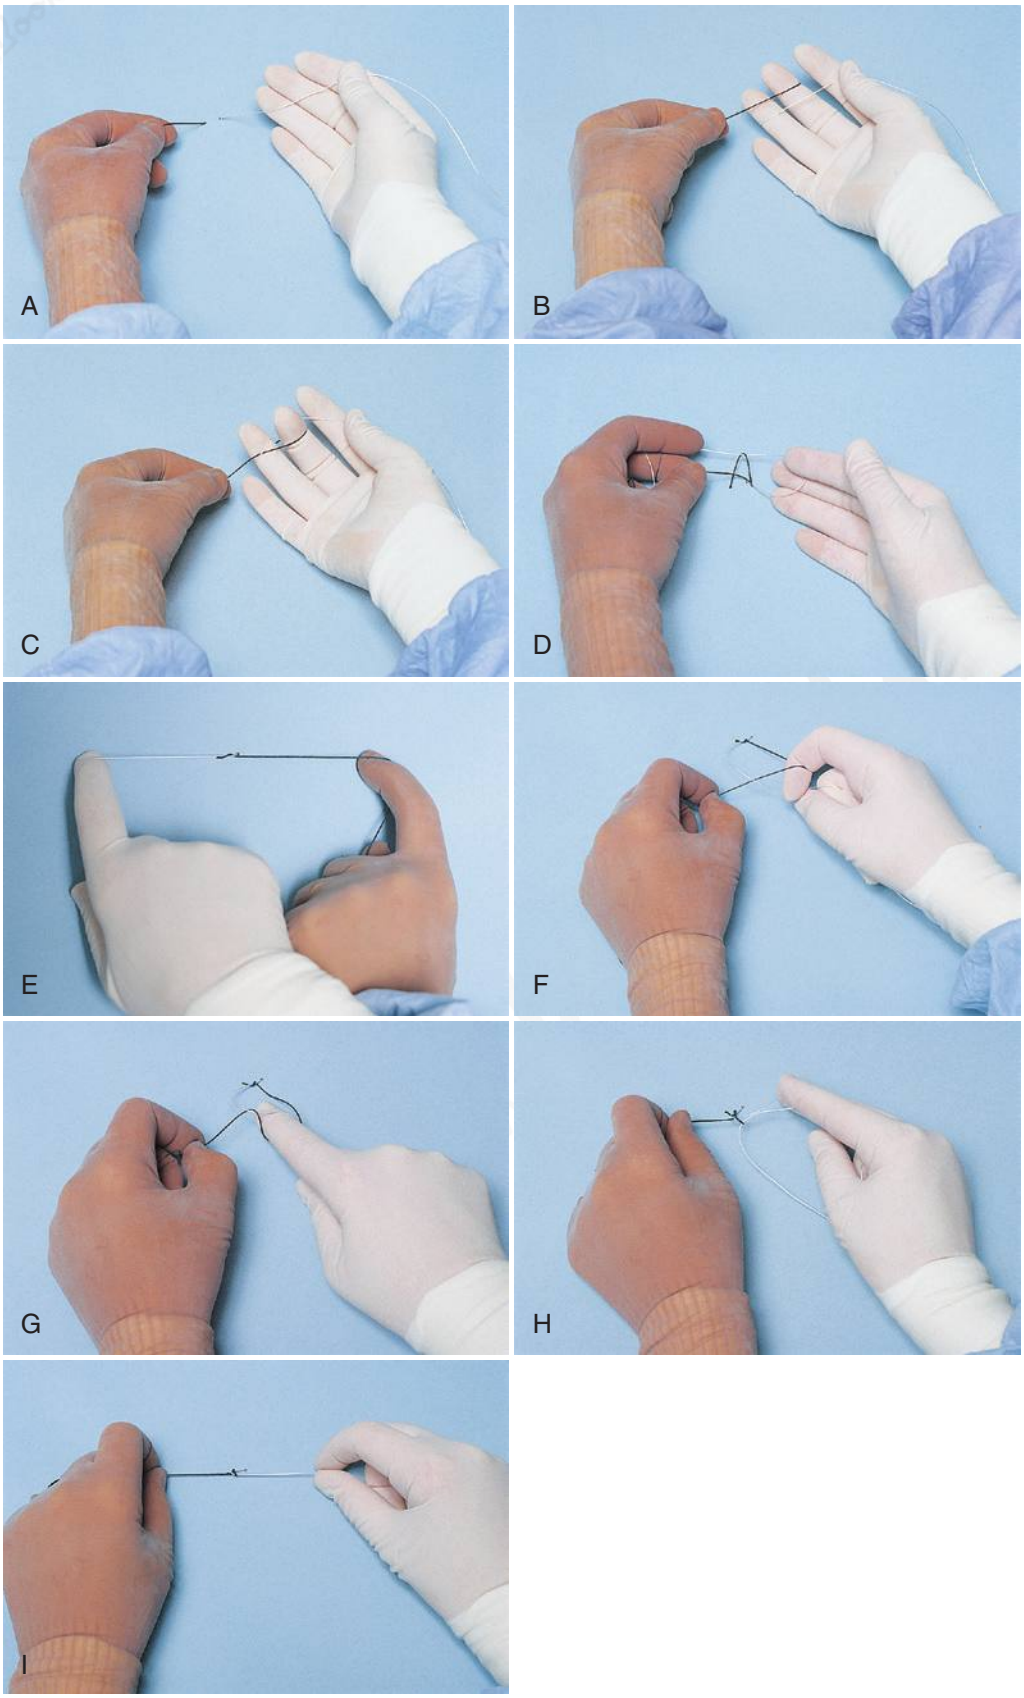

FIG. 8.13 One-handed square knot (right-handed). (A) Reflect the right suture *(white)* between the three fingers of your right hand *(white glove)* and hold it between your index finger and thumb. (B) Hold the left suture *(black)* in your left hand *(dark glove)* and pass it between the index finger and second finger of your right hand. (C) Flex the distal phalanx of the second finger of your right hand and draw the left strand to the right of the right strand. Extend the tip of the second finger so that the white strand is drawn with it through the loop. (D) Pull the right strand through the loop by the tips of the second and third fingers of your right hand. (E) Cross your hands and apply even tension to the two strands. (F) Place the index finger of your right hand between the right *(black)* and left *(white)* strands so that the left-hand strand forms a loop with the right. Flex the distal phalanx of your right index finger. One-handed square knot (right-handed). (G) Extend the distal phalanx of your right index finger to draw the right-hand strand through the loop. (H) Pull the right strand through the loop and (I) apply even tension to complete the square knot. (Modified from Knecht CD, Allen A, Williams DJ, et al. *Fundamental Techniques in Veterinary Surgery.* 3rd ed. Philadelphia: WB Saunders; 1981.)

Burying the Knot (Video 8.2)

The knots of subcutaneous and subcuticular suture patterns are often buried to reduce irritation caused by the knots rubbing against more superficial tissue. Fig. 8.15 presents a description of this procedure using buried square knots. Alternatively, a self-locking knot (e.g., Aberdeen knot) can be used at the beginning and end of continuous closure of subcutaneous and intradermal suture lines. Aberdeen knots are as secure as square knots but have less suture volume.[12]

Suture Removal

Skin sutures should generally be removed once healing is sufficient to prevent dehiscence, usually within 10 to 14 days after surgery. However, prolonged healing, such as in extremely debilitated animals, may require that the sutures be left in place longer. In addition, if fibrosis is desired (e.g., aural hematoma repair), delaying suture removal may be considered.

HEMOSTATIC TECHNIQUES AND MATERIALS

Hemostasis is a complex process that involves platelet activation and circulating clotting factors. Numerous diseases or conditions may interfere with clotting in surgical patients. The reader is referred to other veterinary medicine texts for an in-depth discussion of normal clotting and alterations of clotting caused by disease. In surgery, obtaining hemostasis allows appropriate visualization of tissue during the procedure and prevents life-threatening hemorrhage. Low pressure hemorrhage from small vessels can be controlled by applying pressure to the bleeding points with gauze sponges. Once a thrombus has formed, the sponge should be gently removed to prevent disrupting clots. Soaking the sponge with saline before removal may also help prevent clot disruption. Small hemostatic forceps (e.g., mosquito forceps) may also be used to control bleeding from small vessels. The vessel is grasped and clamped with the forceps for several minutes until coagulation occurs.

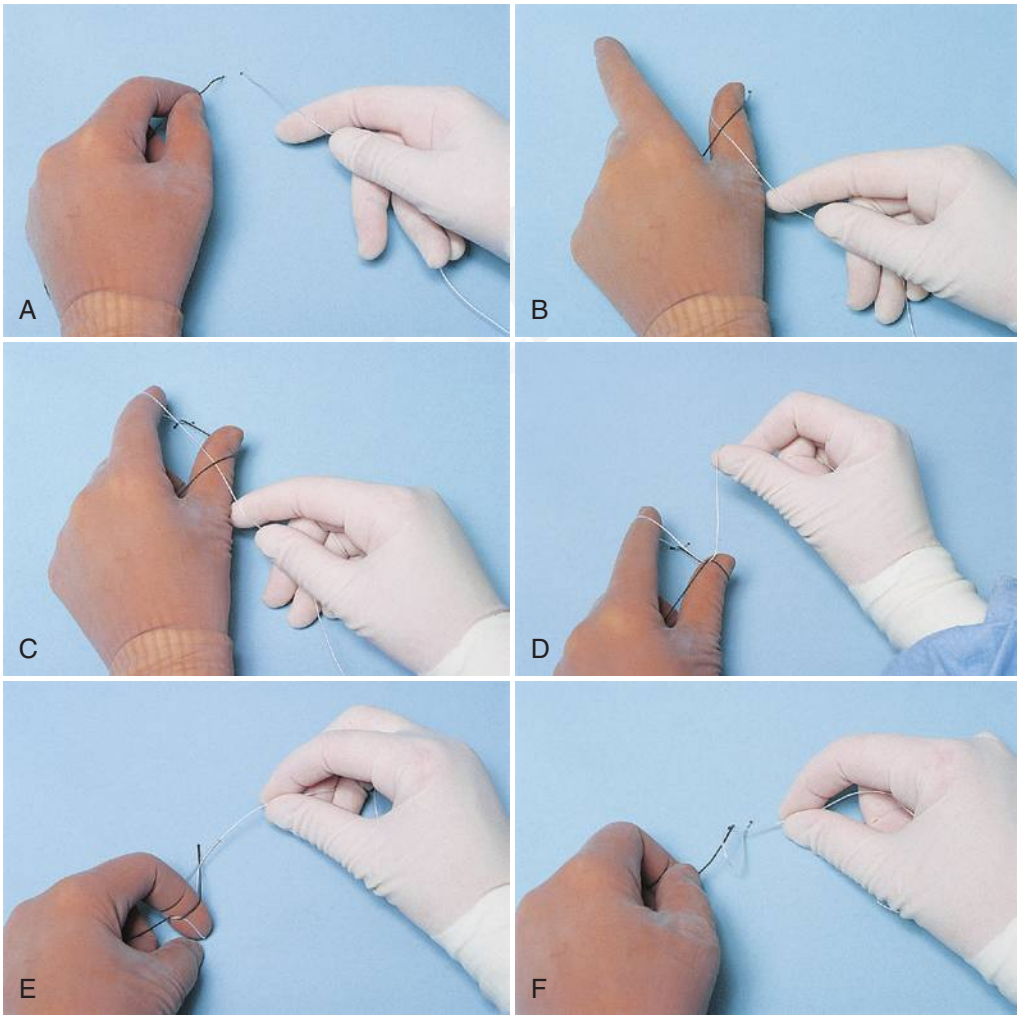

FIG. 8.14 Two-handed square knot (right-handed). (A) Extend the index finger of your right hand *(white glove)* as a bridge and place the right *(white)* strand over it. Hold the left *(black)* strand in the palm of your left hand *(dark glove)*. (B) Pass your left thumb below and around the right strand and then to the left of the left strand. (C) Introduce your left index finger between the crossed strands (with your left thumb). (D) Carry the right strand to your left index finger and thumb and, (E) using your left index finger and thumb, carry it through the loop. (F) Return the suture to your right hand. Two-handed square knot (right-handed).

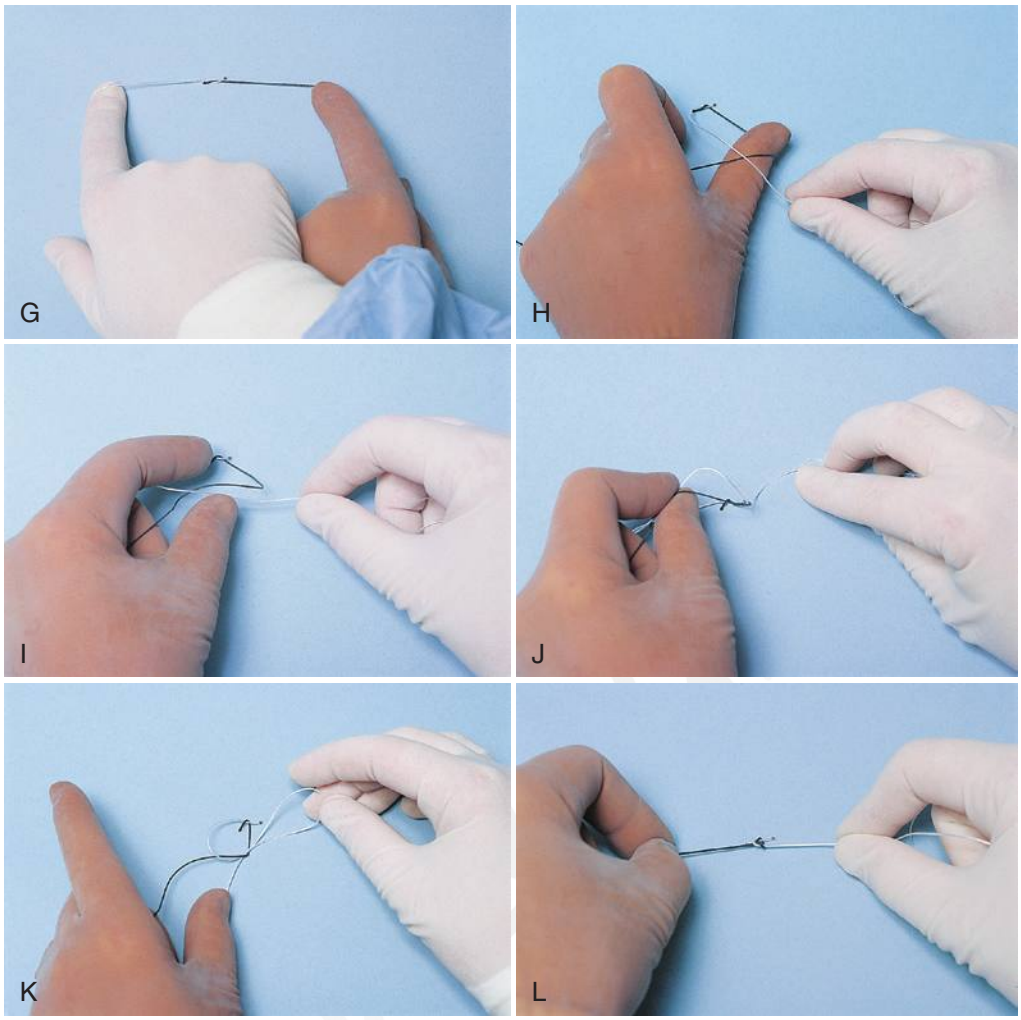

FIG. 8.14, cont'd (G) Cross your hands and apply even tension to the suture ends. (H) Place your left thumb between the two strands and make a loop with your right hand. (I) Place your left index finger through the loop and use it and your left thumb to grasp the left *(white)* strand and (J) pull or push it through the loop. (K) Pass the left strand from your left hand to your right thumb and index finger after passing it through the loop and (L) apply even tension to the suture strands to tighten the square knot. (Modified from Knecht CD, Allen A, Williams DJ, et al. *Fundamental Techniques in Veterinary Surgery*. 2nd ed. Philadelphia: WB Saunders; 1981.)

Alternatively, a ligature may be placed to ensure the bleeding is stopped.

Larger vessels must be ligated. Double ligatures are recommended for larger vessels, particularly arteries. Transfixation ligatures (Fig. 8.16) may be indicated for larger arteries to prevent the ligature from slipping off the vessel end. Using the smallest suture possible for vessel ligation improves knot security. A surgeon's throw should not be used for vessel ligation (see p. 72), although other friction knots would be appropriate (e.g., Miller's knot, constrictor knot, strangle knot).

Topical Hemostatic Agents

Several topical substances are available to control hemorrhage during surgery. Bone wax is a sterile mixture of beeswax, paraffin, and isopropyl palmitate. It is pressed into bleeding channels of bone to control hemorrhage through a tamponade effect. Bone wax should be used sparingly and with caution as it is nonabsorbable and may interfere with bacterial clearance, act as a foreign body, and become a nidus for infection.

Gelfoam is an absorbable gelatin sponge that can be used to control hemorrhage. This material provides a physical matrix that initiates clotting through contact activation. In addition, when applied to an area of hemorrhage, Gelfoam swells and exerts pressure on the wound as it absorbs many times its weight in blood. Absorption occurs in 4 to 6 weeks but should not be left in infected sites and areas with a high risk of infection or in confined places as it may exert unnecessary pressure on neighboring vital structures.

Other gelatin-based hemostatic products include SurgiFlow Hemostatic Matrix and Vetspon. Gelatin products should not be used in closure of skin incisions as they may interfere with healing.

Surgicel is made of oxidized regenerated cellulose. When saturated with blood, it becomes a gelatinous mass that provides

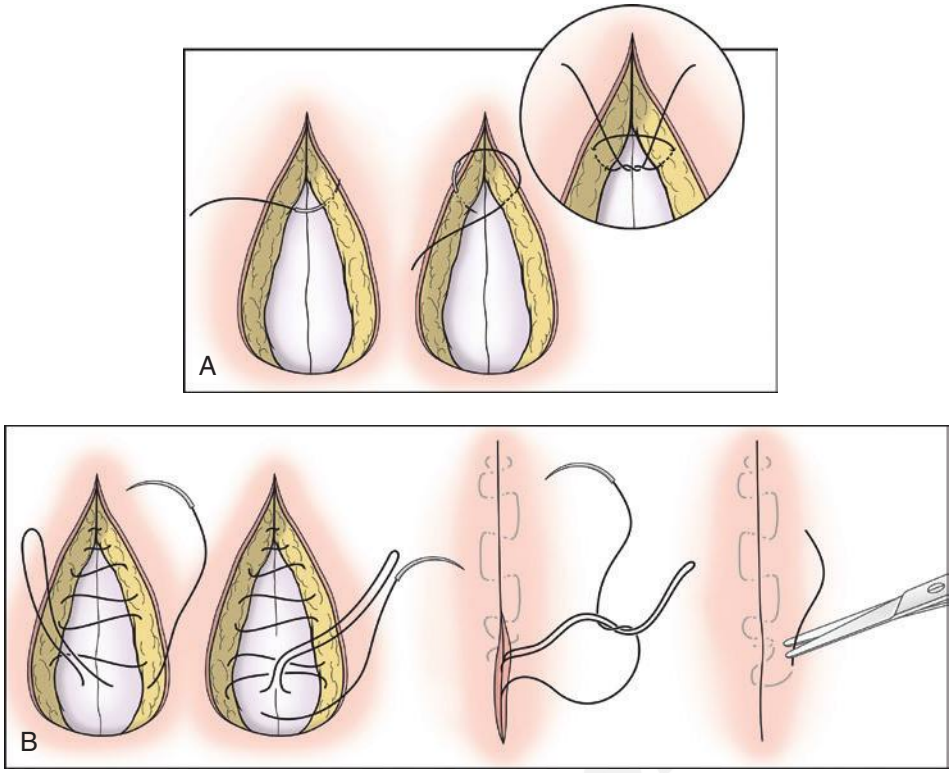

FIG. 8.15 (A) To bury a simple interrupted suture, introduce the needle deep in the far subcutaneous tissue and pass it toward the dermis. Then pass it across the incision line and reintroduce it in the near subcutaneous tissue at the dermis, exiting deep in the incision line. (B) To bury a knot at the end of a continuous suture line, lift a loop of suture from the incision line, introduce the needle from deep to superficial on one side, pass it across the incision, and insert it from superficial to deep in the tissue near the loop. Alternately, after the continuous pattern is completed, advance the needle 2 to 3 mm to the opposite side. Place a vertical bite from the mid-dermis down to subcutaneous tissue. Then insert the needle on the opposite side, vertically aiming up from the subcutaneous tissue, exiting at the mid-dermis within 2 to 3 mm of the commissure. Create a 2-cm loop of suture between the two vertical bites. Take a third vertical bite parallel to the first, initiating in the mid-dermis, but exiting deeper in the subcutaneous layer. Bring the needle up between the exposed loop and final suture crossing the incision. Apply tension to the exposed loop to tighten the horizontal sutures and appose the wound margins, then tie the free suture end to the exposed loop with four to five throws to complete the knot and close the wound. Trim the loop 2 to 3 mm above the knot. Insert the needle close to the knot, aiming to exit the dermis at least 1 cm lateral to the incision. As tension is applied to the suture, the knot is pulled deeper into the tissue, below the dermis. Finally, under tension, trim the free end of suture flush with the skin.

a substrate for clot formation. It can be cut to the desired size and placed on an area of hemorrhage. Surgicel is absorbed by the body, but removal is recommended because it may inhibit callus formation and promote infection. It is not activated by tissue fluids other than blood and therefore should be used only at sites of hemorrhage.

Both gelatin- and cellulose-based materials can be used in conjunction with thrombin to convert fibrin from fibrinogen and promote platelet aggregation (e.g., Floseal and GelFoam Plus).

Avitene is microfibrillar collagen derived from bovine skin that comes in a light flour form or nonwoven web form. It binds tightly to blood surfaces causing contact activation, but also directly activates platelets. It is absorbed from the body in two to three months.

Energy-Based Hemostasis–Electrosurgery

The language regarding the use of electrical current for hemostasis is confusing. The terms *electrocautery* and *electrosurgery* are often used interchangeably when the words actually mean distinctly different things. *Electrocautery* coagulates small vessels or cuts tissue by using heat generated by direct electric current into a metal wire or probe. Electrical current does not enter the patient's body. *Electrosurgery* refers to generating heat inside the tissue using an alternating electric current that passes through the tissue creating a circuit. Electrosurgery is widely used for hemostasis for vessels less than 1.5 to 2 mm in diameter; larger vessels should be addressed by other means.

Standard electrical current alternates at a frequency of 60 cycles per second (Hz). Because nerve and muscle stimulation

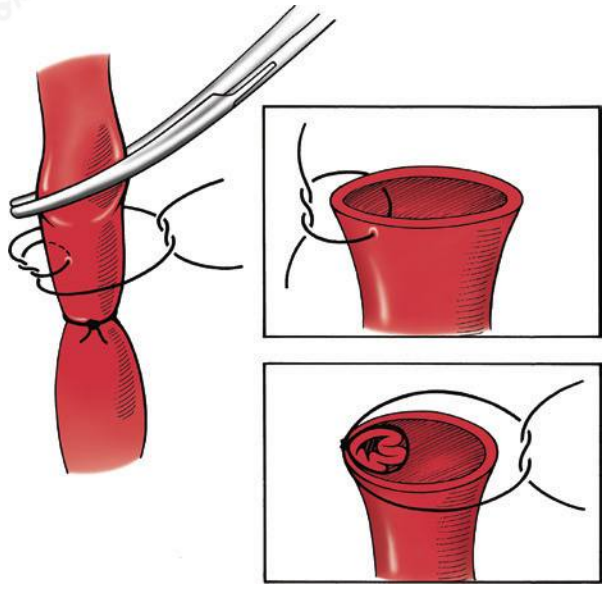

FIG. 8.16 To place a transfixation ligature on a vessel, introduce the needle through the previously ligated tissue. Place a single throw in the suture on the near side, then tie the suture (two square knots) on the opposite side of the vessel.

cease at 100,000 cycles/second (100 kHz), an electrosurgical generator takes 60 cycle current and increases the frequency to more than 200,000 cycles per second. This affords minimal neuromuscular stimulation without risk of electrocution. Electrosurgical generators are able to produce a variety of waveforms that have different effects on tissue. A constant waveform occurs on the "cut" setting; it produces heat quickly to vaporize or cut tissue. The "coagulation" setting uses an intermittent waveform, which produces less heat and creates a coagulum rather than vaporizing tissue. Modern, high-quality electrosurgery units (e.g., Force FX Electrosurgical Generator C; Medtronic Inc.) have a blend setting, which is an intermittent waveform at a higher duty cycle, so that it produces more heat. More coagulation occurs than with a pure cut setting, and more tissue cutting occurs than with a pure coagulation setting.

NOTE Research studies have confirmed that the smoke plume given off during electrocautery can contain toxic gases and vapors, such as benzene, hydrogen cyanide, formaldehyde, bioaerosols, dead and live cellular material (including blood fragments), and viruses. Thus the Occupational Safety and Health Administration recommends that smoke evacuation systems be used to reduce potential acute and chronic health risks to patients and personnel.

Electrosurgery may be performed with monopolar or bipolar devices, in a direct or indirect fashion.

Monopolar Electrosurgery

Monopolar electrosurgery is the most commonly used method of electrosurgery. It involves the flow of current from an active electrode (handpiece) through the patient to a ground plate. The small surface area of the handpiece concentrates the current density, increasing the temperature of the contact tissue and causing coagulation or tissue vaporization. The larger surface area of the ground plate reduces the current density so that minimal tissue heating occurs as the circuit is completed. If an adequate low-impedance ground pad is not present, alternate paths to ground will be inadvertently used by the circuit, resulting in burns to the patient. Most modern electrosurgery units have circuitry to eliminate this danger, but safe practices are still important. The amount of current multiplied by the amount of time the current is applied, and divided by the area of the return path, is proportional to the probability of a burn. Therefore a small ground plate or an alternate path to ground (i.e., through an ECG pad or lead) can easily produce a severe burn. *To reduce the risk of a burn, use a large pad placed in good contact on well-vascularized area of tissue that is close to the operative site.* In addition, keeping electrodes clean and free of eschar will enhance performance by maintaining lower resistance within the circuit. Towels dampened with water or conduction gel can be placed on metal ground plates to improve contact. Adhesive hydrogel patient return electrodes are available with some electrosurgery systems. These electrodes conform to the surface of the patient and provide improved contact over metal plates. Certain models (REM Polyhesive Patient Return Electrode) monitor patient impedance levels and will deactivate the generator if a fault (poor contact) at the electrode is detected.

With monopolar coagulation, the field must be relatively dry and the electrode kept clean and free of debris. Direct contact of the electrode with the tissue produces lower heat sufficient to coagulate. The use of the arc between the electrode and tissue produces higher heat and consequently a cutting or vaporization action. The standard flat-tipped electrode is designed to create an eschar or coagulum directly on tissue. When there is direct contact of the tip with the tissue, the cutting cycle will use far less voltage to accomplish the same coagulation as the coagulation cycle produces. Indirect contact involves touching the electrode to an instrument, usually hemostatic or tissue forceps that has been applied to the bleeding vessel. This technique allows more precise application of energy and effective coagulation.

NOTE Do not activate the generator while the active electrode is touching or in close proximity to another metal object. The instrument (particularly in body cavities) when energized can seek its own pathway to the return electrode, resulting in patient injury. Gloves can occasionally act in a capacitance function and cause burns to the surgeon.

Bipolar Electrosurgery

Bipolar electrosurgery involves the use of a forceps-like handpiece. Instead of passing through the patient's body, the current passes from one tip of the forceps to the opposite tip through the tissue being held between the tips. The tips must be held approximately 1 mm apart for a current to be generated. A ground plate or pad is not necessary for bipolar electrosurgery. Bipolar coagulation is used when precise coagulation is necessary and to prevent damage to adjacent structures, such as in spinal surgery, thyroidectomy, or ophthalmic procedures.

Radiosurgery generators and handpieces (e.g., Surgitron Dual Frequency RF) are similar to standard electrosurgery units, except

FIG. 8.17 (A and B) Force Triad Energy Platform with monopoly electrosurgical cutting and coagulation, bipolar functionality, and vessel sealing system.

that the energy is generated by low-temperature, high-frequency current (4.0 MHz). The radio waves pass from an active electrode in the handpiece to a passive electrode beneath or near the patient. Tissue resistance to the radio waves causes an ionic agitation in the cells at the tip of the active electrode. This results in molecular friction within the tissues and generation of heat. With this technology, there is precise tissue dissection with excellent incisional hemostasis, but with minimal thermal damage to the surrounding tissues.

Carbon Dioxide Laser

Although there are numerous types of surgical lasers available, the most widely used laser in small animal surgery is the carbon dioxide (CO_2) laser. The laser generates a wavelength of 10,600 nm, which is highly and selectively absorbed by water. Tissue vaporization occurs as this light energy is absorbed by water into the soft tissues. Penetration into tissue is shallow and precise with little heat dissipated to surrounding tissues. Proposed advantages of the CO_2 laser include less bleeding, less pain, less tissue swelling, and decreased risk of infection.

Vessel Sealing

Electrothermal, feedback-controlled, bipolar vessel sealing systems (Ligasure, Enseal) (Fig. 8.17) can permanently seal blood vessels up to 7 mm in diameter. The device uses pressure and pulsed, low voltage energy to fuse collagen and elastin of the vessel wall and achieve hemostasis. The amount and duration of energy delivered automatically adjusts to the degree of tissue impedance. A 2014 study showed that a single seal created with a single activation cycle is adequate for sealing canine carotid arteries.[13] This technology is utilized for hemostasis in laparoscopic (e.g., ovariectomy, cryptorchidectomy) and thoracoscopic (e.g., partial pericardectomy, lung lobectomy) surgery, as well as open abdominal procedures (e.g., splenectomy, liver lobectomy, partial pancreatectomy) and upper airway surgery (e.g., soft palate resection, tonsillectomy).

9 Surgical Infections and Antibiotic Selection

Modern antibiotic therapy began with the discovery and mass production of penicillin in 1941. Since then, many otherwise fatal infections have been resolved or prevented through their use. Unfortunately, their great success lead to rampant misuse. Widespread use of prophylactic antibiotics in surgical patients has resulted in de-emphasis of surgical asepsis and development of antibiotic-resistant bacteria. Nosocomial infections with resistant bacteria have been promulgated by prolonged and extensive surgical procedures, invasive supportive therapy, lengthy hospital stays, inappropriate use of antibiotics, increased survival of geriatric and debilitated patients, and use of immunosuppressive drugs.

Antibiotic selection is often based on personal bias versus actual/expected bacterial flora. Antibiotic therapy may be either *prophylactic* or *therapeutic* in nature. Prophylactic antibiotic therapy should primarily be used when there is clearly an increased likelihood of infection or when infection would be catastrophic. Selection of prophylactic antibiotics should be based on expected bacterial flora in the targeted tissue and their anticipated resistance patterns as determined by recent laboratory data. Choice of antibiotics for an established infection (therapeutic antibiotics) is ideally based on culture and susceptibility results; however, antibiotic therapy often needs to be initiated before this information is available. Therefore initial selection should be based on expected flora with a subsequent modification based on culture and sensitivity results.

NOTE Inappropriate administration of antibiotics may not only harm the patient being treated but also promote development of resistant microbes that can harm future patients.

Bacterial survival in a host depends on bacterial virulence and numbers, host immunocompetence, and wound factors that antagonize host defenses (e.g., blood clots, ischemic tissue, fluid pockets, foreign material). Successful antibiotic therapy requires reducing bacterial numbers to the point that host defenses are effective. With competent host defenses, bacteriostatic agents that slow protein synthesis or prevent bacterial replication are often adequate (see later discussion). If host defenses have been significantly compromised, then bactericidal concentrations of antibiotics are generally preferred. In addition to using appropriate antibiotics, wound factors may need to be corrected through wound debridement, drainage, and/or removal of foreign material to achieve a successful outcome.

NOTE Some antibiotics are bacteriostatic at low concentrations and bactericidal at higher concentrations. If susceptibility testing has been done, use an antibiotic to which the bacteria are susceptible regardless of whether it is bacteriostatic or bactericidal.

MECHANISMS OF ANTIBIOTIC ACTION

When antibiotics only inhibit bacterial growth, they are noted as being *bacteriostatic*; when they kill bacteria, they are noted as being *bactericidal*. The distinction between bactericidal and bacteriostatic classifications of antibiotics is relative and depends on the ratio between the minimum bactericidal concentration (MBC) and the minimum inhibitory concentration (MIC). The MIC, generally expressed in micrograms per milliliter (μg/mL), is the lowest concentration of a drug that inhibits visible bacterial growth after overnight incubation. The MBC is the lowest concentration of a drug that kills 99.9% of bacteria after overnight incubation. Antibiotics with a MBC to MIC ratio of 4 or less are classified as bactericidal because plasma and tissue levels that kill 99.9% of the bacteria are typically achieved. Conversely, drugs with a large MBC to MIC ratio may make it difficult to achieve plasma or tissue levels that kill bacteria; such drugs are considered bacteriostatic. However, nonuniform distribution of antibiotics in body tissues can cause culture and susceptibility results to be misleading. An antibiotic may be present in higher than anticipated concentrations in some tissues, making a "bacteriostatic" drug effectively bactericidal for certain bacteria in that tissue. A common example is treatment of urinary tract infections (UTIs). A UTI characterized as "resistant" to a particular antibiotic based on susceptibility testing might be successfully treated if the antibiotic is concentrated in urine. Conversely, a bacteria considered "sensitive" will probably not respond if the infection involves the central nervous system (CNS) and the antibiotic does not penetrate the blood-brain barrier.

Finally, the antibiotic must kill bacteria without harming the host. When the dose required to kill bacteria is greater than can be tolerated by the host (or achieved in the target tissue), then the bacteria are considered "resistant" to that drug.

Antibiotics typically are classified according to their mechanism of action. Broadly, they may destroy or alter the bacterial cell wall or inhibit its synthesis, or inhibit protein or deoxyribonucleic acid (DNA) synthesis.

Destruction of Bacterial Cell Walls

Antibiotics that inhibit synthesis or promote destruction of bacterial cell walls include the β-lactam ring antibiotics (e.g., penicillins, cephalosporins, carbapenems, and monobactams); vancomycin; bacitracin; polymyxin; the antifungal drugs nystatin and amphotericin B; and the imidazoles. β-Lactams bind to proteins in the cell wall (e.g., penicillin-binding proteins [PBPs]), thereby impairing cell wall synthesis, reducing its strength and rigidity, and ultimately causing increased permeability and cell lysis. β-Lactam antibiotics tend to be time dependent, bactericidal, and are typically eliminated via the kidneys. Being time dependent,

ABSTRACT

Surgical infections remain a serious risk in small animal surgery. A thorough understanding of the variety of bacteria and methods of diagnosis and treatment is critical for surgeons and support staff. In addition, the increasing issues with bacterial resistance and methods to combat resistant bacteria should be thoroughly understood.

it is important to administer the drugs frequently enough so that MBCs are maintained for 80% of the treatment interval. Most β-lactams are relatively safe in dogs and cats.

There are over 15 different types of penicillins and over 20 different cephalosporins; therefore only representative examples are considered in this discussion. **Aminopenicillins** (e.g., amoxicillin, ampicillin) are effective against many gram-positive aerobes and some gram-positive and gram-negative anaerobes. The carboxypenicillins (e.g., piperacillin/tazobactam) have better gram-negative and anaerobe spectrums than the aminopenicillins, whereas the ureidopenicillins (e.g., mezlocillin) have the best gram-negative spectrums of all the penicillins. Typical indications include urinary tract, respiratory, soft tissue, and cutaneous infections. Many gram-negative bacteria have resistance factors that inhibit penicillin's activity. Resistance to penicillins is mediated by bacterial penicillinases (a type of β-lactamase), decreased permeability of the cell wall to penicillins caused by altered porin size, and altered PBP structure, which prevents penicillins from binding (e.g., methicillin-resistant staphylococci). Penicillinase inhibitors (e.g., clavulanic acid, sulbactam) may be combined with penicillins (e.g., amoxicillin, ampicillin, piperacillin/tazobactam) to enhance their activity, but these inhibitors do not counter all mechanisms of resistance.

The **cephalosporins** (Table 9.1) are typically more effective than penicillin against gram-negative rods (e.g., Enterobacteriaceae). Resistance to cephalosporins is mediated by the same mechanisms that cause resistance to penicillins. First-generation cephalosporins (e.g., cefazolin) are usually effective against most gram-positive and some gram-negative organisms, but not anaerobes. Second-generation cephalosporins (e.g., cefoxitin) have greater activity against gram-negative bacteria and anaerobes but no additional efficacy against gram-positive organisms. Third-generation cephalosporins (e.g., cefotaxime) are highly effective against more than 90% of gram-negative bacteria, but they often are less active against gram-positive organisms than first-generation cephalosporins. Some third-generation cephalosporins have specific gram-negative spectra, and just because one third-generation cephalosporin is effective in a patient does not mean that another third-generation cephalosporin will also be effective. Cefpodoxime proxetil (Simplicef) is a prodrug whose metabolite is cefpodoxime, a third-generation cephalosporin with good activity against most streptococci and staphylococci and Enterobacteriaceae. It is designed to be given once daily, usually for skin and ear infections, as well as upper respiratory and urinary tract infections.

Imipenem and meropenem are carbapenems (a type of β-lactam antibiotic) that have broad gram-negative and gram-positive spectra and are highly resistant to most β-lactamases, except for the New Delhi metallo-β-lactamase or the *Klebsiella pneumoniae* carbapenemase. Unlike aminoglycosides, they are not nephrotoxic. Imipenem and meropenem are usually effective against most clinically relevant bacterial species, including gram-negative and gram-positive anaerobes and aerobes, but not methicillin-resistant staphylococci or resistant strains of *Enterococcus faecium*. Imipenem should be used only for severely ill patients with sensitivity results documenting that the bacteria is resistant

TABLE 9.1 Select Cephalosporin Drugs

Drug Name	Brand Name	Indications	Dosage
First-Generation Cephalosporins			
Cephalexin	Keflex	Wide spectrum of activity against gram-positive organisms; variable against gram-negative organisms; poor activity against anaerobic infections	22–30 mg/kg PO bid-qid
Cefazolin	Kefzol	As above	20–35 mg/kg IV, IM, SC; tid
Cefadroxil	Cefa-tabs	As above	22–35 mg/kg PO bid
Second- and Third-Generation Cephalosporins			
Cefepime	Maxipime	Fourth-generation cephalosporin with better gram-positive coverage than third-generation drugs	40 mg/kg IV, IM; qid
Cefotetan	Cefotan	Anaerobes and gram-negative bacilli (e.g., septic peritonitis, *Escherichia coli*)	30 mg/kg IV, SC; tid
Cefoxitin	Mefoxin	Anaerobes and gram-negative bacilli (e.g., septic peritonitis)	30 mg/kg IV, IM; tid-qid 22 mg/kg IV (presurgical)
Cefotaxime	Claforan	Wide spectrum of activity against both gram-negative and gram-positive organisms; most active in this group against staphylococci; reaches good concentrations in spinal fluid	*Dogs:* 50 mg/kg IV, IM, SC; bid *Cats:* 20–80 mg/kg IV, IM; qid
Cefovecin	Convenia	For skin and soft tissue infections where first-line drugs fail	8 mg/kg SC every 14 days
Ceftazidime	Fortaz	Effective against *Pseudomonas aeruginosa*	25–30 mg/kg; IM, SC (tid), or IV (qid)
Cefixime	Suprax	Limited activity against most gram-positive organisms; can be given orally; use lower dose for urinary tract infections and higher dose for other infections	10 mg/kg PO bid
Cefpodoxime	Proxetil	Better activity against *Staphylococcus* spp. than other oral third-generation cephalosporins	5–10 mg/kg PO qd
Cefoperazone	Cefobid	Effective against Enterobacteriaceae	22 mg/kg IV, IM; bid-qid
Cefquinome	Cobactan	A fourth-generation cephalosporin with good activity against Enterobacteriaceae	2 mg/kg IV, IM, SC; bid
Ceftriaxone	Rocephin	Often used in CNS infections and borreliosis	25–50 mg/kg IV, IM; qd-bid
Ceftiofur	Naxcel	Activity against gram-positive organisms; can be given once a day for urinary tract infections; not recommended for soft tissue infections in dogs or cats; not effective against enterococci	2.2–4.4 mg/kg SC qd-bid
Cefuroxime	Biociclin	Gram-positive except Enterococcus and MRSP	15–30 mg/kg IV, PO; bid-tid

bid, Twice a day; CNS, central nervous system; *IM,* intramuscular; *IV,* intravenous; *MRSP,* methicillin-resistant *Staphylococcus pseudintermedius; PO,* oral; *qd,* once a day; *qid,* four times a day; *SC,* subcutaneous; *tid,* three times a day.

to all other antibiotics. Unfortunately, excessive use has already produced resistant bacteria, especially Enterobacteriaceae (i.e., *Klebsiella* and *E. coli*).

Aztreonam is a monobactam (another β-lactam) that is resistant to many β-lactamases. It is highly effective against many gram-negative aerobes but has little activity against anaerobes. It has no activity against gram-positive bacteria and must be used in combination with other drugs to achieve broad-spectrum activity.

Inhibition of Protein Synthesis

Chloramphenicol, tetracycline, erythromycin, and clindamycin bind to bacterial ribosomes, causing reversible inhibition of protein synthesis. Chloramphenicol (Table 9.2) has broad-spectrum activity against most anaerobic and aerobic bacteria, as well as *Ehrlichia* spp. and *Rickettsia* spp., but poor activity against *Pseudomonas* spp. It is highly lipophilic and penetrates most organs (e.g., CNS, eye, prostate). Although considered bacteriostatic, it often achieves tissue levels high enough to make it bactericidal. It is eliminated by hepatic metabolism and urinary excretion. The drug may cause idiosyncratic fatal anemia in people, but dogs and cats experience only a mild, transient anemia, if that. It inhibits hepatic P450 cytochromes and can thus affect hepatic metabolism of certain other drugs (e.g., propofol, opiates, barbiturates).

Tetracyclines are effective against many gram-positive and gram-negative bacteria, including *Chlamydia* spp., rickettsia, spirochetes, *Mycoplasma* spp., bacterial L-forms, and some protozoa. They are usually ineffective against staphylococci, enterococci, *Pseudomonas* spp., and Enterobacteriaceae. Doxycycline (see Table 9.2) is usually the preferred tetracycline in small animal practice because it has fewer side effects, penetrates cells better, and has less resistance develop to it compared with other tetracyclines. It is well distributed to most tissues and achieves good intracellular concentrations, although not to the CNS. Products containing calcium chelate and tetracyclines interfere with oral absorption. Binding of the drugs to calcium can be a problem in young or pregnant animals, and tooth discoloration and inhibited bone growth can occur. Doxycycline is primarily eliminated through the intestines in the dog. Typical indications include tick-borne diseases as well as respiratory and prostatic infections. Doxycycline causes hepatotoxicity in some patients, but its main adverse side effect is related to causing esophagitis after oral administration.

NOTE Tetracyclines are caustic, and it is critical that the patient drink water immediately after swallowing a tablet or capsule (in the case of doxycycline, the patient may eat nondairy food). Otherwise the tablet may lodge in the esophagus and cause esophagitis and even a benign stricture (especially in cats).

Erythromycin is a macrolide that is readily absorbed from the upper gastrointestinal system and diffuses well throughout most tissues. All macrolides tend to accumulate in phagocytic cells and are usually eliminated in the bile. Erythromycin has a narrow spectrum of activity and may be associated with nausea and

TABLE 9.2 Dosages of Selected Antibiotics

Generic and Trade Names	Dosage
Amoxicillin plus clavulanate (Clavamox)	*Dogs*: 12.5–25 mg/kg PO bid *Cats*: 62.5 mg/cat PO bid (tid for gram-negative infections)
Azithromycin (Zithromax)	*Dogs*: 10 mg/kg PO qd for 7 days, followed by every other day *Cats*: 5–10 mg/kg PO qd for 7 days, then give every other day; for upper respiratory infections, give 15 mg/kg qd PO for 3 d, then q72h
Clindamycin (Antirobe)	*Dogs:* 11–33 mg/kg PO bid *or* 11 mg/kg IV, bid; dilute and give slowing when giving IV *Cats*: 11–33 mg/kg PO qd *or* 10 mg/kg IV, IM bid
Amikacin (Amiglyde-V)	*Dogs:* 15–22 mg/kg IV, SC, IM; qd (preferably in the morning)
Piperacillin/tazobactam (Zosyn)	50 mg/kg IV, IM; qid
Ampicillin plus sulbactam (Unisyn)	10–20 mg/kg IV, IM; tid
Chloramphenicol (Chloromycetin)	*Dogs*: 50 mg/kg PO, or 10–15 mg/kg IV tid *Cats*: 12.5–20 mg/cat IV, IM bid
Doxycycline (Vibramycin)	5 mg/kg PO bid *or* 10 mg/kg PO qd
Minocycline (Minocin)	*Dogs*: 5–10 mg/kg PO bid *Cats*: 8.8 mg/kg PO qd
Enrofloxacin (Baytril)[a]	*Urinary tract infection:* 2.5 mg/kg IV, IM, SC, PO bid *Deep tissue infection:* 7–20 mg/kg IV, IM, SC, PO qd
Difloxacin (Dicural)	5–10 mg/kg PO qd (use higher dose for organisms with higher MIC)
Orbifloxacin (Orbax)	2.5–7.5 mg/kg PO qd (use higher dose for organisms with higher MIC)
Marbofloxacin (Zeniqun)	2.75–5.5 mg/kg PO qd
Pradofloxacin (Veraflox)	*Dogs*: 3–5 mg/kg PO qd *Cats*: 3–5 mg/kg PO qd for tablets; 5–7.5 mg/kg PO qd for suspension
Trimethoprim-Sulfadiazine (Tribrissen)	15 mg/kg PO bid *or* 30 mg/kg PO qd–bid
Metronidazole (Flagyl)	7.5–10 mg/kg PO, IV bid–tid (dilute and give slowly over 20 min)

[a]When given IV, enrofloxacin is typically diluted and given over 10 to 20 minutes. Recent reports suggest that enrofloxacin may be associated with blindness in cats when doses >5 mg/kg are used. It can be given as a single IV injection daily.

bid, Twice a day; *IM,* intramuscular; *IV,* intravenous; *MIC,* minimum inhibitory concentration; *PO,* oral; *qd,* once a day; *qid,* four times a day; *qod,* every other day; *SC,* subcutaneous; *tid,* three times a day.

vomiting because of its prokinetic activity. New derivatives include clarithromycin and azithromycin. Azithromycin (see Table 9.2) is active against aerobic bacteria, such as staphylococci and streptococci, and anaerobes. It also has good activity against *Mycoplasma* spp. and intracellular organisms, such as *Bartonella* spp., *Toxoplasma* spp., and atypical mycobacteria. Absorption of azithromycin after oral administration is high, and it is well tolerated. The drug achieves extremely high tissue concentrations and only needs to be given once daily.

Clindamycin (see Table 9.2) is a lincosamide that is primarily eliminated by biliary excretion and achieves excellent concentrations in the skin and bones, as well as high concentrations in white blood cells. It is effective against most anaerobic bacteria, plus it is active against many gram-positive pathogens. Typical indications include intra-abdominal infections, osteomyelitis, discospondylitis, and oral/dental disease. Clindamycin can be used in combination therapy directed at *Pseudomonas aeruginosa*; it inhibits bacterial adherence to epithelial cells, making it more susceptible to other antibiotics. Clindamycin is effective against toxoplasmosis and *Neospora*, and it can cause esophagitis if the pill stays in the esophagus (especially in cats).

The aminoglycosides (e.g., amikacin, gentamicin, kanamycin, neomycin, netilmicin, and tobramycin) disrupt protein synthesis by binding irreversibly to bacterial ribosomes, making them bactericidal. They are effective against gram-negative and gram-positive bacteria, including Enterobacteriaceae and pseudomonads, but not anaerobes. Their activity is reduced in necrotic tissue because of free nucleic acid material. Aminoglycosides are polar (i.e., lipid insoluble) and have limited distribution in the extracellular and cerebrospinal fluids. However, distribution into the pleural fluid, bone, joints, and peritoneal cavity is good. Aminoglycosides are poorly absorbed orally. They are concentration dependent rather than time dependent, meaning that they can be given at higher doses at longer intervals (e.g., once daily), which maintains effectiveness but reduces renal toxicity. Amikacin (see Table 9.2) is typically used. Dehydration, electrolyte loss, preexisting renal disease, and concurrent use of other nephrotoxic drugs (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) increase the nephrotoxicity of aminoglycosides. Ototoxicosis and neuromuscular blockade are other possible adverse effects. Using a combination of a β-lactam and an aminoglycoside is often synergistic, plus it helps prevent bacteria from becoming resistant to these drugs.

NOTE A β-lactam drug should never be mixed in the same syringe, vial, or intravenous (IV) line with an aminoglycoside; mixing the two can result in a chemical reaction that inactivates one or both of the drugs.

Inhibition of DNA Synthesis

Fluoroquinolones (e.g., enrofloxacin, difloxacin, ciprofloxacin, ofloxacin, marbofloxacin, pradofloxacin) (see Table 9.2) and potentiated sulfas (e.g., trimethoprim-sulfa) inhibit DNA synthesis. Fluoroquinolones inhibit DNA synthesis by inactivating DNA gyrase. They are bactericidal, concentration-dependent drugs with a prolonged postantibiotic effect. Fluoroquinolones tend to accumulate in phagocytic white blood cells. Enrofloxacin is primarily excreted in the urine; however, approximately 25% is metabolized to ciprofloxacin. It has a principally gram-negative spectrum but is also effective against *Rickettsia rickettsii*, Mycobacteria, and possibly L-form bacteria. Enrofloxacin is poorly effective against most gram-positive cocci and anaerobic bacteria, but the newer fluoroquinolones (e.g., pradofloxacin) have enhanced anaerobic activity. Enrofloxacin has "flexible" dosing depending upon the target bacteria and target tissue (see Table 9.2). Resistance to fluoroquinolones has become common. Side effects include blindness in cats, CNS effects, cartilage lesions in rapidly growing large breed dogs, and vomiting. Rapid IV injection of undiluted enrofloxacin can be fatal.

NOTE When given intravenously, enrofloxacin must be given slowly, in a diluted solution, or the patient may experience morbidity or even death.

Oral ciprofloxacin is less expensive than enrofloxacin but is also less bioavailable in dogs (approximately 30%–40%) than in people (approximately 70%–80%). Therefore it is commonly underdosed when administered to dogs. Marbofloxacin has a broad spectrum of activity against the major pathogens encountered in surgical infections. It is safe in dogs, and a single IV injection of 2 to 4 mg/kg maintains plasma concentrations above the MIC for Enterobacteriaceae and staphylococci for 12 to 24 hours.

Trimethoprim-sulfonamide combinations inhibit sequential steps in folate synthesis, making them time-dependent, bactericidal drugs to which bacteria have difficulty developing resistance. Penetration into tissues depends on the specific sulfonamide used; sulfadiazine penetrates most body tissues well, whereas sulfamethoxazole is limited to the interstitial fluid compartment. Sulfas are renally excreted, but some are metabolized by the liver. In general, they are effective for the treatment of osteomyelitis, prostatitis, pneumonia, tracheobronchitis, pyoderma, and UTI. Trimethoprim-sulfonamide combinations have a broad spectrum of activity against gram-positive and gram-negative bacteria, as well as *Nocardia* spp. and anaerobic bacteria. They are usually not effective against pseudomonads. In vitro and in vivo susceptibilities do not always correlate. Sulfas tend to have poor efficacy in the presence of pus or necrotic tissue. Possible side effects include keratoconjunctivitis sicca, thrombocytopenia, anemia, neutropenia, bone marrow suppression, fever, vomiting, hypersensitivity (i.e., vasculitis or arthritis), and hepatic disease. Some breeds (e.g., miniature Schnauzers, Samoyeds, Doberman pinschers) and some families of dogs seem more likely to suffer side effects, probably because of altered hepatic metabolism.

Metronidazole is very effective against most anaerobic bacteria. It penetrates most body tissues well. Dose-dependent CNS toxicity is common if excessive doses are administered.

DRUGS OF LAST RESORT

The number of antibiotics that are effective against multidrug resistant (MDR) infections (e.g., methicillin-resistant *S. aureus* [MRSA], vancomycin-resistant enterococci, MDR gram-negative rods) is ever diminishing due to transmission of resistance between bacteria, especially in hospital settings. Currently, there are some MDR bacteria for which only one or two drugs are effective.

The antibiotics reserved for such infections are sometimes referred to as *drugs of last resort*. They include vancomycin, the carbapenems (i.e., imipenem, meropenem), the oxazolidinone linezolid (Zyvox), the streptogramin combination of dalfopristin and quinupristin (Synercid), the cyclic lipopeptide daptomycin (Cubicin), the glycopeptide telavancin (Vibativ), the tetracycline tigecycline (Tygacil), the oxazolidinone telithromycin (Ketek), and the newest cephalosporins (i.e., ceftaroline and ceftobiprole). Although tempting to use these antibiotics when faced with a patient seriously ill from a bacterial infection (especially when the clinician wants to impress the client with the fact that their pet is receiving the very newest and most powerful antibiotic available), it is a moral and ethical imperative that veterinarians only use such drugs when the bacteria has been isolated and determined to only respond to one of these antibiotics. The more these drugs are used, the sooner resistant strains will develop. Most dogs with extraintestinal infection by MDR *E. coli* and *Enterobacter* have had prior antibiotic treatment, prolonged hospitalization, or prior surgery (the urinary tract appears to be the most common site of infection with these bacteria).

CAUSES OF ANTIBIOTIC FAILURE AND MECHANISMS OF ANTIBIOTIC RESISTANCE

Successful antibiotic therapy requires administering the appropriate dose of an effective antibiotic that can reach the site of infection so that the bacteria there are killed or suppressed sufficiently to allow the patient's immune system to control the infection. Factors contributing to therapeutic failure include inappropriate dose, frequency, or route of administration; inadequate duration of treatment; inappropriate antibiotic selection; presence of foreign material (i.e., foreign body or implant); inability of sufficient antibiotic to reach the target tissue (e.g., cross the blood-brain barrier); bacterial resistance (see later discussion); depressed host immunity (e.g., concurrent debilitating illness, immunosuppressive drug therapy); pharmacokinetics of the drug; drug reactions; antibiotic antagonism; and incorrect diagnoses (i.e., viral diseases or foreign bodies misdiagnosed as primary bacterial infections).

Unfortunately, even appropriate administration of antibiotics is eventually associated with development of resistance, usually within 1 to 2 decades of introducing a particular drug, although in some cases it occurs within 3 to 4 years. There are two main ways that bacteria develop resistance; they can alter the site that the antibiotic targets (i.e., receptors in/on the bacteria), or they can alter the concentration of the antibiotic in the bacteria. Intracellular concentrations may be altered by enzymatic destruction of the antibiotic (e.g., β-lactamases), decreasing bacterial permeability to the antibiotic (e.g., altering porin size such that antibiotics can no longer access intracellular targets), or developing efflux proteins (i.e., these are closely associated with porins, and they pump specific chemicals out of the bacteria). Alteration of the structural target for the antibiotic includes alteration of PBPs in the cell wall and binding sites on ribosomes.

SURGICAL INFECTIONS

Definitions of Infection

There are numerous means of defining the existence of bacterial infection. Bacterial infection has been defined quantitatively as a wound having more than 10^5 bacteria per gram of tissue. This definition has limited clinical applicability when attempting to determine when to treat an infection or for broader screening and reporting purposes. Alternatively, the Centers for Disease Control and Prevention (CDC) more specifically defines infection based on specific body systems (e.g., bone and joint, CNS, cardiovascular) with subcategories (osteomyelitis, discospondylitis) that require fulfillment of criteria that may or may not include the actual culture of bacteria. *This is significant as bacterial infection can frequently be present in spite of the inability to demonstrate it with a positive culture.* This is particularly true of canine and human joint infections. An additional CDC category of infections is the surgical site infection (SSI). There are no agreed-upon categorizations of SSI in veterinary medicine. Adaptation of the CDC categories are likely appropriate in veterinary patients and include superficial incisional, deep incisional, and organ/space (Fig. 9.1). The criteria for diagnosing an infection in each of these three locations are listed in Box 9.1.

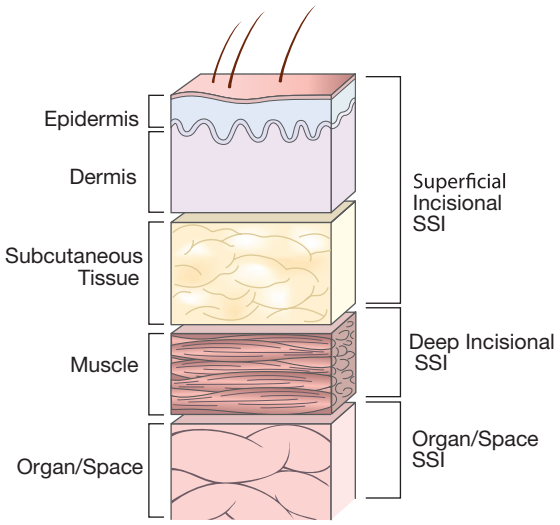

FIG. 9.1 Categorization of surgical site infections (SSIs) by tissue layer. Superficial incisional SSIs are the most commonly reported surgical infections, accounting for more SSIs than deep incisional SSIs and organ space SSIs combined.

Sources of Surgical Site Infections

Sources of surgical infections are separated into endogenous and exogenous. Endogenous sources include skin flora, mucous membranes, gastrointestinal tract, and preexisting infections at the surgical site (abscesses, open wounds). Additionally, endogenous sources of SSI include distant sites of infection such as dental disease, UTI, or endocarditis. Exogenous sources of SSI include surgical personnel, the operating room (OR) environment and ventilation, and surgical tools, equipment, and materials.

Reported Rates of Small Animal Surgical Site Infections

Veterinary studies have estimated the rates of SSI to be between 3% and 10%; however, data from some studies are difficult to interpret based on the variability in their definitions of infection, retrospective nature, small sample size, and use of medical record

BOX 9.1 Surgical Site Infection (CDC Definition)

Superficial Incisional Surgical Site Infection (SSI)

Infection within 30 days after the operation and only involves skin and subcutaneous tissue of the incision and at least one of the following:

1. Purulent drainage, with or without laboratory confirmation, from the superficial incision.
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision.
3. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat and superficial incision is deliberately opened by surgeon, unless incision is culture negative.
4. Diagnosis of superficial incisional SSI made by a surgeon or attending physician.

Deep Incisional Surgical Site Infection

Infection occurs within 30 days after the operation if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operation and infection involves deep soft tissue (e.g., fascia, muscle) of the incision and at least one of the following:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site.
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: fever (>38°C [100°F]), localized pain or tenderness, unless incision is culture negative.
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of deep incisional SSI made by a surgeon or attending physician.

Organ/Space Surgical Site Infection

Infection occurs within 30 days after the operation if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operation and infection involves any part of the anatomy (e.g., organs and spaces) other than the incision that was opened or manipulated during an operation and at least one of the following:

1. Purulent drainage from a drain that is placed through a stab wound into the organ/space.
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space.
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of organ/space SSI made by a surgeon or attending physician.

CDC, Centers for Disease Control and Prevention.
Modified from Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection 1999. Hospital Infection Control Practices Advisory Committee. *Infec Control Hosp Epidemiol.* 1999;20(4):250–278.

review to identify infection. A 2015 prospective cohort study of 846 dogs examined the incidence of SSI in dogs using the CDC definitions and classifications of SSI.[1] The incidence of SSI in this study was 3% overall with 42% classified as superficial, 50% classified as deep, and 8% as organ/space. The most prominent bacterial species cultured in this study was methicillin-resistant *Staphylococcus pseudintermedius* (MRSP) at 47%. The majority of SSIs are recognized within 30 days of surgery, and the CDC has reduced the screening period for SSIs from 1 year postoperatively to 90 days postoperatively.

Factors Affecting Surgical Site Infections

Numerous factors determine the likelihood of development of an SSI. The most commonly identified of these include the classification of the wound, patient-related factors, and procedure-related factors.

Classification of Wounds

Wounds, including surgical wounds, are classified by degree of contamination to help predict the likelihood that infection will develop. The classification scheme was developed by the National Research Council (Table 9.3) to provide a basis for comparison between types of wounds and between institutions. Classification of surgical wounds by degree of contamination results in significant differences in infection rates.

Clean wounds (see Table 9.3) have a published infection rate of approximately 3%. In this category, wounds most likely to result in postoperative infection are those associated with severe trauma with multiple fractures, traumatic procedures (i.e., carpal arthrodesis), or fractures of the distal radius or tibia that require plating.

Clean-contaminated wounds (see Table 9.3) are identified when nonsterile luminal organs are entered without significant spillage of contents. Included in this category are procedures in which a minor break in aseptic technique occurs, such as perforation of a surgical glove. The most recently reported rate of SSI for this category is 3.8%.

Contaminated wounds (see Table 9.3) have a published infection rate that varies from 0% to 28.6%. Contaminated fractures of long bones and the pelvis and contaminated urogenital procedures most frequently become infected. Antibiotic prophylaxis is indicated for contaminated wounds, and drug selection is based initially on anticipated bacterial flora and modified according to culture and sensitivity results. These wounds are not infected initially but have a real potential to become infected. Delicate debridement, copious lavage, and antibiotic therapy can convert these wounds to clean ones, whereas inadequate therapy often results in a dirty, infected wound.

Dirty wounds (see Table 9.3) are those in which gross infection is present at the time of surgical intervention (e.g., traumatic wounds with retained devitalized tissue, foreign bodies, or fecal contamination). Management of this type of wound requires antibiotic therapy (initial selection being based on anticipated flora and later modified by bacterial culture and sensitivity results), copious lavage, debridement, drainage, and possible use of wet-to-dry bandages to further debride the wound during the early postoperative period. The postoperative infection rate for dirty wounds is approximately 20%.

Patient-Related Factors

The risk of SSI may be increased by gender, body weight, and preexisting medical conditions or existing treatments.

Hypotension. In a 2015 study, dogs experiencing hypotension (i.e., mean arterial pressure <60 mm Hg and systemic arterial pressure <80–90 mm Hg) during surgery were 27 times more likely to develop an SSI.[1] The proposed mechanism is a decrease in oxygenated blood flow to the surgical site.

Endocrinopathies. Endocrinopathies including diabetes mellitus, hyperadrenocorticism, and hypothyroidism have been inconsistently reported to result in an increased risk of SSIs in dogs and cats.

Gender. Androgenic hormones may result in an increased risk of SSI in male dogs and cats. Although not definitively proven, this would be similar to the 50% increased risk that has been identified in men compared with women.

Other patient-related factors. Numerous other patient-related factors may increase the risk of SSI in dogs and cats based on

TABLE 9.3 Wound Classification System (National Research Council, Division of Medical Sciences)

Classification	Description	Procedure Type (Examples)	Infection Rate
Clean	Nontraumatic, noninflamed operative wounds in which the respiratory, gastrointestinal, genitourinary, and oropharyngeal tracts are not entered	Exploratory laparotomy Elective neuter Total hip replacement PDA	2.0%–4.9%[a]; 2.6% (tibial tuberosity advancement), 3.5% (elective joint surgery),10% (total hip replacement)[b]; 13% tibial plateau leveling osteotomy[c]
Clean contaminated	Operative wounds in which the respiratory, gastrointestinal, or genitourinary tract is entered under controlled conditions without unusual contamination; an otherwise clean wound in which a drain is placed	Bronchoscopy Cholecystectomy Small intestinal resection Enterotomy Renal transplantation	3.5%–4.5%[a]; 26%[d]
Contaminated	Open, fresh, accidental wounds; procedures in which gastrointestinal contents or infected urine is spilled or a major break in aseptic technique occurs	Bile spillage during cholecystectomy or biliary diversion procedures Open cardiac massage Cystotomy with spillage of infected urine Lacerations	4.6%–9.1%[a]
Dirty	Old traumatic wounds with purulent discharge, devitalized tissue, or foreign bodies; procedures in which a viscus is perforated or fecal contamination occurs	Excision or drainage of an abscess Peritonitis Perforated intestinal tract Ruptured gallbladder caused by necrotizing cholecystitis Bullae osteotomy for otitis media	6.7%–17.8%[a]

similar evidence in humans. Veterinary studies often do not have adequate statistical power to verify these concerns. Potential factors include obesity, hypothermia, immunosuppressive medications, and blood loss.

Procedure-Related Factors

Procedure-related factors that may increase the risk of infection include hair removal, duration of surgery, duration of anesthesia, OR operating room conditions, and presence of surgical implants.

Surgical site clipping. Clipping of incision sites produces microscopic abrasions in the skin that can be colonized by bacteria. To minimize SSI from bacteria, which colonize skin abraded by clippers, skin preparation should be performed immediately before surgery and no earlier if possible (see Chapter 5).[2]

Surgical time. Prolonged surgical times increase the risk of SSI by suppression of the immune system associated with a transient decrease in lymphocytes that has been correlated with the duration of surgery. Prolonged surgical procedures also increase the risk of SSI through increased tissue manipulation, which further compromises immunity. It has been estimated that each additional hour of surgery time doubles the risk of SSI; however, surgical time was not identified as a risk factor for SSI in a 2015 study.[1]

Tissue handling. Proper atraumatic tissue handling and instrument use are also important in preventing infection. Traumatized tissue better supports bacterial growth and has impaired host defenses. Traumatized or necrotic tissue also has reduced oxygen content, which permits the growth of anaerobic bacteria. Phagocytosis and humoral immunity are significantly diminished when tissue integrity is interrupted during surgery. Inexperienced surgeons cause more tissue trauma than experienced surgeons, resulting in greater susceptibility to infection.

Anesthesia time. It has been estimated that each hour of anesthesia increases the risk of SSI by approximately 30%; however, anesthetic time was not identified as a risk factor for SSI in the study by Turk et al.[1] The duration of anesthesia depends on the actual surgical time, plus any preoperative or postoperative procedures performed (including patient preparation and diagnostics). The potential increased risk of SSI is due not only to associated prolonged surgical times but also to possible immune alterations from inhalant anesthesia and potential bacterial contamination with drugs such as propofol. In older studies, animals that received propofol were more likely to develop postoperative wound infections than animals that did not receive the drug. This may be because the propofol can be contaminated by hospital personnel, particularly when the vial is used for multiple patients.

NOTE Prepare and handle propofol using strict aseptic technique. Discard any unused drug promptly.

Operating room conditions. OR practices (principles of aseptic technique, sterilization and disinfection, preparation of the surgical environment, gowning and gloving, and preparation of the surgical patient, operative site, and surgical team) are

important in preventing surgical wound infection and are discussed in Chapters 1 through 6. ORs should be designed with surfaces that are easily cleaned and with a minimum of horizontal open surfaces such as shelves. Protocols should be developed for effective cleaning and regular culturing of the OR surfaces (see Chapter 3), as well as other locations in the hospital, to screen for the growth of potential sources of nosocomial infections, particularly those due to resistant bacteria.

Estimates in human surgery suggest that 30% of SSIs are from airborne pathogens that may originate from either the patient, the OR personnel, or equipment and facilities. OR ventilation systems should be designed to provide 15 total air changes per hour with 3 air changes of outdoor air per hour (see Chapter 3). Increased personnel traffic provides increased sources of airborne bacteria and decreases effectiveness of the ventilation system by movement and opening and closing of the OR door; however, a 2015 prospective study based on CDC guidelines demonstrated no increase in SSIs with increases in personnel in the OR.[1]

Contamination rates of personnel (hands and surgical gloves) and facilities during small animal orthopedic procedures has been demonstrated to be as high as 80%.[3] Yet in this study the bacteria responsible for SSI were most often not the same species as those that contaminated the personnel and equipment, suggesting that the pathogenic bacteria that cause SSI are from outside the OR.

Implanted medical devices. Implanted medical devices (IMDs) are foreign substances used to support, rebuild, or in some fashion mimic the function of an anatomic structure (i.e., total hip replacement, polypropylene mesh, nonabsorbable suture, vascular prostheses, metallic implants, or polymethylmethacrylate bone cement). The risk of SSI is 5.6 times greater in dogs with IMDs than in those without.[1] Antibiotic treatment of SSI in patients with IMDs is seldom successful until the implant is removed because implants inhibit medications and defense mechanisms from reaching bacteria, partly because of the formation of biofilms. Biofilm forms when bacteria, particularly *S. pseudintermedius,* adhere to surfaces and begin to excrete an extracellular matrix and form a bacterial aggregate. Once anchored to a surface, biofilm microorganisms are extremely resistant to antibiotics.

PROPHYLACTIC AND THERAPEUTIC USE OF ANTIBIOTICS

Prophylactic Use of Perioperative Antibiotics

Surgical antibacterial perioperative prophylaxis is defined as a brief course of antibacterial medications administered immediately before a surgical procedure in a patient without a current infection.[4] The mechanism of prevention of SSIs is the reduction in the bacterial load at the surgical site to aid the patient's normal defenses. For this to happen, the drugs must be present at the surgical site during the time of potential contamination. Antibiotics are not a substitute for proper aseptic technique, meticulous and atraumatic tissue handling, careful hemostasis, judicious use of sutures, preservation of blood supply, elimination of dead space, and anatomic apposition of tissues.

Indications for Prophylactic Antibiotics

Clean Wounds

Prophylactic antibiotics are not indicated for most clean procedures; exceptions include placement of an implant or where infection could be catastrophic. Infection may be life-threatening in an athletic animal that can no longer perform. In small animal patients undergoing surgeries where the procedure is categorized as "clean," no significant difference is generally seen in the SSI rate between those that receive appropriate perioperative antibiotic prophylaxis and those that receive no antibiotic prophylaxis; however, additional studies are needed. There are conflicting data on whether prophylactic antibiotics reduce infections in clean procedures when an implant is being placed; however, most studies suggest that their use may reduce infections in these circumstances, and their use is seemingly warranted.

Clean-Contaminated and Contaminated Wounds

Prophylactic antibiotics are indicated for clean-contaminated and contaminated procedures. Surgical procedures warranting use of prophylactic antibiotics are listed in Box 9.2.

Obviously, the bacteria most likely to be responsible for infection should be susceptible to the antibiotic used. Antibiotic selection should be based on clinical experience plus what is known about the microbiology of tissues involved. The goal is to use an antibiotic that is effective against at least 80% of the probable pathogens. Unfortunately, the ability to predict what antibiotic bacteria will be sensitive to is becoming increasingly limited due to widespread resistance.

BOX 9.2 Examples of Surgical Procedures That Warrant Perioperative Prophylactic Antibiotics

General Indications
- Surgery time >90 minutes
- Prosthesis implantation (e.g., mesh, pacemaker, vascular prosthesis, bone cement)
- Patients with a preexisting prosthesis (e.g., total hip, pacemaker, bone cement) undergoing surgical procedures (e.g., dental prophylaxis, traumatic wounds, colorectal surgery)
- Severely infected or traumatized wounds

Orthopedic Procedures
- Total hip replacement
- Open fracture repair
- Extensive fracture repair
- Other elective procedures

Respiratory Procedures
- Resection of infected lung lobe or lobes
- Closure of esophagobronchial fistula

Gastrointestinal Procedures
- Colonic anastomosis or colectomy
- Strangulation or obstruction
- Pancreatic abscess
- Gastric resection for gastric dilation-volvulus
- Anal and rectal surgery
- Esophageal surgery
- Perineal herniorrhaphy
- Hepatobiliary surgery with infection

Urogenital Procedures
- Renal, ureteral, bladder, or urethral surgery with infected urine

Prophylactic use of antibiotics should also be considered for surgical patients predisposed to infections at sites other than the surgical incision. Specifically, the use of perioperative antibiotics may decrease the incidence of urinary tract infections in dogs undergoing surgery for intervertebral disc disease.

Dirty Wounds

Dirty wounds are considered to be infected at the time of surgery. Prophylactic antibiotics are indicated, and selection should be based on the anticipated infecting organisms. Dirty wounds may also be treated with antiseptics such as 0.05% chlorhexidine solution (see Chapter 5), although knowledge of the individual tissue response to antiseptics is important prior to their use.

Selection and Timing of Prophylactic Antibiotics

Antibiotics chosen for surgical prophylaxis should have demonstrated efficacy against the anticipated bacterial contaminants. This will vary with the type and location of the surgical wound. The pathogens usually responsible for postoperative wound infection in small animal surgical patients are *Staphylococcus* spp. (especially *S. pseudintermedius*), *E. coli*, and *Pasteurella* spp. (especially in cats). In a prospective study of 846 dogs, culture-confirmed SSIs were comprised of 64% MRSP, 21% MRSA, and 15% methicillin-susceptible *S. pseudintermedius*. Only 26% of the culture-confirmed SSIs were susceptible to perioperative antibiotics.[1] In another study where *S. pseudintermedius* was also the most common isolate, most isolated pathogens were without acquired microbial resistance and MDR was uncommon.[5] The later study found only three cases of MRSP (1% of all isolates), one of extended spectrum β-lactamase producing *E.coli* infection, and no MRSA infections. The organisms most likely associated with surgical procedures are listed in Table 9.4 according to body system. Special considerations in the selection and administration of prophylactic antibiotics are presented in Box 9.3. Cefazolin has no adverse effects on platelet aggregation, bleeding time, platelet count, platelet size, prothrombin time, or activated partial thromboplastin time and therefore is a good choice for use as a perioperative antibiotic in dogs with conditions predisposing them to hemostatic complications. Intravenous prophylactic antibiotics should be given no earlier than 30 to 60 minutes before the first surgical incision, and they should optimally be discontinued at or within 24 hours of the end of the procedure (see Box 9.3). Because many bacterial isolates that are "sensitive" now have an MIC approaching the threshold of susceptibility, it is generally appropriate to use the higher end of the antibiotic dose. For time-dependent drugs (e.g., β-lactams), the interval for dosing may need to be shortened. For example, cefazolin should probably be readministered at less than 2-hour intervals during the procedure.

Route of Administration

In general, IV administration of prophylactic antibiotics is indicated; however, there is increasing use of topical and local antimicrobial prophylaxis in human medicine. Advantages of local antibiotic administration include high concentrations at the site of infection, a potential for reduced systemic toxicity, and perhaps a reduced risk of antimicrobial resistance.[4] Methods of delivery include installation of ointment, creams, powders, or gels; intraoperative flushing of the wound or cavity, local injections, and antibiotic impregnated or coated beads or implants. Many of these techniques appear promising; however, clinical trials in veterinary medicine are scarce and efficacy is as yet undetermined. The use of antibiotic-impregnated bone cement (PMMA) is common in cemented total joint arthroplasty in dogs. Antibiotic elution from bone cement is bimodal with a rapid initial release followed by a slower release that may last for several months. The efficacy of antibiotic impregnated cement in veterinary total joint replacement has not been evaluated, but its continued use is justified based on human meta-analysis studies demonstrating a significant decrease in the risk of SSIs. The use of antibiotic-impregnated PMMA or calcium sulfate beads in small animals for the treatment of infections is uncommon, and there is limited information regarding efficacy;

TABLE 9.4 Organisms Most Commonly Isolated From Various Body Systems

Procedure, System, or Condition	Likely Pathogens
Thoracic surgeries (pulmonary and cardiovascular procedures)	*Staphylococcus* spp., gram-negative bacilli
Orthopedic surgeries (e.g., total hip replacement, prolonged internal fixation)	*Staphylococcus* spp.
Gastric and upper intestinal surgeries (high-risk patients)	Gram-positive cocci, enteric gram-negative bacilli, anaerobes
Biliary tract surgeries (high-risk patients)	Enteric gram-negative bacilli, anaerobes
Colorectal surgeries	Enteric gram-negative bacilli, anaerobes
Urogenital system (e.g., with pyometra, endometritis)	*Escherichia coli, Streptococcus* spp., anaerobes
Deep, penetrating wounds (e.g., wounds <6 hours old, bite wounds)	Anaerobes, facultative bacteria
Dentistry (patients with valvular heart disease)	*Staphylococcus* spp., *Streptococcus* spp., facultative bacteria, anaerobes

BOX 9.3 Considerations for Selection and Administration of Prophylactic Antibiotics

Antibiotic Selection

- Determine system involved and most likely organism (see Table 9.4)
- Cefazolin attains appropriate concentrations to prevent bacterial growth of the most common contaminants

Timing of Antibiotic Administration

30 minutes to 1 hour before first surgical incision

Cefazolin Dose

22 mg/kg

Routes of Antibiotic Administration

Intravenous; may repeat every 90 minutes depending on length of surgery

Duration of Antibiotic Administration

Discontinue immediately after closure of surgical wound or within 24 hours

however, their use may be justified in cases of severe orthopedic infections. Caution is advised when using antibiotic-impregnated collagen sponges, as they may increase the risk of SSI. In humans undergoing abdominal surgery, the evidence suggests that the application of topical antibiotics should only be considered in morbidly obese patients undergoing laparotomy where the local application of kanamycin has been shown to be of potential benefit.[6]

Use of Prophylactic Antibiotics Postoperatively

Administering prophylactic antibiotics postoperatively is commonplace in both human and veterinary medicine. The widespread use of medications in this manner likely contributes to the development of antibiotic resistance. The CDC and the European Center for Disease Prevention and Control both recommend against the use of prophylactic postoperative antibiotics because of conflicting studies regarding their efficacy and their potential contribution to antibiotic resistance.

Three recent studies[7–9] demonstrated a reduction in SSI in dogs following clean procedures where a medical device was implanted when prophylactic antibiotics were used postoperatively. One study of 97 dogs demonstrated a reduction in SSI from 21% to 4% when prophylactic antibiotics were used postoperatively (oral cephalexin or amoxicillin for 7 days[9]). A study by Andrade et al. showed no difference in SSI when prophylactic antibiotics were used postoperatively (cephalexin, cefpodoxime, amoxicillin, metronidazole, or clindamycin for 10–14 days).[3] The increased risk of SSI in clean procedures with IMDs may justify the use of postoperative prophylactic antibiotics in these cases; however, the risk/benefit ratio of such use should be considered, especially given the negative effects of such usage on the local (hospital and patient bacterial resistance) and global environment.

Therapeutic Antibiotics for Existing Infections

Therapeutic use of antibiotics is based on clinical judgment, knowledge of the antibiotic's mechanism of action (see previous discussion), and microbiologic factors. The goal is to choose a drug that (a) is selectively active for the most likely infecting microorganism(s), (b) has minimal toxicity to the host, (c) kills bacteria at the site of infection, (d) does not negatively influence the host's immune system, and (e) does not promote generation of resistance. Therapeutic antibiotics are indicated in surgical patients with a systemic infection (i.e., septicemia or bacteremia); when infection is present at the surgical site or in a body cavity (i.e., wound infection, pyothorax, or abdominal abscess); or with any contaminated or dirty surgical procedure listed in Box 9.2. In general, antibiotic therapy is instituted before surgery and continued for at least 2 to 3 days after apparent resolution of the infection; the maximum duration of therapy depends on the drug's toxicity and the disease being treated.

The larger the inoculum at a given site, the less likely the success of the antibiotic therapy. More bacteria mean (a) there may be more enzymes present promoting resistance (e.g., β-lactamases), (b) it will require a greater volume of antibiotics to affect all the bacteria, and (c) there is more possibility of resistance developing to the drugs used. Hence it is important to make the first exposure of the bacteria to the antibiotics be as effective as possible (i.e., achieve as high a drug level at the site as possible). Special considerations in the selection and administration of therapeutic antibiotics are listed in Box 9.4.

BOX 9.4 Considerations for Selection and Administration of Therapeutic Antibiotics

Antibiotic Selection

- Determine system involved and most likely pathogen, to establish primary therapy (see Table 9.4).
- Obtain representative samples for cytologic studies and culture and susceptibility testing (e.g., fluid, tissue, implants, necrotic debris). It is best to obtain samples for culture before administering antibiotics, if this wait does not put the patient at inappropriate risk.
- Ensure that antibiotic reaches target tissue.
- If several antibiotics are effective, select the one that is least expensive, least toxic, and most convenient to administer. If the patient will be discharged while still receiving antibiotics, it is often best to choose an orally administered drug.

Timing of Antibiotic Administration

As soon as samples have been obtained, begin empiric antibiotic therapy.

Dose

Follow recommended doses carefully.

Routes of Antibiotic Administration

Treat for 2–3 days and then reassess animal's condition; if improving, continue therapy; if not improving, reevaluate and consider changing antibiotics.

Duration of Antibiotic Administration

Duration depends on effect of antibiotic, toxicity, and disorder being treated.

The success of antibiotic therapy is assessed by observing the patient's response for the first 2 to 3 days of therapy. If the animal's condition has not improved by then, the antimicrobial therapy must be questioned. One should investigate whether the original diagnosis is correct; the culture and sensitivity results are accurate; the pathogen is susceptible to the antibiotic; the proper dosage, route, and frequency are being used; a foreign body or undrained focus of infection is present; a new infection is superimposed on the original infection; and/or the host's defense mechanisms are compromised. With most surgical infections, antibiotic therapy needs adjunctive therapy to be effective. This may mean drainage of accumulations of serum, pus, or blood from surgical wounds or body cavities; concurrent debridement of necrotic tissue; continued lavage of infected wounds; removal of foreign bodies or infected implants; removal of urinary calculi; removal of pus from an abdominal abscess; debridement of chronic osteomyelitis; or drainage of suppurative arthritis.

Nutritional Management of the Surgical Patient

Care of the surgical patient does not end when the procedure is finished. Postoperative care of surgical patients impacts the ultimate outcome; it may even determine survival with critical patients. Postoperative care involves monitoring vital signs, normalizing homeostasis, controlling pain (see Chapter 13), and recognizing complications early. Early recognition of potentially catastrophic conditions facilitates treatment and outcome. Recommendations for postoperative care are included throughout this textbook, with information on the management of specific diseases included in the relevant sections on postoperative care and assessment.

An important component of postoperative care is nutritional support of debilitated or hyporexic patients. Malnutrition is the progressive loss of lean body mass and adipose tissue because of inadequate intake of or increased demand for protein and calories. Possible consequences of protein-calorie malnutrition (PCM) are organ and muscle atrophy, impaired immunocompetence, ineffective wound healing, anemia, hypoproteinemia, diminished resistance to infection, and death. For these reasons, patients with PCM require nutrient supplementation.

Many conditions cause PCM, including starvation, hyporexia, malabsorption syndromes, severe trauma, surgical stress, sepsis, large surface area burns, and various malignancies. Surgery, postoperative complications, and surgically induced hyporexia also increase metabolic demand for protein and calories. PCM shows no age, sex, or breed predisposition; it is common in severely ill animals, with an incidence ranging from 25% to 65%.

Diagnosis of PCM is possible if three or more of the criteria listed in Box 10.1 are present. Physical examination may reveal poor hair coat, pressure sores or wounds that will not heal, tissue wasting, skeletal muscle atrophy, and/or emaciation. Additional physical findings depend on the cause of malnutrition. Thoracic and abdominal radiographs of malnourished patients are generally nonspecific. Imaging techniques occasionally reveal an underlying cause for the patient's hyporexia or emaciation (e.g., intestinal obstruction, abdominal or thoracic mass). Biochemical changes with PCM may include hypoproteinemia, anemia, hypoglycemia, hyperglycemia, and/or hyperlipidemia. Other changes may be related to the underlying disease.

Nutritional supplementation should not be limited to malnourished patients. Acutely ill patients with severe systemic disease (e.g., peritonitis) are unlikely to eat in the postoperative period. Inadequate food intake in critical patients causes catabolism of lean muscle tissue and leads to an acute malnourished state, as described previously. Patients that are mechanically unable to eat (e.g., maxillary/mandibular fractures, oropharyngeal tumors) should also be evaluated for methods to provide adequate nutrition.

Hyperalimentation is the administration of adequate nutrients to malnourished patients or those at risk of malnutrition. *Enteral hyperalimentation* provides nutrients to a functional gastrointestinal tract by means of a nasoesophageal, pharyngostomy, esophagostomy, gastrostomy, or enterostomy tube. *Parenteral hyperalimentation* provides nutrients intravenously; *total parenteral nutrition* (TPN) provides 100% of an animal's nutrient, protein, and caloric requirements; and *partial parenteral nutrition* provides only part of an animal's nutritional needs. In small animal medicine, *parenteral nutrition* (PN) solutions are rarely formulated to fulfill all essential nutrient requirements. Therefore the terms *central parenteral nutrition* (CPN) and *peripheral parenteral nutrition* (PPN) have been generally accepted to reflect the route that PN is administered.

Specific treatment depends on the patient's calculated energy needs, dietary formula chosen, and route of administration (i.e., enteral or parenteral). *Basal energy requirement* (BER) (also called *resting energy requirement*) is based on body weight. Traditionally, *maintenance energy requirement* is then determined by multiplying the BER by an arbitrary factor (Fig. 10.1) to accommodate for the presumptive increase in metabolism associated with the severity of the clinical problem (e.g., cage rest, postsurgical stress, trauma, cancer, sepsis, major burn). Recently, a more conservative approach of starting with BER is advocated to avoid overfeeding and subsequent complications. Such complications include hyperglycemia, gastrointestinal upset, hepatic dysfunction, and increased carbon dioxide production.

DIETS FOR ENTERAL USE

The ideal enteral dietary formula should be well tolerated, easily digested and absorbed, contain essential nutrients, be readily available and inexpensive, have a long shelf life, and be easy to use. The most cost-effective, well-balanced diets for enteral administration are those blenderized from prescription pet food or homemade diets. Caloric density and protein content vary with the diet chosen. Examples of blenderized diets and their compositions are given in Table 10.1. Blenderized diets can be administered through tubes with a diameter of size 8 French (Fr) or larger; a commercially available liquid diet is recommended when feeding through smaller diameter tubes (e.g., 5 Fr).

Liquid diets should be isotonic (i.e., approximately 300 mOsm/L), have a caloric density of approximately 1 kcal/mL, include fiber at 1 to 1.5 g/100 kcal, provide approximately 16% of total calories as protein (i.e., protein content of at least 4 g/100 kcal), and approximately 30% as fat. Liquid diets for enteral use are generally categorized as monomeric (elemental) or polymeric. *Monomeric diets* use small-molecular-weight compounds for nutrients such as crystalline amino acids as the protein source, glucose and oligosaccharides as the carbohydrate source, and medium- or long-chain triglycerides as the essential fatty acid source. These diets generally have approximately twice normal osmolality and are primarily used in patients with malabsorptive gastrointestinal disorders (e.g., short bowel

ABSTRACT

Providing nutrition to surgical patients that are debilitated or hyporexic may influence survival of these critical patients; however, nutritional supplementation should not be restricted to these patients. Acutely ill animals who are unlikely to eat in the postoperative period should also have adequate nutrition provided.

BOX 10.1 Diagnosis of Protein-Calorie Malnutrition[a]

- Weight loss of more than 10% normal body weight
- Anorexia or hyporexia (i.e., suboptimal intake of nutrients) for >5 days or an expected decrease in nutrient intake of >5 days
- Increased nutrient loss (e.g., through vomiting, diarrhea, severe wounds, or burns)
- Increased nutrient needs (e.g., due to trauma, surgery, infection, burns, or fever)
- History of chronic illness
- Serum albumin concentration ≤2.5 g/dL

[a]These are findings that suggest protein-calorie malnutrition (PCM). The more of these findings that are present, the more likely it is that PCM is present. However, not all of these will be found in a patient with PCM, and not every patient with one of these findings will have PCM.

syndrome, severe inflammatory bowel disease). A commonly used commercially available monomeric elemental diet for humans is Vivonex T.E.N. (Nestle Health Science; Table 10.2). Vivonex is low fat and lactose free, but it should only be used in dogs for short-term treatment due to protein levels that are too low to support the nitrogen and amino acid requirements of dogs and cats.

Polymeric enteral diets contain complex large-molecular-weight proteins, carbohydrates, and fats. These diets approach isotonic osmolality, require normal gastrointestinal digestive processes, supply approximately 1 kcal/mL, and are more economical than monomeric diets. They include blenderized diets, commercially available partially hydrolyzed diets, and commercially available liquid diets (see Tables 10.1 and 10.2). Commercial polymeric

TABLE 10.1 Blenderized Diets for Dogs and Cats

Homemade Diets

Liquid Diet for Dogs

Ingredients	*Nutrient Availability*
1 jar (2.5 oz) baby food	1 kcal/mL
1 cooked egg	
15 mL corn oil	
15 mL corn syrup	
100 mL water	

Liquid Diets for Cats

Ingredients	*Nutrient Availability*
Equal parts egg yolk, strained baby food, and water	1.1 kcal/mL
3 oz egg yolk	1.5 kcal/mL
3 oz strained baby food	
3 oz water	
1 tsp cooking oil	
1 T corn syrup	

Prescription Diets

Product	*Amount*	*Amount of Water Added*	*Protein Content*		*Fat Content*	
			(kcal/mL)	*(g/100 kcal)*	*(g/mL)*	*(g/100 kcal)*
Feline a/d	1 can[a]	none	1.2	8.75	0.105	5.5
	1 can[a]	1 can[c]	0.6	4.38	0.053	2.75

Preparation of Prescription and Homemade Diets

Mix the appropriate quantity of each ingredient (see chart).
Blend at high speed for 60 seconds.
Strain twice through kitchen strainer (1-mm mesh).

Advantages

Provides all required nutrients, low cost, appropriate protein and branched-chain amino acid content, normal stool consistency, manageable viscosity for 8 Fr catheter or larger.

Disadvantages

Cannot be used if the lumen diameter of the feeding tube is smaller than 8 Fr.

[a]1 can is equal to 156 g.
[b]½ can is equal to 224 g.
[c]1 can is equal to 156 mL.
[d]¾ cup is equal to 170 mL.
[e]1¼ cup is equal to 284 mL.

Calculate basal energy requirement (BER)

Animals less than 2 kg body weight: $70 \times (\text{body weight (kg)})^{0.75} = \text{BER (kcal/day)}$

Animals more than 2 kg body weight: $30 \times \text{body weight (kg)} + 70 = \text{BER (kcal/day)}$

Calculate maintenance energy requirement (MER)

Associated clinical problems	Factor
Cage rest	1.00 - 1.25
Postsurgical stress	1.25 - 1.35
Trauma or cancer	1.35 - 1.50
Sepsis	1.50 - 1.70
Major burns	1.70 - 2.00

factor chosen × BER (kcal/day) = MER (kcal/day)

Calculate volume of formula required (See Tables 10.1 and 10.2 for formula composition.)

name of formula chosen: MER (kcal/day) ÷ kcal/mL = mL of formula per day

Calculate protein requirement

Species	Maintenance	Hepatic or renal failure
Canine:	5.0 - 7.5 g/100 kcal	< 3.0 g/100 kcal
Feline:	6.0 - 9.0 g/100 kcal	< 4.0 g/100 kcal

protein requirement chosen g/100 kcal × MER (100 kcal/day) = protein requirement (g/day)

Calculate needed protein supplementation if required

name of formula chosen: protein content (g/mL) × mL of formula per day = protein provided (g/day)

protein requirement (g/day) − protein provided (g/day) = supplemental protein required (g/day) ÷ 0.76 g protein per g ProMod = grams of ProMod per day

FIG. 10.1 Formulas used to calculate basal and maintenance energy requirements for dogs and cats.

TABLE 10.2 Commercially Available Diets and Their Composition[a]

Product	Caloric Content (kcal/mL)	PROTEIN CONTENT (g/100 kcal)	PROTEIN CONTENT (g/mL)	Fat Content (g/100 kcal)	Osmolality (mOsm/kg)
Polymeric Diets					
Clinicare canine/feline	1.00	8.2	0.082	4.6	340
Monomeric Diets[b]					
Vivonex RTF	1.00	5.0	0..05	1.16	630
Vital HN	1.00	4.7	0.042	1.08	500

[a]These figures should be used for the energy requirement calculations in Fig. 10.1.
[b]There are no monomeric or elemental liquid diets available for dogs and cats. The products listed are for human use and, although they might be indicated for severe gastrointestinal disease or demonstrated intolerance of a polymeric diet, they lack essential nutrients for dogs and cats and should only be used short-term or they require supplementation. They are rarely used in veterinary medicine.

diets are available in a variety of osmolalities, caloric densities, and compositions (see Table 10.2). These diets are indicated for malnourished patients with intact digestive and absorptive functions or those suspected of having food allergies. These diets also should be used for patients that must be fed through small-diameter tubes, such as nasoesophageal, gastroduodenostomy, or enterostomy tubes. Polymeric liquid enteral diets have been shown to be effective for nutritional support in critically ill and injured animals.

DIETS FOR PARENTERAL NUTRITION

Diets available for CPN should be customized to meet an animal's protein, carbohydrate, and fat requirements; caloric needs are calculated as described in Fig. 10.1. A common composition is 8.5% amino acids with electrolytes (protein source), 10% to 20% lipids (fat source), and 50% dextrose (carbohydrate source). B-complex vitamins are added at 1 to 2 mL/L.

Diets for PPN are made with the same ingredients used for CPN except that the osmolarity of PPN solutions is diluted by using sterile water or by reducing the amount of dextrose in order to prevent thrombophlebitis. As a result, the caloric density of these solutions is reduced.

The clinical use of ready-made PN solutions in veterinary medicine has recently been described. These formulas do not require compounding and tend to be less expensive. Vamin 9 (Fresenius Kabi) is a lipid-free formula that was evaluated in 70 dogs.[1] Metabolic complications were frequent, but only hyperkalemia was associated with a negative outcome. Mechanical complications were common when this solution was administered through a peripheral vein. Procalamine is a lipid-free, moderately hyperosmolar solution that was evaluated in 36 dogs.[2] Hyperkalemia was not noted in this study; however, other electrolyte disturbances were common, particularly hyponatremia and hyperglycemia.

In vitro studies have shown that PN formulas do not directly contribute to colloid oncotic pressure; however, PN has been shown to positively affect nitrogen balance, wound healing, and the patient's recovery. Possible problems include catheter management (i.e., sterile placement, maintaining sterility of the catheter entrance, and routine changing of infusion sets), expensive equipment (i.e., infusion pump), expensive feeding formulas, technical problems (i.e., routine patient monitoring during administration, proper diet preparation, and storage), metabolic complications, and sepsis. Hyperglycemia was the most common metabolic complication noted in one veterinary study.[3] In addition, if the gastrointestinal tract is not adequately stimulated by luminal nutrients and hormonal or neurovascular mechanisms, the intestines and pancreas may atrophy. Intestinal mucosal compromise predisposes the intestinal mucosa to bacterial translocation into the portal circulation and could theoretically lead to sepsis. In general, these problems make parenteral hyperalimentation much less desirable than enteral hyperalimentation.

BOX 10.2 Drugs Used as Appetite Stimulants

Mirtazapine (Remeron)[a]
Cats: 1.9 mg/cat PO q24h: range is 1.875–3.75 mg PO q24–48h
Dogs: 0.5 mg/kg PO q24h: this usually equates to 3.75–7.5 mg PO q24h

Cyproheptadine (Periactin)
Cats: 2 mg/cat PO

Capromorelin (Entyce)
Dogs: 3 mg/kg PO qd for 4 d
Cats: FDA approval expected in 2018[b]

[a]Preferred pharmacologic appetite stimulant in cats and dogs. This drug may have dangerous interactions with other drugs, especially those that can cause a "serotonin storm" such as cytochrome P450 inhibitors (ketoconazole, cimetidine, macrolides), furazolidone, monoamine oxidase inhibitors, amitriptyline, and warfarin.
[b]Emesis, hypersalivation, lethargy/depression, head shaking, and lip smacking may be seen in cats after administration, but these signs generally resolve within 5 minutes.
PO, Orally; *q,* every.

ENHANCING APPETITE

Oral feeding is preferable to parenteral nutrition if adequate nutrients can be consumed to meet protein and caloric requirements. Several techniques have been used successfully to encourage an animal to eat. If the owners can manage the patient at home, the likelihood of eating is higher in a familiar environment. Petting and vocal reassurance are also helpful, albeit time consuming. Highly palatable foods or food coverings, such as gravy, may stimulate the appetite, and warming foods increases aroma and palatability. Supplementing potassium (i.e., 2–44 mEq/day potassium gluconate for dogs, depending on size; 2–5 mEq/day for cats), vitamin B complex (in maintenance fluids), and/or zinc may also increase appetite. Pharmacologic appetite stimulants are available; currently only mirtazapine and cyproheptadine are recommended for use (Box 10.2).[4] Cyproheptadine stimulates appetite through antagonism of serotonin (5-HT2) receptors in the ventromedial hypothalamus. It is metabolized in the liver and therefore not recommended for cats with hepatic lipidosis. Mirtazapine antagonizes presynaptic alpha-2 receptors,

causing an increase in norepinephrine, but also antagonizes 5-HT2 receptors. Mirtazapine has been shown to be an effective appetite stimulant and antiemetic in cats with chronic kidney disease.[5] Ghrelin receptor agonists (e.g., capromorelin) have recently been approved as appetite stimulants in dogs. Initial observations suggest they are usually effective.

METHODS OF PROVIDING HYPERALIMENTATION

Parenteral Nutrition

For placement of CPN catheters, patients should usually be sedated or anesthetized.

Insert a 16-gauge, 18-cm, single- or double-lumen silicone elastomer catheter into the right or left external jugular vein. Position the catheter tip in the cranial vena cava and create a subcutaneous tunnel such that the catheter hub emerges on the dorsum of the neck. Anchor the catheter to the vein, to subcutaneous tissue along the tunnel, and to skin at the exit point with 4-0 to 5-0 nonabsorbable monofilament suture. Attach an extension set to the catheter hub, and bandage the catheter in place with sterile gauze, cast padding, and self-adherent wrap. After each use flush the catheter with heparinized saline (0.9% sterile saline with 1 IU/mL heparin). Remove the neck bandage every 2 days, clean the catheter entrance site with povidone-iodine or chlorhexidine solution, change the administration set, and apply a new bandage.

NOTE Designate the catheter as a dedicated-use or sole-use catheter and do not use it for obtaining blood samples or administering other medications unless there are severe extenuating circumstances.

PPN is administered through a catheter in a small peripheral vein. Although a dedicated catheter is ideal, it is not as critical with PPN as it is with CPN. PPN is generally administered short term (e.g., <5 days) to nondebilitated patients that are unable to tolerate full enteral feeding.

Enteral Hyperalimentation

Enteral hyperalimentation is practical, safe, easy, economical, physiologic, well tolerated, and has minimal morbidity in patients with a functional gastrointestinal tract. Enteral hyperalimentation is indicated in any animal with overt or impending PCM. Such patients include those that are hypermetabolic (e.g., patients with severe burns, sepsis, postsurgical stress, trauma, or cancer) and those with chronic hyporexia or malnutrition, as evidenced by a greater than 10% loss of normal body weight. Enteral hyperalimentation can also be used whenever 3 to 5 days of anorexia are anticipated, such as after oral, pharyngeal, esophagogastric, duodenal, pancreatic, or biliary tract surgery; during postoperative management of septic or cancer patients (particularly if chemotherapy is instituted); and when the patient's mental status prevents self-feeding, such as with head trauma or after brain surgery.

Although enteral hyperalimentation is desirable for most patients with actual or pending PCM, infusion of nutrients into the intestines may be ineffective or even contraindicated in patients with small bowel obstruction that cannot be resolved and those with very severe and persistent adynamic ileus. In these patients, enteral feeding may worsen vomiting or diarrhea. Parenteral nutrition should be considered in such instances.

In general, oral alimentation is more efficient, easier, safer, and allows greater flexibility in formula composition. The further aboral materials are delivered, the less efficient the assimilation and digestion of nutrients and the greater the care necessary in choosing formula composition. Route of administration dictates feeding tube diameter (Box 10.3), which in turn dictates the usable feeding formulas. The most common routes of administration for enteral hyperalimentation are nasoesophageal, nasogastric, esophagostomy, gastrostomy, gastroduodenostomy, and enterostomy tubes. The need for pharyngostomy tubes have been largely replaced by esophagostomy tubes. Each route has its indications, contraindications, advantages, disadvantages, and complications.

BOX 10.3 Tube Diameter Used Based on Route of Administration of Enteral Diets

5 Fr Tube Diameter
- Nasoesophageal (cats, dogs <15 kg)
- Enterostomy (cats, dogs <15 kg)

8 Fr Tube Diameter
- Nasoesophageal (dogs >15 kg)
- Enterostomy (dogs >15 kg)

16 Fr or Larger Tube Diameter
- Pharyngostomy
- Esophagostomy
- Gastrostomy

BOX 10.4 Recommended Tube Sizes for Nasoesophageal Placement

Cats, dogs <15 kg: 5 Fr × 91 cm
Dogs >15 kg: 8 Fr × 91 cm

Nasoesophageal and Nasogastric Intubation

Nasoesophageal (NE) and nasogastric (NG) tubes are a primary means of short-term enteral nutrition in most veterinary patients. NE and NG intubation is easy, effective, and efficient. The availability of small-bore, soft rubber (polyvinyl chloride), and Silastic feeding tubes (i.e., 5 Fr) and of low-viscosity, nutritionally complete liquid diet formulations (see Table 10.1), in addition to patient tolerance of tube placement, have made NE and NG feeding popular. Advantages of NE and NG tubes include ease of placement, acceptance by most patients, ease of tube care and feeding, patients' ability to eat and drink around the tube, and flexibility that allows tube removal an any time after placement. In addition, NG tubes provide a means for gastric decompression. The major disadvantages of NE and NG tubes are the small tube size, inadvertent tracheal placement, and premature removal by the patient. Feeding can be accomplished through continuous rate infusion or bolus feedings because no difference has been shown with the incidence of gastrointestinal or mechanical complications. A patient may occasionally vomit out or regurgitate the tube. Light general anesthesia may be necessary to place these tubes, but a topical anesthetic or light sedation is usually sufficient.

Instill proparacaine hydrochloride (0.5–1 mL; 0.5%) into the nasal cavity and elevate the head to encourage the anesthetic to coat the nasal mucosa (Video 10.1). Repeat the application to ensure adequate anesthesia of nasal mucous membranes. If the patient will not tolerate nasal intubation, consider topical lidocaine (e.g., 1–2 mL of 2% lidocaine), heavy sedation, or light general anesthesia. Select an appropriate-sized feeding tube (Box 10.4). For NE tubes, estimate the length of tube to be placed in the esophagus by measuring the tube from the nasal planum, along the patient's side, to the seventh

FIG. 10.2 Direct the nasoesophageal tube from ventrolateral in the external nares to caudoventral and medial as the tube enters the nasal cavity.

FIG. 10.3 In cats, secure nasoesophageal feeding tubes to the dorsal nasal midline and forehead.

or eighth intercostal space. For NG tubes, measure the tube from the nasal planum, along the patient's side, to the last rib. Place a tape marker on the tube once the appropriate measurement has been taken. Before passing the tip of the tube, lubricate it lightly with 5% viscous lidocaine and hold the patient's head in a normal functional position (i.e., avoid hyperflexion or hyperextension). Identify the prominent alar fold and direct the tube from a ventrolateral location in the external nares to a caudoventral and medial direction as it enters the nasal cavity (Fig. 10.2). When the tube has been introduced 2 to 3 cm into the nostril, contact with the median septum at the floor of the nasal cavity can be felt. *Push the external nares dorsally to facilitate opening of the ventral meatus. Elevate the proximal end of the tube and advance it into the oropharynx and esophagus.* It will generally "drop" into the oropharynx and stimulate a swallowing reflex. Several methods can be used to confirm placement in the esophagus or stomach: (1) check for negative pressure, (2) inject 3 to 5 mL of sterile saline through the tube and see if a cough is elicited, (3) inject 6 to 12 mL of air and auscultate for borborygmus at the xiphoid, (4) connect the tube to a capnograph, (5) check the pH of aspirated fluid, or (6) confirm tube placement using a lateral thoracic radiograph. If the patient requires general anesthesia, correct tube placement can be visually confirmed using a laryngoscope. *Once satisfied that the tube has been properly placed, suture it to the nose and head to prevent removal by the patient using 3-0 monofilament nonabsorbable suture (e.g., nylon). In cats, it is important that the tube is not in contact with the whiskers; position it directly over the dorsal aspect of the nose and forehead (Fig. 10.3), and secure it with a Chinese finger-trap friction suture (see p. 924). In dogs, secure the tube to the lateral aspect of the nose and dorsal nasal midline with a Chinese finger-trap friction suture or cyanoacrylate glue. Place a column of water in the tube before capping it to prevent air intake, reflux of esophageal contents, or occlusion of the tube by diet.*

NOTE Use an Elizabethan collar immediately after surgery until it is determined if the patient will tolerate the NE or NG feeding tube.

When comparing the use of NE versus NG tubes in dogs, NE tubes tended to be implemented in younger dogs.[6] There was no difference in the overall low complication rate between NE and NG tubes.

Nasojejunal Tubes

Direct intestinal feeding can be accomplished through placement of long, weighted nasojejunal tubes for patients where gastric feeding is contraindicated or poorly tolerated. Fluoroscopy or endoscopy is required to ensure placement of the end of the tube beyond the duodenal flexure. As the tubes are slightly larger than what would be used for NG tubes, complications such as sneezing, nasal discharge, and vomiting are common.

Esophagostomy Tubes

Esophagostomy tubes are now the primary means of long-term enteral feeding in most veterinary patients. Esophagostomy feeding is indicated in hyporexic patients with disorders of the oral cavity or pharynx and those with a functional gastrointestinal tract distal to the esophagus. These tubes are contraindicated in patients with primary or secondary esophageal dysfunction, such as with esophageal stricture, postesophageal surgery, removal of an esophageal foreign body, or with esophagitis or megaesophagus. Advantages of esophagostomy tubes include ease of placement, acceptance by patients, placement of large-bore tubes that allow blenderized diets, ease of tube care and feeding, patients' ability to eat and drink around the tube, and flexibility that allows tube removal any time after placement. Esophageal tube placement eliminates the coughing, laryngospasm, partial airway obstruction, and aspiration that can be associated with improperly placed pharyngostomy tubes. The major disadvantage of esophagostomy tubes is the need for general anesthesia for tube placement.

Anesthetize the animal and place it in right lateral recumbency (left side uppermost) (Video 10.2). The tube may be placed on either the right or left side of the midcervical region; however, the esophagus lies left of the midline, making left-sided placement more desirable. *Prepare the midcervical area from the angle of the mandible to the thoracic inlet for aseptic surgery. Premeasure a 16 to 24 Fr polyvinyl chloride feeding tube from its insertion point to the level of the seventh or eighth intercostal space (ensuring mid-esophageal to caudal-esophageal placement), and mark it. Alternatively, have an additional tube of identical length available to assess length of placement of the original tube. Enlarge one lateral opening of the feeding tube to encourage smoother flow of a blended diet (Fig. 10.4) or cut the end of the tube off at an oblique angle.* A curved Rochester-Carmalt is used for esophagostomy tube placement in

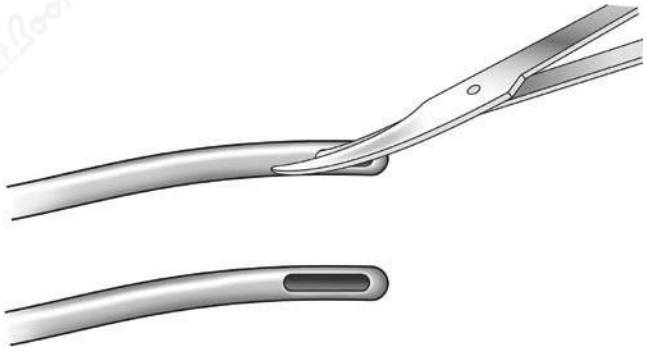

FIG. 10.4 For esophagostomy tube, enlarge the lateral openings of the tubes 3 to 4 mm to encourage a smooth flow of blended diets.

cats and small to medium sized dogs; however, an ELD feeding tube placement device (Fig. 10.5) or similar product can be used in large dogs. *Place the curved tip of the forceps through the oral cavity into the esophagus to the level of the midcervical region (i.e., equidistant from the angle of the mandible and the point of the shoulder). Palpate the tip as it bulges through the cervical skin. Make a small incision over the tip and push the forceps through the esophageal wall, subcutaneous tissue, and skin. Grasp the tube with the forceps, apply a small amount of lubricant, and pull the tube through the incision and out the oral cavity. Redirect the tube down the esophagus using forceps, a stylet, or digital manipulation. Confirm length of placement by location of the premarked area on the tube or by comparing to a tube of identical length. Secure the tube to the cervical skin using a Chinese finger-trap friction suture with 2-0 monofilament nonabsorbable suture (e.g., nylon). Bandage the tube loosely around the neck. Place a column of water in the tube, and cap the exposed end.*

Alternatively, for large dogs, use an ELD device instead of Rochester-Carmalt forceps. The ELD is placed through the oral cavity into the midcervical area of the esophagus. A small skin incision is made over the ELD tip as it protrudes through the skin. The spring-loaded blade is activated by pushing the plunger at the end of the handle. The trocar should be visible through the skin incision, but the tissues around it can be carefully dissected using a scalpel blade such that the entire shaft of the instrument protrudes through the incision (Fig. 10.6A and B). *Place a 2-0 nonabsorbable suture through the side holes of the feeding tube and the hole in the instrument trocar. Tighten the suture until the tip of the instrument blade and the tip of the feeding tube are in close apposition (see Fig. 10.6C). Retract the blade into the instrument shaft so that the tip of the feeding tube enters the instrument shaft (i.e., deactivating the instrument blade), and lubricate the tube and the instrument shaft. Retract the instrument and pull the feeding tube into the oral cavity to its predetermined measurement (Fig. 10.7A). Remove the suture to free the feeding tube from the instrument blade and, in dogs, place a stylet through one of the side holes of the feeding tube and against its tip (see Fig. 10.7B). Lubricate the tube and advance it into the esophagus until the entire oral portion of the feeding tube disappears (see Fig. 10.7C) and the tube passes down the esophagus without twisting or bending. Carefully retract the stylet from the oral cavity to ensure its release from the tube. Secure the tube to the cervical skin with a Chinese finger-trap friction suture with 2-0 monofilament nonabsorbable suture (e.g., nylon; see p. 924). Bandage the tube loosely around the neck. Place a column of water in the tube, and cap the exposed end.*

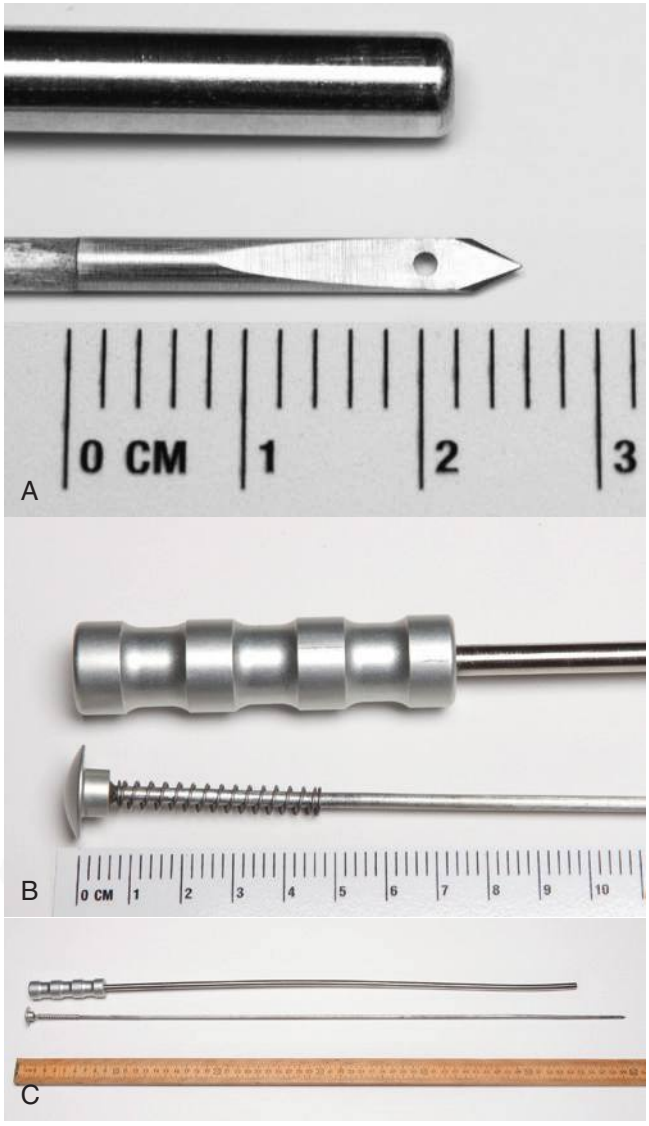

FIG. 10.5 (A) ELD feeding tube placement device and stylet. (B) Activated spring-loaded blade *(top)* and stylet *(bottom)*. (C) Complete trochar and cannula, disassembled, with a ruler to show length. (From Devitt CM, Seim HB III. Clinical evaluation of tube esophagostomy in small animals. *J Am Anim Hosp Assoc.* 1997;33:55.)

A one-step technique for esophagostomy tube placement in cats has been described using a specific applicator (von Werthen esophageal feeding tube applicator; B. Braun Vet Care) or using a large gauge, over-the-needle catheter. The disadvantage of the latter technique is the small diameter of the tube that can be placed by this method.

NOTE In dogs and cats, a small diameter, rigid endoscope can be used to direct the tube into the esophagus and ensure that there are no kinks or other problems. A lateral thoracic radiograph can also confirm appropriate placement.

Most patients tolerate esophagostomy tubes, and Elizabethan collars are seldom necessary. Esophagostomy tubes can be safely removed immediately after placement or can be left in place for several weeks or months. The tube exit site may require light

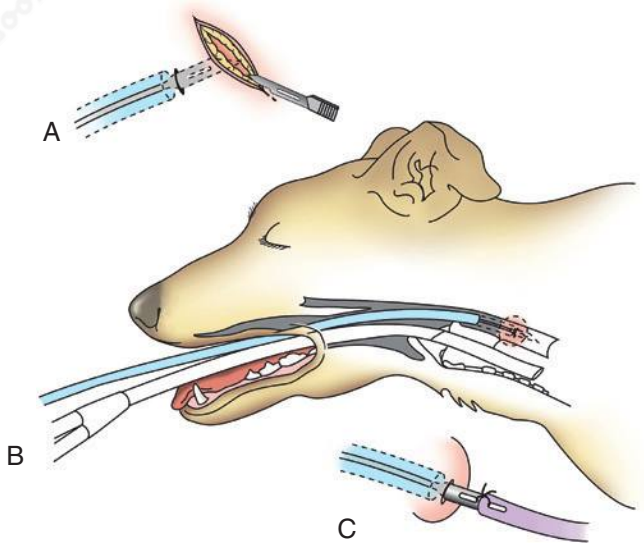

FIG. 10.6 Esophageal tube placement. (A) Place the instrument shaft in the oral cavity and palpate the tip as it bulges the cervical skin; make an incision over the tip. (B) Activate the instrument blade until it is visible through the skin incision; enlarge the incision to allow penetration of the instrument shaft. (C) Use 2-0 nonabsorbable suture (e.g., nylon) to secure the tip of the feeding tube to the tip of the blade; retract the blade so that the tip of the feeding tube contacts the instrument shaft.

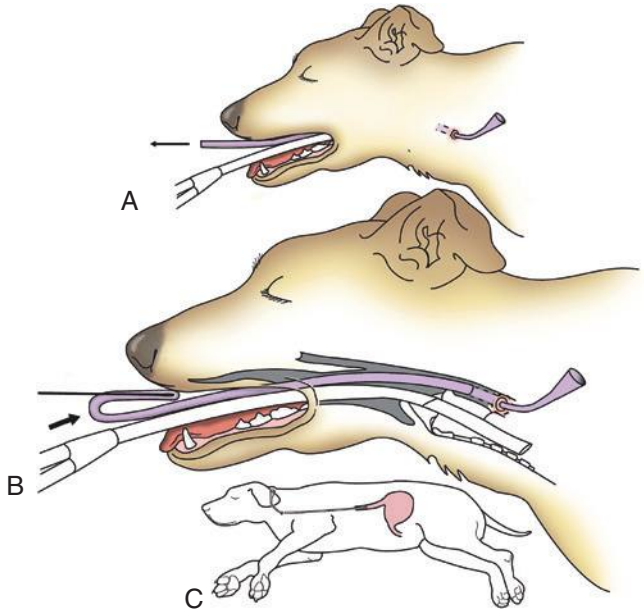

FIG. 10.7 Esophageal tube placement (continued from Fig. 10.6). (A) Retract the instrument and pull the feeding tube into the oral cavity. (B) In dogs, place a stylet into one of the lateral holes of the feeding tube and against its tip; advance the tube into the esophagus. (C) The esophageal tube should lie in the mid-esophageal region.

bandaging and periodic cleaning with an antiseptic solution. The tube is removed by cutting the finger-trap suture and gently pulling the tube through the skin. No further exit wound care is necessary; the hole seals in 1 or 2 days and is healed by 4 to 5 days.

Complications associated with esophagostomy tube placement include early removal by the patient or vomiting the tube up and chewing off the end. Esophageal perforation has occurred in cats but is unlikely if a stylet is not used. Esophageal perforation is not expected in dogs. Significant complications (e.g., jugular vein laceration, carotid artery laceration, esophagitis, esophageal stricture, esophageal diverticulum, subcutaneous cervical cellulitis) are rare. Reflux esophagitis can occur from improper tube placement (i.e., through the lower esophageal sphincter), or the tube itself can irritate esophageal tissue. Making sure that the distal tip of the soft rubber or Silastic tube is in the midesophageal region notably reduces the incidence of esophageal injury and reflux esophagitis.

Gastrostomy Tubes

Gastrostomy tubes are indicated in patients with a functional stomach and gastrointestinal tract that are anorexic, at risk for PCM, or are undergoing operations of the oral cavity, larynx, pharynx, or esophagus. These tubes are avoided in patients with primary gastric disease (e.g., gastritis, gastric ulceration, gastric neoplasia). Advantages of gastrostomy tubes include ease of placement, patient tolerance, availability of large-bore feeding tubes, ease of feeding and tube care, and that oral feeding can begin or continue while the gastrostomy tube is in place. Disadvantages include the need for general anesthesia and potentially specialized equipment (e.g., an endoscope), invasion of the peritoneal cavity, and inability to remove the tube for at least 7 to 14 days postplacement (i.e., the time needed to allow adhesion formation between the stomach and abdominal wall). Premature removal puts the animal at risk for peritonitis from gastric contents leaking into the abdomen. Very large dogs may be problematic as it can sometimes be difficult to achieve a good adhesion between the stomach and the abdominal wall when placing a gastrostomy tube with a device or an endoscope. In these circumstances, it may be best to place the gastrostomy tube surgically. In addition, tubes placed blindly using a large stomach tube or spring-loaded device can easily be malpositioned such that they are placed at the lower esophageal sphincter (resulting in vomiting and gastroesophageal reflux) or so far caudally that the stomach may pull off the tube when the stomach is filled with food. Rarely the tube may be associated with gastric bleeding. Low-profile gastrostomy ports are sometimes used in animals for which long-term nutritional management or medication administration is needed.

Methods of placement of gastrostomy tubes include blind (nonendoscopic) percutaneous gastrostomy, percutaneous endoscopic gastrostomy (PEG), or surgical placement through a left flank approach or midline laparotomy.

Percutaneous Endoscopic Gastrostomy Tube Placement

Advantages of endoscopic placement is that tube placement occurs under direct visualization, and gastric insufflation displaces omentum, mesentery, spleen, and small intestines, which decreases risk of iatrogenic damage. This technique may not be appropriate for larger animals (e.g., >25 kg) because it can be hard to ensure that an adequate adhesion will form between the stomach and the abdominal wall at the ostomy site. Recently it was shown that animals receiving a PEG tube while concurrently on corticosteroid therapy had a significantly higher rate of major complications when compared to animals with PEG tubes not on corticosteroid therapy.[7] There are various commercial kits available containing the necessary equipment for placing

gastrostomy tubes. The general idea of placement (which may vary slightly, depending upon the kit) is as follows:

Place the animal under general anesthesia. Position the animal in right lateral recumbency and clip and prep the area caudal to the last rib. The animal is positioned in right lateral recumbency, and the area caudal to the last rib is clipped and aseptically prepped. Pass the endoscope into the stomach, and insufflate the stomach with air. Make a 1 mm skin incision in the left flank 1 to 2 cm caudal to the last rib and 2 to 3 cm distal to the transverse spinous processes of lumbar vertebrae two or three. Pass an 18-gauge needle through the skin incision and into the stomach lumen. Pass the strand of the suture material provided by the kit through the needle and into the stomach, retrieve it using endoscopic grasping forceps, and bring it out through the mouth. Once the strand of suture is entering the left flank and exiting the oral cavity, attach the suture to the feeding tube as directed by the kit instructions. In large dogs, a percutaneous suture of No. 1 monofilament nonabsorbable material can be placed from through the skin and abdominal wall, into the gastric lumen, back out of the skin, and tied under direct visualization with the endoscope. This keeps the stomach in apposition with the body wall so it is more likely for a strong adhesion to form, protecting the peritoneal cavity from leakage.

Blind Percutaneous Gastrostomy Tube Placement

This technique should only be performed after one has done several gastrostomy tube placements using endoscopic guidance to help better understand the anatomy of the stomach and configuration within the abdominal cavity. Advantages of this technique are that no special instrumentation is required for placement and it is easy to perform. Disadvantages are that the stomach is not surgically pexied to the body wall (early removal by the patient could result in peritonitis), novices can easily malposition the tube too far orad or too far caudad in the stomach, it is possible to penetrate and trap omentum, mesentery, or spleen, and tube placement must be confirmed endoscopically or radiographically.

Placement of the blind percutaneous gastrostomy tube is performed similarly to PEG tubes described earlier except that entrance of the hypodermic needle into the stomach is performed blindly. *Place the animal under general anesthesia. Position the animal in right lateral recumbency and clip and aseptically prepare the area caudal to the last rib. The animal is positioned in right lateral recumbency, and the area caudal to the last rib is clipped and aseptically prepped. Pass a stiff, large-bore stomach tube or feeding tube placement device (e.g., ELD; Fig. 10.8A) into the stomach until it can be palpated bulging against the left body wall 1 to 2 cm caudal to the last rib and 2 to 3 cm distal to the transverse processes of lumbar vertebrae two or three. If a stomach tube is used, pass an 18-gauge hypodermic needle through the skin into the lumen of the stomach tube. Place the suture strand through the needle, into the stomach tube, and out through the mouth. Remove the stomach tube. If a feeding tube placement device is used (see esophagostomy tube placement earlier), activate the device and thread the suture through the hole in the instrument blade (see Fig. 10.8B). Retract the blade into the instrument shaft and withdraw the instrument out through the mouth (see Fig. 10.8C).* In each case the suture enters the stomach through the left flank and exits through the oral cavity. *Attach the end of the suture to the gastrostomy tube. Pull the No. 1 suture exiting the left flank until the catheter tip exits the skin (see Fig. 10.8D). Enlarge the skin incision to 3 to 4 mm, allowing easy delivery of the catheter. Pull the catheter until the mushroom tip is snugly against the body wall, ensuring a seal between the stomach wall and the body wall (see Fig. 10.8E). Secure the tube to the skin with a Chinese finger-trap suture using 2-0 nonabsorbable suture (e.g., nylon). Alternatively, use the piece of tube previously cut off to create an external flange.*

Flank Incision Gastrostomy Tube Placement

Advantages of this technique include ease of tube placement, ease of finding the stomach in an anorexic patient, quick placement, no need for special equipment, creation of an initial seal between the stomach wall and the body wall, and confirmation of proper placement during the procedure. The disadvantage is lack of visualization of gastric anatomy, which may cause malpositioning of the tube.

Prepare the patient as described previously, but in addition, place quarter-towels and a fenestrated drape over the left flank to create a sterile field. Have a nonsterile assistant pass a large-bore, stiff plastic tube into the stomach. The surgeon, who is sterile, palpates the left flank area until the end of the stomach tube can be palpated and grasped (Fig. 10.9A). Manipulate the tube to a location 2 to 3 cm caudal to the thirteenth rib and 2 to 3 cm distal to the transverse processes of the lumbar vertebrae. Hold the tube stable and make a skin incision over the end of the stomach tube. Bluntly dissect the subcutaneous tissues and abdominal muscles to expose the wall of the stomach over the tube; take care not to enter the lumen of the stomach (see Fig. 10.9B). Place a purse-string suture in the stomach wall around the tube (see Fig. 10.9C). Use a No. 11 scalpel blade to make a stab incision into the lumen of the stomach in the middle of the purse-string suture; make the incision large enough to easily accommodate the selected tube. Place a 20 to 24 Fr Foley catheter into the lumen of the stomach and inflate the bulb (see Fig. 10.9D). Place traction on the purse-string suture and slowly withdraw the stiff stomach tube from the oral cavity. Place gentle traction on the Foley catheter to bring the inflated bulb against the stomach wall (see Fig. 10.9E). Snugly tie the purse-string suture around the Foley catheter. Place three to four simple interrupted 2-0 absorbable sutures (e.g., PDS or Maxon) from the stomach wall to the body wall to firmly pexy the stomach in place. Close the subcutaneous tissue and skin around the existing Foley catheter, push the Foley catheter 1 to 2 cm into the stomach lumen, and secure the Foley catheter to the skin with a Chinese finger-trap friction suture with 2-0 nonabsorbable suture (see Fig. 10.9F).

Gastrostomy Tube Placement by Midline Laparotomy

This procedure is generally performed when tube placement is ancillary to another abdominal procedure, such as biopsy or removal of an abdominal mass. Advantages to this method are that placement is directly visualized, and a secure surgical gastropexy can be performed. The disadvantage is that placement is more invasive when compared to the techniques listed previously due to the surgical approach.

Pass the distal end of a 20 Fr Foley or Pezzer catheter (i.e., bulb or mushroom tip) into the abdominal cavity through a stab incision in the left body wall. Exteriorize the stomach and place a purse-string suture in the ventrolateral wall of the body of the stomach. Make a stab incision in the center of the purse-string suture with a No. 11 scalpel blade and place the distal end of the feeding catheter in the lumen of the stomach. Tighten the purse-string suture around the catheter and inflate the catheter bulb (i.e., Foley catheter) with saline. Place gentle traction on the catheter to bring the body of the stomach in close apposition to the left body wall. Pexy the stomach wall to the abdominal wall with four 2-0 or 3-0 synthetic standard absorbable sutures (e.g., polydioxanone or polyglyconate). Secure the feeding tube to the skin with a Chinese finger-trap suture of 2-0 nonabsorbable suture (e.g., nylon). Close the abdomen routinely.

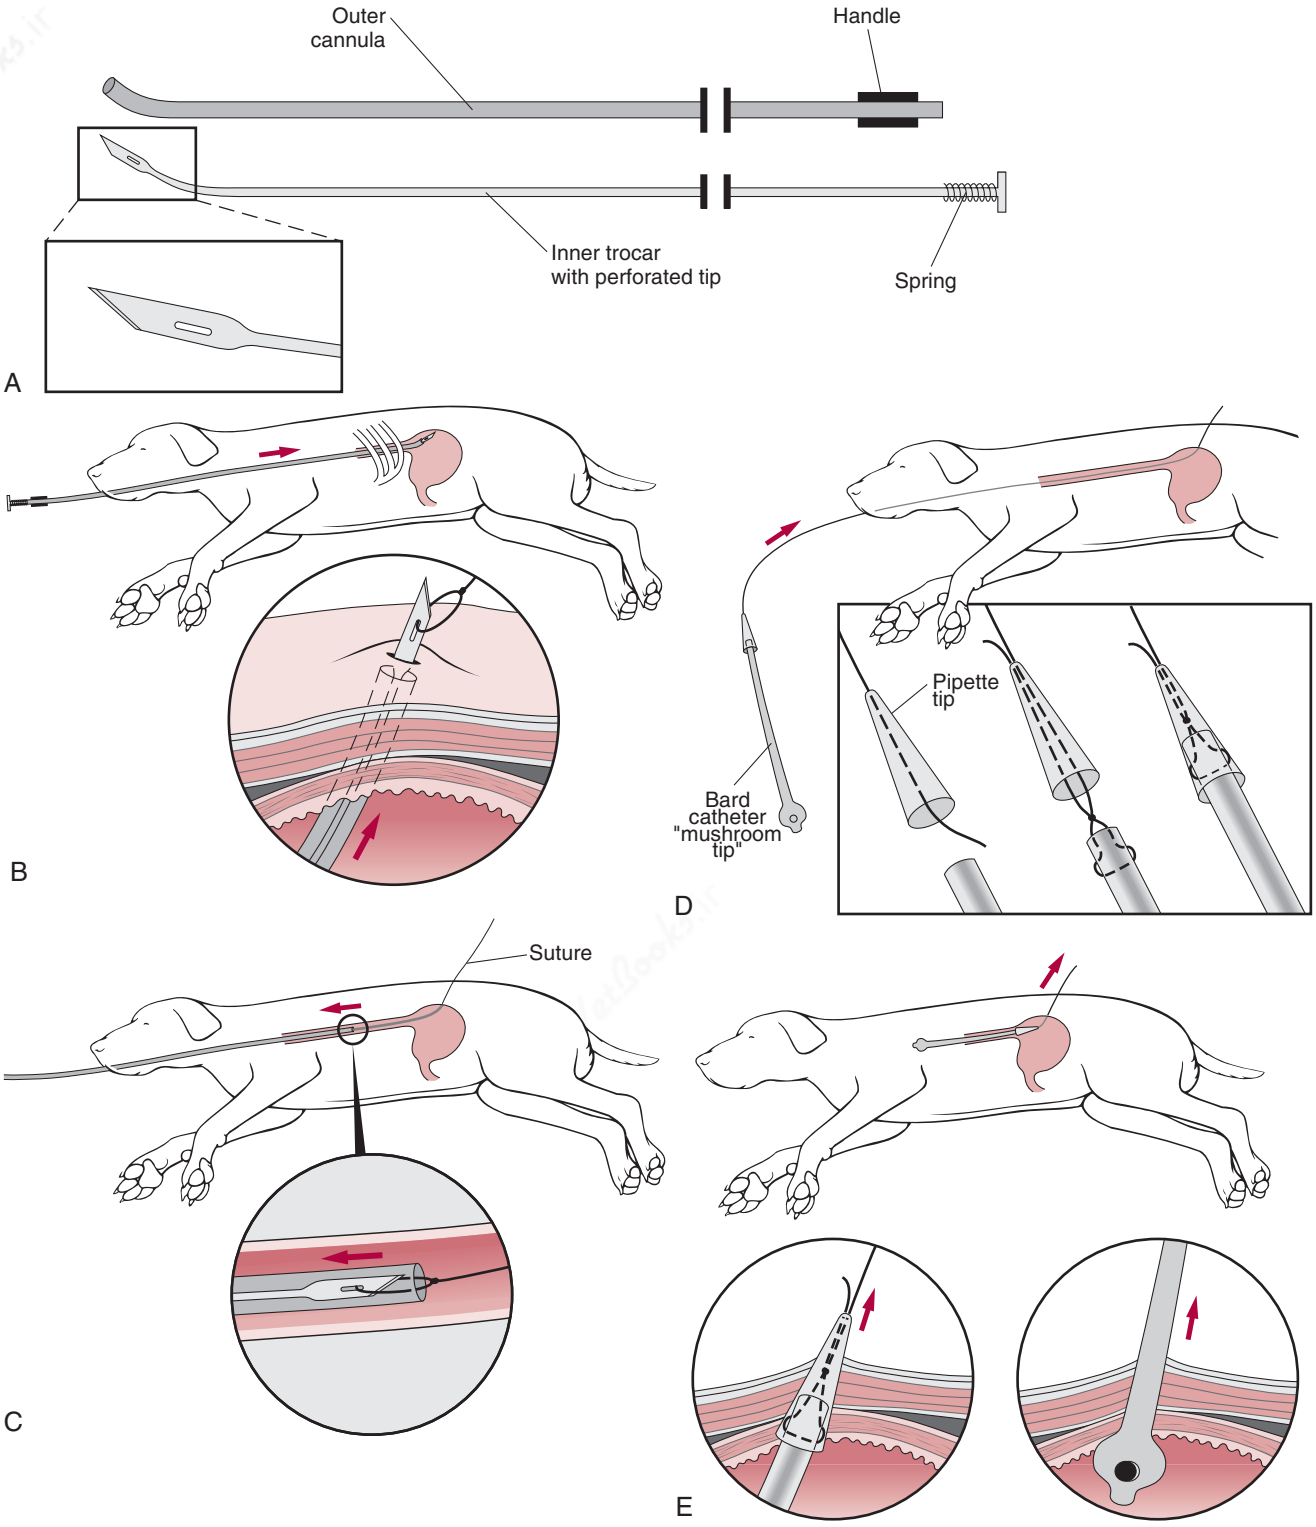

FIG. 10.8 (A) Schematic view of a device designed to place gastrostomy tubes without endoscopy. The trocar *(lower)* is placed through the cannula *(upper)*. The cutting tip *(inset)* is not extended until the device has been properly placed. (B) Schematic view showing how the device is placed in an animal receiving a gastrostomy tube. Note that the tip of the device ultimately arrives at a point 2 to 3 cm caudal to the last rib and 2 to 3 cm distal to the transverse processes of lumbar vertebrae two or three. Push the trocar tip through the cannula so that the blade tip extends through the skin *(insert),* and tie a suture to the tip. (C) Retract the entire device (cannula and trocar) through the mouth, bringing the suture with it. (D) Fasten the end of the suture that is brought out of the mouth to the tip of a mushroom-tip catheter. Note how a pipette tip is placed where the suture attaches to the tip of the catheter. (E) Pull the suture through the skin, pulling the mushroom-tip catheter into the stomach. The pipette tip facilitates passage of the catheter through the abdominal wall. Withdraw the catheter until the mushroom tip is against the gastric mucosa; the stomach is pulled snugly against the abdominal wall.

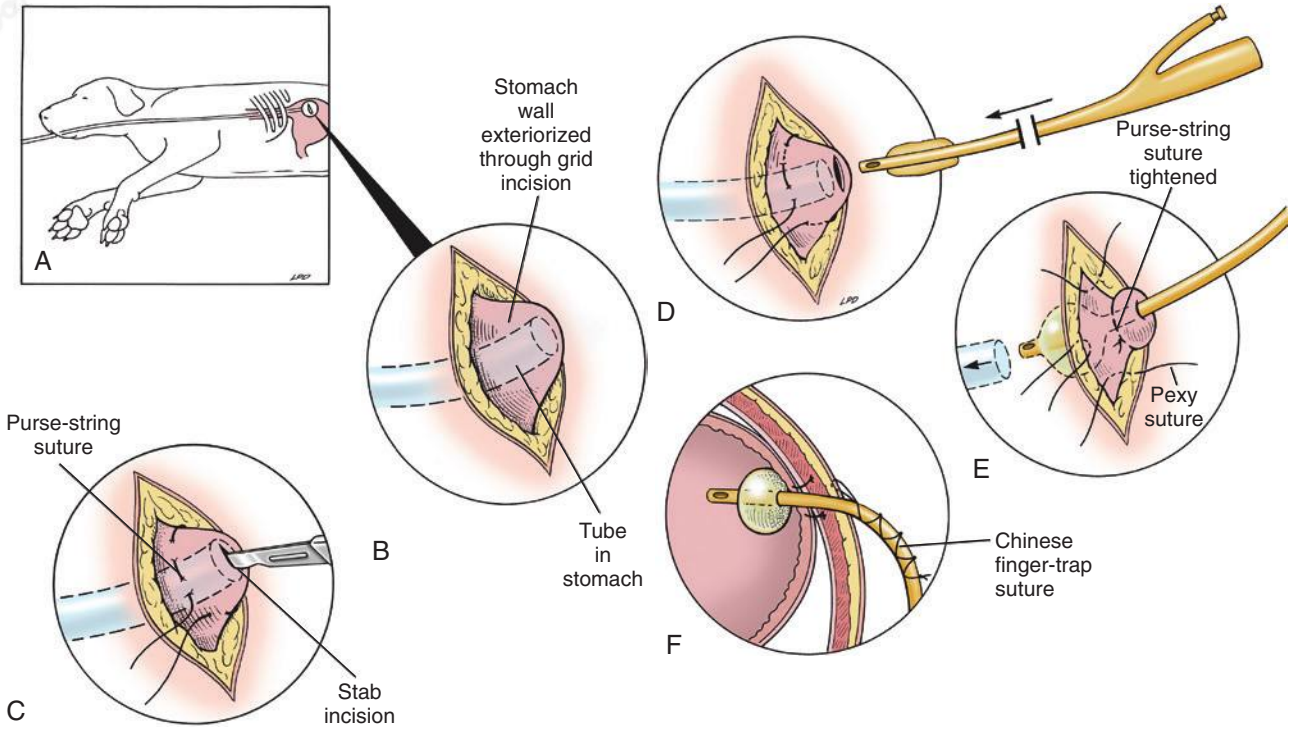

FIG. 10.9 Percutaneous gastrostomy tube placement with gastropexy. (A) Pass a large-bore, stiff plastic stomach tube into the stomach. Palpate the end of the tube at the flank. (B) Grasp the tube and move it to a point 2 to 3 cm caudal to the thirteenth rib and 2 to 3 cm distal to the transverse processes of the lumbar vertebrae. Secure the tube with thumb and finger, make an incision through the skin and subcutaneous tissue, and bluntly dissect the abdominal muscles to expose the gastric wall over the tube. (C) Place a purse-string suture in the gastric wall around the tube and puncture the wall with a scalpel blade. (D) Place the Foley or Pezzer catheter into the lumen of the stomach and into the tube. (E) Tighten the purse-string suture, remove the stomach tube, inflate the bulb of the Foley catheter, and suture the gastric wall to the abdominal wall. (F) Note the proper tube placement of the inflated Foley catheter, the gastropexy, and the Chinese finger-trap friction suture to secure the tube in place.

Low-Profile Gastrostomy Tube Devices

Various low-profile gastrostomy tube devices are available in different configurations and generally serve two main functions. First, some owners prefer to use them when a PEG tube will be required for a lengthy period because the low-profile devices do not have a long tube exiting the body, which makes them aesthetically more appealing. Tubes that do not "dangle" from the body may also be easier to care for (i.e., they are less likely to be pulled out or chewed out by the patient). Second, and perhaps the major value of low-profile devices, is that they allow quick and easy replacement of gastrostomy tubes that have inadvertently been pulled out or have so deteriorated that they must be replaced. The low-profile device is inserted into the stoma made by the first gastrostomy tube. However, these stomas close rapidly (i.e., <24 hours) after removal of the gastrostomy tube; therefore speed is of the essence. If the patient cannot be seen within several hours after removal of the first gastrostomy tube, a relatively large-diameter sterile red latex male urinary catheter or similar tube should be placed in the stoma to prevent it from closing down until the low-profile device can be placed.

NOTE If you need to replace a gastrostomy tube but do not have a low-profile device, simply insert the string through the existing gastrostomy tube before removal and use it to place a second, regular gastrostomy tube.

The most catastrophic complication associated with gastrostomy tubes is leakage of gastric contents into the abdominal cavity with subsequent generalized peritonitis. This may occur with premature tube removal, when overfeeding large breed dogs (i.e., a very heavy stomach can pull the stomach off the tube), or secondary to improper placement of a low-profile tube when trying to replace an old gastrostomy tube. This complication can generally be prevented by using a technique that results in a sutured pexy of the stomach to the body wall (flank or midline surgical approach). Other complications of gastrostomy tubes include vomiting, peristomal infection (relatively common, although often minor and easily managed), and migration of the tip of the catheter into the pylorus. The balloon on Foley-type catheters usually disintegrates over time; hence, these catheters are not always optimal for long-term use. There are many

dedicated gastrostomy catheters that have mushroom tips that can last for months. As noted previously, low-profile gastrostomy devices may be better tolerated by owners when tubes are needed to remain in place for some time (e.g., dogs with megaesophagus, esophageal stricture, chronic renal failure).

Enterostomy Tubes

Enterostomy (jejunostomy) feeding tubes are indicated in patients with gastric, intestinal, or pancreatic disease and in patients having biliary tract surgery in which the intestinal tract distal to the disease or surgical site is functional. Immediate feeding of a highly digestible, low-bulk diet in patients undergoing colonic surgery or that will undergo colonic surgery can be accomplished using an enterostomy feeding tube. Patients with preexisting PCM that must have major abdominal surgery are candidates for early enteral hyperalimentation by means of an enterostomy tube.

The main reason to use enterostomy tubes is to bypass a dysfunctional stomach or duodenum. Flexible endoscopy, laparotomy, or laparoscopy is required for placement of an enterostomy feeding tube. A 5 Fr, 90-cm infant feeding tube is recommended for cats and for small and medium size dogs. An 8 Fr feeding tube may be used in large and giant breed dogs. Due to the small size of the tubes, liquid diet formulations are used for nutritional supplementation. Enteral feeding through enterostomy tubes is typically performed in a hospitalized setting as a continuous rate infusion to minimize the chance of discomfort associated with overdistension of the intestine. Although premature removal and associated peritonitis is the most significant complication associated with jejunostomy tubes, this event is uncommon. A 2016 study of 64 dogs with jejunostomy tubes placed during abdominal surgery found a 22% rate of complications, none of which was life-threatening.[8] Diarrhea (high fecal score) is expected following intestinal feeding regardless of diet chosen.

Enterostomy Tube Placement by Flexible Endoscopy

Nasoenterostomy tubes may be placed by flexible endoscopy. *Place a guidewire, flexible end first, through the nose and into the oropharynx. Grasp the tip of the guidewire with flexible endoscopic forceps placed through the endoscope, and then pass the endoscope into the duodenum, "dragging" the guidewire into the distal duodenum with it. Then, release the tip of the guidewire and withdraw the endoscope from the patient. Next, introduce the feeding tube over the guidewire and advance it until the tip of the feeding catheter is present in the distal duodenum or proximal jejunum. Carefully remove the guidewire and fix the tube to the external nares as described under nasoesophageal tubes.*

Surgical Placement of Enterostomy Tube

Bring the distal tip of the feeding tube into the abdominal cavity through a 2- to 3-mm stab incision made on the right or left body wall with a No. 11 scalpel blade or a 10-gauge hypodermic needle (Fig. 10.10 and Video 10.3). Select a segment of proximal jejunum and identify the normal direction of flow of ingesta (i.e., aboral and oral end). Ensure that the selected intestine is easily mobilized to the feeding tube entrance on the body wall. Make a 1- to 1.5-cm linear incision in the seromuscular layers of the antimesenteric border of the selected jejunal segment (Fig. 10.11A). Use a No. 11 scalpel blade to enter the lumen of the jejunum at the most aboral end of the incision. Insert the distal end of the feeding tube through the incision and pass 10 to 12 inches (25 to 30 cm) of the tube in an aboral direction into the jejunal lumen. Position the exiting

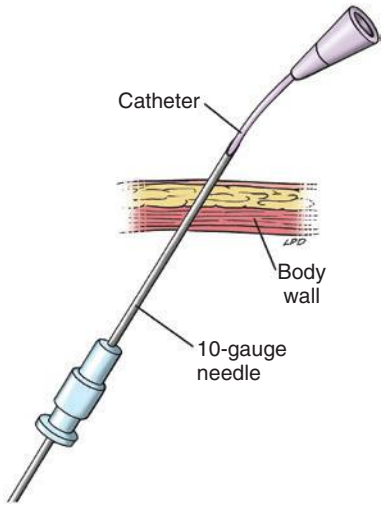

FIG. 10.10 For placement of an enterostomy tube, a 10-gauge hypodermic needle facilitates transabdominal placement of a 5 Fr feeding tube.

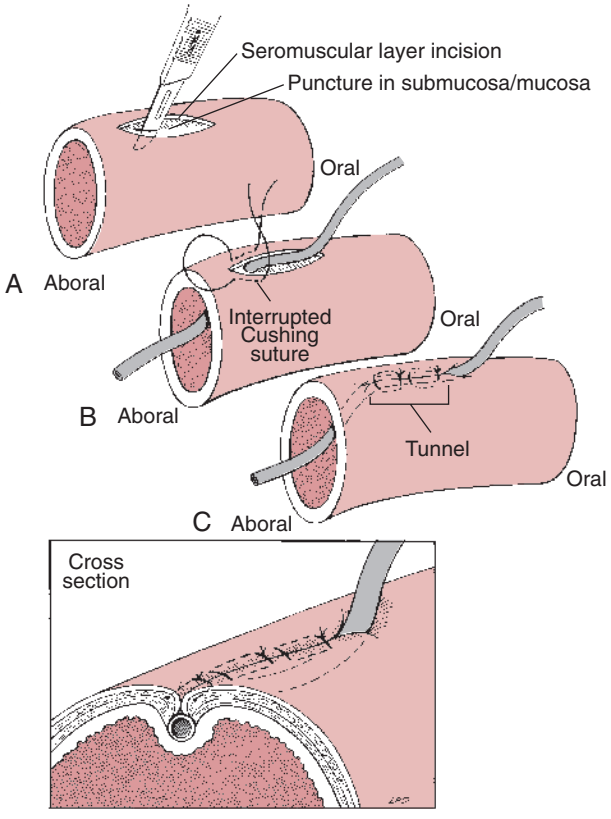

FIG. 10.11 Placement of an enterostomy tube. (A) Make a 1- to 1.5-cm linear incision in the seromuscular layers of the antimesenteric border of the selected jejunal segment; use the tip of a scalpel blade to puncture a hole in the aboral aspect of the seromuscular incision. (B) and (C) Place the distal end of the feeding tube through the incision; lay the exiting portion of the tube in the 1- to 1.5-cm seromuscular incision and construct a "tunnel" by inverting the seromuscular layer over the tube with three or four Cushing sutures of 4-0 absorbable material.

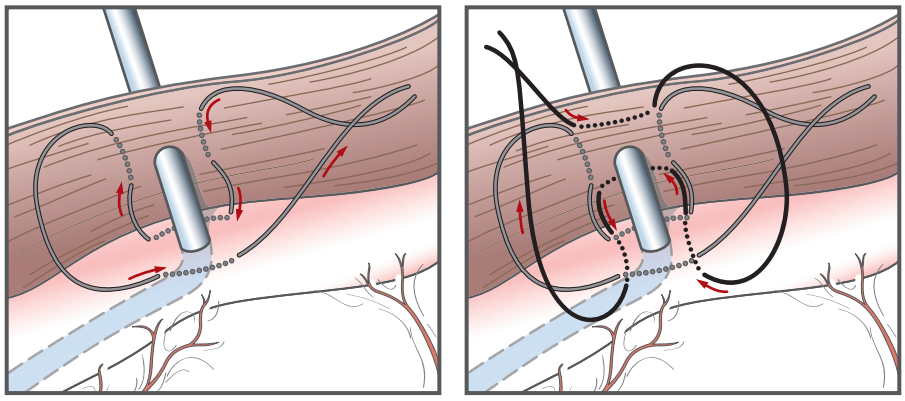

FIG. 10.12 Interlocking box technique for securing enterostomy tubes to the abdominal wall.

portion of the tube in the 1- to 1.5-cm seromuscular incision, and suture it in this "tunnel" by inverting the seromuscular layer over the tube with three or four Cushing or horizontal mattress sutures of 4-0 or 5-0 synthetic monofilament absorbable suture material (e.g., polydioxanone or polyglyconate) (see Fig. 10.11B–C). Alternatively, place a small purse-string suture in the antimesenteric border using 4-0 or 5-0 synthetic monofilament absorbable suture material. Use a No. 11 scalpel blade to make a stab incision in the middle of the purse-string suture and insert the feeding tube as described earlier. Tighten the purse-string suture.

In an in vitro study, no significant difference in bursting pressure was found between purse-string and seromuscular incision techniques.[9]

Pexy the jejunal tube exit site to the exit site at the body wall with four to five simple interrupted sutures of 4-0 standard absorbable suture (e.g., polydioxanone or polyglyconate); secure the feeding tube to the skin using a Chinese finger-trap friction suture of 3-0 nonabsorbable material (e.g., nylon). Alternatively, an interlocking box technique (Fig. 10.12) has also been described in which two complete suture boxes are placed and secured between the jejunal segment and abdominal wall. This technique is thought to decrease the risk of leakage and allow for earlier tube removal.

Laparoscopic-assisted jejunostomy tube placement has been described. Standard laparoscopy procedures for abdominal exploratory are followed with ultimately a segment of jejunum exteriorized through an instrument portal. Jejunostomy tube placement is performed similarly to what was described earlier.

Patients with enterostomy feeding tubes can be fed immediately after surgery. The exit point of the feeding tube should be incorporated into a body bandage to prevent premature removal by the patient, technical staff, or client. A column of water should be kept in the tube between uses. Possible complications include premature removal, tube-induced jejunal perforation, peritoneal leakage, and subcutaneous leakage. Theoretically, enterostomy tubes can be removed almost immediately after placement, but experience suggests that they should be left in place for at least a week before removal to minimize the chance of post-removal peritonitis. Subcutaneous leakage can be prevented by securely fixing the tube to the skin, and peritoneal leakage is prevented by taking care to include a 360-degree jejunal-abdominal wall pexy.

Gastrojejunostomy Tubes

Several products (e.g., Kangaroo gastrostomy feeding tube with Y-ports) are available that combine gastric and intestinal feeding tubes. These tubes provide access to the stomach and small intestine without the need for an enterotomy. The most significant advantage over other tubes is the ability to institute postgastric feeding while simultaneously allowing for gastric decompression.

CALCULATION OF RATE AND VOLUME OF FEEDING

Once the number of calories necessary to meet the patient's total caloric requirement has been calculated, the rate and volume of feeding are determined based on the route of administration (e.g., oral, nasoesophageal, pharyngostomy, esophagostomy, gastrostomy, or enterostomy). With gastric feeding (i.e., oral, nasoesophageal, esophagostomy, pharyngostomy, and gastrostomy tubes), the amount fed is determined by the patient's stomach capacity. The normal canine and feline gastric capacity is approximately 80 mL of fluid per kilogram of body weight. However, anorexic patients can typically accommodate only 30 to 40 mL/kg of body weight when feeding begins. A gradual increase over 2 to 3 days allows the stomach to accommodate progressively larger volumes. The patient should have a minimum of three feedings daily; however, if vomiting and abdominal distention occur, the daily volume should be reduced and the number of daily feedings increased. In animals that routinely vomit after administration of the diet through a nasoesophageal, esophagostomy, or gastrostomy tube, it is often advantageous to drip commercially prepared liquid diets into the tube as a constant-rate infusion (CRI). Simultaneous administration of antiemetics and/or gastric prokinetic agents may also be beneficial.

With enterostomy feedings, the rate and volume must be carefully regulated to prevent overdistention. Each patient is unique in the amount of fluid the small intestine will accommodate; guidelines for feeding by enterostomy tube are presented in Box 10.5. These are only guidelines; some patients require a longer adjustment time (5–7 days), whereas others allow total volume feeding in 2 to 3 days. Signs of overfeeding include vomiting, diarrhea, abdominal distention, cramping, or all of these. Diluting the diet concentration and reducing the rate and volume of administration generally resolve these complications.

PARENTERAL FEEDING COMPLICATIONS

Complications associated with PN include catheter occlusion, catheter displacement, phlebitis, thrombosis, sepsis, hyperglycemia, hypophosphatemia, hyperlipidemia, azotemia, and electrolyte

BOX 10.5 Guidelines for Feeding via an Enterostomy Tube

- Calculate total caloric requirement.
- Give ¼ of the calculated volume during the first 24 hours; a minimum of four to five feedings per day is recommended.[a]
- Give ½ of the calculated volume during the second 24 hours in four to five feedings.[a]
- Give ¾ of the calculated volume during the third 24 hours in four to five feedings.[a]
- Give the entire calculated volume during the fourth 24 hours in four to five feedings.[a]

[a]Continuous feeding by means of an infusion pump is preferred.

imbalances. If sepsis is suspected, it is usually best to replace the IV catheter and submit the tip of the old catheter for culture and susceptibility testing.

Rarely, insulin may be needed to control persistent hyperglycemia. In the rare case in which insulin seems required, a nutritionist with experience with PN should be consulted. Initially, a very low dose (e.g., 0.25 unit of regular insulin/4.5 kg body weight in dogs) may be tried and the patient closely monitored. One must anticipate that the need for insulin will disappear as the patient adapts. Cats are much more sensitive to the effects of insulin than dogs, and insulin should be avoided, if possible. Life-threatening hypophosphatemia and/or hypokalemia may occur secondary to administration of insulin to emaciated patients.

Complications associated with PPN have been infrequently reported. Most complications are mild and do not require discontinuation of PPN.

ENTERAL FEEDING COMPLICATIONS

Three types of complications can occur with enteral hyperalimentation: mechanical complications, gastrointestinal complications, and metabolic complications. In most cases complications can be prevented by proper tube placement technique, by using an appropriate-diameter, soft rubber feeding tube and the proper diet, by carefully calculating feeding schedules, and by proper tube management during and between feedings.

Mechanical Complications

Mechanical complications include inadvertent placement of the tube into the trachea (nasoesophageal, esophagostomy, and pharyngostomy tubes) or peritoneal cavity (gastrostomy or enterostomy tubes), gastrointestinal perforation by the feeding tube (gastrostomy and enterostomy tubes), regurgitation or vomiting of the tube (nasoesophageal, esophagostomy, and pharyngostomy tubes), esophageal irritation (nasoesophageal, esophagostomy, and pharyngostomy tubes), gastric outflow obstruction (gastrostomy tubes), infection at the tube exit site, occlusion of the tube, or premature tube removal by the patient. Inadvertent placement of feeding tubes in the trachea or peritoneal cavity can be prevented by paying careful attention during tube placement. If there is any question about the tube's location, a small amount of sterile aqueous contrast material should be injected through the feeding tube and a radiograph taken. Gastrointestinal perforation has been virtually eliminated by use of small-bore, Silastic, or soft rubber enterostomy feeding tubes. In cats, esophageal perforation (esophagostomy tube) has largely been eliminated by discontinuation of the use of a stylet during tube placement. Premature tube removal by the patient can usually be prevented by adequate mechanical restraint (e.g., bandaging, Elizabethan collar) and secure attachment of the tube to its exit site (i.e., Chinese finger-trap friction sutures). Use of small-bore, soft rubber feeding tubes has improved patient tolerance. Esophagitis secondary to nasoesophageal, esophagostomy, or pharyngostomy tubes occurs; however, use of Silastic or soft rubber feeding tubes has reduced the frequency. Midesophageal placement of the tip eliminates reflux esophagitis.

Stoma site infection can be minimized by proper tube management. The area should be kept clean and covered with a loose bandage. Care should be taken when feeding the patient to prevent diet formula from contaminating the exit site. Rhinitis secondary to placement of a nasoesophageal tube occurs, but use of small-bore, soft-rubber tubes makes this uncommon.

Small-bore feeding tubes (5–8 Fr) can become occluded with the diet formula. This is best prevented by using a commercial liquid diet rather than a blenderized diet preparation. Flushing material out of the tube when feeding is finished and capping the tube to maintain a column of water help prevent occlusion by gastrointestinal reflux. Large-bore feeding tubes accept blenderized diets, but similar precautions should be taken to prevent occlusion. If a tube becomes occluded, flexible endoscopy forceps can be passed into the tube to remove the clogged material. If endoscopy forceps are unsuccessful, a carbonated liquid (e.g., cola) can be infused into the tube; the effervescence of the liquid and its acid pH may encourage removal of clogged material. If this is unsuccessful, tube replacement may be necessary.

Gastrointestinal Complications

Common gastrointestinal complications of enteral nutritional therapy include vomiting, cramping, abdominal distention, or diarrhea. The most common causes are feeding too rapidly, feeding too large a volume, and feeding diets with a high osmolality. Treatment is aimed at reducing the rate and volume fed or diluting the diet formula.

Metabolic Complications

The most common metabolic complications of enteral nutritional therapy are hyperglycemia and hypophosphatemia. However, they tend to be less common and usually less severe than is seen with parenteral nutrition.

Fundamentals of Physical Rehabilitation

DEFINITIONS

Osteokinematics is the branch of biomechanics concerned with the description of bone movement when a bone swings through a range of motion (ROM) around the axis in a joint (i.e., flexion, extension, abduction, adduction, rotation). **Arthrokinematics** is the manner in which adjoining joint surfaces move in relation to each other during bone movements. Arthrokinematic movements occur as glides, rolls, or spins and accessory motions such as distraction, shear, and compression. A **roll** is a rotary movement (one bone rolling on another); a **spin** is also a rotary movement (one body spinning on another). A **slide or glide** is a translatory movement (sliding of one joint surface over another). **Sarcopenia** is a gradual loss of muscle mass as a result of aging. **Proprioceptive neuromuscular facilitation** (PNF) uses the body's proprioceptive system to facilitate or inhibit muscle contraction. By stimulating the distal segments, the proprioceptors in the more proximal segments are stimulated. The purpose of PNF is to enhance and create movement in areas where the neurologic system has been compromised.

OVERVIEW OF REHABILITATION THERAPY

Human physiotherapy, or physical therapy, is a relatively new medical discipline that began in Sweden in the early 1800s; modern physical therapy was developed in Britain in the early 1900s. Physiotherapy was initially focused on the treatment of polio victims, but after the outbreak of World War I, the field concentrated on helping to restore mobility to injured soldiers. The first school of physiotherapy was established at Walter Reed Army Hospital in Washington, DC.[1]

Interest in the veterinary derivative of human physiotherapy began initially in the 1970s with the publication of a book called *Physical Therapy for Animals: Selected Techniques* by Ann Downer, PT. Shortly thereafter, national presentations to such groups as the American College of Veterinary Surgeons, American Physical Therapy Association, and the American Veterinary Medical Association led to increased interest in canine rehabilitation. Interest in canine sports medicine began at about the same time with publication of *Canine Sports Medicine and Surgery* and with the formation of the International Racing Greyhound Symposium, associated with what was then known as the Eastern States Veterinary Conference (now the North American Veterinary Conference). Rehabilitation was a frequent topic at this conference and was expanded to include all sporting dogs.[2] Today, physical rehabilitation is becoming common in small animal practices. These exercises and modalities are used not only for recovery from orthopedic and neurologic conditions, but also for wellness care and preventive medicine in the form of weight management and maintenance of muscle strength and conditioning, particularly for athletes and geriatric animals. Current practices combine the knowledge and skills of veterinarians, veterinary technicians, human physiotherapists, and physiotherapy assistants. Formal training and accreditation are now available for veterinarians and veterinary technicians, and advanced specialty training is available through the American College of Veterinary Sports Medicine and Rehabilitation.

With advances in surgery and with an increasing number of owners who regard their pets as family members, demand for rehabilitation for veterinary patients is increasing. Postoperative care focusing on decreasing pain, inflammation, and joint stiffness while improving mobility and quality of life may result in shorter hospital stays and improved patient and client well-being. Rehabilitation for the veterinary patient with orthopedic or neurologic disease has as its overlying principle a return to normal mobility and neuromuscular function. The goals of rehabilitation are first and foremost to relieve pain and ameliorate discomfort while ensuring that the patient's condition does not worsen, particularly in the light of spinal instability or surgical repair. Once pain control has been adequately addressed (see Chapter 13), therapists can focus on restoring normal muscular function, minimizing muscular atrophy and other secondary problems, and improving and restoring mobility.

Rehabilitation therapy emphasizes return to function and maximum recovery from the disease process or surgical procedure, as well as the improvement of overall well-being, rather than the treatment of a specific disease or diagnosis. Postoperative orthopedic or neurologic surgery patients are among the many patients that benefit from physical rehabilitation (Box 11.1). Other patients include those with chronic osteoarthritis, severely debilitated patients, oncology patients, obese patients (to aid in weight loss), canine athletes and working dogs (to enhance condition or performance), and patients with orthopedic or neurologic disease that require nonsurgical management. Improvement in pain control, joint ROM, muscle strength and coordination, balance and proprioception, and decrease in contracture and fibrosis are some of the objectives of physical rehabilitation. Return to function and recovery are achieved through the use of the many different modalities and techniques discussed in this chapter.

ROLE OF EXERCISE PHYSIOLOGY IN REHABILITATION

Exercising animals rely on skeletal muscles to perform; skeletal muscle performance is dependent on muscle fiber type. Traditionally, muscles are classified as type I (oxidative or slow twitch) or type II (glycolytic or fast twitch).[3] Postural muscles (i.e.,

ABSTRACT

Physical rehabilitation is the newest specialty in veterinary medicine and encompasses a variety of fields, including exercise physiology, orthopedics, neurology, myology, nutrition, and pain management, among others. It is crucial for optimal postsurgical, nonsurgical, and long-term management of many orthopedic and neurological conditions. Rehabilitation assessment of orthopedic or neurologic conditions involves collecting subjective and objective data about the patient, including goals for rehabilitation, posture, gait analysis, range of motion, strength, and specialized tests. An individualized rehabilitation plan is formulated based on the primary diagnosis, taking into consideration the tissue types involved and chronicity of the injury. Treatment interventions may include manual therapies, therapeutic exercises, hydrotherapy, modalities, and neurologic reeducation.

BOX 11.1 Benefits of Rehabilitation Therapy

- Decreased pain
- Increased rate of recovery following injury or surgery
- Improvement in quality of movement and performance
- Increased strength and endurance
- Improvement in flexibility and biomechanics
- Reduction in the incidence of future injury both due to restoration of normal biomechanics and through client/owner education
- Positive psychological effect for both the pet and for the owner
- Minimally invasive approach
- Minimal complications if administered properly

quadriceps femoris) are capable of slow and sustained contraction and contain more type I fibers than mobilizing muscles (i.e., gracilis muscle), which contain more type II fibers. Type I muscle fibers may be considered the "endurance muscle fibers" and are prominent in dogs that run long distances, such as sled dogs. Type II fibers provide the power and speed muscles fibers prominent in sprinting dogs, such as greyhounds. When compared to humans, dogs have a high oxidative capacity in their muscles because they are adapted for endurance activities[4]; nonetheless, certain breeds (e.g., greyhounds) have more type II muscle fibers than other dogs, making them better sprinters.

When muscles are immobilized, such as in casts or splints, or following long periods of cage rest, muscle strength decreases rapidly with as much as 50% of strength lost within the first week. With disuse, postural muscles that contain more type I fibers atrophy more than the mobilizing muscles containing type II fibers. However, with geriatric sarcopenia the opposite is true; more type II muscle fibers atrophy than type I fibers. This is an important consideration in designing a rehabilitation program for an athlete with muscle loss due to injury versus a geriatric patient with age-related atrophy. Historically, veterinary orthopedic postoperative care consisted of 6 to 12 weeks of cage rest after surgery. This may be acceptable for fracture healing; however, muscle physiology research has shown that the longer a muscle is immobilized or not moved in a normal manner, the more difficult it is to return that muscle to full strength and function. All postoperative patients can benefit from a rehabilitation program that starts as soon as possible after surgery to minimize muscle atrophy and return the patient to full function as quickly as possible.

Muscle contractions can be described as having two variables: force and length. *Force* is either tension or load. *Load* is the force exerted on the muscle by an object, and muscle tension is the force the muscle exerts on an object. *Isometric* contractions occur when muscle tension changes without a change in muscle length; *isotonic* contractions occur when muscle tension remains the same but muscle length changes. Canine rehabilitation is concerned with isotonic contractions. Isotonic contractions occur as either concentric or eccentric contraction. *Concentric contraction* occurs when the muscle contracts, tension in the muscle increases, and shortening occurs. *Eccentric contraction* occurs when the muscle contracts but lengthens because the tension generated in the muscle is insufficient to overcome the load pulling down on the muscle. The eccentric contraction is controlling the movement: it is the natural braking force that occurs during movement.[5] Eccentric contractions tend to preferentially strengthen type II muscle fibers, whereas concentric contractions favor type I fibers. In general, in an exercise program concentric exercises are performed first to help accustom the muscle to movement. Eccentric exercises are added later because, although they help develop strength, they have the potential to cause muscle damage and delayed onset muscle soreness. A balanced program between concentric and eccentric muscle contractions is desirable.[6]

REHABILITATION EVALUATION

An ideal rehabilitation evaluation involves a thorough history, physical examination, and a complete orthopedic and neurologic examination, followed by a specific rehabilitation examination. Historical data of interest to the rehabilitation professional include onset and duration of the problem, body part involved, trauma or activities associated with the injury, current pain score, lifestyle and exercise habits, weight loss or gain, and type of surgery (if any) performed. A general physical examination focusing on any pathology affecting the cardiovascular, neuromuscular, pulmonary, endocrine/metabolic, or integumentary system is critical because all these systems can affect muscular performance. It is also important to evaluate the patient's psychological state and willingness to perform any exercises, as well as the experience of the owner or handler. Orthopedic and neurologic examinations are discussed in Chapters 31 and 38, respectively; only the rehabilitation examination is outlined here. A rehabilitation examination is comprised of a thorough myofascial examination, including muscle girth assessment, examination of each joint, goniometric measurements, subjective and objective (force plate, pressure mat, stance mat) lameness assessment, gait analysis, pain score assessment, body condition score, muscle condition score, modified Frankel score (Box 11.2), and—where available and desired—dual energy x-ray absorptiometry assessment and advanced imaging (i.e., computed tomography, magnetic resonance imaging).[7]

Understanding gait and canine locomotion is vital to diagnosing many neurologic and orthopedic conditions. When possible the lameness evaluation and gait analysis should take place before the other physical examinations because palpation of the muscles, limbs, and joints may alter subtle lamenesses. Subjective lameness evaluation involves visualizing the patient from all angles at both a walk and a trot. It is often easier to detect lameness when the patient is walking because it is a slower gait; however, subtle

BOX 11.3 Numerical Rating Scale

0 = Normal gait pattern
1 = Mild intermittent lameness
2 = Moderate lameness, normal stride length, partial weight bearing
3 = Moderate lameness, shortened stride length, partial weight bearing
4 = Severe lameness with toe touching and minimal limb use
5 = Non–weight-bearing lameness

lameness may be more visible at the trot because this is the only gait that allows individual limb evaluation.[6,8] Patients should be examined on a nonslippery, flat surface such grass or a cement or rubber flooring. The patient should be examined walking toward and away from the examiner, as well as from the side, and while sitting and standing. Having the patient walk through a cavaletti course (see p. 118) and perform weaves and figure eights around cones (see p. 119) is an excellent way to evaluate intermittent lameness. Videotaping these sessions can be helpful and allows the therapist to compare sessions. Either a numerical rating score (Box 11.3) or a visual analogue scale can be used if they are used consistently.[8] Visual gait observation is inferior to objective gait analysis; however, it is still a useful tool in clinical practice.[8]

Validated objective gait analysis is the preferred method of lameness evaluation and is often used to detect subtle lameness because it allows quantification of gait parameters. Currently there are three validated methods of objective gait analysis: kinematic analysis, kinetic analysis (force plate analysis), and temporospatial gait analysis (pressure-sensing walkways). *Kinematic analysis* (involving markers on joints, 3D cameras, and special software) and force plate analysis are used primarily by research institutions due to the cost of the equipment. Pressure-sensing walkways are more affordable but are not widely used by most rehabilitation practitioners; however, these methods do provide an objective outcome measure that quantifies lameness and improvement with rehabilitation.[9]

A myofascial examination includes palpation of the body, origin, and insertion of each muscle; and assessing for functional muscle disorders (acute indirect muscle disorders without macroscopic evidence of a muscle tear), as well as structural muscle injuries (indirect muscle disorders with macroscopic evidence of a muscle tear). Particular attention should be paid to the identification of myofascial trigger points. *Myofascial trigger points* are defined as a hyperirritable spot within a taut band of skeletal muscle that is a source of pain and disability. Identification of trigger points is by manual palpation through either flat or pincher palpation (Video 11.1).[10]

Central to a myofascial examination is the determination of muscle circumference of the major muscles of front and back legs. The girth of the affected leg is compared with the unaffected leg on the opposite side to determine extent of muscle atrophy and to give a baseline for therapeutic outcome measures. This measurement is done using a weighted tape measure. If an ordinary tape measure is used, the measurement will depend on how tightly the tape is pulled. If the examiner pulls tighter, tissue compression will be greater and the measured circumference may be smaller; thus two consecutive measurements may be quite different. By applying a constant tension, accurate and repeatable measurements can be obtained. If multiple examiners are evaluating the patient, it is important that each uses the same anatomic landmarks to ensure accurate measurements. Other variables such as coat length and position of animal (standing or lying) should be taken into consideration when measuring girth circumference (Fig. 11.1).

FIG. 11.1 Measurement of thigh circumference using a gulick.

BOX 11.4 Calculating Energy Requirement

Resting energy requirement (RER) = 70 × (Ideal body weight in kg)$^{0.75}$
Nonobese energy requirement = RER × 1.0 to 1.3 (depending on activity)
Obese energy requirement = 0.7 × RER
Goal: provide sufficient energy to achieve 1% weight loss per week until ideal weight is achieved

Data from Brooks D, Churchill J, Fein K, et al. 2014 AAHA weight management guidelines for dogs and cats. *J Am Anim Hosp Assoc.* 2014;50(1):1-11.

Pain is considered to be the fourth vital sign and is frequently overlooked.[11] Pain scoring is an important part of the rehabilitation evaluation and should be done consistently at every patient visit. Using a validated pain scale such as the Glasgow Chronic Pain Index or the Helsinki Chronic Pain scale (see Chapter 13) can ensure that the patient is comfortable and willing to participate in rehabilitation. Exercises and modalities should be adjusted according to the patient's pain score.

Body condition scoring (BCS) and muscle condition scoring (MCS) are two vital pieces of information required from all patients (Figs. 11.2 and 11.3). Many veterinary patients are obese, and some are also sarcopenic. BCS and MCS should be documented at the initial evaluation and can be used to document progress through rehabilitation. Calculation of ideal body weight and number of calories needed to achieve that weight, as well as grams of protein required in the diet for optimal weight loss and muscle integrity, should be addressed with all patients (Box 11.4; see also Chapter 10). Most rehabilitation patients require 3.75 g of dietary protein per kilogram of body weight for maintenance of lean body mass, muscle mass, weight loss, and healing. Senior dogs require 5 g of dietary protein per kilogram of body weight to maintain muscle integrity.[12,13] If this protein requirement is not met by the dog's diet, additional supplemental protein, such as whey protein powder, may be required.

The rehabilitation evaluation concludes with a complete set of goniometric measurements. This is best accomplished with the patient lying on its side, restrained by an assistant. A commercial goniometer should be used and measurements taken at the most comfortable degree of flexion and extension for each joint with one arm of the goniometer along each long axis of

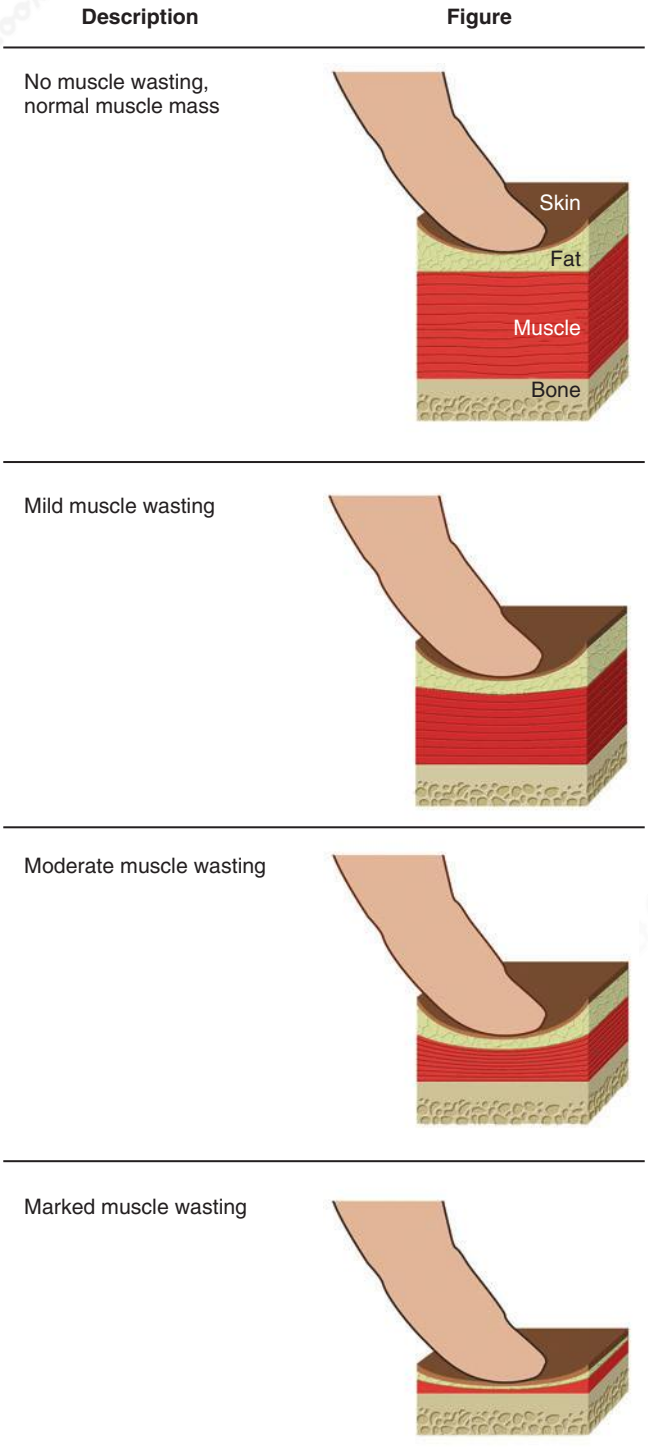

FIG. 11.3 Muscle condition scoring. (Modified from Baldwin K, Bartges J, Buffington T, et al. AAHA nutritional assessment guidelines for dogs and cats. *J Am Anim Hosp Assoc.2010;*46[4]: 285–296.)

the bone proximal and distal to the joint in question. The center of the goniometer is placed over the axis of joint rotation as determined by flexion and extension (Fig. 11.4). Measurements are recorded for each limb and compared with a set of normal values, as well as to the contralateral limb (Table 11.1). The

Modified from Jaegger GJ, Marcellin-Little DJ, Levine D. Reliability of goniometry in Labrador retrievers. *Am J Vet Res.* 2002;63(7):979–986.

published normal values are for Labrador retrievers. Variation may occur among breeds; therefore calculating the angles of the contralateral, unaffected limb is important for comparison.[14]

DEVELOPING A REHABILITATION PLAN

The purpose of the rehabilitation assessment is to determine the patient's major problems, both structural and functional. Once the problems are identified, the therapist develops a plan specific to the patient's needs and that meets the owner's expectations, financial and time commitments, and desired outcome. The rehabilitation plan for a geriatric, sarcopenic dog with a long bone fracture will be different from that of a canine athlete that has undergone a tibial plateau leveling osteotomy (TPLO) procedure. The plan should be specific, with described outcomes and timelines. Regular scheduled evaluations should be a part of the plan. The therapist must be able to modify the plan based on the patient's progress. Table 11.2 shows an example of a detailed rehabilitation plan for a TPLO procedure in a young dog.

TABLE 11.2 Example Rehabilitation Protocol for a Young Dog After TPLO

Treatments/ Modalities	Days 1–7	Days 7–21	3–4 Weeks	5–7 Weeks	8–12 Weeks
Pain medications	As directed	As directed	PRN	PRN	PRN
Cryotherapy	10–15 minutes 3 times daily before walks or exercises	Use after exercise for 15 minutes	PRN	PRN	PRN
Heat therapy		Use heat before exercise or if dog is stiff	PRN	PRN	PRN
Massage	5 minutes 3 times daily prior to starting exercises; massage from toes to hip	Continue twice daily	Twice daily	Twice daily	Only if desired
PROM	10 repetitions 3 times daily, all joints affected limb—start above and below knee	Continue twice daily. If dog is using leg really well then decrease	Discontinue if dog is walking well and ROM is normal		
Laser therapy	Daily or every other day for first week	Every other day for first week then twice weekly	Twice weekly	Twice weekly	Discontinue
Walks	5-minute supported leash walk 2–3 times daily	Increase each walk by 2–3 minutes each week	Increase by 5 minutes each week	Increase by 5 minutes each week	15–20-minute walks 2–3 times daily
NMES	10 minutes twice daily	10 minutes twice daily	Discontinue if dog is doing well		
Balancing		5 minutes twice daily	5 minutes twice daily	One-leg standing up to 5 minutes	Replace with hill walks
Cavalettis/obstacles/ sit-to-stand		5 minutes twice daily	5 minutes twice daily	5 minutes twice daily	5 minutes twice daily
Weaving/circles		2–3 minutes once daily	5 minutes twice daily	5 minutes twice daily	5 minutes twice daily
Hills				Zigzag low, slow hills 5 minutes up and down	Increase to 10 minutes twice daily
Underwater treadmill		10 minutes 3 times weekly after sutures are removed	10 minutes 3 times weekly	15–20 minutes twice weekly	15–30 minutes twice weekly until released from rehab
Swimming					8 weeks post-TPLO for 5–10 minutes if all healed

NMES, Neuromuscular electrical stimulation; *PROM,* passive range of motion; *ROM,* range of motion; *TPLO,* tibial plateau leveling osteotomy.

THERAPEUTIC MODALITIES: GENERAL CONSIDERATIONS

Therapeutic modalities are used to augment medications and reduce pharmaceutical dosages, as well as to speed and direct healing in order to return the patient to full function as quickly as possible. The most common modalities used for pain relief include heat, cryotherapy, manual therapies such as massage, joint mobilizations and stretching, laser therapy, transcutaneous electrical nerve stimulation (TENS), and therapeutic ultrasound (TUS). Muscle strengthening and reeducation are accomplished using neuromuscular electrical stimulation (NMES), therapeutic exercises, hydrotherapy, and PNF. Assistive devices, such as harnesses, slings, boots, carts, orthotics, or incontinence aids, are often essential to the well-being and recovery of surgical or neurologic patients (Fig. 11.5).

Cryotherapy

Cryotherapy or cold packing has historically been the most common nonpharmaceutical method of treating postoperative or acute postinjury pain and inflammation. It is most effective when applied immediately after acute trauma and for up to 72 hours afterwards. It is a superficial treatment, but the depth of tissue cooling can be as great as 4 cm. Cryotherapy may also be used after exercise and before painful modalities.[15–17] Benefits of cryotherapy are listed in Box 11.5.

Cryotherapy can be delivered in several ways, including reusable ice packs, circulating cold-water blankets, ice packs,

FIG. 11.5 A dog with custom orthotics. Rehabilitation patients may require custom orthotics for recovery.

BOX 11.5 Benefits of Cryotherapy

- Local vasoconstriction, which decreases blood flow thereby decreasing swelling, interstitial hemorrhage, and inflammation.
- Reduction of enzymatic tissue activity and damage through inhibition of the release of histamine, protease, hyaluronidase, and collagenase.
- Reduction of cellular metabolism. This is important because decreased tissue oxygen requirements prevent secondary cellular hypoxic injuries.
- Reduction in pain perception. Analgesia and a reduction in muscle spasm occur due to a decrease in nerve conduction velocity.

Data from Otte JW, Merrick MA, Ingersoll CD, et al. Subcutaneous adipose tissue thickness alters cooling time during cryotherapy. *Arch Phys Med Rehab.* 2002;83(11):1501–1505; and Millard RP, Towle-Millard HA, Rankin DC, et al. Effect of cold compress application on tissue temperature in healthy dogs. *Am J Vet Res.* 2013;74(3):443–447.

cold compression devices, ice cups, iced frozen towels, or vapocoolant sprays. Cold compression devices are frequently used after surgery. Circulating cold-water blankets can be used to decrease total body temperature and thereby decrease intracranial pressure in head trauma patients, but ice packs and ice massage are most commonly used for acute injuries in clinical practice (Fig. 11.6).

Ice packs can be either bags of crushed ice, ice-alcohol slushes, or gel packs. Gel packs, particularly human physiotherapy gel packs, are extremely convenient because they can be kept in the freezer yet still retain the ability to mold well to the desired area. Canine-specific cold packs that fit into preformed sleeves are available commercially. A thin, moist towel should be placed between the patient and ice pack to improve cooling and avoid damaging the skin.[18] The length of time to apply the ice pack

FIG. 11.6 A dog with a cold compression system placed after surgery.

BOX 11.6 Precautions and Contraindications for Cryotherapy

- Avoid any previous areas of frostbite.
- Apply with caution in very old, very young, very small, or hypertensive patients, as blood pressure can be affected.
- Avoid superficial wounds, superficial nerves, areas of decreased sensation, and open fractures.
- Check the patient's skin for redness or blanching after the first 5 minutes to avoid cold injury. Do not apply ice for more than 20 minutes per session.

Data from Niebaum K. Rehabilitation physical modalities. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation.* Ames, IA: Wiley-Blackwell; 2013:115–131.

BOX 11.7 Tips for Using Ice Packs

- Make your own ice gel packs using 3 parts water to 1 part rubbing alcohol and freezing this mixture in resealable freezer bags of various sizes. These packs will stay malleable in the freezer.
- Bags of frozen peas can be used because they are malleable, but they will not cool as well as other methods because they contain air.
- Duration of ice pack application (for an average dog) is 10 to 15 minutes on, then 10 to 15 minutes off, repeated twice. Repeat every 4 hours for the first 24 to 48 hours.

varies with patient size, size and depth of the ice pack, and the target tissue. The average size dog will require 10 to 15 minutes of cooling, whereas a large dog may require 15 to 20 minutes and a very small dog may only need 5 to 8 minutes of icing. Fatter dogs will require more time to cool the target tissue because adipose tissue is a poor conductor of heat.

Ice massage can be used for small areas and may be used before other manual therapies. Water can be frozen in paper cups and the paper torn away as the ice melts. An ice popsicle can be made by placing a tongue depressor in the center of the cup before freezing, which provides the therapist a handle for applying the ice. Treatment duration for ice massage is generally 5 to 10 minutes. Although cryotherapy is generally safe, certain precautions and contraindications exist (Box 11.6). Tips for using ice packs are provided in Box 11.7.

Thermal Therapy

Superficial heating or thermal therapy is one of the oldest physical modalities. It is generally used after icing, before exercise or

BOX 11.8 Benefits of Heat Therapy

- Vasodilation increases circulation to tissues, which increases tissue metabolic rate, improves tissue oxygenation, and decreases tissue edema and inflammation.
- Pain relief, which is mediated by an increase in the pain threshold.
- Decreased muscle spasm and relaxed muscle tone, which are thought to occur due to decreased muscle ischemia.
- Increased extensibility of soft tissue. Hot packing before stretching promotes flexibility and increases range of motion. When soft tissue is heated before stretching, the effect of the stretch lasts longer, and less force is required to maintain an effective stretch.

Data from Niebaum K. Rehabilitation physical modalities. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation.* Ames, IA: Wiley-Blackwell; 2013:115–131.

BOX 11.9 Precautions and Contraindications When Applying Heat Therapy

- Protect the patient's skin by wrapping the hot pack in a towel and checking the skin frequently. Discontinue heating if skin has white areas or red mottled areas.
- Do not use heat in areas of impaired sensation or with acute inflammation.
- Use with caution in obese, pregnant, and cardiac patients, as well as very young or very old patients.
- Absolute contraindications include active bleeding, malignancy, fever, and open wounds.

Data from Niebaum K. Rehabilitation physical modalities. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation.* Ames, IA: Wiley-Blackwell; 2013:115–131.

BOX 11.10 Tips for Using Hot Packs

- If using commercial gel packs or oat bags, be sure to mix the gel or oats well within the bag before applying to the patient to avoid hot areas. Always place a towel between the heat source and the skin.
- To determine if the hot pack will be comfortable for the patient, check the temperature by applying it to your inner arm or neck. Put your hand between the hot pack and skin at least every 5 minutes to monitor the temperature.
- If using towels, fold in thirds and roll (if using around a joint) or accordion fold (if using for a larger area). Immerse in hot water, squeeze the water out, and apply to affected area. Cover with a large dry towel to keep the heat in.
- Always use hot packing before stretching.

stretching, or to relieve pain and muscle spasms. Benefits of heat therapy are provided in Box 11.8.[15] Thermal therapy can be delivered by hot packs, hydrotherapy, infrared lamps, heating blankets, and TUS. Moist hot packs are most commonly used. Commercial physical therapy gel packs or oat or bean bags can be heated in the microwave, covered with a thin towel, and used. A hot, wet towel covered by a dry towel works well to apply moist heat. Duration of treatment depends on the patient and condition treated; however, heat treatments generally last 15 to 30 minutes and may be applied up to four times daily. Hot packs work well in conjunction with other forms of therapy, such as massage and exercise therapy.

Another way of applying thermal therapy is by using warm water baths. The patient or the affected area can be immersed in a warm bath, a whirlpool, or a hydro treadmill. The advantage of immersion therapy is that the increased hydrostatic pressure of the water decreases edema and improves lymphatic circulation. The water is often circulated with jets, and the patient receives the benefit of heat, massage, and increased hydrostatic pressure. Heating pads and infrared lamps have the potential to burn the patient and are not recommended, particularly for patients with neurologic disease who may be unable to move away from the source of heat. Precautions and contraindications for thermal therapy are listed in Box 11.9.[15] Tips for using hot packs are provided in Box 11.10.

Therapeutic Ultrasound

Human physical therapists have used TUS to treat patients with pain for many years. The major indication for use of this modality

FIG. 11.7 Therapeutic ultrasound being applied to the paraspinal muscles in a dog.

is deep tissue heating; however, other uses such as enhancement of wound and fracture healing by means of tissue modulation and modification of cellular function have been investigated (Fig. 11.7). Researchers have demonstrated nonthermal effects of TUS that include increased nerve conduction velocities of both sensory and motor nerves and improved nerve healing.[19–21] TUS works by the conversion of electricity to sound waves through the piezoelectric effect on the crystal in the transducer head of the machine. It is used to heat tissues from 1 to 5 cm in depth without superficial heating. The frequency, intensity, and mode of the treatment can be modified by the therapist according to the patient's condition. The thermal effects of TUS mirror those of superficial heating and include vasodilation, pain relief, increased flexibility of soft tissue, and decreased muscle spasm.[19–21] TUS requires a coupling medium to be placed between the sound head and the skin, as air attenuates the ultrasound beam. In general, a water-soluble ultrasound gel is smoothed over the skin, with the sound head having direct contact with the gel. TUS has some very specific contraindications and precautions (Box 11.11).[15]

Phonophoresis is the delivery of pharmaceutical agents using TUS. It is commonly used in human physiotherapy, but rarely in veterinary medicine. It can deliver local anesthetics or dexamethasone into painful muscles after surgery or injury.

BOX 11.11 Precautions and Contraindications of Therapeutic Ultrasound

- Avoid therapeutic ultrasound over cardiac pacemakers, eyes, the gravid uterus or testes, spinal cord after laminectomy, open epiphyseal plates, bleeding areas, and areas of infection or malignancy as this may damage tissue, induce parturition, or cause metastasis.
- Use caution over fractures; in areas of decreased circulation, temperature, or pain sensation; in sedated animals; in areas of boney prominences; and over metal implants as this may damage tissue.

Data from Maxwell L. Therapeutic ultrasound: its effects on the cellular & molecular mechanisms of inflammation and repair. *Physiotherapy.* 1992;78:421; Raso VV, Barbier CH, Mazzer N, Fasan VS. Can therapeutic ultrasound influence the regeneration of peripheral nerves? *J Neurosci Methods.* 2005;142(2):185–192; and Kramer JF. Sensory and motor nerve conduction velocities following therapeutic ultrasound. *Aust J Physiother.* 1987;33(4):235–243.

Phonophoresis is used with muscle strain or painful muscles secondary to intervertebral disc disease surgery or medical therapy. Phonophoresis for these conditions is done using a compounded gel (dexamethasone 0.4%/lidocaine 0.1%). The settings currently used for phonophoresis treatments are 0.9 W/cm^2, 1 mHz, 100% duty cycle, and 4 minutes per probe head that will fit in the area treated.[22] Because veterinary patients are hairy, some therapists shave the area before TUS, whereas others use larger amounts of gel. However, Steiss and Adams have shown that ultrasound treatment applied through an intact coat considerably warms the coat with loss of thermal effects in underlying tissues.[23]

NOTE Clipping the hair, whether it is long or short, provides more consistent results with TUS and reduces the amount of heat lost in the hair coat.

Laser Therapy

Laser is an acronym for *light amplification by simulated emission of radiation*. Laser therapy is used in veterinary medicine to manage pain and inflammation and improve healing,[18,24] including promotion of healing following nerve and spinal cord injuries (Fig. 11.8). Research has shown laser therapy is associated with increased axonal sprouting and growth, increased myelination, reduced neuronal degeneration, and improved nerve recovery after injury.[18] Physiologic effects of laser stimulation are provided in Box 11.12.

Lasers used for therapy are different than surgical lasers and are considered low-level lasers or therapeutic lasers, depending on the laser's power. A laser is by definition collimated and monochromatic. The wavelength determines the penetration of the laser energy. Laser power is measured in milliwatts or watts. There are four classes of lasers that are divided according to the power produced. Class 1 lasers produce less than 0.5 mW (e.g., a supermarket scanner). Class 2 lasers produce up to 1.0 mW (e.g., laser pointers). Class 3a, 3b, and 4 are the classes into which most therapy lasers fall. Classes 3a, 3b, and 4 lasers produce 1.0 to 100 mW, 100 to 500 mW, and greater than 500 mW, respectively. Surgical lasers are class 4.

NOTE Laser therapy is beneficial after spinal surgery in dogs with intervertebral disc disease lesions of the T3–L3 region. If laser is applied daily for 5 days after surgery, time to ambulation is decreased.[8]

BOX 11.12 Physiologic Effects of Laser Stimulation

- Chromophores in the cell mitochondria absorb the laser light energy, causing increased production of oxygen, adenosine triphosphate, and DNA; increased cell permeability; and decreased cyclooxygenase and prostaglandin E2 production.
- Stimulation of stem cells.
- Promotion of tissue repair through angiogenesis, stimulation of fibroblast production and collagen synthesis, and growth factor release.
- Increased activity of leukocytes.
- Increased healing of nerves, connective tissue, and ligaments.
- Pain reduction through change in nerve conduction and increased levels of endogenous opiates or through stimulation of acupuncture points.

Data from Draper WE, Schubert TA, Clemmons RM, Miles SA. Low-level laser therapy reduces time to ambulation in dogs after hemilaminectomy: a preliminary study. *J Small Anim Pract.* 2012;53(8):465–469; and Looney A, Huntingford JL, Blaeser L, et al. A comparison of sham versus actual low level light therapy (LLLT) in treatment of canine elbow osteoarthritis pain and lameness. 44th Annual Veterinary Orthopedic Society Conference, Snowbird, UT, March 11–18, 2017.

FIG. 11.8 A dog with a shoulder injury receiving laser therapy. Note the protective eyewear that the persons administering the therapy and the dog are wearing.

NOTE To observe beneficial effects and mitigate pain, dogs with elbow arthritis and lumbosacral disease may need increased dosages of laser (i.e., 18–20 J/cm^2).[24]

Laser therapy is measured in joules (J) of energy, which is the power emitted over time. One joule is the amount of energy delivered by one watt of laser energy in one second. For example, it takes 2 seconds for a 500-mW laser to deliver 1 J of energy (500 mW × 2 seconds = 1 W second or J). A 10 W laser will deliver 1 J in ⅒ of a second. From a therapeutic standpoint, a higher-power laser will deliver a therapeutic dose in a shorter period. Research has shown different laser energy doses for therapy; however, for tissue healing the dose is usually 1 to

BOX 11.13 Precautions and Contraindications for Laser Therapy

- Use protective eyewear and do not treat the eye area; laser light can damage the retina.
- Use caution over metal implants.
- Use with caution in seizure patients.
- Do not treat over the gravid uterus, neoplasia, growth plates, or open fontanels; this may cause metastasis or induce parturition.
- Dark-colored skin can absorb light and undergo excess heating, thus burning the patient.

Data from Niebaum K. Rehabilitation physical modalities. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation.* Ames, IA: Wiley-Blackwell; 2013:115–131; Draper WE, Schubert TA, Clemmons RM, Miles SA. Low-level laser therapy reduces time to ambulation in dogs after hemilaminectomy: a preliminary study. *J Small Anim Pract.* 2012;53(8):465–469; and Looney A, Huntingford JL, Blaeser L, et al. A comparison of sham versus actual low level light therapy (LLLT) in treatment of canine elbow osteoarthritis pain and lameness. 44th Annual Veterinary Orthopedic Society Conference, Snowbird, UT, March 11–18, 2017.

5 J/cm^2 and for pain 4 to 10 J/cm^2. With lower-power lasers, such as class 3a and 3b lasers, spot treatment is generally done, whereas with a class 4 laser the dose is administered in a sweeping fashion. Precautions when using lasers are provided in Box 11.13.

NOTE When using class 3b and class 4 lasers in dogs with dark hair, hold the head of the laser off the skin by 1 inch to avoid heating the hair. Be sure the head is perpendicular to the skin.

Transcutaneous Electrical Nerve Stimulation and Neuromuscular Electrical Stimulation

TENS is one of two electrical stimulating modalities used in rehabilitation therapy for pain control, the other being NMES. TENS works on the sensory nerves to provide pain relief by applying high-frequency current to the skin and mediating pain relief through the gate theory of pain inhibition. TENS is generally applied immediately postoperatively, but it may be used to provide pain relief during treatment. The effect of TENS is transient in veterinary patients; however, longer-acting relief may be achieved using a high-intensity low-frequency current, known as *acupuncture-like TENS*, which is applied to acupuncture points and causes endorphin release. Precautions and contraindications when using any type of electrical stimulation, whether for pain relief or strengthening, are provided in Box 11.14.[15]

Different equipment is used for TENS compared with NMES. NMES is most frequently used in rehabilitation of neurologic patients (particularly tetraparetic or paraparetic animals) because it stimulates motor nerve and muscle fibers (Fig. 11.9). NMES contracts muscles, reduces edema, and assists with wound healing. In a weight-bearing animal it can be used to increase the force of contraction. It can also be used to assist gait retraining after surgery or injury. It is generally performed daily, or at least three times weekly, and with an amplitude sufficient to cause contraction. Postoperative NMES works best if done in the first 1 to 4 weeks after surgery or injury and is of questionable value in cases of lower motor neuron disease. Parameters for NMES are provided in Box 11.15.

Electrical stimulation is applied from the unit by leads and electrodes. These must be flexible and conform to the skin. The electrodes need to have low resistance and be highly conductive, inexpensive, and reusable. Most TENS and NMES machines have disposable electrodes meant for human use, which are of limited use in veterinary patients due to their hair. Nonsticky carbon electrodes that can have gel applied and are taped to the skin are preferable. Treatment time for both modalities is generally 15 to 20 minutes.

BOX 11.14 Precautions and Contraindications When Using Electrical Stimulation

- Do not use over the heart or in animals with pacemakers; this may induce abnormal rhythms.
- Do not apply over the pregnant uterus; this may induce parturition.
- Do not use over areas of neoplasia or thrombosis; this may cause metastasis or a thromboembolism.
- Do not use in animals with seizures.
- Do not apply over the carotid artery.
- Use with caution in areas of skin damage or decreased sensation.

Data from Niebaum K. Rehabilitation physical modalities. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation.* Ames, IA: Wiley-Blackwell; 2013:115–131.

BOX 11.15 Parameters for Neuromuscular Electrical Stimulation

- Frequency: 25–50 Hz
- Pulse duration: 100–400 μs
- Ramp up and down: 2–4 seconds
- On/off time ratio: 1:3–1:5

FIG. 11.9 Proper application of neuromuscular electrical stimulation for muscle stimulation after surgery.

Extracorporeal Shock Wave Therapy

Extracorporeal shock wave therapy (ESWT) has been used extensively since the 1970s to treat musculoskeletal problems in horses. In human medicine it has been used for lithotripsy and such musculoskeletal conditions as plantar fasciitis, calcifying tendonitis, and delayed unions. In dogs it has been used in the treatment of osteoarthritis, particularly elbow arthritis, supraspinatus tendinopathy, and patellar ligament desmitis.[25] Although the exact mechanism by which ESWT acts on bone is not fully understood, studies have shown greater osteogenic activity and strength in treated bone in addition to decreased inflammation, short-term analgesia, and increased vascularization of surrounding tissue. Extracorporeal shock wave generators produce acoustic waves of high pressure and velocity. These waves are characterized by high-amplitude acoustic pressures and differ from ultrasound waves because of their lower frequency, minimal tissue absorption, and lack of a thermal effect.[26]

ESWT can be delivered as focused or radial shock waves. Focused shock waves converge on a small target point and do not expose surrounding tissues to the same peak pressures as the focused point. There are three types of focused shock wave generators: *piezoelectric*, which uses crystals to generate the shock wave; *electromagnetic*, where magnetic fields produce the shock wave; and *electrohydraulic*, which uses a high-voltage spark gap that causes plasma bubble generation. In the latter, expansion and collapse of the bubble produces the shock wave.

Radial shock waves are generated pneumatically and move more slowly through the tissue with a lower pressure, reduced depth of penetration, and exposure of all tissues to the same pressure. The stimulation effects and therapeutic mechanism of focused verses radial shock waves are similar; however, radial shock waves are well suited for indications closer to the surface of the body, whereas for deeper target areas, focused shock wave therapy seems to be more favorable.[26]

Application of ESWT requires heavy sedation or light anesthesia because the procedure is painful. The area to be treated needs to be clipped and ultrasound gel applied as a coupling agent. The direction of the application and length of time depends on the condition and body part treated. In general, most conditions require 500 to 1000 shocks, with two treatments 3 to 4 weeks apart. Adverse effects can include bruising, petechiae, and pain. These patients commonly require nonsteroidal antiinflammatory drugs after treatment. Precautions and contraindications for ESWT are provided in Box 11.16.[26]

Manual Therapies for Pain Relief

Manual therapy techniques are used in canine rehabilitation practice to modulate pain; induce relaxation; improve tissue extensibility; increase ROM; mobilize joints and soft tissues; and reduce soft tissue swelling, inflammation, and edema. Common manual therapies include joint mobilizations, massage, passive ROM, and stretching. Some manual therapies require minimal training, whereas others, such as joint mobilization, require a high level of skill to be performed safely and effectively. Specific canine indications for manual therapy include pain and restricted motion secondary to canine hip dysplasia, elbow dysplasia, intervertebral disc disease, and osteoarthritis. Mobilizations, whether joint or soft tissue, are passive movements that are either oscillatory or a sustained stretch performed in such a manner that the patient can prevent the motion if so desired.[25,27] These motions can be performed anywhere within the available ROM.

BOX 11.16 Precautions and Contraindications for Extracorporeal Shock Wave Therapy

1. Do not expose the lung fields, brain, heart, major blood vessels, nerves, or a gravid uterus to shock waves; this may cause disruption in the organs, damage the fetus, or induce parturition.
2. Do not use near gas-filled cavities or organs because the pressure waves may enhance gas bubbles and damage the organs.
3. Do not apply over areas that are infected or over neoplasia or unstable fractures.
4. Do not use in dogs with immune-mediated joint disease or in those with neurologic deficits.

Data from Adamson CP, Taylor RA. Preliminary functional outcomes of extracorporeal shockwave therapy on ten dogs with various orthopedic conditions. *Proceedings of the Second International Symposium on Rehabilitation and Physical Therapy in Veterinary Medicine, Aug 10-14*, Knoxville, TN: University of Tennessee; 2002:195; and Ogden JA, Alvarez RG, Levitt R, Marlow M. Shock wave therapy (orthotripsy) in musculoskeletal disorders. *Clin Orthop Relat Res.* 2001;(387):22–40.

TABLE 11.3 Maitland Grades of Joint Mobilization

Grade	Description	Use
1	Fast, small amplitude at beginning of ROM	Pain relief
2	Slow, large amplitude, first half ROM	Provide early ROM, pain relief
3	Slow, large amplitude, mid to end ROM	Stretches joint capsule and ligament
4	Fast, small amplitude at end of ROM	Resolve inappropriate fibrous tissue adjacent to joint
5	Manipulation: small amplitude quick thrust	Chiropractic adjustment

ROM, Range of motion.
Data from Coates J. Manual therapy. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation.* Ames, IA: Wiley-Blackwell; 2013:100–114.

Joint mobilization is used to assess the joint and improve the actions between joint surfaces (*joint arthrokinematics*). It involves stretching the joint capsule, ligaments, and any fibrous tissue that may be present. Joint mobilizations include glides or slides, oscillations (rolls, spins), distractions, and compressions of the joint. The goals of joint mobilization are to improve joint arthrokinematics, decrease pain, improve joint alignment, and reduce muscle spasm.[27] Joint mobilizations are graded according to the scale provided in Table 11.3.

Joint mobilizations are used after surgery or injury in any joints that are stiff and painful. The effectiveness of these manual therapy techniques depends on the skill level of the therapist. Joint mobilizations should only be practiced by those who have had sufficient training in these techniques. Contraindications to joint mobilization are provided in Box 11.17.[25]

Massage or Soft Tissue Mobilization

Soft tissue mobilization (STM) or massage involves tissue manipulation not associated with bones or joints. The pain-relieving effects of massage are produced through the release of endorphins and activation of neuropeptides, the intercellular messages within the nervous system. Manual manipulation of tissue can increase circulation, loosen stiff muscles, reduce excess interstitial fluid, and help minimize muscle atrophy (Fig. 11.10).

BOX 11.17 Precautions and Contraindications for the Use of Joint Mobilization

- Do not use in areas of spinal instability.
- Use with caution if there is a neoplasm or infection (osteomyelitis) present in the adjacent bones.
- Be cautious if there are sutures over the joint.
- Perform with care if there is a recent, nonhealed, or partially healed fracture.
- Perform cautiously if the animal has unmitigated pain.
- Beware if the joint feels "bony" or empty or if there are muscle spasms.

Data from Coates J. Manual therapy. In: Zink MC, Van Dyke JB, eds. *Canine Sports Medicine and Rehabilitation*. Ames, IA: Wiley-Blackwell; 2013:100–114.

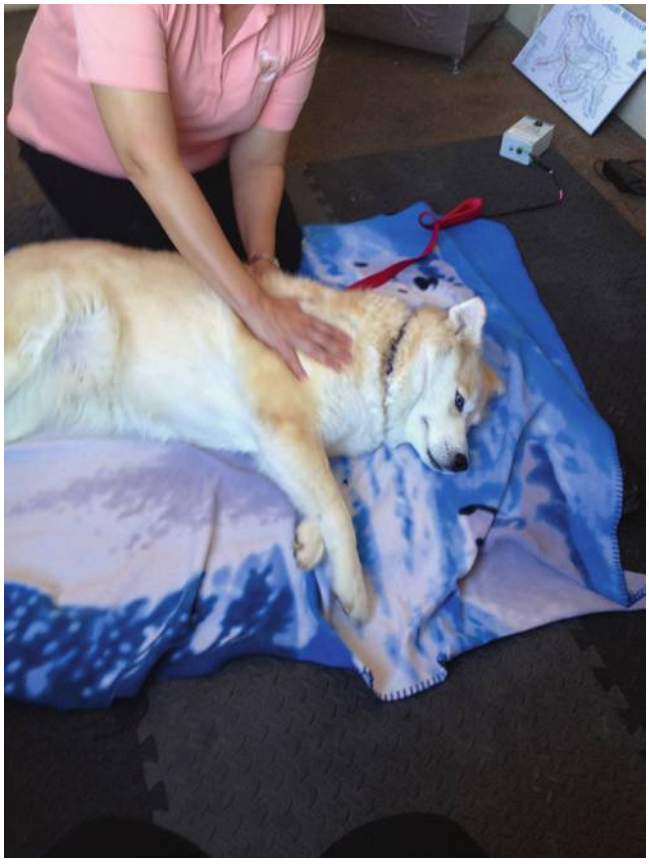

FIG. 11.10 Chronic pain patient receiving a massage.

Massage is particularly important in recumbent neurologic or orthopedic patients with paresis or painful and stiff muscles. If the dog is confined or on restricted exercise, STM can help retain muscle tone and condition. Teaching STM techniques to the owner provides psychological benefit to the dog and the owner associated with increased touch; in addition, the owners feel that they are participating in the dog's recovery. Several massage techniques can be used depending on the patient needs. Massage is generally done for 15 to 20 minutes and can be done several times a day, if needed (Video 11.2).

Various STM techniques may be chosen depending on the treatment goal and the patient's condition. *Effleurage* is long slow strokes with light to moderate pressure that runs parallel to the muscle fibers. It is often used at the beginning of the massage. *Petrissage* is short, quick strokes with moderate to deep pressure that is parallel perpendicular, or across the direction of the muscle fibers. Wringing, skin rolling, and kneading are all part of petrissage. Tapping on the muscle, or *tapotement,* is done with fingertips to stimulate weak muscles (Video 11.3). Friction or cross friction massage is performed by applying moderate pressure to scars, tendons, and ligaments to break up scar tissue. It can be performed perpendicular to the tendon, along the tendon, or circularly over the tendon and is usually done for 5 to 10 minutes. *Trigger point therapy* is a technique that applies digital pressure to a trigger point, which is a firm, tender area of muscle. Trigger points can be treated with pressure, dry needling, or injection.[28] Precautions and contraindications for massage are provided in Box 11.18.[28]

BOX 11.18 Precautions and Contraindications for Massage

- Fever or shock
- Areas of acute inflammation
- Infectious skin diseases
- Acute viral infections

Modified from Sutton A, Whitlock D. Massage. In: Millis DL, Levine D, eds. *Canine Rehabilitation and Physical Therapy*. 2nd ed. Philadelphia: Elsevier; 2014:464–483.

Passive Range of Motion and Stretching

ROM exercises and stretching are important after surgery, in neurologic patients, or for those with chronic disease. The normal ROM of a joint is affected by the joint structure and integrity and the type of soft tissue surrounding it. Normal ROM can be measured by a goniometer, with each joint having characteristic angles of flexion and extension (see Fig. 11.4). When joint motion is restricted, normal muscle ROM or functional excursion may also be restricted. Functional excursion of a muscle is defined as the amount the muscle can shorten after having been maximally elongated. Muscles that cross two joints, such as the biceps brachii, may lose functional excursion more quickly than muscles that cross only one joint. In these muscles in particular, passive range of motion (PROM) exercises are important to prevent disuse atrophy and mitigate the effects of immobilization.[28]

PROM involves taking the joint through its normal, comfortable ROM. It is performed by a therapist to increase muscle extensibility, prevent and treat stiffness, improve and maintain joint arthrokinematics, and to improve lymphatic drainage and circulation. PROM is necessary for all rehabilitation patients but is particularly useful for the nonambulatory patient. It can be accomplished with the patient in lateral recumbency, over a therapy ball or peanut, or in a sling or cart to maintain a standing position. The latter two allow gravity to pull the limbs down and provide sensory input to the limbs. Each limb should be done separately and at a minimum of three times a day. It is important to move all the joints of each limb when doing PROM, not just the joints on the affected limb. When performing PROM, the origin of the muscle is stabilized and the insertion moved (Fig. 11.11). A 30-second passive stretch is usually adequate. The stretch must be effective and not painful. Neurologic and postoperative patients are at risk for contractures of tendons and ligaments, which can be mitigated by PROM. Caution should be used when performing PROM in animals that are geriatric, have decreased sensation, or are in pain or when it is done immediately after surgery. Forceful PROM can damage bone and cartilage (Video 11.4).

FIG. 11.11 Passive range of motion being performed in a patient with joint disease.

NOTE PROM works best on warmed muscles that have been heated with hot packs.

To avoid pain and spasm, flex and extend each joint of the affected limb approximately 10 times before flexing the entire limb.

Special Considerations for Neurologic Patients

Proprioceptive Neuromuscular Facilitation

After stretching and PROM, it is important to reeducate unresponsive muscles. In general, these are muscles that are antagonistic to those shortened through contracture, or by spasticity. This reeducation process takes place through PNF patterning. PNF is used to simulate movement patterns that are ingrained and functional. Common patterns include walking, running, scratching, sit to stand, movement from lateral to sternal recumbency, kicking back, and turning. PNF patterns can be done in any position depending on the disability. One example of PNF patterning is passive walking or running, which is often performed in paretic dogs in an underwater treadmill (UWTM) with a therapist moving the legs and placing the dog's feet. Use of therabands to assist in gait patterning is another example of PNF patterning. To be effective these patterns should be repeated multiple times per day.[29] Tips for stimulating a neurologic patient are given in Box 11.19 (Videos 11.5 to 11.7).

THERAPEUTIC EXERCISES

Therapeutic exercises are a crucial component of any patient's rehabilitation program, regardless of problem or diagnosis. Exercises need to be tailored to the individual patient considering the patient's age and physical condition, condition treated, and resources available. Exercises can be used for weight loss; to improve a patient's ROM; to improve muscle strength, weight bearing, flexibility, balance, and proprioception; to improve aerobic capacity (endurance) and performance; and to decrease pain and improve healing after surgery. Therapeutic exercises, as part of a home exercise program, allow owners to become involved in their pet's recovery and often strengthens the bond with a disabled pet.

After evaluating the patient, identifying problems and structure(s) involved, as well as the amount of tissue healing that has taken place, the therapist must set both long- and short-term goals. It is important that the owner's goals are in line with those of therapist. Each part of the program (proprioception, strength, endurance, and flexibility) should have specific goals, which will vary with the patient and injury. Once the goals are set and the program is designed, it is important for the therapist to evaluate the patient at each visit. Asking and documenting questions about soreness or activity after the last session is crucial. This allows the therapist to adjust the program as needed so the patient continues to progress through the rehabilitation process. At no time should the patient be harmed or uncomfortable. If soreness persists longer than 2 hours after exercise, the exercise may be too intense or the patient may need to be reevaluated. Prophylactic pain control and ice application after exercise may be needed, particularly for postoperative patients. In weak, ataxic, or nonambulatory patients, assistive devices must be used for exercise; this can include booties to protect feet from scuffing the floor or harnesses or slings to assist in ambulation. Frequency, intensity, and duration of exercise are increased as the patient heals to further challenge them and to strengthen muscles. It is usually safe to increase the activity by 10% to 15% each week if the patient does not experience an increase in pain or a loss of function.[23] It is important to monitor the patient for signs of fatigue (e.g., lagging behind, refusing to do exercises, panting, laying down, having a spade-shaped tongue, drooping of the tail and ears, or developing an elevated heart rate or muscle trembling). If these signs occur, one additional rep should be requested from the patient to preclude avoidance behavior. The patient's behavior the next day should be noted and the exercise program adjusted if necessary.[30–32]

Harnesses, safety vests, and leashes should be used to control the patient during exercise. Harnesses that do not restrict shoulder motion are used for rehabilitation. For patients that are not ambulatory or ataxic, front and back end harnesses may be used to assist both the patient and therapist (Fig. 11.12). Booties should be used on slippery surfaces or if the dog is weak and drags its

BOX 11.19 Tips for Stimulation of the Neurologic Patient

- Try a small vibrator or an electric toothbrush to stimulate weak muscles.
- Tap over muscle bellies to stimulate muscles to contract.
- Consider postural reflexes such as wheelbarrowing or hopping.
- Wrap a tensor around the patient from the front to the back to create awareness and connect front and rear of the animal. Alternatively, use a medical shirt or storm coat to do this.
- Remember that any sensory stimulation you can provide will stimulate the superficial receptors.
- Be sure to counsel clients regarding lifestyle changes (e.g., keep the animal on nonslip flooring, raise the food and water bowls, and don't allow the animal to use stairs or jump.)

FIG. 11.12 A poodle in an assistive harness on a BOSU ball. This harness has back and front end handles, making it easier to safely perform exercise.

feet. Doing exercises over balls, foam rollers, or peanuts or while in a sling can be useful for neurologic patients.

Equipment Required for Therapeutic Exercise

Many therapeutic exercises require minimal equipment; however, others require specific pieces of equipment such as physioballs or rolls, cavellettis, weave poles and cones, planks/blocks or stairs, balance boards or discs, therabands, mini-trampolines, or land treadmills (Table 11.4).

Balance and Proprioceptive Exercises

Balance and proprioceptive exercises are used to encourage limb use and improve body awareness and proprioception; some also strengthen selected muscles.[30–32] These exercises allow the patient to recognize that the affected limb is no longer painful and that it is possible to regain a normal posture. Some of these exercises can be started as early as 24 hours postoperatively.

Assisted Standing Exercises

These exercises are used for nonambulatory patients. *Support the patient with a harness or sling. Using the pelvis, assist the patient from a seated to a standing position. Encourage the patient to support weight for as long as possible. Increase the time as the animal gains strength and regains balance (Video 11.8).*

Rhythmic Stabilization/Weight Shifting

These exercises are used to increase weight bearing and balance. *Perform while the dog is standing on a flat, even surface. Place your hands on either side of the dog's ilium and slowly sway the dog from side to side, making sure both legs are weight bearing. Do not use enough force to cause the dog to lose its balance.*

TABLE 11.4 Equipment Required for Therapeutic Exercise Typically Found in a Rehabilitation Center

Equipment	Used To
Physio balls or rolls	• Build strength in all quadrants • Develop core strength, balance, and proprioception
Cavalettis or ground poles	• Train gait, improve proprioception, and strengthen the forelimb and hind limb flexor muscles • Improve active range of motion of all joints
Weave poles and cones	• Create lateral flexion of the spine • Strengthen the adductor and abductor muscles • Improve balance and proprioception
Planks/blocks or stairs	• Strengthen limb muscles • Develop core musculature • Improve proprioception
Balance boards or discs	• Develop strength and balance, particularly in the stabilizer muscles
Therabands	• Can be used as part of an exercise program to facilitate limb movement in neurologic cases, or • To facilitate muscle strengthening and gait training
Mini-trampolines	• Balance and proprioceptive training in cats and small dogs • Particularly useful following spinal surgery to regain core muscle strength
Land treadmills	• Can be used in place of outdoor walking to build cardiovascular fitness and strengthen limb muscles

Weight Shifting, Unsteady Surface

These exercises are used to improve weight bearing and proprioception. This exercise, which can be done in many ways, is performed on an unsteady surface such as a ball, air mattress, or cushion. *Start with two paws on the uneven surface and move the patient around it, then have the patient walk across the surface. Progress to standing on the surface while you apply gentle pressure to each hip or shoulder in a back-and-forth motion to challenge balance. Be sure to use a harness to control the patient so it does not lose balance and fall.*

Balance Boards, Balance Discs, or BOSU Ball

In addition to balance and proprioceptive training, this exercise also strengthens limb muscles (Fig. 11.13). *Place either both front or hind legs (the affected leg and contralateral unaffected leg) on the disc, or alternatively place all four feet on it. Control the patient with a harness and rock the board back and forth. To encourage the dog to walk and stretch while maintaining their balance, have it take treats from different locations on the board. Attempt to have the dog maintain balance despite movement of the board or disc. Start with 3 to 5 minutes twice daily and increase the duration as the patient gains strength. To increase the challenge, place two legs on a peanut or physio roll or BOSU ball.* For home exercises, cushions or air mattresses can be used.

Cavaletti Course

A cavaletti course strengthens limb muscles, improves joint ROM, and benefits all ambulatory patients, including geriatric patients,

FIG. 11.13 A border collie on a rocker board used to improve balance and proprioception.

FIG. 11.14 A rottweiler using a cavaletti course to improve proprioception, increase joint flexion, and strengthen muscles.

canine athletes, and those who have had surgery (Fig. 11.14). Cavaletti courses come in many sizes and shapes and have been used extensively for training in the equine world. The distance between poles and their heights can vary depending on the animal's size and mobility, but the poles should be spaced an even distance apart. *Walk the animal very slowly over the poles while attempting to keep it from touching the poles. In general, start with 5 minutes twice daily and work up to 10 minutes twice daily.* For canine athletes, this exercise may eventually be done at a trot and as part of gait retraining. Other obstacles such as hockey sticks, pool noodles, or broomsticks can be used by the client at home (Video 11.9).

Weave Cones

For this exercise, place six to eight objects 1.5 to 3 feet (0.5 to 1 meter) apart (depending on patient size) and weave the dog in and out of the objects (Fig. 11.15). Use an odd number of cones to improve proprioception and flexibility on only one side of the body; use an even number to work both sides of the body. Pivot the dog sharply at the end of the pattern. Perform this exercise for 5 minutes twice a day. Postoperative orthopedic patients can start this exercise once the fixation is stable; neurologic patients can start once ambulatory (Video 11.10).

Figure Eights

Figure eight exercises are used to improve balance, coordination, spinal ROM, and weight bearing and can also be done with cones. They are completed by walking the outline of the number 8 around two cones. The figure eight is normally twice the height of the dog. *Perform this activity at a slow speed, which allows for an increase in spinal ROM. Do it for a few minutes at a time to avoid making the animal (or the therapist) dizzy.*

Planking on Blocks and Balls

These exercises are used to strengthen core muscles. *To perform, place one paw on each block with the animal in a standing position and have it hold the stance for increasing periods of time. Over time, move the blocks closer to midline or place both paws on one block. Alternatively, use peanut balls to simulate a plank exercise with the dog holding the plank for a period of time.*

Ball Work

Ball work increases proprioception, allows for advanced strengthening and balance, and increases core and trunk stability. Most exercises can be performed on a theraball. *Start the dog on solid ground; once the dog has mastered these exercises, slowly introduce balls. Use a large egg-shaped ball to work on balance and proprioception. Have the dog balance and do sit-to-stands on the ball. Start with four to five reps and work up to 10 to 12 reps, with three sets of each exercise (Video 11.11).*

Core Strengthening

Exercises that help strengthen the core include crawling, sit up and beg, and diagonal leg lifts.[30–32]

Crawling

Crawling improves spinal mobility and ROM and helps strengthen both fore and hind limbs. Dogs can be taught to crawl under beds, boxes, chairs, through an agility tunnel, or simply along the floor. The higher the crawling tunnel that is created, the easier the exercise is for the patient. *Begin with short distances and put treats along the tunnel to encourage the dog to move forward. Gradually increase the distance. Remember to add a command word and always reward while they are learning. Aim to have the dog crawl for 5 minutes per session twice daily (Video 11.12).*

Sit Up and Beg

This exercise helps core strengthening and hind leg strength. *Initially, have the dog sit squarely and then get up onto the back*

FIG. 11.15 A German shepherd using weave poles to improve proprioception and flexibility.

legs as though it were begging. Use treats if necessary. You may need to hold one front leg if the dog is unstable until it is stronger (higher is easier for the dog). To strengthen the hind limbs once the dog can hold the beg position, ask it to stand on its hind limbs by holding the treat higher. Then ask the dog to get back into the beg position. The up and down from beg to stand is similar to performing squats for humans. *Eventually work up to two sets of 8 to 10 reps, twice daily (Video 11.13).*

NOTE Sit up and beg exercises should not be done if the dog has back or hip issues; this may aggravate already injured areas.

Diagonal Leg Lifts

These exercises help with core strengthening as well as balance, weight shifting, and leg strengthening (Fig. 11.16). *Lift one front leg off the ground along with the diagonal hind leg. Lift both legs simultaneously and provide minimal support to the limbs. Hold this pose for 10 to 30 seconds and repeat 8 to 10 times. When this exercise is easy for the dog, progress to having the dog stand on four blocks and then lift the diagonal legs. Finally, add some weight shifting to cause the dog to balance further.* Diagonal leg lifts on a therapy ball can be done as a further challenge for the dog (Video 11.14).

Hind Limb Exercises

These exercises include sit-to-stand, backwards walking, side stepping, incline walking, standing with elevated front legs, and ladder walking.[30–32]

Sit to Stand

This exercise helps improve strength in the pelvic limbs, particularly in the gluteal and hamstring muscles. *Ensure that the dog sits squarely and that he uses both pelvic legs to propel the body up.* A square sit occurs when the hips, stifles, and tarsi are in a straight line with the shoulders, which are perfectly aligned with the carpal joints. *If the dog kicks one leg out to the side, have the dog stand again and sit while placing your leg against the dog's paw, thus ensuring a square sit. Alternately, ask the dog to sit against the wall with the affected leg against the wall, thus preventing the leg from moving laterally. Repeat this exercise often for increased strengthening (Video 11.15).*

FIG. 11.16 A cat undergoing diagonal left lifts for core strengthening.

Backwards Walking

This exercise helps strengthen the pelvic legs (particularly the hamstring muscle group) and increase balance, coordination, and proprioception. *Start with the dog parallel to a wall, sofa, or anything straight. Hold a treat at chest level and walk toward the dog, saying "back."* Most dogs will try to turn while they are learning to walk backwards; thus it is important to reward the dog when it takes a step backwards. *Alternatively, have a couch parallel to the wall just far enough from the wall that the dog cannot turn around. Entice the dog forward with a treat, then say "back" and encourage it to walk backwards for another treat.* This is an important exercise to teach all dogs and puppies because at some time in their lives all dogs will need more hind limb strength. *Perform a backwards walking session for 5 to 10 minutes, twice daily (Video 11.16).*

Side Stepping

This exercise helps with both the fore and hind limb strengthening. *Stand with the front of your body facing the side of the dog, grasp the dog's collar in one hand, and hold the other hand on the dog's opposite hip. Then walk toward the dog, encouraging it to side step. If there is a problem controlling the back end of the dog during this exercise, use a front and back end harness for extra back end control. Perform this exercise both ways to strengthen the adductor, abductor, and pectoral muscles.*[47]

Incline Walking

This exercise helps build muscles in the rear legs due to the weight being shifted towards the back. *Start with shallow inclines and then add steeper inclines when the pet is comfortable and adjusting well. Incorporate zigzag hill walking, where the patient walks in a zigzag pattern across the hill, up and down. Start with 5 minutes and gradually work up to 20 minutes twice daily, incorporating hills (Video 11.17).*

Standing With Elevated Front Legs

This exercise is used to improve rear leg weight bearing and strength, ROM, and hip extension. *Have the owner sit on the stairs or a couch. With the dog's back legs firmly on the ground, place the front legs one or two stairs up or on the couch cushion (height depends*

on dog's body length). This causes the dog's weight to shift to the pelvic limbs, thus causing the weaker hind legs to support the majority of the body weight. *Start with 10 seconds and work up 30 seconds at a time. Aim for 10 reps at a time (Video 11.18).*

Ladder Walking

This exercise strengthens legs and improves ROM, balance, coordination, and proprioception. The exercise is performed with a ladder flat on the ground and is similar to cavalettis but can be modified to be easy or difficult. *Initially, walk the dog forward over the rungs. Over time teach the dog to walk backwards and sidestep through the ladder. Start with 5 minutes twice daily and work up in frequency.*

Front Limb Exercises

Exercises specific for the front limbs include the high-five salute, wheelbarrow, stairs, play bow, and digging.[30–32]

High-Five Salute

This exercise helps with ROM and strengthening of the forelimbs. *Start with the dog sitting, then have the dog bring its paw up to its head and away as though saluting.* This particular exercise takes some training for most dogs. When "giving a paw," dogs usually only move their forelimb distal to the elbow. In this exercise, they need to move their shoulder to strengthen the extensor, abductors, and adductor muscles of the shoulder. *Start with a treat in your hand. When the dog paws at the treat, give the treat. Move your hand higher and into the position you wish the dog to reach (Video 11.19).*

Wheelbarrow

This exercise helps strengthen the front limb and the core. This may seem like an easy exercise, but it is quite challenging and needs to be done slowly and cautiously. *Never pick the dog up by the pelvic limbs. Start with lifting the patient by the caudal part of the abdomen so that the rear legs are a few inches off the ground. Observe contractions of the core muscles. Keep the stationary position for a while until the dog is comfortable with being lifted. Next, slow movement forwards and backwards can be added, making sure to monitor the animal's spinal alignment. Keep the spine perfectly straight to prevent injury. Do not push the patient too quickly; this can cause tripping and inevitably the dog's head will hit the ground. Do not do this exercise in a patient with spinal issues, shoulder problems, or carpal hyperextension.*

Stairs

Descending stairs helps build muscle in the front legs, as most of the weight is forced to the front half when walking down stairs. This exercise is very similar to walking on a decline. *Start with a shallow decline and gradually use a steeper decline as the patient progresses. Add changes only when the animal is comfortable and adjusting well. Start with slow stair walking 5 minutes twice daily and increase the time as the patient becomes stronger.*

Play Bow

This exercise helps increase forelimb strength and flexibility and promotes core strengthening. *Hold a treat in one hand and place your other hand under the patient's abdomen. Move the treat to the floor, allowing the dog's head and shoulders to follow while holding the abdomen up so that the back legs are standing and front legs are down. Do 8 to 10 reps initially and add more sets as the patient becomes stronger.*

Digging

Digging helps strengthen the front limbs and improves ROM, proprioception, and core strength. *When performing this exercise, have a command and a designated area where digging can occur, such as soft sand, soil, or light snow when in season. Do not use stones, which may hurt the paws. Bury a cookie or favorite bone so that the dog can dig it up.* Caution: some owners do not wish to encourage digging!

NEUROLOGIC REHABILITATION EXERCISES

Assisted Standing

This exercise builds and maintains muscles needed for balance, proprioception, and locomotion. These muscles quickly become atrophied if they are not used, which frequently occurs with paresis. *Place a therapy ball, rolled towel, cushion, foam roller, or other device (depending on the size of the dog) under the dog's abdomen.* While performing assisted standing, it is crucial to keep the pet's feet in a normal, anatomically correct standing position without knuckling. *Provide larger dogs with additional abdominal support from a sling or back end harness. If needed, have an assistant help place the feet.* Smaller dogs and cats generally require only one person if their abdomen is supported by a theraball. *Continue only until you see the first signs of fatigue. After a brief rest, repeat the procedure but do not exhaust the patient (Videos 11.20 to 11.22).*

Physio Ball

Physio ball work is particularly important for rehabilitation of neurologic patients. It can be used for assisted standing as described earlier, for assisted walking, and to regain balance and coordination. *Place the front end of the patient on the ball and rock it back and forth. If needed, have an assistant help place the feet on the ball. The dog may progress to sit-to-stands on the ball with assistance* (Fig. 11.17).

FIG. 11.17 A dog on a ball performing a sit-to-stand exercise. This exercise may need two people for a large dog.

Weight Shifting

Weight shifting is used for neurologic patients that need to practice balancing on three limbs. *To perform this exercise, place the dog in a standing position and lift one limb. When the dog starts to sway, replace the limb. Rotate all four paws through this exercise.*

Treadmill Gait Training

Land and water treadmills are used for gait retraining for neurologic patients. Walking on a treadmill with a 5% incline has been shown to improve hamstring strength. The patient often must be supported with a sling. *Move the dog's legs in a proper gaiting pattern (right rear to right front, left rear to left front).*[10] *To overcome adductor spasticity, tickle the caudomedial aspect of the pelvic limb to prevent crossing over. As the gait becomes more normal, add walking and hills to the exercise (see Video 11.21).*

Tapping

Tapping is used as part of the nursing care for animals recovering from paralysis. *Tap over a muscle belly to elicit muscle contractions and stimulate the muscle spindle fibers and Golgi tendon organs in muscle and tendon. Perform for 3 to 5 minutes a few times a day (see Video 11.3).*

Tensor Bandaging or Medical Shirts

These items are used in dogs with neurologic conditions to connect the front and back end of the dog and create body awareness. *Place the wrap such that it exerts slight pressure on the body to help with the neurologic coordination.* Many of these dogs can wear such shirts or wraps throughout recovery.

Tactile Stimulation

Touch is used to provide stimulation to the superficial receptors in the patient's skin. *Brush the dog, tap, pinch, or use a vibrator to provide additional sensory stimulation to increase input into the nervous system.*

Mental Stimulation of Neurologic Patients

Mental stimulation is used to engage the patient mentally, which speeds recovery. Be aware that the patient's mental state plays a big role in recovery. Dogs can become depressed if they cannot move, go outside, or interact with their family. *Stimulate the dog by taking it outside or on "walks" in a wagon or stroller, moving around the house frequently if the patient is unable to move, or provide new treats or squeaky toys.*

AQUATIC THERAPY

Aquatic therapy can consist of deep water swimming or UWTM therapy. Water offers a safe and effective medium for improving strength, muscular endurance, cardiovascular fitness, ROM, agility, psychological well-being, and pain reduction. Metabolic energy requirements for exercise are greater when the same exercise is performed in the water versus on land. Shmalberg and colleagues have demonstrated that a dog trotting in a UWTM burns 5 to 10 times the energy of an equivalent trot on land.[33] Benefits of aquatic therapy are provided in Box 11.20.

Aquatic Therapy Equipment

Most rehabilitation services will have a pool, a UWTM, or both. However, aquatic therapy can take place in a wading pool, hot tub, bath tub, or a lake depending on the patient and the skill of the therapist. Studies have shown that a dog immersed in water to the level of the greater trochanter only bears 38% of the weight on his joints compared with the same dog on land.[34]

Life vests are needed for most patients and help ensure that the therapy is safe and effective. Ramps or other devices may be needed to get the patient into the water. Therabands, floating toys, small floating surf boards, pool noodles, and children's water wings are all essential pieces of equipment. The disadvantage of aquatic therapy is the initial cost and upkeep of a pool or UWTM. Precautions and considerations for aquatic therapy are listed in Box 11.21.

UWTM therapy is the preferred method of strengthening rehabilitation patients, whether the patient is ambulatory or not. UWTM therapy assists with both joint kinetics and kinematics. By increasing or decreasing the level and speed of the treadmill, joint flexion and extension are maximized, unlike swimming, in which normal kinematics are altered. Active ROM is also improved because the patients lift their legs higher while walking in the treadmill (Fig. 11.18). Gait retraining and sequencing is possible using the treadmill whether the patient is ambulatory or not. A therapist can assist the patient in ambulation by manual placement of the feet to stimulate muscle memory and retraining. Tetraparetic animals can be assisted in the UWTM by means of slings or harnesses. Two therapists may be required to assist these animals (see Video 11.6).

NOTE All dogs should have a therapist with them in the UWTM. This allows the therapist to quickly adjust if the patient requires it and provides added safety and enhanced efficacy of therapy.

BOX 11.20 Benefits of Aquatic Therapy to the Rehabilitation Patient

- Water provides buoyancy, which creates an environment of reduced gravity, thereby allowing greater joint range of motion with decreased pain, earlier postoperative intervention, early ambulation for neurologic patients, and a controlled exercise environment.
- Water exerts hydrostatic pressure, which reduces edema and nociceptor activity, which reduces pain.
- Water creates resistance due to its viscosity. This resistance strengthens the muscles as the patient pushes against it and provides stability. Dogs who are unable to walk on land often can stand and ambulate when in the water. Dogs with weak or atrophied muscles or obese patients that struggle to move on land often do well in the underwater treadmill.
- Warm water provides muscle relaxation.
- Water provides muscle stimulation for atrophied muscles.

Data from Levine D, Millis DL, Flocker J, MacGuire L. Aquatic therapy. In: Millis DL, Levine D, eds. *Canine Rehabilitation and Physical Therapy*. 2nd ed. Philadelphia: Elsevier; 2014:526–542.

BOX 11.21 Precautions and Contraindications for Aquatic Therapy

1. Prevention of wound infection—make sure all surgical incisions are healed before beginning aquatic therapy.
2. Panic by the patient—some dogs are afraid of water. In general, most patients tolerate the underwater treadmill better than swimming as their feet are on the ground.
3. Assessment of cardiovascular fitness—as it requires more energy to swim, postoperative, geriatric, and obese patients may tire easily. The therapist needs to schedule a number of breaks in each session to allow the dog to rest.

Data from Levine D, Millis DL, Flocker J, MacGuire L. Aquatic therapy. In: Millis DL, Levine D, eds. *Canine Rehabilitation and Physical Therapy*. 2nd ed. Philadelphia: Elsevier; 2014:526–542.

FIG. 11.18 A dog with joint disease using an underwater treadmill.

FIG. 11.19 A dog swimming in a therapy pool. This is great cardiovascular conditioning for canine athletes.

With deep water swimming, life vests should be used and a therapist should assist the patient in the pool. A trained therapist can help the patient recreate movement patterns in the water that may not be able to be performed on land. Swimming is a demanding exercise and may not be appropriate for the postoperative patient (Fig. 11.19). The length of time that the patient swims depends on condition and degree of disability. Thirty-minute sessions are often used, with many rests between swim cycles. Vital signs need to be monitored by checking pulse, tongue, facial expression, and speed of swimming, as well as any change in emotional state. Pool noodles or flutter boards can be used for increased buoyancy, if needed. Deep water swimming is often added to the rehabilitation plan if the patient is a canine athlete that needs further cardiovascular conditioning. Tips for performing hydrotherapy are provided in Box 11.22.

SPECIAL CONSIDERATIONS FOR COMMON CONDITIONS

Common conditions that may require special consideration for rehabilitation include fracture patients, neurologic patients, patients post–joint surgery, and patients with osteoarthritis. Tips for dealing with each condition are included in Boxes 11.23 to 11.26.

BOX 11.22 Tips for Performing Hydrotherapy

- Maintain the water temperature between 82°F and 88°F, (27.5°C–31°C) depending on the time of year. This is comfortable for most patients.
- Fill the water level in an underwater treadmill such that it is at the level of the greater trochanter for most patients.
- Treadmill speed is dependent on dog size and condition. Generally, neurologic patients are started at 0.1–0.4 mph (0.16–0.6 kph) and adjusted accordingly. Most orthopedic patients start at 0.3–1.0 mph (0.5–1.6 kph) depending on the condition and the size of the dog. The dog needs to be able to walk at a normal pace to perform the appropriate gait pattern.
- Start most patients with three short sessions of 1–3 minutes with breaks for massage and passive range of motion.
- Use swim diapers for all neurologic patients. Express the bladder for patients with urinary incontinence and stimulate them to defecate by using a cotton swab in the anal area.
- Do not use hydrotherapy in animals with diarrhea, poor anal tone, or open sores.

Data from Levine D, Millis DL, Flocker J, MacGuire L. Aquatic therapy. In: Millis DL, Levine D, eds. *Canine Rehabilitation and Physical Therapy*. 2nd ed. Philadelphia: Elsevier; 2014:526–542.

BOX 11.23 Clinical Tips for Rehabilitation of Fracture Patients

- Consider the well-being of the entire patient. In early fracture healing, overuse can lead to implant failure; however, excessive cage rest can lead to delayed healing, contracture, decreased range of motion, and muscle atrophy. Remember safety but strike a happy medium.
- Delay hydrotherapy until incisions are healed to prevent infection.
- Use slings, harnesses, or assistive devices at all times in early rehabilitation to ensure safety and protect the fracture repair.
- Limit active exercise to 15 minutes twice daily for the first 4 weeks, increasing gradually.

BOX 11.24 Clinical Tips for Neurologic Patients

- Begin therapy as soon after surgery as possible.
- Use stimulation, proprioceptive neuromuscular facilitation patterns, and neuromuscular electrical stimulation early and often with these patients.
- Acupuncture, as discussed in Chapter 13, works well for stimulation of these patients.
- Use an underwater treadmill and laser therapy early in neurologic patients to reduce time to ambulation.
- Gait patterning is extremely important for these patients. See text on p. 117 regarding stimulation of, and exercises for, the neurologic patient.

BOX 11.25 Clinical Tips for Patients After Joint Surgery

- Work closely with the surgeon and have an understanding of the procedure performed and the limitations that it puts on the patient.
- Primary goal after joint surgery is to restore weight bearing to the affected limb as safely and quickly as possible.
- Animals with extracapsular cruciate repairs and femoral head and neck osteotomies can begin rehabilitation immediately after surgery.
- Patients who have undergone a tibial plateau leveling osteotomy procedure should start rehabilitation immediately, but water therapy should be delayed to prevent patellar desmitis. Treat these patients similarly to patients after fracture repair.

BOX 11.26 Clinical Tips for Patients With Osteoarthritis

- Many of these patients are obese and calorie and protein requirements should be calculated. A dietary consult should be included for all patients with osteoarthritis.
- This is a waxing and waning disease that needs to be treated with multimodal therapy. Therapeutic exercises, laser, acupuncture, massage, heat therapy, and underwater treadmills are appropriate for these patients.
- These patients benefit from a home exercise program to help to manage their disease.

12 Principles of Anesthesia and Anesthetics

GENERAL CONSIDERATIONS

Anesthesia of the small animal patient can be done safely when care and consideration are used in the selection and administration of anesthetic and analgesic agents and when anesthesia equipment is used correctly. The use of an anesthesia/surgery checklist is recommended to improve safety and to avoid potential errors. A routine checklist has been provided in Fig. 12.1.

Anesthesia (general and local), sedation, and analgesia (see Chapter 13) are used to alleviate pain, produce muscle relaxation and amnesia for humane and safe care of veterinary patients, and to create a quiet, nonmoving surgical field for surgeons. Before anesthesia or sedation the patient should have a complete physical exam (see Chapter 4). The American Society of Anesthesiologists has developed a physical classification system that is subjectively used to help determine the risk factor a patient may face when undergoing anesthesia (see Table 4.1). Fluid therapy (see later and Chapter 4) and blood replacement (see Table 4.5 and Box 4.1) are also important considerations during anesthesia.

General anesthesia is drug-induced unconsciousness that is controlled by reversible depression of the central nervous system (CNS) and perception. *Balanced anesthesia* is achieved by the use of multiple agents and techniques, with the goal of minimizing high drug doses and potential complications associated with the use of any one single agent. *Total intravenous (IV) anesthesia*, as the name implies, denotes the maintenance of general anesthesia without the use of inhalants. The classic stages of anesthesia (disorientation, excitement, anesthesia, and moribund) are provided in Box 12.1.

NOTE Be aware that when newer inhalant agents are given, or balanced or total IV anesthesia are used, the classic stages of anesthesia are not always reliable indicators of anesthetic depth.

Premedication is commonly given intramuscularly (IM) or subcutaneously (SC) to alleviate stress to the animal, provide analgesia and restraint, and decrease the amount of inhalant anesthesia that will be needed. In an animal that already has an IV catheter in place, premedication agents may be given intravenously or can be part of an induction protocol.

ANESTHETIC AGENTS

Numerous anesthetic agents are used in dogs and cats. Table 12.1 lists drugs and their class, doses, onset and duration of action, and their uses and precautions.

Antimuscarinics

Antimuscarinics (**atropine, glycopyrrolate**) competitively inhibit acetylcholine at parasympathetic muscarinic (cholinergic) receptors. Indications for their use are provided in Table 12.1. Antimuscarinics can cause transient slowing of the heart rate (including atrioventricular block) before the onset of the peripheral anticholinergic effect. This occurs because of inhibition of presynaptic cholinergic receptors that are part of the sympathetic pathways. Bradycardia is most common after IV administration and can last up to 3 minutes before an increase in heart rate occurs. It is more likely to occur with atropine than with glycopyrrolate because of the greater anticholinergic effects of atropine on the heart and because of its rapid onset of action. Usually this paradoxical bradycardia quickly resolves, but if necessary the dose can be repeated to cover additional cholinergic receptors to obtain the desired cardiac effect.[1] Glycopyrrolate is a quaternary ammonium that does not readily cross the blood-brain and placental barrier. The antisialagogue effect is more potent than that of atropine and, it is less likely to cause tachycardia.[1] See Table 12.1 for doses, onset and duration of action, and precautions.

Tranquilizers

Tranquilizers (e.g., acepromazine, diazepam, midazolam, zolazepam) are used to reduce anxiety and are not reliable by themselves for sedation or chemical restraint. It is important to remember that they do not have analgesic effects.

Phenothiazines

Acepromazine, a phenothiazine, antagonizes dopamine and serotonin neurotransmission (see Table 12.1 for dose and onset and duration of action). Dopamine antagonism creates calming and antiemetic effects. Acepromazine also blocks central norepinephrine and epinephrine transmission. The peripheral action is blockade of alpha-1 vascular receptors leading to vasodilation and potential hypotension. See Table 12.1 for precautions associated with the use of this drug. Acepromazine is metabolized in the liver and excreted by the kidneys and therefore should be used cautiously in patients with hepatic or renal dysfunction. In dogs with preexisting seizure disorders there is no clinical evidence that administration of acepromazine increases seizure activity.[2,3] It does cause marked relaxation of the splenic smooth muscle, leading to pooling of red blood cells in the spleen. It has minimal respiratory depressive effects, so it can be used to provide tranquilization in animals with respiratory distress. It is not a controlled drug, and there is no antagonist. Acepromazine has been used in combination with opioids, alpha-2 agonists, and dissociatives. It is generally only recommended for use in young and healthy patients. In this patient population, it can provide profound sedation that may assist in quieting animals, both preoperatively and postoperatively (see later).

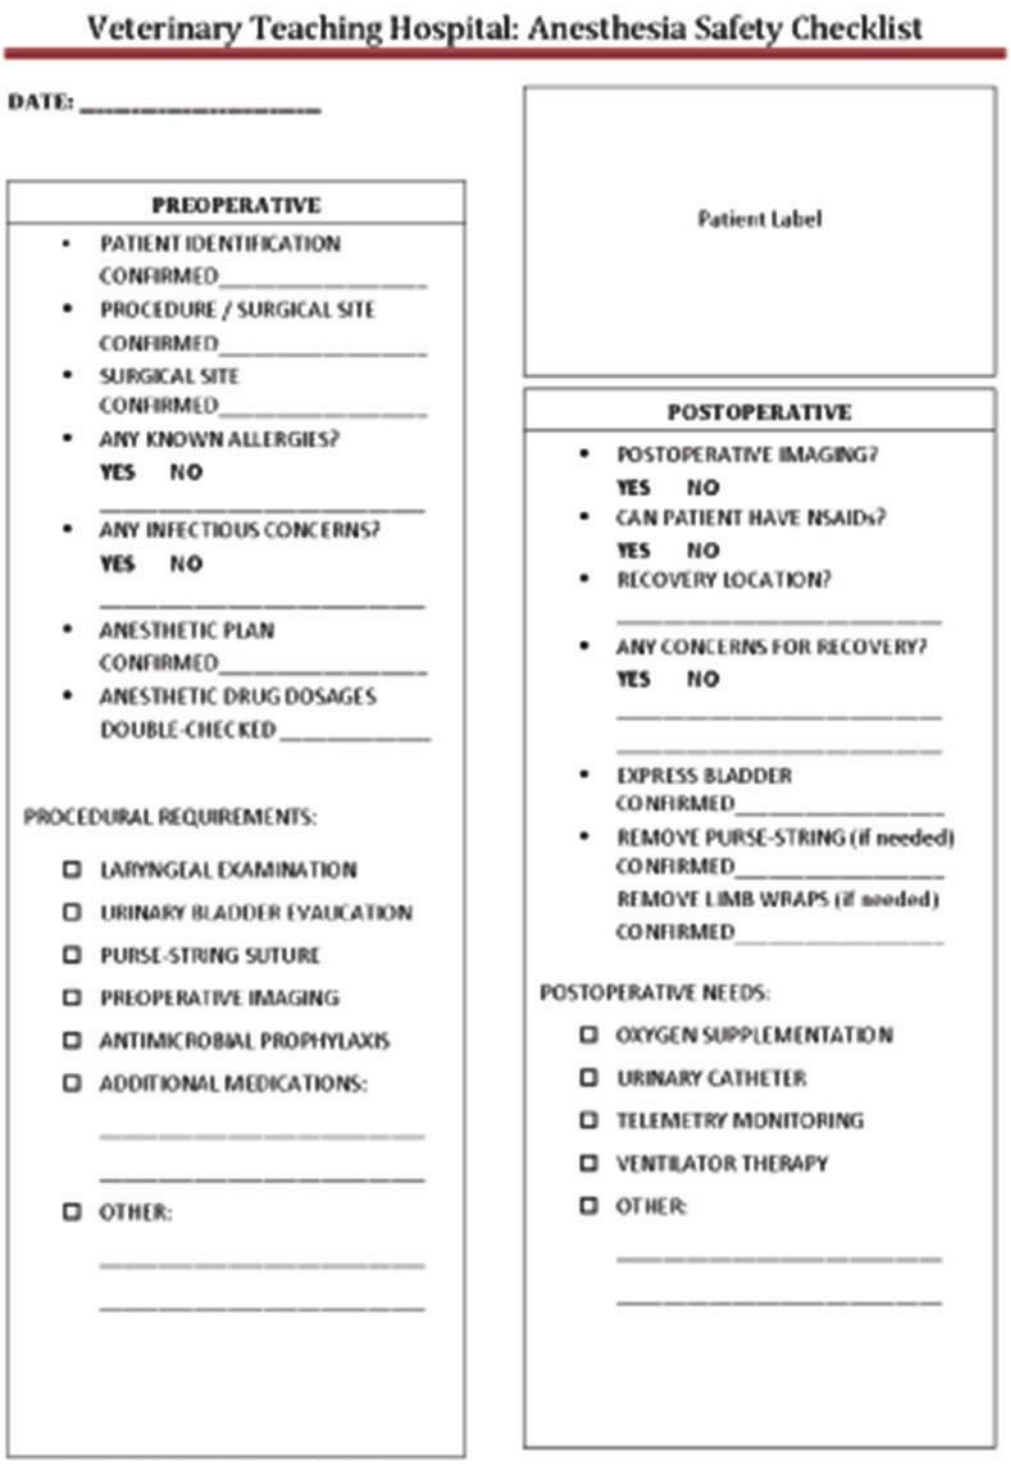
Text continued on p. 131

ABSTRACT

Safe anesthesia is part of a successful surgical procedure. Anesthesia can consist of general anesthesia, intravenous anesthesia, and local or regional blocks to supplement the anesthetic episode. Various drug classes are utilized to provide anesthesia and analgesia, including tranquilizers, alpha-2 agonists, dissociatives, opioids, and local anesthetics.

KEYWORDS

tranquilizers
alpha-2 agonists
dissociatives
opioids
local anesthetics



Veterinary Teaching Hospital: Anesthesia Safety Checklist

DATE: _____

PREOPERATIVE

- PATIENT IDENTIFICATION CONFIRMED _____
- PROCEDURE / SURGICAL SITE CONFIRMED _____
- SURGICAL SITE CONFIRMED _____
- ANY KNOWN ALLERGIES? YES NO _____
- ANY INFECTIOUS CONCERNS? YES NO _____
- ANESTHETIC PLAN CONFIRMED _____
- ANESTHETIC DRUG DOSAGES DOUBLE-CHECKED _____

PROCEDURAL REQUIREMENTS:

- ☐ LARYNGEAL EXAMINATION
- ☐ URINARY BLADDER EVALUATION
- ☐ PURSE-STRING SUTURE
- ☐ PREOPERATIVE IMAGING
- ☐ ANTIMICROBIAL PROPHYLAXIS
- ☐ ADDITIONAL MEDICATIONS: _____ _____
- ☐ OTHER: _____ _____

Patient Label

POSTOPERATIVE

- POSTOPERATIVE IMAGING? YES NO
- CAN PATIENT HAVE NSAIDs? YES NO
- RECOVERY LOCATION? _____
- ANY CONCERNS FOR RECOVERY? YES NO _____ _____
- EXPRESS BLADDER CONFIRMED _____
- REMOVE PURSE-STRING (if needed) CONFIRMED _____
  REMOVE LIMB WRAPS (if needed) CONFIRMED _____

POSTOPERATIVE NEEDS:

- ☐ OXYGEN SUPPLEMENTATION
- ☐ URINARY CATHETER
- ☐ TELEMETRY MONITORING
- ☐ VENTILATOR THERAPY
- ☐ OTHER: _____ _____

FIG. 12.1 Example of a routine anesthetic safety checklist.

NOTE A rare idiosyncratic reaction of profound aggression has been reported in dogs following oral or parental acepromazine administration. The reported dogs did not manifest aggression prior to drug administration, nor on recovery from the drug effect. Though this is a rare event, due to the potential for serious injury, it is recommended that treated dogs be supervised when around other animals or children, especially if the dog has received acepromazine for the first time.[4]

NOTE Use acepromazine cautiously, if at all, in boxer dogs due to possible cardiovascular collapse.

BOX 12.1 Stages of Inhalant Anesthesia

Stage I: Voluntary movement and excitement from initial administration until loss of consciousness. Release of epinephrine can occur during this stage.

Stage II: Delirium and involuntary movement until the onset of a regular pattern of breathing. Release of epinephrine can occur during this stage.

Stage III: Surgical anesthesia. Muscle relaxation develops. In this stage planes of anesthesia have been described:

- Light plane (plane 1): has eye movement reflexes.
- Medium plane (plane 2): has progressive intercostal paralysis.
- Deep plane (plane 3): has diaphragmatic respiration.

A normal surgical level of medium depth would be stage III, plane 2.

Deep surgical anesthesia would be stage III, plane 3, with a centered and dilated pupil.

Stage IV: Extreme central nervous system depression and a shock state. Death will ensue unless the anesthesia is withdrawn and resuscitation instituted.

Modified from Tranquilli WJ, Grimm KA. Introduction: use, definitions, history, concepts, classification, and considerations for anesthesia and analgesia. In: Grimm KA, Lamont LA, Tranquilli WJ, et al, eds. *Veterinary Anesthesia and Analgesia.* 5th ed. Ames, IA: Wiley-Blackwell; 2015:3–10.

TABLE 12.1 Anesthetic Agents

Anesthetic Agent/ Class	Dose	Onset and Duration of Action	Uses/Precautions
Antimuscarinics			• Used to prevent vagal-induced bradycardia and decrease excessive salivations Side effects include: • Tachycardia • Decreased respiratory secretion; makes secretions more viscous • Bronchodilation • Decreased GI motility • Transient bradycardia may occur before anticholinergic effect • May increase myocardial work and oxygen consumption
Atropine	0.04 mg/kg IM, 0.02 mg/kg IV	Onset of action: 15–20 min IM Duration of action: 1–1.5 h	• Bradycardia is more likely than with glycopyrrolate • Causes mydriasis • Can cause tachyarrhythmias
Glycopyrrolate (Robinul-V)	0.01 mg/kg IM, IV	Onset of action: 30–45 min IM Duration of action: 2–4 h	• Less likely to cause tachycardia than atropine • Does not readily cross the blood-brain barrier or placenta • More potent than atropine
Tranquilizers			• Used to produce a calming effect • Not reliable by themselves for sedation or chemical restraint (mild sedatives) • Do not have analgesic effects • Wide margin of safety • Can be given IM, IV, PO, transmucosally, or rectally
Benzodiazepines			
Diazepam (Valium), Schedule IV	0.2–0.5 mg/kg IM, IV CRI: 0.1–0.5 mg/kg/h	Onset of action: allow at least 20 min after intramuscular administration Duration of action: 1–4 h	• Reversible • Contains propylene glycol • Can cause phlebitis; use large vein for CRIs • Painful when given IM • Increasing the dose does not produce a proportional increase in sedation
Midazolam (Versed), Schedule IV	0.07–0.4 mg/kg IM, IV CRI: 0.1–0.5 mg/kg/h	Onset of action: 5–10 min Duration of action: 1–2 h	• Water soluble • Excellent absorption
Flumazenil (Romazicon)	0.01–0.02 mg/kg IV	Onset of action: rapid Duration of action: 1 h	• Used to reverse benzodiazepine effects • Expensive • Is not a scheduled drug
Phenothiazines			• Vasodilatory • Long duration of action • Does not provide analgesia

Continued

TABLE 12.1 Anesthetic Agents—cont'd

Anesthetic Agent/ Class	Dose	Onset and Duration of Action	Uses/Precautions
Acepromazine (PromAce)	0.01–0.1 mg/kg IM, IV	Onset of action: IM, 35–40 min; IV, 5–15 min Duration of action: dose dependent, 3–8 h	• Do not give more than 3 mg total IM • Use with caution in boxers and animals with hepatic or renal dysfunction • Do not use in animals with hypovolemia, hypotension, or shock • May cause collapse when given intravenously to an extremely excited or stressed animal
Opioids			• Antidiuresis is due to release of ADH (which can lead to urinary retention) • Cause analgesia, antidiuresis, decreased GI motility, and sedation
Mu Agonists *Schedule II Drugs*			• May cause respiratory depression and bradycardia • Good analgesic • Minimal effect on CV parameters • Monitor cats for hyperthermia, most commonly occurs with hydromorphone • Reverse with naloxone • May need an antimuscarinic when given as a CRI
Morphine	*Dogs:* 0.2–2 mg/kg IM, SC CRI 0.1–0.3 loading dose then 0.1 mg/kg/h *Cats:* IM 0.05–0.4 mg/kg	Onset of action: IM, 5–10 min Duration of action: 3–6 h	• May cause emesis • Give IV slowly as it can cause histamine release
Oxymorphone (Numorphan)[a]	*Dogs:* 0.02–0.2 mg/kg IM, IV, SC *Cats:* 0.02–0.17 mg/kg IM, 0.02–0.05 mg/kg IV	Onset of action: IM, 5–10 min Duration of action: 1–3 h	• Safe to give IV; no histamine release
Meperidine (Demerol, Validus, Pethidine)	*Dogs:* 1–5 mg/kg IM, SC *Cats:* 0.5–5 mg/kg IM, SC	Onset of action: 5–10 min Duration of action: 1–2 h	• IV not recommended due to histamine release
Methadone (Dolophine, Methadose, Amidon)	*Dogs:* 0.2–1.5 mg/kg IM, IV *Cats:* 0.1–0.5 mg/kg IM, IV	Onset of action: 10–15 min Duration: 3–4 h	• Safe to give IV; no histamine release • Minimal incidence of vomiting • Poor sedation when given alone
Hydromorphone (Dilaudid)	*Dogs:* 0.05–0.2 mg/kg IM, IV, SC CRI 0.025–0.05 mg/kg IV loading dose, then 0.01–0.04 mg/kg/h *Cats:* 0.02–0.2 mg/kg IM, IV	Onset of action: 15 min Duration of action: 1–3 h	• Safe to give IV; no histamine release • Less likely than morphine or oxymorphone to cause vomiting
Fentanyl (Sublimaze)	0.005–0.015 mg/kg IM, IV, SC CRI for dogs 5–10 µg/kg IV loading dose, then 0.7–1 µg/kg/min, or 5–10 µg/kg/h CRI for cats 2–3 µg IV loading dose, then 0.3–0.4 µg/kg/min, or 2–5 µg/kg/h	Onset of action: 5–10 min Duration of action: 15–30 min Transdermal patch: time of drug uptake to effective drug concentrations is variable, depending on skin temperature, blood flow to the skin, and patch adherence to the skin: from 12 hours in cats to up to 24 hours in dogs. The duration of effect is approximately 4 days	• Safe to give IV; no histamine release • Large volumes needed for IM or SC • May cause bradycardia and respiratory depression
Remifentanil (Ultiva)	*Dogs:* CRI 0.25–0.5 µg/kg/min has been used in conjunction with a propofol CRI at 0.2 mg/kg/min *Cats:* 3 µg/kg IV; CRI 0.1–0.3 µg/kg per minute alone or in combination with ketamine at 0.5 mg/kg IV followed by 1.8 mg/kg/h	Onset of action: rapid Duration of action: short, must be given as CRI, half-life 6 min	• Elimination is independent of hepatic or renal function • Bradycardia may occur and may require treatment with an antimuscarinic • It is a potent respiratory depressant and may necessitate controlled ventilation

TABLE 12.1 Anesthetic Agents—cont'd

Anesthetic Agent/ Class	Dose	Onset and Duration of Action	Uses/Precautions
Mu Antagonist/ Kappa Agonist			• Partial reversal of mu agonist drugs • Minimal CV effects • Mild analgesic
Butorphanol (Torbugesic,Torbutrol), Schedule IV	0.1–0.8 mg/kg IM, IV, SC CRI 0.1–0.2 mg/kg IV loading dose, then 0.1–0.2 mg/kg/h	Onset of action: 5–7 min Duration of action: 45 min–1.5 h	• Can be used to partially reverse mu opioid agonist but maintain kappa effects
Nalbuphine (Nubain)	0.25–2 mg/kg IM, IV, SC	Onset of action: 5–10 min Duration of action: 1–2 h	• Minimal to no sedation; use with a tranquilizer or sedative • Not a scheduled drug
Partial mu Agonists: Schedule III Drugs			
Buprenorphine (Buprenex, Simbadol)	0.005–0.02 mg/kg IM, IV, SC *Cats:* 0.24 mg/kg once a day for up to 3 days, SC	Onset of action: 20–30 min Duration of action: 3–6 h Onset of action: 1 hr Duration of action: 24–48 h	• Effects difficult to reverse • Good for moderate pain • Large safety profile • Adverse side effects may include hyperactivity, difficulty in handling, disorientation, agitation and dilated pupils; but more commonly cats become quiet, euphoric, purring, rubbing and kneading with their forepaws.[7]
Opioid antagonist: Naloxone (Narcan)	0.001–0.04 mg/kg IM, IV	Onset of action: 5 min Duration of action: 30–60 min	• Reverses opioid effects • May cause tachycardia, hypertension, pain, and excitement • Renarcotization may occur when used to reverse a long-acting opioid
Opioid agonist and inhibits reuptake of serotonin and norepinephrine: Tramadol; Schedule IV	2–10 mg/kg every 6–12 h	Onset of action: variable Duration of action: variable, hours	• Mu agonist • Metabolite m1 has activity • Centrally acting • Naloxone will only partially antagonize effects of tramadol • Unpleasant taste • May see sedation at higher dose
Dissociatives			
Ketamine (Ketaset, Ketaved, Vetalar); Schedule III	4–11 mg/kg IV, IM CRI 0.5 mg/kg IV loading dose then 0.1–0.5 mg/kg/h	Onset of action: 10 min Duration of action: dose dependent, 20–30 min	• Can cause excess salivation, so it is commonly used with an antimuscarinic • May increase heart rate and ICP and IOP • Renal elimination in the cat • Well absorbed, but stings on injection • Can cause seizure-like activity in dogs when given alone, so it is commonly used with benzodiazepines • Will cross the placenta and lead to depression of neurologic reflexes in cesarean-delivered neonates
Tiletamine (dissociative) and zolazepam (benzodiazepine; Telazol); Schedule III	2–4 mg/kg IM, IV as part of premed or induction Diagnostic procedures: *Dogs:* 6.6–9.9 mg/kg IM *Cats:* 9.7–11.9 mg/kg IM Minor procedures (e.g., laceration repair): *Dogs:* 9.9–13.2 mg/kg IM *Cats:* 10.6–12.5 mg/kg IM	Onset of action: 5 min but can vary Duration of action: dose dependent, 20–30 min	• As given for ketamine • Profound hypothermia and prolonged recovery may occur • Most useful for restraint or very short procedures • Because onset of action is variable, observe the patient carefully after administration • May cause respiratory depression • Do not use in animals with pancreatic disease, renal pathology, or severe cardiac or pulmonary dysfunction • Do not use for caesarean section • Do not use with phenothiazine-derivate drugs • Do not exceed maximum allowable dose for supplementation of increment sedation or total anesthesia of 26.4 mg/kg IM for dogs and 72 mg/kg IM for cats

Continued

TABLE 12.1 Anesthetic Agents—cont'd

Anesthetic Agent/ Class	Dose	Onset and Duration of Action	Uses/Precautions
Barbiturates			
Thiopental (Pentothal); Schedule III	Titrate to effect: 4–20 mg/kg IV	Onset of action: ultra-short acting; 20–30 s Duration of action: short (15 min), dose dependent	• Can cause CV and respiratory depression • Can decrease ICP and IOP pressure • Effects may be potentiated by concurrent acidosis or hypoproteinemia • Tissue necrosis if given perivascularly • See caution in text regarding sighthounds, greyhounds, wolfhounds, and Afghan hounds
Propofol (Diprivan); Schedule IV	2–8 mg/kg IV only CRI 0.05–0.4 mg/kg/min	Onset of action: rapid acting Duration of action: 5–10 min	• May cause respiratory and myocardial depression, peripheral vasodilation, and Heinz body anemia with repeated use in cats • Not an analgesic • Use it with caution in patients with volume depletion or CV compromise
Propofol 28 (PropoFlo); Schedule IV	2–8 mg/kg IV only CRI 0.05–0.4 mg/kg/min	Onset of action: rapid acting Duration of action: 5–10 min	• Can be used in healthy cats as a single induction dose, not as a CRI • Cumulative toxic effects include ataxia, hyperesthesia, fasciculations, blindness, aggression, convulsions, respiratory failure, and death
Etomidate (Amidate)	0.5–4 mg/kg IV dog dose 1–2 mg/kg IV cat dose	Onset of action: rapid Duration of action: single IV dose 10–20 min	• Contains propylene glycol, may cause hemolysis • Maintains CV stability • Suppresses adrenocortical function for 2–6 h following a single bolus dose • Side effects include involuntary muscle movements, hypertonus, and tremors, which can be minimized by giving IV benzodiazepine beforehand • Additional side effects are vomiting and excitement
Sedatives			
Alpha-A Agonists			• Cause sedation, analgesia, muscle relaxation • Pancreatic insulin inhibition causes hyperglycemia • ADH inhibition causes diuresis
Dexmedetomidine (Dexdomitor)	2–40 µg/kg IM, IV, transmucosally CRI 1 µg/kg loading dose, then 0.5–2 µg/kg/h	Onset of action: 10–20 min Duration of action: 3 h	• Initially causes vasoconstriction and hypertension, followed by hypotension • May cause cardiovascular collapse • May cause vomiting and/or aerophagia • Provides good sedation and analgesia • Commonly combined with opioids or ketamine • Use in healthy animals only; avoid using in very debilitated, old, or young animals
Xylazine (Rompun)	0.1–1 mg/kg IM, IV, SC	Onset of action: 5–10 min Duration of action: 20–30 min	• Causes emesis in cats and occasionally in dogs • Causes bradycardia • Dogs may develop bloat from aerophagia
Alpha-2 Antagonist			• Side effects include tachycardia, systemic and pulmonary hypertension, and anxiety • IM administration is preferred to avoid rapid vasodilation • If giving a reversal agent intravenously, it must be given slowly to avoid sudden awakening and excitement or potential cardiac arrest because the patient may experience sudden pain with resultant catecholamine surge
Atipamezole (Antisedan)	0.04–0.5 mg/kg IM, IV, SC Equal volume of dexmedetomidine	Onset of action: 10 min Duration of action: 2–3 h	
Tolazoline	0.5–4 mg/kg IV, IM, SC	Onset of action: within 5 minutes of IV administration Duration of action: short, may need to be redosed	
Yohimbine	0.05–0.1 mg/kg slow IV, 0.25–0.5 IM, SC	Onset of action: within 3 min when given IV Duration of action: 1.5–2 h	• Doses higher than 0.1 mg/kg are recommended to be given IM or SC • High doses can cause excitement in dogs

TABLE 12.1 Anesthetic Agents—cont'd

Anesthetic Agent/ Class	Dose	Onset and Duration of Action	Uses/Precautions
Neuroactive Steroid			
Alfaxalone (Alfaxan); Schedule IV	1–5 mg/kg IV; CRI 0.07–0.11 mg/kg/min	Onset of action: rapid Duration of action: dose dependent, 14–50 min	• Can cause respiratory and CV depression, rapid onset, and is not analgesic • Sedation may be needed to improve recovery • Does not contain a preservative
Other			
Lidocaine	CRI 1–2 mg/kg IV loading dose, then 1–3 mg/kg/h	Onset of action: rapid Duration of action: IV bolus, 10–20 min	• Can be used to provide analgesia and decrease MAC • Is antiarrhythmic and can scavenge free oxygen radicals • Not recommended for use in cats due to CV depression
Inhalants		Anesthetic depth can be adjusted rapidly; rapid uptake and recovery	• Produce dose-dependent CV depression and peripheral vasodilation • Decrease metabolic rate, mean arterial blood pressure, and cerebral perfusion pressure
Isoflurane MAC: dog = 1.2; cat = 1.63	MAC: dog = 1.2; cat = 1.63		
Sevoflurane (Ultane)	MAC: dog = 2.1; cat = 2.58		
Desflurane	MAC: dog = 7.2; cat = 9.8		• Requires a special heated vaporizer due to high vapor pressure

[a]At the time of publication, oxymorphone was not readily available; however, a dose has been provided throughout in the event it is compounded or becomes available.
ADH, Antidiuretic hormone; *CRI,* constant-rate infusion; *CV,* cardiovascular; *GI,* gastrointestinal; *ICP,* intracranial pressure; *IM,* intramuscularly; *IOP,* intraocular pressure; *IV,* intravenous; *MAC,* minimum alveolar concentration; *SC,* subcutaneously.

Benzodiazepines and Benzodiazepine Antagonists

Benzodiazepines potentiate the primary inhibitory neurotransmitters of the CNS, gamma-aminobutyric acid type A ($GABA_A$) receptors. There are five main pharmacologic effects: anxiolysis, sedation, anticonvulsant activity, spinal cord–mediated muscle relaxation, and amnesia. Benzodiazepines undergo hepatic metabolism. Animals receiving benzodiazepines alone become disinhibited; therefore the behavioral response can vary from patient to patient and from species to species. Some animals become quiet and sedate, whereas others can become more vocal, excited, euphoric, dysphoric, and even aggressive. Dysphoria and aggressive behavior limit the use of benzodiazepines, especially when given alone in cats. These unwanted side effects can persist postoperatively when longer-acting drugs, such as diazepam, are used (see Table 12.1). Benzodiazepines are usually used in combination with other agents such as opioids, sedatives, or dissociatives; however, they can be used alone in neonatal or extremely ill or depressed animals. Benzodiazepines are a schedule IV agent. They have minimal effect on the cardiovascular and respiratory systems and do not produce analgesia.

Diazepam (see Table 12.1) is highly lipid soluble and has a prolonged duration of action. Liver metabolism produces active metabolites with prolonged half-lives that undergo renal excretion. Diazepam can cause hypotension if given rapidly intravenously and may be painful on injection; slow administration and dilution with a crystalloid will decrease these side effects. Diazepam is often given at induction with ketamine, barbiturates, propofol, etomidate, or opioids. Its use in these combinations takes advantage of its sedative and relaxation properties and allows reduced dosing of the other induction medications.

Midazolam (see Table 12.1) can be given intravenously and does not create phlebitis or pain on injection. It has a rapid onset of action and rapid metabolism. It is especially useful as a premedication when combined with an opioid in pediatric, geriatric, and ill animals. Midazolam undergoes hepatic metabolism and renal excretion. It is useful in combination with ketamine, propofol, etomidate, opioids, or barbiturates for induction. *Zolazepam* is combined with tiletamine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, and is most useful for restraint or for very short procedures. See precautions in Table 12.1. *Flumazenil* is a benzodiazepine antagonist (see Table 12.1). It works well but is expensive. It is not a controlled agent.[1]

Recommendations for Handling Aggressive or Dangerous Dogs

Oral medications can be given to aggressive or dangerous dogs when administration of parenteral medications is difficult or not possible. The goal is to quiet and calm the dog to allow safe handling and for subsequent administration of parental agents. Medications given orally require a longer onset time to be effective than when given parenterally. When working with aggressive or dangerous dogs it is important to communicate to the owner the potential risks and side effects of drugs used in a patient that has not had a complete physical exam. Additionally, it is imperative that you know the patient's general health status. Low-stress handling measures, such as avoiding a busy waiting room, going straight to a quiet exam room, and keeping the dog in a quiet environment, are helpful. Tips for administering medications to aggressive or dangerous dogs are provided in Box 12.2. If possible have the owner administer the agent(s) orally into the cheek pouch or squirt it into the mouth (see Box 12.2). Oral-transmucosal administration avoids the first-pass hepatic effect, and the oral mucosa's rich blood supply allows for therapeutic circulating concentrations to be achieved.[5–7] The "chill protocol" developed by Dr. Alicia Karas is useful for anxious pets. The protocol requires that the owner give oral

BOX 12.2 Drugs That May Be Useful When Handling Aggressive or Dangerous Dogs

Detomidine, Oral Gel

- 0.5–2 mg/m^2 applied to the buccal pouch
- Onset of sedation: ~30–45 min
- Duration of sedation: ~30–90 min
- Considerations and precautions
- Dogs will develop bradycardia

Dexmedetomidine, Injectable

- 16.1–40 µg/kg sprayed into the mouth or buccal cheek pouch via a 3 mL syringe with a 22-gauge needle using forceful pressure from a distance of 0.6 m
- Onset of sedation: ~11–34 min
- Duration of sedation: ~30–70 min (longer sedation occurs with the oral gel)
- Considerations and precautions:
  - Level of sedation is sufficient to allow basket muzzle placement or safe restraint
  - Reversal can be done by injection of atipamezole IM

Telazol, Injectable

- Dose: 10–20 mg/kg in combination with acepromazine at 2 mg/kg sprayed into the cheek pouch, as described for dexmedetomidine
- Onset of sedation: sternal and lateral recumbency will occur at approximately 50 minutes
- Duration of sedation: return to normal ambulation may take up to 5 hours
- Considerations and precautions:
  - Dogs may be slightly to moderately ataxic
  - Not all dogs will become recumbent
  - May have a prolonged effect

"Chill Protocol"[a] (Use in Combination With the Below)

- Dose:
  - Gabapentin, 20 mg/kg PO the night before the visit or early the morning of the visit; consider reducing the dose in elderly dogs
  - Melatonin: 1–5 mg PO (1 mg for small dogs, up to 5 mg for dogs >40 kg), give with gabapentin
  - Acepromazine: 0.025–0.05 mg/kg PO, have the owner give 30 minutes prior to leaving the house (dose is the same as for an injection IM)
- Onset of sedation: see earlier
- Duration of sedation: variable; the dog may be quiet for as long as 24 hours, return to normal ambulation may take up to 5 hours
- Considerations and precautions:
  - The owner must supervise the pet as the pet will be wobbly and may misjudge stairs and jumping from the car.
  - Gabapentin is a sedative and anxiolytic with renal elimination; use with caution in dogs that are dehydrated or that have renal disease.
  - Acepromazine may cause hypotension and is a sympatholytic; use with caution in sick patients; consider giving the owner two syringes without needles in case they spill one.

[a]Courtesy Alicia M. Karas.

medications prior to the visit (see Box 12.2). When the dog arrives, quietly place a muzzle on it and then inject other medications IM, or place an IV catheter for drug injection. Further sedation may consist of opioid, dissociative, or alpha-2 agonist combinations.

NOTE Remember to remove the dog's muzzle after injection of any medication that is known to cause vomiting.

Alpha-2 Agonists and Antagonists

Alpha-2 agonists cause central presynaptic inhibition of norepinephrine release, have vagomimetic actions, and induce peripheral activation of postsynaptic alpha receptors in the vasculature, pancreas, and gastrointestinal tract. They undergo hepatic metabolism. Effects from administration of an alpha-2 agonist are sedation, analgesia, muscle relaxation, bradycardia, peripheral vasoconstriction, and vomiting. There is an initial vasoconstrictive-hypertensive phase followed by a hypotensive phase. Bradycardia is due to vagal stimulation and reflex response to the hypertension, leading to a decreased cardiac output. Heart rate and rhythm should be monitored, as the bradycardia can progress to second-degree atrioventricular block. Use of anticholinergics to treat the bradycardia is controversial. An anticholinergic given when the blood pressure is high may lead to extreme hypertension and tachycardia. In this case, it may be better to reverse the alpha-2 agonist to improve the heart rate. If the blood pressure is normal to low, consider the use of an anticholinergic to treat bradycardia. Animals that are highly stressed or excited may not sedate well. Sedated animals may still respond with a reflex action such as biting. Alpha-2 agonists can be used in combination with opioids and dissociatives. Alpha-2 agonists are not controlled drugs and are reversible.

Dexmedetomidine (see Table 12.1) is the most potent of the alpha-2 agonists and has profound, long-lasting effects. It provides good sedation and analgesia. It is useful as a restraint drug, especially when combined with ketamine and an opioid. If reversed, it is recommended to give the reversal agent (atipamezole; see below) IM to avoid sudden awakening that could lead to excitement or pain, and profound hypotension. Dexmedetomidine can be combined with opioids to decrease the dose of both drugs and create neuroleptanalgesia. When used as premedicant it will decrease anesthetic drug doses. It can be part of a technique for injectable anesthesia for minor procedures or used to treat dysphoria and anxiety during anesthetic recovery.

Alpha-2 antagonists include *yohimbine, tolazoline,* and *atipamezole,* the latter of which was designed for use with dexmedetomidine (see Table 12.1). Of these, atipamezole is the most selective and effective. These reversal agents antagonize both sedation and analgesia. If an alpha-2 agonist has been used in combination with a dissociative, reversal of the alpha-2 agonist may result in unmasking of the dissociative that permits its adverse effects (i.e., muscle rigidity, excitement) to be seen.[1]

Opioids

Opioids can be used as preanesthetics, intraoperatively, and postoperatively to provide sedation and analgesia (see Table 12.1). They are controlled drugs and are reversible. The opioid receptors are mu (µ), kappa (κ), and delta (δ). Mu receptors can also cause emesis, (which is most likely when given IM or SC), euphoria, and respiratory depression. Opioids have minimal cardiovascular compromise, so they are commonly used in unstable patients. Bradycardia can occur and may be treated with antimuscarinics. They can cause a dose-dependent respiratory depression. Dogs may pant excessively due to thermoregulatory center disruption or initial stimulation of the respiratory center. Euphoria and dysphoria can occur in some dogs and is common in cats, but occurs less commonly when combined with a tranquilizer or sedative. Opioids should be used cautiously in animals with head injury as hypoventilation can increase CO_2, which causes

cerebral vasodilation and increases intracranial pressure. Opioids can be used safely if intermittent positive pressure ventilation is provided. They undergo hepatic metabolism. All mu opioid agonists are schedule II drugs that require strict record keeping. Full mu agonists are morphine, hydromorphone, oxymorphone, fentanyl, remifentanil, meperidine, and methadone.

Morphine is an excellent analgesic (see Table 12.1) that undergoes 50% hepatic and 50% extrahepatic metabolism. Morphine, when given rapidly intravenously, can result in histamine release leading to profound hypotension. *Oxymorphone* (see Table 12.1) is an excellent premedicant in pediatric, geriatric, and debilitated animals and is often combined with midazolam. *Hydromorphone* (see Table 12.1) is less likely to cause vomiting as compared with morphine or oxymorphone. Hyperthermia may be seen in cats during recovery following anesthesia, and hydromorphone may make them more prone to this complication. Cats that are hypothermic during surgery or the procedure seem to rebound and become hyperthermic in recovery; thus all cats should have their temperature monitored closely in recovery.[8]

NOTE Hyperthermia seen in cats during recovery is usually self-limiting, but remove heating sources as a precaution. You may need to place them on a metal cage floor. A low dose of acepromazine (0.01 mg/kg IV), if safe to give, will calm them, and may decrease body temperature due to vasodilation.

Fentanyl is a potent mu agonist commonly used intravenously as a constant-rate infusion (CRI) to provide analgesia (see Table 12.1). It can be used in intensive care settings at the lower dose range to provide analgesia. Fentanyl also comes as a transdermal patch. The skin should be clipped and cleaned prior to patch application. In some animals pain may not be completely controlled and adverse opioid effects may occur. The patch is easily removed and may be consumed by the animal or children, which may be toxic. The potential for human abuse is also present. *Methadone* is a synthetic mu agonist with some NMDA antagonist effects. It is less likely to cause vomiting than morphine; however, it does not create good sedation when given alone. *Meperidine* can cause tachycardia because it has a chemical structure similar to atropine. Meperidine may produce serotonergic effects, so it should not be used with other serotoninergic drugs or monoamine oxidase inhibitors.

Remifentanil is a synthetic opioid with direct action on mu opioid receptors. It has an ultrashort duration of action and is metabolized by nonspecific esterases in blood and tissue. The metabolite is excreted by the kidneys. Remifentanil has been used with propofol as a CRI to provide total IV anesthesia in dogs. It provides intraoperative analgesia when given as a CRI. Remifentanil does not affect myocardial contractility or cause histamine release but may lead to hypotension. It is good for use in animals with liver compromise or for short procedures and has been used in dogs for liver biopsy.[9] Its use decreases the amount of inhalant needed for general anesthesia, which may help preserve hepatic blood flow. Remifentanil has been used in cats as a CRI to decrease the level of inhalant needed for general anesthesia.[10] Recovery is very rapid, within 5 to 10 minutes, even after prolonged infusions as there is no drug accumulation. There is no residual analgesia, so a longer-duration analgesic should be given to patients that have had a painful procedure. This analgesic should be given prior to recovery from remifentanil. There is no residual respiratory depression following recovery from remifentanil.

Buprenorphine is a partial mu agonist and kappa antagonist. It is commonly used in cats and can be given transmucosally on the oral mucus membranes. Buprenorphine has a large safety profile. A new proprietary formulation of buprenorphine (Simbadol) has been developed for use in cats.[11] The first dose should be administered approximately 1 hour prior to surgery. It has a high affinity for the mu opioid receptor. Adverse side effects may occur (see Table 12.1), but cats more commonly become quiet and euphoric, and they purr, rub, and knead with their forepaws.[11] Buprenorphine in metabolized and excreted by the liver. Reversal with naloxone may be difficult. It should *not* be dispensed to the owner for administration.

Butorphanol is a kappa agonist and mu antagonist. It creates mild analgesia. It does not give reliable sedation by itself, so it is often combined with a tranquilizer or sedative. Butorphanol is used to treat mild to moderate pain; it is not expected to be completely effective for severe pain. It is an effective antitussive. It can be used to reverse mu agonist effects, but maintain some analgesia at a dose of 0.1 mg/kg IV.

Nalbuphine provides mild analgesia but minimal to no sedation. It can be used to reverse mu agonist effects, but maintain some analgesia. It is not scheduled. *Tramadol* (see Table 12.1) is metabolized to O-desmethyltramadol (M1), which has mu agonist activity; in addition it acts as a serotonin and norepinephrine reuptake inhibitor. The analgesic effects are weak in dogs because they do not make substantial amounts of O-desmethyltramadol. Cats, however, produce substantial amounts of O-desmethyltramadol, so it may be an effective analgesic in this species, but the bitter taste makes oral administration difficult. It is not recommended to give tramadol with meperidine, tricyclic antidepressants such as amitriptyline or clomipramine, or selective serotonin reuptake inhibitors such as fluoxetine and paroxetine, as there is a risk of serotonin syndrome, clinical signs of which include fever, seizures, muscle tremors/fasciculations, hyperthermia, salivation, and rarely death.

Barbiturates

Thiopental, an ultra-short-acting thiobarbiturate, is used for induction. It comes as a crystalline powder and is reconstituted to 2.5%, 5%, or 10% solutions with sterile water or saline. In small animals a 2.5% solution is most commonly used to avoid vascular irritation. The resulting solution is alkaline (pH 10–11) and can cause tissue necrosis if injected perivascularly. If perivascular administration occurs, dilution of the drug with saline injected into the tissue should be done to help minimize tissue damage. Lidocaine can also be injected into the site to produce vasodilation and local anesthesia.[12]

Barbiturates produce CNS depression by activation at the $GABA_A$ receptor. When given intravenously they equilibrate rapidly across the blood-brain barrier to the well-perfused brain, inducing anesthesia. The drug concentration in the blood and brain falls rapidly as the drug redistributes to less perfused muscular tissue, allowing for the return of consciousness. Repeated dosing will result in a prolonged recovery as muscle tissue reaches equilibrium with blood concentrations. Metabolism is hepatic, with hepatic enzyme P450 system induction and renal excretion. The barbiturates are cerebral protectants; cerebral metabolic oxygen, cerebral blood flow, and intracranial pressure are decreased. These properties make thiopental an appropriate choice for induction of patients with intracranial disease and

seizures. Thiopental can decrease stroke volume and myocardial contractility. Venodilation and sequestration of red cells occurs in the spleen with an accompaniment increase in splenic size. Ventricular arrhythmias and bigeminy may occur, and thiopental sensitizes the myocardium to epinephrine-induced arrhythmias. There is a dose-dependent respiratory depression, which may result in apnea. Barbiturates are a good choice for laryngeal exam as the laryngeal reflexes are minimally affected. They cross the placenta, causing more respiratory depression in puppies following a cesarian section than does the barbiturate-like sedative propofol (see later). Barbiturates do not produce antinociception, and the only analgesia seen is during unconsciousness; therefore analgesics should be given with painful procedures.

NOTE Greyhounds can have prolonged recoveries following thiopental administration due to a relative deficiency in hepatic microsomal enzymes needed for metabolism, and also because of their lean bodies and low fat stores. Barbiturates are not commonly recommended for use in sighthounds, greyhounds, wolfhounds, or Afghan hounds but can be used if there is appropriate premedication to decrease the amount of barbiturate needed.

Propofol is highly lipid soluble and is formulated as an emulsion. It is used for IV induction and, because it has a short duration and does not accumulate in the body, it is safe to use as a CRI for total IV anesthesia. The original formula does not contain a preservative and will support bacterial and fungal growth; therefore strict aseptic technique in drug handling is required. An open drug vial should be discarded after 6 hours, and when giving as a CRI the administration set should be changed every 12 hours. The anesthetic effect is through interaction at the $GABA_A$ receptor. Propofol must be given intravenously to be effective, though if given perivascularly it does not cause tissue necrosis. It has a rapid onset and reduces cerebral metabolism of oxygen and intracranial pressure. Propofol does have anticonvulsant effects and has been used in seizure control. It is a dose-dependent cardiovascular depressant and vasodilator leading to hypotension. A dose-dependent respiratory depressant effect often causing apnea also occurs. Propofol crosses the placenta but has a rapid clearance from the neonatal circulation. It does not provide analgesia.

PropoFlo 28 is new formulation of propofol that has a shelf life of 28 days due to the preservative benzyl alcohol. It has the same properties and dose as regular propofol. It comes in a multiuse vial at 10 mg/mL and is an emulsion. It is labeled for IV use in dogs; it is not labeled for use in cats due to the benzyl alcohol, which may be toxic to cats because they lack adequate glucuronic acid conjugation, which results in a decreased rate of metabolism and cumulative toxic effects (see Table 12.1). This new formulation has been used in healthy cats as a single IV induction dose with no adverse effects.[13] In those cats that are ill, have liver disease, will need multiple anesthetic episodes, or require a CRI, the original propofol is recommended. Repeated administration of propofol, daily or as a CRI, may induce oxidative injury to feline red cells.

Nonbarbiturate Hypnotics

Etomidate (see Table 12.1) is an imidazole derivative with agonist activity at the GABA receptor. Etomidate causes vasoconstriction of the cerebral vasculature leading to reduced cerebral blood flow and metabolism of oxygen. It is given intravenously for induction and is quickly hydrolyzed by esterases in the liver and plasma to inert metabolites. It has a rapid onset and may be painful upon injection. This pain may be reduced by IV administration of an opioid prior to etomidate, use of a large vein, and administration through a running IV line. Hemolysis can occur due to an osmolality of 4640 mOsm/L from the propylene glycol in the formulation. Hemolysis may be more likely in cats due to the fragility of their red blood cells. There is a lack of cardiovascular depression, and thus minimal effect on cardiac function, that makes it useful for induction of unstable cardiac patients. Etomidate has a minimal effect on the respiratory system. The drug does cause adrenocortical function suppression of 2 to 6 hours following an induction dose. Care should be taken if using this drug in patients with adrenocortical disease and if highly stressed. Long duration of this drug as a CRI is not recommended. There are no analgesic properties.

Neuroactive Steroids

Alfaxalone (Alfaxan) is a clear, aqueous solution for IV injection, registered for the induction and maintenance of anaesthesia in dogs and cats. It is a neurosteroid injectable anesthetic. It does not contain a preservative, so an open vial must be discarded after 6 hours. It causes CNS depression by binding to GABA receptors. It has rapid liver metabolism and elimination. There is a wide margin of safety. It is labeled for IV use only in dogs and cats. It is water soluble, nonirritating, and therefore not painful when given IM, which is useful in cats and small dogs. It is useful combined with an opioid for intramuscular sedation in the aggressive ill cat. Cerebral blood flow, intracranial pressure, and cerebral metabolic oxygen demands are decreased. There is dose-dependent cardiovascular depression, respiratory depression, and apnea. There is good muscle relaxation and rapid recovery. The animal may have a rough recovery, with paddling, muscle rigidity, myoclonus, and excitement. Adding a sedative or analgesic may help avoid this. Alfaxalone may be an alternative to propofol. Alfaxalone has been used for safe induction of anesthesia in dogs undergoing cesarean section; it had a negligible effect on the puppies.[14]

Dissociatives

The dissociatives, *ketamine* and *tiletamine*, interfere with transmission of nervous impulses between the thalamocortical and limbic systems, causing a dissociation between subconscious and conscious systems. There is noncompetitive antagonism of NMDA-type glutamate receptors. They provide dose-dependent effects ranging from mild chemical restraint to general anesthesia with a wide margin of safety. They can be used IM to sedate dogs and cats, especially aggressive animals (see Box 12.2). They can be used for IV induction and IM or intravenously for injectable anesthesia. Ketamine is used as a racemic mixture; the positive (S) isomer produces more intense analgesia, has more rapid metabolism, and has a lower incidence of emergency reactions than the negative I isomer. Tiletamine is only available in 1:1 combination with the benzodiazepine zolazepam (Telazol). It comes in powder form, is reconstituted with 5 mL of diluent, and loses potency over time. Dogs may have a rough recovery due to slow metabolism of tiletamine, causing muscle rigidity, sympathetic stimulation, and emergence delirium; a tranquilizer may need to be given to smooth recovery. In cats, the action of the benzodiazepine zolazepam lasts longer. The tiletamine/zolazepam powder can be reconstituted with 100 mg of xylazine and 400 mg of ketamine to give a potent combination used for

chemical restraint/anesthesia. Careful drug administration is necessary due to the small volume used; profound hypothermia and prolonged recovery may occur. The dissociatives do not have a reversal agent, but zolazepam can be reversed with flumazenil and an alpha-2 antagonist can be used to reverse xylazine.

The dissociatives have a rapid onset of action with a short duration. There is hepatic metabolism, with ketamine producing the active metabolite norketamine. In dogs, norketamine is inactivated prior to renal excretion, whereas in cats, norketamine is excreted unchanged in the urine. Emergence delirium can be seen on recovery; treatment with agents such as benzodiazepines, acepromazine, or an alpha-2 agonist may decrease the incidence and severity of the delirium. CNS effects include an increase in cerebral metabolism of oxygen and intracranial pressure. The stimulation of the CNS leads to increased sympathetic outflow, resulting in increased blood pressure, heart rate, cardiac output, myocardial work, and oxygen requirements. When the catecholamine stores and sympathetic nervous system compensatory system are exhausted, ketamine has direct negative inotropic effects. Dissociatives can cause excess salivation and are therefore commonly used with an antimuscarinic. The dissociatives do not cause significant respiratory depression. They do not produce muscle relaxation; increased tone of extraocular muscles can create increases in intraocular pressure. Muscle relaxation is improved with the addition of a benzodiazepine or alpha-2 agonist. Dissociatives do provide somatic analgesia. The blockade of the excitatory neurotransmitter glutamate at the NMDA receptor plays a role in the prevention or minimization of central sensitization and wind-up. These agents are most commonly used in combination with tranquilizers, opioids, and alpha-2 agonists.

Inhalants

Inhalants are widely used to provide anesthesia. They do require special equipment for use but have a rapid onset and recovery via the lungs. The two commonly used inhalant agents are isoflurane and sevoflurane (see Table 12.1). The delivery gas for inhalants is oxygen. Anesthetic potency is defined by the minimum alveolar concentration of an anesthetic that produces immobility in 50% of patients exposed to a supramaximal noxious stimulus. These potent inhalants cause vasodilation that leads to a loss of cerebrovascular autoregulation, and the loss of vascular resistance increases cerebral blood flow. There is a subsequent increase in intracranial pressure. There can be a decrease in cardiac output and stroke volume due to a dose-related depression in myocardial contractility. The inhalants cause respiratory depression, which may necessitate intermittent positive-pressure ventilation (IPPV).

Anesthesia Equipment and Devices

Animals needing general anesthesia for longer procedures should be intubated to provide an airway for delivery of oxygen and inhalant gases, protect the lung from aspiration, and prevent contamination of the environment with waste gases. Intubation also allows for IPPV to help prevent hypoxemia and overcome respiratory depression; ventilation is required during a thoracotomy or diaphragmatic hernia repair.

Endotracheal Tubes, Endobronchial Blockers, and Supraglottic Devices

Endotracheal tubes are used to seal the trachea during inhalant anesthesia or to protect the airway in an anesthetized dog or cat. The most common type used in veterinary medicine is the **Magill tube**, which ranges in size from 3 to 40 mm (internal diameter). These tubes have a beveled tip and are curved and may be cuffed or uncuffed, although cuffed tubes are most commonly used. Uncuffed tubes may be used in very small animals, where the cuff may be sufficiently large to prevent placement of a tube of adequate diameter. **Cole tubes,** originally designed for pediatric anesthesia, are less commonly used in veterinary medicine but have been used in cats. These tubes are designed such that the shoulder of the tube touches the larynx and provides an air-tight seal. The size of the tube is based on the weight of the animal (Table 12.2); however, remember that weight guidelines are based on lean body weight and that overweight animals do not have larger tracheas than thinner animals. Brachycephalic breeds typically have narrower tracheas than dogs or cats of similar size that are mesocephalic or dolichocephalic. It is wise to have a tube one size larger and one size smaller readily available.

From McKelvey D, Hollingshead KW. *Small Animal Anesthesia: Canine and Feline Practice.* St. Louis, Mosby; 1994.

NOTE Lube the tube before inserting, being careful to not occlude the "eye" of the tube. Use a cuffed tube if possible and inflate the cuff gently to avoid traumatizing the trachea. Check for leaks in the tube cuff prior to induction.

One lung ventilation (OLV) can be achieved using endobronchial blockade, selective intubation, or a double-lumen tube (DLT). Ventilating one lung is done to improve surgical conditions for thoracoscopy, to control contamination or hemorrhage, or when there is unilateral pathology. Endobronchial intubation can be done with a long endotracheal tube and is relatively easy to perform; the disadvantage is that it provides less direct control to make changes in the nonintubated lung.

A **DLT** is two single-lumen tubes bonded together and comes as either a right- or left-sided tube, corresponding to the right or left mainstem bronchus where the tube is designed to fit. The

tube has two cuffs; one occludes the trachea and the other occludes the bronchus. The later cuff and pilot tube are usually colored blue to differentiate them from the tracheal cuff. Correct tube placement is confirmed by direct visualization using a small-diameter bronchoscope. Correct placement should result in lung sounds only in the ventilated lung field. A DLT is capable of providing gas flow directly to a bronchus isolated from the rest of the lung by an expandable cuff or through a tracheal port that provides gas flow cranial to the obstructed bronchus. They are designed with an angled bronchial tip that can be inserted into either the left or right mainstem bronchus. This allows for ventilation of the lung field in which the bronchial tip has been placed into that mainstem bronchus. If the fresh gas flow is directed to the tracheal lumen only, then ventilation of the contralateral lung field will occur. Thus when the DLT is correctly positioned, there is flexibility in choosing to ventilate left, right, or both lung fields. Blind placement of the DLT with thoracoscopy assistance is possible.

There are three DLTs available that have been used in dogs: the Robertshaw left-sided tube, Carlens left-sided tube, and Dr. White right-sided tube. The Robertshaw left-sided tube is the simplest design with a tip that is angled to the left approximately 30 degrees to the main body of the tube. It has a tracheal lumen that opens just before the tip angulation point. The bronchial tip of the tube has a near-spherical balloon that inflates just oral to the termination of the tube, which has an end-hole design. The Carlens tube is similar to the Robertshaw tube but incorporates a small hook just distal to the opening of the tracheal lumen. This hook is designed to catch on the carina and prevent passage of the tube deeper into the bronchial tree. The Dr. White right-sided tube is similar in design but has a right-sided angulation to the tube tip. It incorporates the carinal hook similar to the Carlens tube but has an L-shaped balloon with a side- and end-hole bronchial tube tip. This bronchial tube tip is aimed at providing ventilation to the more cranially positioned right cranial lobar bronchus. A thoracoscope can be used for tube placement allowing for direct observation of lung lobe inflation during ventilation. It is possible to have the tubes positioned too far cranially, resulting in partial prolapse of the balloon into the trachea. Complete balloon prolapse into the trachea obstructs the lumen and results in total airway obstruction in some cases (Fig. 12.2).[15]

An advantage of the DLT is that they allow for alternating hemithorax OLV by simply switching the anesthetic gas supply from the bronchial lumen to the tracheal lumen without having to use intraoperative bronchoscopy to guide tube manipulation. The carinal hook may not offer an advantage when used in dogs, as they are more difficult to guide through the larynx and have greater potential to create laryngeal trauma as they are advanced through the rima glottidis.[15]

Endobronchial blockers (EBBs) are long catheters tipped with an elliptical or round inflatable cuff, which is blue. Bronchial blockers are used coaxially or in parallel with a standard endotracheal tube. The bronchial blocker is placed with fiberoptic–assisted direct visualization; a single lung lobe or the entire hemithorax can be blocked. Once the blocker is correctly placed, the cuff is inflated to prevent ventilation to that lung segment. EBBs are used in small dogs as the smallest DLT are 28 Fr, which precludes their use in animals weighing less than 10 kg. EBBs have been described for creation of OLV in small patients as they are available in a 5 Fr size.

Supraglottic airway devices (SGAD) include laryngeal mask airways and V-gels (Fig. 12.3). These devices do not require the use of a laryngoscope for placement. They are an alternative to the standard endotracheal tube and may be easier to place. When properly placed, they fit over and form a seal around the glottis. A specific SGAD, V-gel, has been designed for cats. It is relatively easy to place and has been used to maintain inhalant general anesthesia in cats undergoing abdominal surgery.[16] Placement of the V-gel may require a more superficial level of anesthesia and less induction agent when compared with a standard endotracheal tube. Cats with a V-gel in place have undergone controlled mechanical ventilation up to 16 cmH_2O pressure with no leakage.[17] The endotracheal tube or SGAD is attached to the breathing circuit, which, in turn, is connected to the anesthesia machine.

FIG. 12.2 A left-sided Robertshaw double lumen endotracheal tube. Double lumen tubes can be used to selectively ventilate one or both lung fields.

FIG. 12.3 Supraglottic airway device, feline V-gel (Docsinnovent Ltd.).

FIG. 12.4 The circle rebreathing system on a small animal anesthesia machine.

FIG. 12.5 Nonrebreathing circuit (Norman Elbow), Mapleson F, Jackson-Rees with the relief valve located on the bag. Note the circuit connection to the common gas outlet.

Anesthesia Machines

The anesthesia machine consists of a source of oxygen, an oxygen regulator and flowmeter, and a precision vaporizer. All waste gases should be scavenged. The breathing circuit directs oxygen and inhalant to the patient, removes carbon dioxide or prevents rebreathing, and provides a means of controlling ventilation.

The **circle or rebreathing system** is the most commonly used system in veterinary anesthesia (Video 12.1; Fig. 12.4). The circle system produces a unidirectional flow of gas and absorbs carbon dioxide from exhaled gas. The components are a fresh gas inlet, inspiratory one-way valve, breathing tubes, expiratory one-way valve, adjustable pressure limiting valve or "pop-off" valve, reservoir bag, and carbon dioxide absorber. The fresh gas flow determines how much rebreathing occurs. For complete rebreathing, the oxygen flow rate is metabolic oxygen consumption of the patient, 3 to 14 mL/kg per minute. Partial rebreathing is greater than metabolic oxygen consumption, 20 mL/kg per minute. Nonrebreathing to minimal rebreathing occurs when the oxygen flow is greater than 200 mL/kg per minute and is not normally used. Initially high gas flows are used to cause rapid inspired concentration within the system and then flow rates are decreased for the maintenance phase; it is more economical to use lower flow rates when possible. Higher gas flows are used in the recovery phase to help wash the inhalant gases out of the system to speed awakening.

Nonrebreathing systems are characterized by the absence of the unidirectional valves and the carbon dioxide absorber (Fig. 12.5). The carbon dioxide is removed by being flushed from the system with a high gas flow. Flow rates vary from 130 to 300 mL/kg per minute. This system is used is patients that weigh less than 10 kg as the high gas flow is not economical in larger patients. The nonrebreathing system has lower resistance to breathing and a smaller total circuit volume. The Bain system is a coaxial design, with the inner tube being the inspired gas and the outer tube containing exhaled gases that have less bulk, and provides a means for potentially warming the inspired gas as the warmer exhaled gas passes around the inner tube (Figs. 12.6 to 12.8).[18]

Monitoring

Monitoring the anesthetized patient is necessary to avoid potential complications, provide an early warning of life-threatening developments, and to ensure a safe outcome following anesthesia. Monitoring should begin during the induction phase and continue into recovery. There are three main areas to monitor in the anesthetized patient: depth of anesthesia, cardiovascular and respiratory parameters, and body temperature. Physiologic parameters to asses include heart rate, blood pressure, respiratory rate, mucous membrane color, capillary refill time, hemoglobin saturation, and end-tidal CO_2. Spontaneous movement is a reliable sign of light level of anesthesia. An abrupt increase in heart rate, blood pressure, and respiratory rate are indicators of a response to surgical stimulus and a light level of anesthesia. Loose jaw tone, absence of palpebral reflex, and muscle relaxation are observed during medium to deep anesthesia levels.

Cardiovascular System

The cardiovascular system is evaluated via the heart rate and rhythm, peripheral pulse rate and rhythm, tissue perfusion, and blood pressure. Heart rate is an important determinant of cardiac output; excessive bradycardia will result in a decreased cardiac output. Excessive tachycardia will also decrease cardiac output due to decreased filling time and reduced stroke volume. An ECG is important for the identification of potential arrhythmias.

FIG. 12.6 The Bain, coaxial nonrebreathing, Mapleson D circuit attached to a small animal anesthesia machine. The inner green tube carries the fresh inhaled gases to the patient, and the clear outer tube removes the exhaled gases from the patient. Note the connection of the circuit to the common gas outlet.

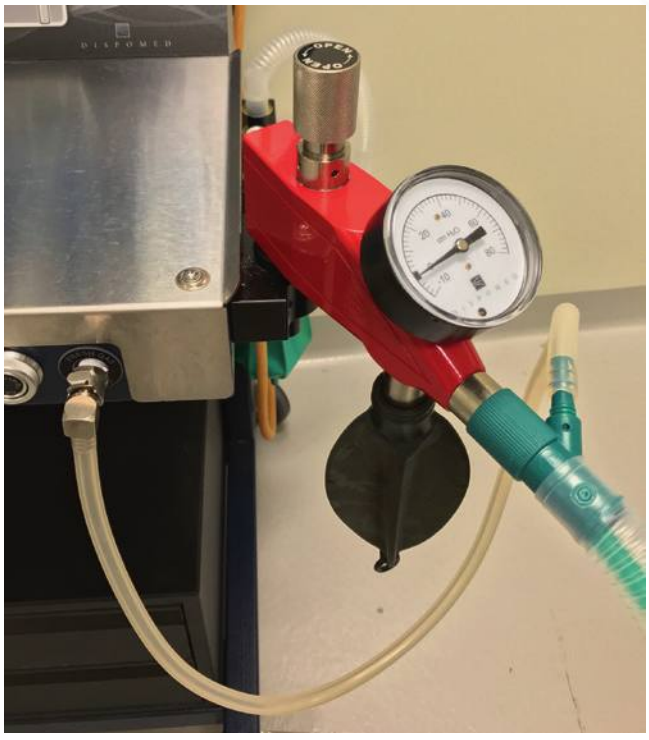

FIG. 12.7 Bain mount for the nonrebreathing circuit. It provides a fixed connection point for the bag, the adjustable pressure-limiting valve, and a pressure gauge. Note the circuit connection to the common gas outlet.

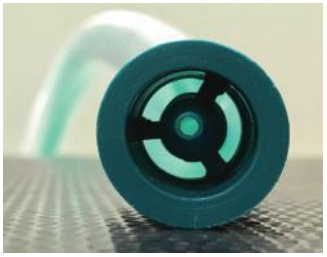

FIG. 12.8 The patient end of the coaxial Bain nonrebreathing circuit. The inner port is for the fresh inhaled gas, and the exhaled gas flows out the larger port holes around the inner port.

The most common intraoperative complication is hypotension. When blood pressure is low, tissue perfusion becomes compromised. Hypotension is a mean arterial blood pressure less than or equal to 60 mmHg or a systolic pressure of less than or equal to 80 mmHg. Common causes of hypotension are hypovolemia, poor cardiac output, and vasodilation. Blood pressure can be measured indirectly with sphygmomanometry, placing an occlusive cuff over an artery on a forelimb, hind limb, or tail. The width of the cuff should be 40% of the circumference of the appendage. A Doppler ultrasound piezoelectric crystal is placed over an artery distal to the cuff on the appendage. The cuff is manually inflated and then deflated to the first audible sound, which is systolic blood pressure. The oscillometry device will automatically inflate/deflate the cuff and record the systolic, diastolic, mean blood pressure, and heart rate at determined time intervals. Oscillometry determines blood pressure by analyzing fluctuations of pressure within the cuff. The gold standard for blood pressure measurement is direct catheterization of an artery. This gives beat-to-beat blood pressure measurements. Commonly used arteries for direct arterial measurements are the dorsal metatarsal, radial/carpal, coccygeal, lingual, femoral, and auricular.

Respiratory System

The respiratory system is evaluated by observation of the respiratory rate and depth of breathing via chest, abdominal, or reservoir bag excursions. A respiratory rate of 6 breaths per minute or less is indicative of hypoventilation. Chest wall movement with no corresponding movement of the reservoir bag is indicative of an airway obstruction or a tension pneumothorax. An arterial blood gas is the gold standard for evaluation of ventilation and oxygenation. Noninvasive techniques are capnometry for ventilation and pulse oximetry for oxygenation. Normal carbon dioxide partial pressure ($PaCO_2$) is 35 to 45 mmHg. A $PaCO_2$ of more than 60 mm Hg is respiratory acidosis due to hypoventilation and would be an indication for IPPV. A $PaCO_2$ below 20 mm Hg is indicative of respiratory alkalosis and decreased cerebral blood flow, seen with hyperventilation. The end-tidal CO_2 gas sample is taken at the end of exhalation and is a surrogate marker for $PaCO_2$. The end-tidal CO_2 is usually 3 to 6 mm Hg lower than $PaCO_2$. Capnography is the waveform of the exhaled CO_2; this capnogram curve, if abnormal in shape, can be used to identify complications. A sloping inspiratory waveform indicates a leak during inspiration, dilution with fresh gas during a long pause between breaths, or prolonged inspiration. A waveform with a sloping expiration indicates a partial airway obstruction or impaired lung deflation. A normal PaO_2 on room air should be between 80 and 110 mm Hg. Hypoxemia is a PaO_2 of less than

80 mm Hg, and potentially life-threatening hypoxemia is a PaO_2 less than 60 mm Hg. When on an oxygen-enriched gas the PaO_2 should be above 110 mm Hg. The pulse oximeter measures the hemoglobin saturation with oxygen (SpO_2), and this is used as a surrogate for PaO_2. The normal value for SpO_2 is 98% to 99%. Hypoxemia is a SpO_2 less than 95%, which corresponds to a PaO_2 of 80 mm Hg, with severe hypoxemia at less than 90%, which is a PaO_2 of 60 mm Hg. The pulse oximetry probe is placed across an arterial bed such as the tongue, ear pinnae, lip, or toe web.[19]

Body Temperature

Body temperatures of 90°F to 94°F (32°C–34°C) result in reduced anesthetic requirements, impaired cardiovascular function, hypoventilation, decreased resistance to infection, and a prolonged recovery. Hyperthermia (105°F [40.5°C]) can occur with overzealous application of warming devices and in dogs with thick hair coats and warming devices in place; cell damages occur with temperatures at or above 108°F (42°C). It is important to monitor body temperature during anesthesia and into recovery. Cats given opioids as part of their anesthetic episode seem prone to hyperthermia in recovery. Hyperthermia is inversely related to the body temperature at extubation; the colder the cats were at extubation, the warmer they become during the postoperative period. This exaggerated rebound from hypothermia may be enabled by the resetting action of opioids upon the hypothalamic thermoregulatory threshold.[5] The hyperthermia is usually self-limiting but can be treated by giving naloxone at 0.01 mg/kg IM or SC; this would also result in reversal of opioid-induced analgesia. If a mu opioid agonist has been given, partial reversal to retain some analgesia can be achieved with butorphanol at 0.1 mg/kg IV or IM. Acepromazine at 0.01 to 0.05 mg/kg can be given to provide calming and may improve heat loss through vasodilation. Fans, removal of any warming devices, and placing the cat on the uncovered cage floor also aid in heat loss.

Fluid Therapy

IV fluid therapy should be tailored to the individual animal based on its needs, taking into consideration acute versus chronic conditions, pathology such as electrolyte abnormalities, acid-base disturbances, changes in volume such as dehydration or blood loss, and changes in distribution such as pleural effusion. If possible, correct fluid and electrolyte imbalances prior to anesthesia and surgery (see Chapter 4). In healthy patients the suggested initial rate for fluids during surgery is 3 mL/kg per hour in cats and 5 mL/kg per hour in dogs. If the patient requires replacement and maintenance fluid therapy, the fluid rate may need to be 10 mL/kg per hour. The fluid rate should be reduced in procedures that are of long duration, provided the patient is stable, to avoid overhydration.

Fluid bolus administration is often used to treat hypotension during anesthesia. A fluid bolus may be appropriate if there is relative hypovolemia caused by peripheral vasodilation contributing to the hypotension. Anesthetic depth should be assessed and the level of inhalant decreased if possible. A crystalloid bolus, such as lactated Ringer's solution, can be given at a rate of 3 to 10 mg/kg IV and repeated once. If the response is inadequate, a colloid such as hetastarch may be considered. It is given at a dose of 5 to 10 mL/kg in dogs and 1 to 5 mL/kg in cats, titrating to effect to avoid vascular overload. Blood pressure should be monitored every 3 to 5 minutes. If, following fluid bolus therapy, the animal remains hypotensive and is not hypovolemic, other methods should be considered, such as inotropes/vasopressors or balanced anesthetic techniques to further reduce the inhalant levels. Cats require close monitoring to avoid volume overload.[20]

Pain Management and Acupuncture

Pain perception is the unpleasant sensory and emotional experience associated with either actual or potential tissue damage; pain management is an important aspect of surgery in all animals. Because animals cannot express pain in the same manner as humans, it is important that surgeons be able to recognize pain in their patients and that they preemptively do everything possible to avoid or limit pain and distress prior to, during, and after surgery. Behavioral and physiologic manifestations of pain are provided in Box 13.1. Pain management guidelines have been established for dogs and cats and are detailed in this chapter. Pain management can involve a variety of techniques and agents to provide multimodal analgesia for the care of the surgical patient.

DEFINITIONS

There are varying types of pain; *nociceptive pain* occurs when peripheral neural receptors are activated by noxious stimuli, such as a surgical incision or trauma, whereas *inflammatory pain* is due to activation of the immune system in response to injury or infection. *Pathologic* or *maladaptive pain* occurs when pain is amplified and sustained, leading to peripheral and central hypersensitization, and is characterized by hyperalgesia, allodynia (pain, generally on the skin, caused by something that would not normally cause pain), expansion of the painful field beyond the normal boundaries, and protracted pain. *Neuropathic pain* is a disease of the central nervous system (CNS) and occurs under conditions that create genomic and phenotypic changes.

NEUROANATOMY OF NOCICEPTION

The simplified pathway for transmission of nociceptive information from the periphery to the brain consists of a three-neuron system. There is a primary peripheral nociceptive neuron (cell body in dorsal root ganglion), a spinal cord projection neuron (in the dorsal gray matter), and a thalamic relay neuron (that subsequently transmits information to the somesthetic cerebral cortex) (Fig. 13.1).[1–4] Roughly half of all afferent axons in cutaneous nerves are related to nociception (pain sensation). Most of the nociceptive receptors are the free nerve endings (dendritic zones) of general somatic afferent (GSA) neurons, whose respective cell bodies are located in the dorsal root ganglia of all spinal nerves, as well as the ganglia of some cranial nerves (CNs; primarily CN V). An area of skin that is innervated by a specific dorsal root is called a *dermatome*, and there is some degree of overlap of dermatomal regions.[1,3,4] The types of axons conveying nociceptive signals include Aδ (delta) and C fibers. Aδ fibers are lightly myelinated and larger than the C fibers; they are thought to transmit "fast" painful stimuli, such as sharp, pricking pain that is localizable to a particular body area. The much more numerous C fibers are unmyelinated and conduct more slowly; the nature of pain impulses carried by C fibers is often described as a dull, aching, or throbbing pain.[2,3]

The axons of nociceptive neurons travel through peripheral nerves, spinal nerves, and dorsal nerve roots to reach the spinal cord in the region of the dorsolateral sulcus. At this point, these afferent axons traverse the spinal cord in a white matter tract called the *dorsolateral fasciculus* (Lissauer's tract), within which collateral branches of the telodendria traverse the spinal cord cranially and caudally over several spinal cord segments. Axonal terminals (telodendria) from this tract then synapse either on interneurons or projection neurons in the dorsal gray column (Fig. 13.2). The gray matter of the dorsal horn is arranged in layers or laminae, and the majority of the primary nociceptive telodendria synapse on neurons in layers I to IV. The *marginal nucleus* (lamina I), *substantia gelatinosa* (lamina II), and *nucleus proprius* (primarily lamina III) are most relevant to this discussion (see Fig. 13.2). Projection neurons from the dorsal gray column provide axons that form the ascending pain pathways of the spinal cord. Interneurons from these laminae have a number of roles, including segmental reflex activity and modulation of other synapses within the spinal cord gray matter.[1–4]

Clinically relevant spinal cord pain projection pathways include the *spinothalamic tract,* the *spinocervicothalamic tract,* the *spinomesencephalic tract,* and the *spinoreticular tract* (Fig. 13.3). Of most clinical importance in terms of conscious perception and reaction to noxious stimuli are the spinothalamic and spinocervicothalamic tract. The spinomesencephalic tract and spinoreticular tract are important in the understanding of several central pain modulating mechanisms (discussed later). Axons of dorsal gray horn projection neurons that give rise to the spinothalamic tract travel in the ventral aspect of the lateral funiculus of the spinal cord; these axons eventually reach neuronal cell bodies of the ventrocaudolateral (VCL) nucleus of the thalamus. These VCL nuclei provide axons to neurons in the somesthetic cerebral cortex. In primates, the spinothalamic tract is lateralized; the majority of the projection neuron axons cross to the opposite side of the spinal cord before ascending to the brain stem. In dogs and cats, the spinothalamic tract is thought to be more of a bilateral, multisynaptic pathway. The spinocervicothalamic tract may be a more clinically important nociceptive pathway in dogs and cats, and does appear to be more lateralizing than the spinothalamic pathway. Axons of dorsal gray horn projection neurons for this pathway ascend the spinal cord ipsilaterally in the dorsal aspect of the lateral funiculus. These axons terminate in another gray matter nucleus located in the first two cervical spinal cord segments (on the lateral side of the dorsal gray column), called the *lateral cervical nucleus* (LCN). Projection

ABSTRACT

Analgesia is necessary for patient comfort and to improve outcomes. Analgesia can be achieved by various techniques and drugs. Multimodal analgesia allows for decreased systemic side effects by minimizing the amount of any single drug given. Local and regional blocks provide additional analgesia.

constant rate infusions

BOX 13.1 Signs of Pain in Dogs and Cats

Abnormal posture: Hunched up, sitting in abnormal position, praying position
Abnormal gait: Stiff, non–weight bearing, limp
Abnormal movement: Thrashing, restlessness, no movement when not sleeping
Vocalization: Whining, crying, screaming, howling, no sound
Miscellaneous: Looking/licking or chewing painful area, reaction when touched
Behavior changes: Low and/or no wagging tail, head down, depressed, not grooming, tachypnea, trembling, shaking, low appetite, bites, recumbent, unaware
Physiologic signs: Tachypnea, tachycardia, hypertension, dilated pupils, increased serum cortisol and epinephrine

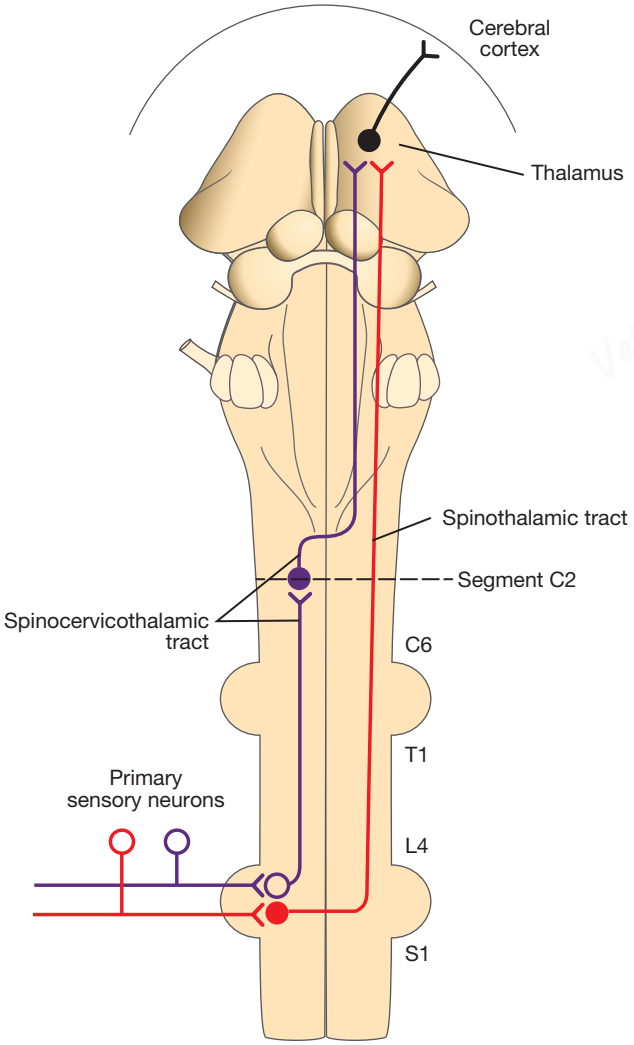

FIG. 13.1 Diagrammatic representation of simplified three-neuron (spinothalamic tract) or four-neuron (spinocervicothalamic tract) nociceptive pathways. (Modified from Uemura EE. Somatosensory system. In: Uemura EE, ed. *Fundamentals of Canine Neuroanatomy and Neurophysiology*. Ames, IA: Wiley-Blackwell; 2015: 128–155.)

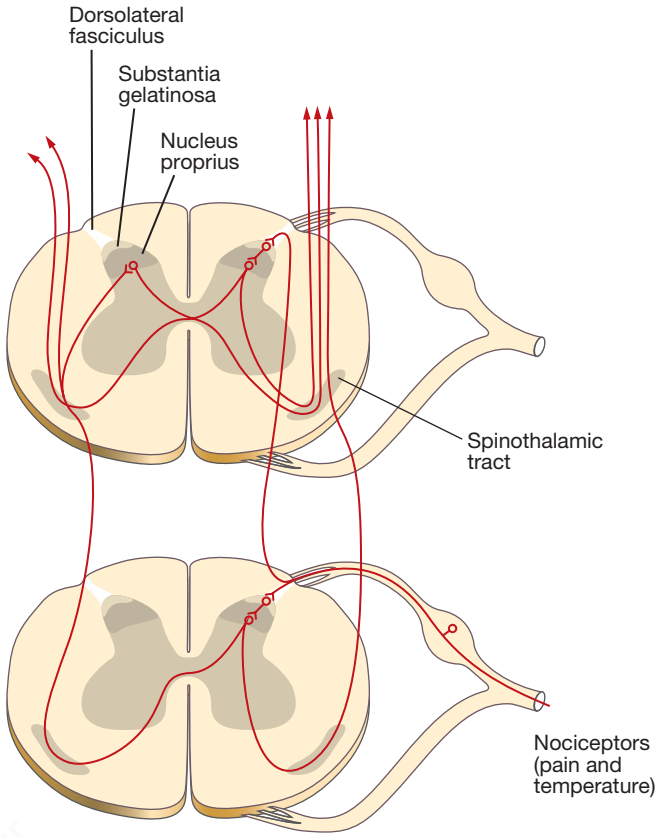

FIG. 13.2 Classic spinothalamic tract nociceptive pathway for dogs and cats. (Modified from Pypendop BH, Barter LS. Pharmacologic management of pain for patients with neurologic disease. In: Dewey CW, da Costa RC, eds. *Practical Guide to Canine and Feline Neurology*. 3rd ed. Ames, IA: Wiley-Blackwell; 2016:585–597.)

neurons from the LCN cross the midline at the level of the medial lemniscus of the brain stem to reach the VCL nucleus of the thalamus.[1,4] The nociceptive pathways (on the whole) in dogs and cats appear to be lateralized, as are many other sensory modalities. Dogs and cats with *hemineglect* (hemi-inattention) syndrome tend to have difficulty localizing (or sometimes even acknowledging) noxious stimuli (e.g., skin pinch with a hemostat) applied to the inattentive side of the body.

Nociceptive information from the face and head is conveyed primarily via CN V and its associated nucleus and tract in the brain stem. The anatomic arrangement is similar to that already described for the body, in that there is a nociceptive first-order neuron with its cell body in a peripheral ganglion (in this case the trigeminal ganglion in the petrosal bone), a white matter tract in the CNS (the spinal tract of CN V), a gray matter nucleus in the CNS (nucleus of the spinal tract of CN V), and thalamic relay nuclei that convey impulses to the somesthetic cerebral cortex (Fig. 13.4). The spinal tract of CN V is continuous with the dorsolateral fasciculus of the spinal cord, and the nucleus of the spinal tract of CN V is continuous with the substantia gelatinosa of the spinal cord. Sensation from the face is also lateralized in dogs and cats. The majority of axons from the nucleus of the spinal tract of CN V from one side of the face will cross at the medial lemniscus to the opposite

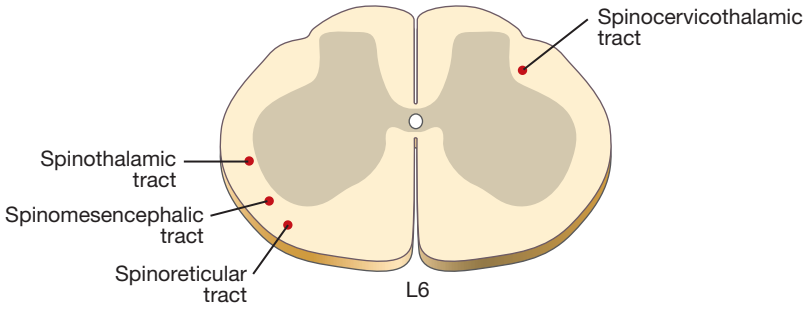

FIG. 13.3 Approximate locations of clinically relevant nociceptive tracts in the lumbar white matter. (Modified from Evans HE, de Lahunta A, eds. *Miller's Anatomy of the Dog.* 4th ed. Philadelphia: Elsevier; 2013.)

ventrocaudomedial nucleus of the thalamus. This information is then relayed to the cerebral cortex for perception.[1,4]

Visceral nociception is conveyed by axons similarly as already described, but the axons are usually referred to as *general visceral afferent* (GVA) axons. The GVA axons travel to the spinal cord in sympathetic and parasympathetic nerves to reach the dorsolateral fasciculus. At this point, the pathway for nociception is exactly as described for the body. In fact, the GVA axons synapse on the same pool of dorsal horn gray matter neurons as do the GSA neurons in a specific body region. In other words, there is a visceral sensory map that corresponds to the dermatomal map for specific regions of the body.[1,5,6] This concept is important in understanding phenomena such as referred pain and some of the suspected mechanisms of acupuncture.

NEUROPHYSIOLOGY AND MODULATION OF NOCICEPTION

Local inflammatory mediators in peripheral tissue are responsible for creating the signal that will ultimately be perceived as pain. Such mediators released by tissue after injury include bradykinin, prostaglandins, leukotrienes, serotonin, arachidonic acid, histamine, nerve growth factor, tumor necrosis factor, substance P, acetylcholine, adenosine triphosphate, and protons. Many of these inflammatory mediators and cytokines are released from epithelial cells, endothelial cells, mast cells, macrophages, and platelets. Prostaglandin E2 (PGE2) is an arachidonic acid metabolite generated by cyclooxygenase (COX) released from damaged cells. Bradykinin is a potent pain-producing peptide; it directly activates Aδ and C fibers and increases the synthesis and release of prostaglandins by nearby cells.[2,7–10] If unabated, stimulation of peripheral nociceptors by these mediators can lead to release of additional inflammatory mediators by the nociceptors themselves, leading to amplification of the local inflammation via a process of *neurogenic inflammation*. In addition to cytokines already mentioned, nociceptors may release other chemicals such as substance P and calcitonin gene-related peptide. Both these peptides can cause increased tissue edema by direct actions on venules. They also activate local mast cells, leading to histamine release; histamine accentuates the pain response by decreasing the threshold for nociceptor activation. These processes can ultimately lead to *peripheral sensitization*, a phenomenon in which nociceptor afferent neurons become hyperexcitable to stimuli, effectively increasing the gain of the response of these peripheral neurons to potentially noxious stimuli.[2,5,9,10]

In the CNS, similar processes are thought to contribute to the development of hyperesthesia, allodynia, and chronic pain states. *Central sensitization* refers to enhancement of the pain response to a certain level of stimulus over time, due to similar mechanisms of increasing the responsiveness of neuronal pathways in the spinal component of the nociceptive pathway. With constant overstimulation of dorsal horn gray matter neurons by peripheral nociceptors (particularly C fibers), neurotransmitters such as glutamate and substance P that bind to postsynaptic dorsal horn gray matter neurons will eventually increase the efficiency of pain transmission at the spinal cord level. Glutamate is the predominant excitatory neurotransmitter released by Aδ and C fibers in the spinal cord gray matter. Substance P is released mainly by C fibers. Substance P can enhance and prolong the

BOX 13.2 Examples of Mechanisms of the Central Sensitization Process

- Wind-up via excessive glutamate activation of neuronal NMDA receptors.
- Release of normal inhibition of NMDA receptor overstimulation via co-release of substance P and CGRP from hyperstimulated C-fibers (see earlier). This involves Mg^{++} channels.
- Transcriptional and translational changes in postsynaptic dorsal horn neurons (pain "memory").
- Activation of central nervous system microglial cells (by substance P, glutamate, etc.), which upregulate cyclooxygenase-2, and release other neuroactive substances (which increase excitability of dorsal horn neurons).
- Axonal sprouting, altered neuronal connectivity and cell death; all associated with microglial cell activation.

actions of glutamate on dorsal horn neurons. Mechanisms of the central sensitization process include changes in the neurochemical environment as well as cytoarchitectural changes in the spinal cord (Box 13.2). The various physiologic processes described that perpetuate painful conditions form the basis for the development of phenomena like wind-up, hyperesthesia, allodynia, and chronic pain.[5,9,10]

In addition to mechanisms within the peripheral nervous system (PNS) and CNS that serve to exacerbate painful states, there are a number of segmental (spinal cord) and suprasegmental (brain) modulatory systems within the CNS that act to ameliorate the sensation of pain. At the spinal cord level, some interneurons of the dorsal gray column are inhibitory to projection neurons that provide the majority of axons for the various pain-transmitting spinal cord pathways. These interneurons can be stimulated by fast-conducting, nonnociceptive myelinated Aβ fibers (normally convey touch, pressure, and some proprioceptive sensation) as well as by a subset of nonnociceptive Aδ fibers. When stimulated, these fibers can, via excitation of the inhibitory interneuron, prohibit firing of the slower conducting C fibers. In other words, by the time the nociceptive stimulus carried by the C fiber arrives at the dorsal horn, an inhibitory interneuron that has been excited by a faster conducting myelinated fiber has already been given the signal to prohibit C fiber stimulation of dorsal horn projection neurons. This is the basis of the *gate control theory*. In essence, the faster conducting nonnociceptive fibers "close the gate" to slower conducting nociceptive fibers. The inhibitory interneurons involved in this phenomenon are believed to be enkephalinergic and may prohibit substance P release from C fibers.[7,9,11]

Several regions of the brain are involved in suprasegmental modification of nociception. These brain regions give rise to descending tracts that exert an analgesic effect at the level of the dorsal gray column of the spinal cord. They include the periaqueductal gray (PAG) matter of the mesencephalon, ventral tegmental area of the mesencephalon, locus ceruleus of the pons, median raphe magnus nucleus of the myelencephalon, hypothalamus, pituitary, and some areas of the cerebrum. Within the dorsal gray matter of the spinal cord, there are extrasynaptic receptors on the telodendria of primary nociceptive neurons (presynaptic) and dendritic zones of nociceptive projection neurons (postsynaptic). These include adrenergic, serotonergic, opioid, and gamma-aminobutyric acid type B ($GABA_B$) receptors. When these receptors are stimulated by descending pain

BOX 13.3 Summary of Specific Regions of the Brain and Information Involved in Suprasegmental Inhibition of Nociceptive Pathways Along With Their Respective Primary Neurotransmitters

- *Dorsolateral prefrontal cerebral cortex* and *cingulate gyrus*: activates periaqueductal gray (PAG) and raphe magnus nuclei via *endorphins*.
- *Hypothalamus*: sends long axons to activate neurons of the *PAG* via *β-endorphins*.
- *Pituitary*: releases *endorphins* into the blood (humoral effect) and cerebrospinal fluid. The pituitary gland also releases *adrenocorticotrophic hormone* and *oxytocin* into the bloodstream, both of which can have analgesic effects.
- *PAG matter of the mesencephalon*: indirectly causes release of *serotonin* and *noradrenaline* in the region of the dorsal horn, via stimulating (via *enkephalins*) the raphe magnus nucleus of the myelencephalon (serotonin) and the locus ceruleus of the pons (noradrenaline). The PAG neurons also have projections to the thalamus and cerebrum.
- *Ventral tegmental area of the mesencephalon:* provides *dopaminergic* and *serotonergic* inhibitory axons to dorsal horn neurons.
- *Locus ceruleus of the pons*: releases *noradrenaline* in the dorsal horn, stimulating alpha-2 adrenoreceptors.
- *Raphe magnus nucleus of the myelencephalon*: releases *serotonin* in the dorsal horn gray matter.

modulating tracts, transmission of nociceptive stimuli from the dorsal horn gray matter to the respective spinal cord tracts is impaired. Specific information regarding regions of the brain involved in suprasegmental inhibition of nociceptive pathways along with their respective primary neurotransmitters is summarized in Box 13.3.

Although this may seem complicated, it can be summarized as an organized network of neurons and axonal connections that serves to diminish the pain that would otherwise be experienced by patients if the dorsal horn nociceptive projection neurons were not under the control of these brain influences. Once potentially noxious stimuli reach these centers from ascending spinal cord tracts, mechanisms to ameliorate the pain are immediately employed.[5,10,12] For example, a nociceptive stimulus is experienced by a patient, and this stimulus is carried via the spinomesencephalic tract to the PAG and ventral tegmental area of the mesencephalon. These mesencephalic centers, in turn, may activate other regions of this descending pain-alleviating system, such as the raphe magnus nucleus of the myelencephalon and the locus ceruleus of the pons. Eventually, axons from several of these brain centers travel caudally in the dorsolateral funiculus to reach their target dorsal horn projection neurons, which they subsequently inhibit.

Understanding the concept of referred pain from an anatomic and physiologic perspective is important for correctly localizing the source(s) of pain and providing effective treatment. Referred pain does not mean pain that is so intense that it radiates from the initial site of stimulation to other regions. *Referred pain* describes painful stimuli that the brain interprets as emanating from a region different than the actual source. This is an anatomic phenomenon and is based on shared interneuron pools in the dorsal gray matter of the spinal cord. GSA and GVA telodendria synapse segmentally on the same dorsal horn neuronal cell bodies in a certain spinal cord segment. In general, there are not enough dorsal gray horn interneurons to go around, so they are shared by GSA and GVA neurons. In other words, a dermatomal distribution of GSA neurons has a corresponding GVA component. For

example, pain in the thoracolumbar spine region may, in some cases, be interpreted as abdominal pain in the same cross-sectional region of the patient.[1,5,6] The concept of the brain interpreting a noxious stimulus as coming from a visceral versus somatic site or vice versa due to shared dorsal gray horn neurons is called the *common pool theory*. There is also another theory based on this anatomic arrangement, called the *viscerovisceral reflex arc theory*. According to this theory, a noxious visceral stimulus is carried by GVA neurons to the dorsal horn neurons, resulting in excitation of sympathetic general visceral efferent fibers in that spinal cord segment. The resultant excessive sympathetic outflow in that segment causes peripheral vasospasm. The vasospasm leads to release of inflammatory cytokines, which then stimulate GSAs. The GSAs feed back into the same spinal cord segment dorsal horn neurons. By this mechanism, an initially viscerally located noxious stimulus is converted to a somatically located noxious stimulus.[1,6]

A variety of techniques may be utilized in the treatment of pain states, such as pharmacologic agents, physical therapy, and acupuncture. Treatment of pain may require only one therapy or a combination of different techniques. Pharmacologic agents used include opioids, *N*-methyl-D-aspartate (NMDA) antagonists, local anesthetics, alpha-2 agonists, nonsteroidal antiinflammatory drugs (NSAIDs), gabapentin, amantadine, amitriptyline, selective serotonin reuptake inhibitors, acetaminophen, maropitant, and bisphosphonates. Pain should be treated until the pain has resolved; this requires a pain management plan with reassessment of the treatment to ensure adequate analgesia is being achieved. Knowledge of the severity of pain typically caused by various procedures is helpful in determining treatment (Table 13.1). To be consistent in the diagnosis of a painful state, it is often helpful to use a pain scoring system (Figs. 13.5–13.7).

DRUGS USED FOR ANALGESIA

Opioids (see Chapter 12) are good analgesics and are commonly used both intraoperatively and postoperatively, and as part of a premedication protocol. The full mu agonists provide the most reliable analgesia (see Table 12.2). *Fentanyl* is commonly used as a constant-rate infusion (CRI) for analgesia in dogs and cats because it has an elimination half-life of approximately 45 minutes (Tables 13.2 and 13.3, Box 13.4). A loading dose is given intravenously prior to initiation of the CRI to help maintain plasma levels. When used as a CRI some animals may have a decreased appetite. Fentanyl comes as a transdermal patch that is applied to the skin (see Table 13.2 and p. 133). The other commonly used mu agonists used for analgesia include *hydromorphone, morphine, oxymorphone, remifentanil,* and *meperidine* (see Chapter 12 and Table 13.2).

Ketamine, an **NMDA receptor antagonist**, can be used as part of a multimodal technique for pain management (see Chapter 12 and Table 13.2). Subanesthetic doses of ketamine delivered as a CRI may be helpful in treating acute postoperative and posttraumatic pain, neuropathic pain, and maladaptive pain states. Glutamate, the NMDA receptor, contributes to central sensitization, and hyperalgesia and therapy at this receptor may help minimize "wind-up" and modify the plasticity of the nervous system.[13]

Dexmedetomidine, an **alpha-2 agonist,** is an effective sedative and analgesic (see Chapter 12 and Tables 13.2 and 13.4). Due to its cardiovascular depressant effects, it is typically given as an adjunct with other analgesics. Its effects the alpha-2 receptor in the dorsal horn of the spinal cord, brain stem, and in the periphery. It provides excellent visceral analgesia with a duration of 1 to 2 hours. A microdose CRI (see Table 13.2) can offer a constant and titratable level of analgesia; however, decreased cardiac output may still be seen. Alpha-2 agonists are synergistic with opioids. The effects of alpha-2 agonists can be reversed with *atipamezole* (see Chapter 12 and Table 13.2).[14]

Local anesthetic agents (e.g., lidocaine, bupivacaine) may be given as a local anesthetic (local block), epidural, or used intravenously as a CRI (see Table 13.2). They act mainly by inhibiting sodium influx through sodium-specific ion channels in the neuronal cell membrane. *Lidocaine* can be used in dogs as a CRI to provide analgesia and decrease the amount of inhalant needed; it can be continued into recovery and in the intensive care unit. It also has antiarrhythmic effects and reactive oxygen scavenging properties; this may be useful in gastric dilatation volvulus or gastrointestinal (GI) surgery of compromised bowel. Work in cats has shown that lidocaine causes cardiopulmonary depression

TABLE 13.1 Characterization of Pain

Type of Pain	Examples
Severe to excruciating	Neuropathic pain, extensive inflammation, bone cancer, meningitis, necrotizing pancreatitis, multiple trauma
Severe	Fracture repair, corneal ulceration, thoracotomy, extensive laparotomies, intraarticular surgery, total ear canal ablation, intervertebral disc disease, thrombosis and ischemia, uveitis, mastitis, limb amputation, gastric/organ torsion, glaucoma
Moderate	Laparotomy, inguinal hernia repair, castration and ovariohysterectomy (old or obese patients), some dental procedures, enucleation, minimally invasive orthopedic procedures, chest drains
Mild to moderate	Ovariohysterectomy (young), lump removal, some dental procedures, cystitis, otitis lacerations

BOX 13.4 Continuous-Rate Infusions

- Intraoperative and postoperative infusions
  - Hydromorphone: 0.025–0.1 mg/kg per hour IV
  - Fentanyl: 5–20 µg/kg IV loading dose, then 2–20 µg/kg per hour
  - Dexmedetomidine: 1–5 µg/kg IV loading dose, then 1 µg/kg per hour
  - Ketamine: 0.5 mg/kg IV loading dose, then 10 µg/kg per min IV CRI intraoperatively and 2 µg/kg per min IV CRI postoperatively
- FLK[a]
  - Fentanyl: 1–5 µg/kg per hour IV, plus
  - Lidocaine: 25–50 µg/kg per min IV, plus
  - Ketamine: 10 µg/kg per min IV
- MLK[a]
  - Morphine[b]: 3.3 µg/kg per min IV, plus
  - Lidocaine: 50 µg/kg per min IV, plus
  - Ketamine: 10 µg/kg per min IV

[a]Not recommended for use in cats.
[b]Give slowly to prevent histamine release.
CRI, Constant-rate infusion; *FLK,* fentanyl, lidocaine, ketamine; *IV,* intravenous; *MLK,* morphine, lidocaine, ketamine.

SHORT FORM OF THE GLASGOW COMPOSITE PAIN SCALE

Dog's name _____

Hospital Number _____ **Date** / / **Time**

Surgery Yes/No (delete as appropriate)

Procedure or Condition_____

_____

In the sections below please circle the appropriate score in each list and sum these to give the total score.

A. Look at dog in Kennel

Is the dog?

(i)		(ii)	
Quiet	0	Ignoring any wound or painful area	0
Crying or whimpering	1	Looking at wound or painful area	1
Groaning	2	Licking wound or painful area	2
Screaming	3	Rubbing wound or painful area	3
		Chewing wound or painful area	4

In the case of spinal, pelvic or multiple limb fractures, or where assistance is required to aid locomotion do not carry out section **B** and proceed to **C**
Please tick if this is the case ☐ then proceed to C.

B. Put lead on dog and lead out of the kennel.

When the dog rises/walks is it?

(iii)	
Normal	0
Lame	1
Slow or reluctant	2
Stiff	3
It refuses to move	4

C. If it has a wound or painful area including abdomen, apply gentle pressure 2 inches round the site.

Does it?

(iv)	
Do nothing	0
Look round	1
Flinch	2
Growl or guard area	3
Snap	4
Cry	5

D. Overall

Is the dog? *(v)*		*Is the dog?* *(vi)*	
Happy and content or happy and bouncy	0	Comfortable	0
Quiet	1	Unsettled	1
Indifferent or non-responsive to surroundings	2	Restless	2
Nervous or anxious or fearful	3	Hunched or tense	3
Depressed or non-responsive to stimulation	4	Rigid	4

TABLE 13.2 Analgesics: Indications and Dosages

Analgesic	Use/Indication	Route of Administration	Dose
Amantadine	Chronic pain	PO	*Dogs:* 3–5 mg/kg q24h, *or* 2–10 mg/kg q8–12h *Cats:* 3–5 mg/kg q12–24h
Amitriptyline	Idiopathic lower urinary tract disease	PO	*Cats:* 1–2 mg/kg/day *Dogs:* 1.1–1.3 mg/kg q12h
	Neuropathic pain	PO	Same as above
Atipamezole	Reverse alpha-2 agonists	IV, IM, SC	0.05–0.2 mg/kg once
Bupivacaine	Local anesthetic	Nerve block (SC)	1–2 mg/kg q6h
		Epidural	*Dogs:* 0.5–1 mg/kg *Cats:* 0.5–1 mg/kg
		Soaker catheter	2 mg/kg; total daily dose not to exceed 12 mg/kg
		Ring block (declaw)	0.2–0.3 mg/kg SC divided into 3 doses First dose: lateral and proximal to accessory carpal pad Second dose: medial to accessory carpal pad Third dose: dorsal-medial aspect of the proximal carpus
		Retrobulbar block	Maximum volume of 2 mL
Buprenorphine	Moderate pain	IM, IV	*Dogs:* 0.005–0.02 mg/kg q4–8h *Cats:* 0.02–0.04 mg/kg q4–8h
		Oral transmucosal	*Cats:* 0.01–0.02 mg/kg q6–8h
		Epidural	0.003–0.006 mg/kg
Butorphanol	Mild to moderate pain; mild sedation	IV, IM	0.1–0.4 mg/kg q1–3h
	Partial reversal of a μ opioid agonist	IV	0.05–0.1 mg/kg q1–3h
		CRI (IV)	Loading dose: 0.1 mg/kg Maintenance dose: 0.03–0.4 mg/kg q1h
Carprofen	Antiinflammatory	SC	*Dogs:* 2–4 mg/kg single dose, once; 4.4 mg/kg q24h; *or* 2.2 mg/kg q12–24h
	Mild to moderate pain	PO	
		SC	*Cats:* 4 mg/kg, once
Deracoxib	Chronic pain	PO	*Dogs:* 1–2 mg/kg q24h
	Acute postoperative pain	PO	*Dogs:* 3–4 mg/kg q24h, do not give for >7 days
Dexmedetomidine	Mild to moderate pain	IV	1–10 μg/kg q4h
		CRI (IV)	Loading dose: 1 μg/kg; maintenance dose: 0.5–3 μg/kg/h Dose can be variable depending on level of pain being treated
Etodolac	Antiinflammatory	PO	*Dogs:* 5–15 mg/kg q24h
Fentanyl	Moderate to severe pain	CRI (IV)	*Dogs:* loading dose, 2 μg/kg IV; maintenance dose: 2–10 μg/kg q1h *Cats:* loading dose, 1 μg/kg IV; maintenance dose, 1–4 μg/kg q1h
		IV, IM, SC	Dogs and cats: 5–15 μg/kg q1–3h
		Patch	Dogs and cats: <5 kg, 25 μg patch *Dogs:* 5–10 kg, 25 μg patch 10–20 kg, 50 μg patch 20–30 kg, 75 μg patch >30 kg, 100 μg patch
Firocoxib	Antiinflammatory	PO	*Dogs:* 5 mg/kg q24h
Gabapentin	Neuropathic pain	PO	Dose is variable depending on the level of pain and may need to be increased over time to be effective. Starting dose: 1.25–4 mg/kg q24h; may increase to (see text): *Dogs:* 10–20 mg/kg q8–12h *Cats:* 8–10 mg/kg q8h, or 3 mg/kg q6h
Grapiprant	Pain and inflammation associated with osteoarthritis	PO	*Dogs:* 2 mg/kg q24h
Hydromorphone HCl	Moderate to severe pain	IM, SC	*Dogs:* 0.05–0.2 mg/kg q2–4h *Cats:* 0.03–0.1 mg/kg q2–4h
		IV	*Dogs:* 0.05–0.1 mg/kg q2–4h *Cats:* 0.05–0.1 mg/kg q2–4h
Ketamine	Analgesia without sedation	IV	0.1–1 mg/kg 5–20 min
		CRI (IV)	Loading dose: 0.5 mg/kg Maintenance during surgery: 0.6 mg/kg q1h Maintenance after surgery: 0.12 mg/kg q1h IV for 24 h
Ketoprofen	Antiinflammatory	IV, SC, IM	*Dogs:* 2 mg/kg once, *or* 1 mg/kg q24h
		SC	*Cats:* 2 mg/kg q24h; up to 3 doses

TABLE 13.2 Analgesics: Indications and Dosages—cont'd

Analgesic	Use/Indication	Route of Administration	Dose
Lidocaine	Local anesthetic	Nerve block (SC)	1–2 mg/kg
		Intratesticular injection for castration	Do not exceed 4 mg/kg; inject into body of each testicle
		CRI (IV)	*Dogs:* loading dose, 1–2 mg/kg; maintenance dose, 2–3 mg/kg q1h Doses as high as 6–12 mg/kg q1h have been used but require close monitoring to avoid toxicity.
		Patch	Animal dose has not been established, but the patch contains 700 mg of lidocaine. Significant systemic absorption has not been found to occur. The patch should be cut to fit the size of the area.
		Soaker catheter	2–4 mg/kg q2–3h
		IV regional block for extremities	2–4 mg/kg
		Retrobulbar block	Maximum volume of 2 mL
Maropitant	Mild to moderate pain	CRI (IV)	*Dogs:* loading dose, 1 mg/kg; maintenance dose, 30 or 150 µg/kg q1h
	Premedicant for ovariohysterectomy	SC	*Dogs:* 1 mg/kg
		IV	*Cats:* 1 mg/kg
Meloxicam	Antiinflammatory	IV, SC, PO	*Dogs:* 0.2 mg/kg once, then 0.1 mg/kg SC or PO q24h
		SC, PO	*Cats:* 0.2 mg/kg once, *or* 0.1 mg/kg q24h for up to 3 doses
Morphine, preservative free	Mild to moderate pain	Epidural	0.1 mg/kg
Morphine sulfate	Moderate to severe pain and sedation	IM, SC	*Dogs:* 0.5–2 mg/kg q4h *Cats:* 0.05–0.4 mg/kg q3–4h
		CRI (IV)	*Dogs:* 0.18 mg/kg q1h
Naloxone	Reverse opioid agonists	IM, IV, SC	0.002–0.1 mg/kg
Nocita	Postoperative pain from cranial cruciate surgery	Tissue infiltration	5.3 mg/kg administered by tissue infiltration just prior to closure (see text)
Oxymorphone	Moderate to severe pain and sedation	IM, IV	*Dogs:* 0.03–0.1 mg/kg q2–4h *Cats:* 0.01–0.05 mg/kg q2–4h
Pregabalin (see also p. 1140)	Neuropathic pain	PO	*Dogs:* 2.0 mg/kg q8–12h *Cats:* 1.0–2.0 mg/kg q12h
Remifentanil	Short-term analgesia	CRI (IV)	Loading dose: 3 µg/kg Maintenance dose: 0.1–0.3 µg/kg/min
Robenacoxib	Antiinflammatory	SC between the shoulder blades	*Cats:* 2 mg/kg
		PO	*Cats:* up to 3 days (based on weight of cat): 2.5–6 kg: 6 mg/cat q24h 6.1–12 kg: 12 mg/cat q24h *Cats:* 3–11 days: 1 mg/kg q24h
Tepoxalin	Analgesia and antiinflammatory	PO	*Dogs:* 10 mg/kg q24h

CRI, Constant-rate infusion; *IM,* intramuscular; *IV,* intravenous; *PO,* orally; *q,* every; *SC,* subcutaneous.

TABLE 13.3 Guidelines for Intermittent Bolus Administration of Select Opioids

Drug	Route	Dose	Frequency
Morphine	IV, IM, SC	Dogs: 0.5–2.0 mg/kg Cats: 0.05–0.4 mg/kg Give IV slowly to avoid histamine release	3–4 h
Hydromorphone	IM, SC	Dogs: 0.05–0.2 mg/kg Cats[a]: 0.05–0.1 mg/kg	2–4 h
	IV	Dogs: 0.05–0.1 mg/kg Cats[a]: 0.03–0.05 mg/kg	
Fentanyl	IV, IM, SC	5–15 µg/kg	Titrate to effect by giving boluses every 3–5 min PRN
Butorphanol	IV, IM, SC	0.1–0.4 mg/kg	1–3 h
Buprenorphine	IV, IM	Dogs: 0.005–0.02 mg/kg Cats: 0.02–0.04 mg/kg	4–8 h

[a]Hyperthermia is a risk in cats, even at recommended doses.
IM, Intramuscular; *IV,* intravenous; *PRN,* when necessary; *SC,* subcutaneous.

TABLE 13.4 Dexmedetomidine-Butorphanol-Ketamine Combination in Healthy Cats[a]

Level of Sedation or Procedure	Dexmedetomidine (0.5 mg/mL) mL (μg/kg)	Butorphanol (10 mg/mL) mL (mg/kg)	Ketamine (100 mg/mL) mL (mg/kg)	Atipamezole[b] (5 mg/mL) mL (μg/kg)
Profound sedation-analgesia	0.1 (11)	0.1 (0.22)	0.1 (2.2)	0.1 (111)
Castration or laceration repair	0.2 (22)	0.2 (0.44)	0.2 (4.4)	0.2 (222)
Ovariohysterectomy or onychectomy[c]	0.3 (33)	0.3 (0.66)	0.4 (6.6)	0.3 (333)

[a]Based on a 4.5 kg (10 lb) cat. All drugs (except atipamezole) can be mixed in one syringe and administered as a single intramuscular (IM) injection. If given as intravenous (IV), the drug doses in this combination should be halved; however, if a deeper plane of anesthesia is desired, the full IM dose can be given IV.
[b]If reversal is necessary.
[c]More invasive procedures should have a stronger opioid chosen for postoperative analgesia.
From Ko JC, Knesl O, Weil AB, et al. FAQs: analgesia, sedation, and anesthesia: making the switch from medetomidine to dexmedetomidine. *Comp Cont Edu Vet.* 2009;31[suppl 1A]:1.

and should be used cautiously, if at all, as a CRI. Lidocaine has been used in combination with opioids (i.e., morphine, fentanyl) and ketamine as part of a multimodal therapy. These agents can be mixed together in a common bag or syringe, but separate infusions allow dose tailoring to better meet the patient's needs.[14]

A soaker catheter can be placed in a wound to provide continuous analgesia (see p. 149). Lidocaine can be given at 2- to 3-hour intervals (see Table 13.2). A lidocaine patch, developed for treating human postherpetic neuralgia, has been used in animals. The patch is applied to the skin or over the surgical incision. It can be left in place for 3 to 5 days and provides peripheral analgesia with minimal systemic side effects. The patch is not a controlled substance and can be cut to fit the site without affecting drug delivery.[15] *Bupivacaine* can be used perineurally or via the soaker catheter (see Table 13.2) but should never be given intravenously due to its cardiotoxicity.[14] It has a longer onset time of 15 to 20 minutes compared with lidocaine, with a duration of 4 to 6 hours (see Chapter 12).

NSAIDs are useful for pain management because inflammation plays a significant role in the pain process. There are several NSAIDs available for use in dogs and cats, including carprofen (Rimadyl), deracoxib (Deramaxx), meloxicam (Metacam), etodolac (Etogesic), tepoxalin (Zubrin), and robenacoxib (Onsior) (see Table 13.2). The analgesic and antiinflammatory effect is related to the inhibition of the COX enzyme isoforms. COX-1 is responsible for basal prostaglandin production for normal homeostatic processes in the body, including gastric mucus production, platelet function, and hemostasis. COX-2 is found at sites of inflammation and some basal production of constitutive prostaglandins. Selective inhibition of COX-2 would provide analgesic and antiinflammatory effects without the adverse effects of COX-1 inhibition. No available drug is a pure COX-2 inhibitor. NSAIDs should be used cautiously in patients with hypotension, hypovolemia, and renal disease. NSAID use with renal disease has the potential for renal vascular vasoconstriction, which could worsen renal insufficiency. NSAIDs are metabolized in the liver and excess dosing may lead to hepatotoxicity. Grapiprant (Galliprant) is a new, first-in-class piprant (PGE2 EP4 receptor antagonist, non-COX inhibiting) NSAID that is indicated for the control of pain and inflammation associated with osteoarthritis in dogs (see p. 1140 and Table 13.2). It is a once daily oral medication.

NOTE All NSAIDs (including the newer COX-2 selective drugs) have the very real potential for GI ulceration and perforation, even when used at recommended doses.

NSAIDs have a slow onset time of 45 to 60 minutes but provide analgesia for an extended duration, 12 to 24 hours. *Carprofen* is widely used in dogs; there are reports of idiosyncratic hepatic toxicity that will resolve if detected early and if carprofen is discontinued (see Table 13.2). Dogs should be screened for liver dysfunction prior to carprofen use. Labrador retrievers have been suggested to be at increased risk. This might be because many Labrador retrievers have a propensity to accumulate toxic amounts of copper in the liver. *Ketoprofen* in dogs seems to have an increased incidence of the adverse side effects of prolonged bleeding times and gastric lesions (see Table 13.2). A proton pump inhibitor (e.g., omeprazole; 1–2 mg/kg PO every 12 hours) may be given if the patient has GI problems or has had such in the past when receiving NSAIDs. They may also be of benefit when a NSAID that is known to have a distinctly high incidence of problems (e.g., piroxicam) is being administered. Renal insufficiency has been reported in cats. *Meloxicam* has been used in dogs and is safe for perioperative use; it can also be used in cats at the prescribed dose and duration (see Table 13.2). *Robenacoxib* (Onsior) is a feline-specific agent with a high safety index in cats (see Table 13.2). It has a terminal half-life of 1.9 hours in cats with an efficacy persisting for 22 hours.[16] *Tepoxalin* (Zubrin) inhibits COX-1, COX- 2, and lipoxygenase, preventing the synthesis of leukotrienes. It is administered orally as a wafer that dissolves in the mouth (see Table 13.2).

NSAIDs are commonly used in combination with opioids for a combined therapeutic effect. All NSAIDs should be dosed at the lowest effective dose and frequency. All patients should have a thorough exam prior to administration of NSAIDs.[17]

NOTE Do not use NSAIDs and glucocorticoids concurrently due to the substantially increased potential for GI ulceration and perforation.

Piprants are a new class of compounds that block specific prostaglandin receptors without interfering with prostanoid

production. *Grapiprant* (see Table 13.2) is an EP4 piprant, also known as an EP4 prostaglandin receptor antagonist. This receptor is involved in the mediation of inflammatory pain, especially that associated with osteoarthritis. It is used orally in dogs and cats.[18] Grapiprant binds to the canine EP4 receptor with high affinity and is extremely well tolerated. Dogs can be treated with a dose of 2 mg/kg PO for up to 28 days for osteoarthritis pain.[19]

Gabapentin is a structural analogue of GABA but does not interact with GABA receptors to produce analgesia. It is used to treat neuropathic pain (see Table 13.2). The mechanism of action is not fully understood but may involve inhibition of N-type voltage-dependent neuronal calcium channels. A common side effect in dogs is sedation (see Box 12.2). The effectiveness of analgesia in cats is unknown. Gabapentin is commonly used as part of multimodal analgesic therapy.[20]

Amantadine is a dopamine agonist and NMDA receptor antagonist. The potential analgesic effect is mediated through NMDA antagonism. It appears to be most effective in cases of chronic pain and with central sensitization. It undergoes renal excretion in dogs. When used at higher doses, monitor for CNS excitement (see Table 13.2). CNS stimulation is a side effect of the dopamine agonist activity, and it should be used with caution in patients receiving other dopaminergic agents, such as the monoamine oxidase inhibitor selegiline, or agents inhibiting the reuptake of serotonin (i.e., the tricyclic antidepressant amitriptyline and the selective serotonin reuptake inhibitor fluoxetine). When used together, there is the risk of *serotonin syndrome*. This syndrome can be fatal and is characterized by CNS stimulation, muscle tremors, tachycardia, tachypnea, and hypertension. Hepatic dysfunction may enhance this risk as these agents are metabolized by the CYP 450 pathway. Meperidine, fentanyl, tramadol, and methadone increase the CNS concentration of serotonin and may contribute to serotonin syndrome, although the risk is unknown.[20]

Amitriptyline is a tricyclic antidepressant. It is a selective serotonin reuptake inhibitor leading to increases in synaptic levels of serotonin and norepinephrine. Other actions including sodium channel blockade, NMDA receptor antagonism, and antihistamine activity may contribute to the analgesic effect. Sedation may be a side effect. Overdose may lead to tachycardia, ventricular tachyarrhythmias, hypersalivation, and vomiting. In dogs, hepatic metabolism produces the active metabolite nortriptyline; both it and amitriptyline are excreted unchanged in the urine.[20]

Maropitant is a neurokinin 1 (NK-1) receptor antagonist primarily used for antiemesis. However, it also has anesthetic-sparing effects during visceral stimulation. The NK-1 receptor and its agonist substance P have been reported in pain pathways at the level of the CNS and PNS. The dorsal root ganglia and spinal cord dorsal horn contain large amounts of NK-1 receptors and substance P vesicles. Maropitant has been used in dogs undergoing ovarian stimulation (see Table 13.2)[21] and as a preoperative medication in dogs undergoing ovariohysterectomy. Those dogs receiving maropitant returned to eating sooner.[22]

REGIONAL TECHNIQUES

Local anesthetic agents may be used for regional blocks. Lidocaine or bupivacaine are most commonly used; bupivacaine has the longer duration of action. To enhance the analgesic effect, buprenorphine or dexmedetomidine can be added to the local agent. All blocks are placed following a sterile prep of the area, and the individual placing the block should wear sterile gloves. Prior to any injection of local anesthetic nerve block, aspiration should be performed to decrease the risk of intravascular injection. If there is resistance to the injection, it may indicate that the solution is being injected directly into the nerve; this should be avoided.

An intratesticular injection of lidocaine can be used in dogs and cats to augment analgesia for castration. Lidocaine is injected into the body of each testicle (see Table 13.2).[23] For cats undergoing a declaw procedure, a bupivacaine nerve block can provide analgesia into the postoperative period (see Table 13.2). It is injected subcutaneously, lateral and proximal to the accessory carpal pad to block the dorsal branch of the ulnar nerve, and medial to the accessory pad to block the median nerve and palmar branch of the ulnar nerve. The third site is the dorsal-medial aspect of the proximal carpus to block the superficial branch of the radial nerve.[23]

Animals undergoing rhinoscopies and nasal biopsies will benefit from a caudal maxillary block via the infraobital foramen. The local anesthetic is applied to the maxillary nerve through the infraorbital canal. The needle can be introduced through the skin or the mucosa over the foramen. The foramen is on the lateral side of the maxilla, slightly rostroventral to the eye and dorsal to the distal root of the maxillary third premolar tooth. *Place the thumb of the free hand on the foramen and the needle tip into the foramen. Aspirate and then slowly inject the local anesthetic.*[24]

Dental blocks can be utilized to help provide analgesia for mandibulectomy or maxillectomy procedures. Nerves blocked when performing a *maxillary nerve block* are the maxillary; infraorbital; caudal, middle, and superior alveolar dental; incisivomaxillary; and rostral superior alveolar dental. This provides anesthesia to the ipsilateral maxilla including the teeth, bone, and soft tissues (including the skin of the nose, cheek, and upper lip). This block can be done intraorally or transcutaneously.

Intraoral dental block: *Place the needle behind the last molar tooth and the maxillary tuberosity* (the thin caudal margin of the maxilla covering the roots of the last molar tooth). *Open the mouth and palpate the maxillary tuberosity. Insert a short needle between your finger and the bone. Position it as perpendicular as possible to the hard palate or with a slight medial direction with the needle bevel directed rostrally. Once in place, aspirate and slowly inject the local anesthetic.*

Transcutaneous dental block: *Insert the needle between the caudal margin of the maxilla and the coronoid process of the mandible below the rostroventral border of the zygomatic arch. Palpate the structures on the side of the face just below the ocular globe. Insert the needle perpendicular to the skin and advance a short distance to the pterygopalatine fossa and the maxillary nerve. Aspirate and then slowly inject the local anesthetic.*

Caudal inferior alveolar nerve block: This block is performed to provide analgesia for a mandibulectomy. The mandibular teeth, rostral lower lip, and rostral intermandibular region are anesthetized. If the local anesthetic diffuses to the lingual nerve, desensitization of the soft tissue and periosteum of the lingual side of the mandible, floor of the mouth, and rostral two-thirds of the tongue may develop. This loss of tactile and pain sensation in the tongue can lead to self-inflicted chewing injury in the recovery period until normal sensation returns. If this should happen, the animal may need to be sedated to prevent tongue injury until the block wears off. To help prevent this complication, it is very important to keep the needle bevel next to the mandible and with the bevel directed toward the bony surface with both the intraoral and extraoral techniques.

Intraoral approach: *Open the mouth and displace the tongue to the contralateral side. Palpate the mandibular foramen and advance the needle through the mucosa medial to the mandible at the level of the last mandibular molar tooth. Direct the needle ventrocaudally towards the angular process between the finger and the mandibular bone to reach the mandibular foramen. Aspirate and then inject slowly;* tissues at the injection site should swell during the injection.

Extraoral approach: *Place the animal in lateral recumbency with the side to be blocked uppermost. Open the mouth and place your hand between the patient's tongue and mandible. Advance your finger ventrocaudally along the mandible until you palpate the foramen at the rostral margin of the medial pterygoid muscle. Advance the needle through the mucosa medial to the mandible, at the level of the last mandibular tooth. Direct the needle ventrocaudally towards the angular process to reach the mandibular foramen. Direct the needle bevel toward the bony surface and slowly advance the tip of the needle medial to the mandible to the mandibular foramen that you are palpating intraorally. Direct the needle tip over the foramen and nerve. Aspirate and then inject;* swelling of the tissues should be detected through the intraoral palpation site.[24]

Intravenous (IV) regional anesthesia or a **Bier block** can be done using lidocaine for analgesia and anesthesia of the extremities distal to the elbow and hock (see Table 13.2). The animal must be under heavy sedation or general anesthesia when using this technique due to the discomfort caused by the tourniquet. This technique should be done for short duration procedures, 90 minutes or less, due to the tissue ischemia that can result from the tourniquet. Anesthesia occurs distal to the tourniquet, with onset beginning distally and progressing proximally. The local anesthetic should be injected as far distally as possible in the limb to be blocked. When the tourniquet is released, the analgesic effects may persist for up to 30 minutes. The tourniquet must prevent blood from entering the limb and prevent the local anesthetic from entering the systemic circulation. The tourniquet can be a rubber or elasticized cloth or pneumatic cuff. When using a nonpneumatic tourniquet the area under the tourniquet should be protected with soft padding to prevent compressive tissue damage. A pneumatic cuff tourniquet should have a pressure 50 to 100 mm Hg above the systolic blood pressure to prevent blood leakage. *Place a distal IV catheter in the limb to be blocked and secure it in place. Use an esmarch or similar elastic bandage to exsanguinate the limb. Wrap the bandage concentrically around the limb starting at the toes and wrapping proximally, being careful not to dislodge the IV catheter. Apply the tourniquet and note the time. Once the tourniquet is in place, carefully remove the exsanguinating bandage. Slowly inject the lidocaine into the catheter over 2 to 3 minutes. Avoid high injection pressures. At the completion of the procedure, remove the tourniquet slowly to allow blood flow to return to the limb. Observe the procedure site for bleeding.* Once the tourniquet is released, any remaining local anesthetic will be delivered to the systemic circulation. *Monitor the patient for any signs of local toxicity such as hypotension and bradyarrhythmias for 10 to 15 minutes after tourniquet removal.*[25]

Intercostal nerve blocks are used to provide analgesia in animals undergoing a thoracotomy. It may also improve ventilation postoperatively. It can be done when the skin incision has been made, prior to incising the intercostal muscles, or through the skin prior to incision. The intercostal nerve lies immediately caudal to the associated rib. Aspiration prior to local injection is important as the intercostal vessels are closely associated with the nerves. Bupivacaine is most commonly used for this block due to its long duration of action. *Place the patient in lateral recumbency with the operative side up. Using a 1.5-inch needle, block the nerve at the incision site and block two nerves on either side of the incision site to provide a wide section of analgesia.*[26] *Palpate the rib immediately cranial to the incision site as far dorsally as possible to target the nerve as proximally as possible. Advance the needle through the skin onto the lateral aspect of the rib. Walk the needle tip off the rib caudally to the rib; do not place the needle beyond the depth of the rib. Aspirate and then inject the local anesthetic.*

Brachial plexus blocks can be used to provide analgesia for structures distal to the elbow. The brachial plexus of the dog consists of the ventral branches of C6, C7, C8, and T1 spinal nerves. The important nerves are the suprascapular, subscapular, axillary, musculocutaneous, radial, median, and ulnar. This block can be done by palpation only or with nerve stimulation guidance. When doing nerve stimulation guidance an insulated needle is used; when done by palpation only an appropriate length spinal needle is used. *Anesthetize the patient and place in lateral recumbency with the leg to be blocked uppermost. Hold the leg in a natural position perpendicular to the longitudinal axis of the body. Inject cranial to the acromion and medial to the subscapular muscle.*[27]

Retrobulbar blocks can be used to provide analgesia for eye enucleation. It will provide analgesia and prevent ocular movement during surgery. Skin infection, ocular neoplasia, or ocular fungal infection may be relative contraindications to placement of the block to avoid seeding abnormal cells into the deeper tissues. An inferior temporal palpebral approach is preferred. Lidocaine or bupivacaine are commonly used; bupivacaine provides a longer duration of action (see Table 13.2). A 1.5-inch (40 mm), 22-gauge spinal needle bent to approximately a 20-degree angle is used. The needle can be passed through the lower eyelid or through the transconjunctiva. *Using the lateral canthus and middle of the lower lid as landmarks, position the needle midway between these landmarks along the inferior eyelid at the level of the orbital rim. Direct the needle along the floor of the orbit. You will note a slight pop when you pierce the orbital fascia; then redirect the needle dorsally and towards the nose to reach the apex of the orbit. Inject the local anesthetic slowly. If there is resistance to injection, this could be due to penetration of the perineural sheath or abutment on the bony orbit; draw back and redirect.* Complications include inadvertent penetration of the globe, intrathecal injection due to penetration of the optic nerve, retrobulbar hemorrhage, or optic nerve damage.[28]

Radial, ulnar, musculocutaneous, and median (RUMM) nerve blocks can be used to provide analgesia to the distal aspect of the thoracic limb in dogs. This is a two-injection technique to obtain a peripheral block of the radial, ulnar, musculocutaneous, and median nerves. *For the radial nerve, place the dog in lateral recumbency with the leg to be blocked upwards. Flex the elbow 90 degrees to allow the soft tissue structures to be less stretched and therefore easier to manipulate. Measure the length of the lateral aspect of the humerus along a line connecting the most prominent craniodorsal point of the greater tubercle and the most prominent point of the lateral epicondyle. Divide this length into thirds. Locate the radial nerve at the junction of the middle and distal thirds, approximately 1 cm caudal to this line and lying between the lateral head of the triceps and the brachialis muscle. Palpate a branch of the radial nerve crossing the humerus slightly distal to this point. Palpate the brachialis muscle and apply craniomedial pressure so that your thumb is on the shaft of the humerus. Move the brachialis*

muscle cranially away from the lateral head of the triceps. Insert a 22-gauge spinal needle caudal to your thumb at a 45-degree angle, perpendicular to the long axis of the humerus, penetrating the lateral head of the triceps muscle so that the needle contacts the caudolateral aspect of the humeral shaft at the location of the radial nerve. Face the bevel of the needle cranially. Remove the stylet and withdraw the needle slightly so it is no longer contacting the bone. Aspirate and then inject the local anesthetic. Block the ulnar, median, and musculocutaneous nerves with the dog in a lateral position and the leg to be blocked downward. Pull the upper leg caudally and position the down leg with the elbow flexed at 90 degrees. Measure the length of the medial aspect of the humerus along a line connecting the most prominent craniodorsal point of the greater tubercle with the medial epicondyle. The median, ulnar, and musculocutaneous nerves are close to one another, approximately half the distance along this line from the medial epicondyle at the most proximal point at which the humeral shaft can be palpated. *Locate this point, apply digital pressure to the medial aspect of the limb, and palpate the humerus. Insert a 22-gauge spinal needle at a 45-degree angle from a caudal direction, perpendicular to the long axis of the humerus and caudal to the finger applying pressure, until it contacts the caudomedial aspect of the humerus. Face the needle bevel up. Release the digital pressure, remove the stylet, aspirate, and inject half the local anesthetic and then continue injecting as the needle is withdrawn.*[29] The use of ultrasound guidance and a peripheral nerve stimulator may improve the ability to locate the nerves and may enhance the success rate of the block.[30]

Femoral/sciatic nerve blocks can be done in dogs to provide analgesia for rear limb procedures (Videos 13.1 to 13.4). The femoral nerve innervates the femur, stifle, medial stifle joint capsule, intraarticular stifle structures, and skin of the medial aspect of the hind leg. The sciatic nerve innervates the caudolateral stifle, joint capsule, lateral meniscus, tibia, tarsus, digits, and skin of the caudal and lateral aspects of the hind leg. Complete local anesthesia of the stifle can be achieved with a block of both the femoral and sciatic nerves. This block has been shown to be as effective as an epidural for postoperative rear leg analgesia and is less apt to cause urinary retention.[31] The block is best performed with a peripheral nerve stimulator utilizing an insulated stimulator needle. *Position the dog in lateral recumbency with the affected leg up. Block the sciatic nerve by placing the stimulator needle at a point one-third the distance between the greater trochanter and ischiatic tuberosity. Flex the hock to confirm location of the needle close to the nerve. The femoral triangle is defined by the iliopsoas, pectineus, and sartorius muscles. Insert the stimulator needle at a 20-degree angle toward the iliopsoas, immediately cranial to the femoral artery. Extend the stifle to confirm proximity of the needle to the femoral nerve.* The needle stimulates muscle contraction at a current of 0.4 mA. *Aspirate the needle and if you do not see blood, block both nerves with injections of 0.5% bupivacaine until muscle contraction is lost.*

Cranial cruciate surgery local blocks. Nocita, a novel extended-release formulation of bupivacaine, has been approved for use in dogs to treat postoperative pain from cranial cruciate surgery. A single dose is infiltrated into the surgical site. In this formulation, multivescular liposomes composed of nonconcentric bilayers of phospholipids, cholesterol, and triglycerides encapsulate bupivacaine and are designed such that the bupivacaine is gradually released from the vesicles over 96 hours as the lipid bilayers break down (see Table 13.2). The dose is administered by tissue infiltration just prior to closure of the cranial cruciate ligament surgery. Measurable analgesic effect appears to last for up to 72 hours. *Using a 1- to 1.5-inch (25–40 mm) long needle, infiltrate the surgical site by inserting the needle to near the hub and injecting the solution as the needle is pulled out. Insert the needle at varying angles and then approximately parallel to the surface of the skin. Repeat the injections to create an area of infiltrated tissue around and at all levels of the wound. Inject approximately 25%, 50%, and 25% of the solution into the tissues around the joint capsule, fascial tissue, and subcuticular tissue, respectively.* Dilution of the solution with saline can be done with a maximal dilution of 1:1.[32]

Epidurals can be used in dogs and cats to provide anesthesia and analgesia for procedures in the caudal half of the animal (Table 13.5). The local anesthetics work on the nerve root. The pelvic limb is supplied by spinal nerves arising from L3 to S1.

TABLE 13.5 Epidural Anesthesia in the Dog

Epidural Volumes

Low epidural:
- 0.2 mL/kg results in analgesia/anesthesia of pelvis and caudal abdomen

High epidural:
- 0.3 mL/kg results in analgesia/anesthesia of pelvis, abdomen, and thorax
- Usually performed with only an opioid (saline can be used to increase the volume)
- Local anesthetics should be avoided in high epidurals to prevent sympathetic trunk blockade and intercostal nerve paralysis

Drug	Dose (mg/kg)	Onset of Action (min)	Duration of Action (h)
Lidocaine 2%[a]	0.5	10	1–1.5
Bupivacaine (0.25% or 0.5%)[a] (preservative free)	0.5	20–30	4.5–6
Ropivacaine (0.5%)[a]	0.5	20–30	4.5–6
Fentanyl	0.001	15–20	3–6
Morphine (preservative free)[b]	0.1	30–60	10–24
Buprenorphine	0.004	30–45	12–18

[a]A block to T1 leads to intercostal nerve paralysis and bradycardia; a block to C5–C7 leads to phrenic nerve paralysis.
[b]Dosage, onset, and duration are based on clinical experience; each patient should be evaluated individually. Reduce the dose by at least half for spinal administration of local anesthetics; reduce the epidural dose by 25% in geriatric, obese, and pregnant animals and in those with space-occupying lesions of the spinal cord or conditions in which venous engorgement is expected.
Protocols courtesy Dr. Stuart Clark-Price.

The volume of agent given must be sufficient to reach L3 to achieve sensory and motor block of the entire limb. The drug should be administered slowly over 1 to 2 minutes to keep it from going too far cranially. The injection should flow smoothly and without resistance. To help monitor the resistance, a small air bubble of 1 to 3 mL should be aspirated into the syringe; this bubble should be next to the plunger. Once the syringe is connected to the needle placed for injection into the animal, this bubble should not compress more than 50% of the starting volume as the drug is administered. If the bubble compresses too much, this is suggestive of resistance and the injection should be stopped and the needle readjusted. The air is not to be injected into the epidural space. Contraindications for an epidural can be remembered with the acronym CHINAS as described in Box 13.5. An epidural is done in a heavily sedated animal after a local block has been performed at the site of injection or in an animal under general anesthesia.

Agents commonly used for epidurals include local anesthetics, opioids, and alpha-2 adrenergic agonists; combinations of these agents can also be utilized. Local anesthetics commonly used are preservative-free lidocaine and bupivacaine; these agents block sensory, motor, and sympathetic nerves, which can lead to vasodilation and loss of motor function. The effects are dose dependent, with higher doses leading to a more profound block. Preservative-free morphine is the opioid most often used. Morphine is hydrophilic and less lipid soluble than fentanyl, leading to a longer duration of action. Opioids affect sensory nerves only, preserving motor function. The longest duration of action (12 to 24 hours) is achieved with a combination of morphine and bupivacaine. Opioids can cause urinary retention; thus it is recommended to express the urinary bladder of an animal that has received a preoperative opioid epidural prior to recovery from anesthesia. If urinary retention is present the following morning, an IV dose of naloxone will often result in immediate urination. Pruritus has also been reported as a potential adverse effect of opioid epidurals; IV naloxone may be given to attempt to reverse this affect. Alpha-2 adrenergic agonists (e.g., dexmedetomidine) have been used epidurally; these agents will also have dose-dependent systemic effects such as sedation, supraspinal analgesia, bradycardia, peripheral vasoconstriction, and vomiting.

BOX 13.5 Contraindications for an Epidural: CHINAS

C = Coagulation disorders; due to the increased risk of hemorrhage, potentially leading to a hematoma causing spinal compression and neurologic deficits

H =Hypovolemia and hypotension; hypotension could be exacerbated with a sympathetic nerve blockade; local anesthetics will cause vasodilation

I = Infections; especially of the skin can lead to introduction of infection into the vertebral canal

N = Neoplasia or neurologic deficits. It is recommended to not pass the needle through a neoplastic area as this could see tumor cells into the vertebral canal, and if the animal has preexisting disease, an epidural can make it difficult to monitor resolution or progression of the condition

A = Anatomy; abnormalities of the lumbosacral space will lead to difficulty in palpating the landmarks

S = Sepsis or bacteremia; laceration of a vessel in the epidural space could lead to hematogenous spread of the infection into the epidural/spinal space

The lumbosacral space is the preferred site for epidural injection due to the relatively wide intervertebral space at L7 to S1. *Place the animal in either sternal or lateral recumbency (Video 13.5). Perform a sterile prep wearing sterile gloves. If the animal is in sternal recumbency, pull the pelvic limbs forward to widen the intervertebral space; in lateral recumbency, keep the spine either neutral or flexed.* In animals with pelvic or femoral fractures that are displaced it may be best to perform the epidural with the animal in the lateral position. *Use a 22- to 20-gauge, 1.5- to 2.5-inch (40–60 mm) spinal needle (depending on the size of the animal) or a Tuohy needle (22 to 18 gauge). Palpate the L7-S1 space. Insert the needle perpendicular to the skin on the dorsal midline, caudal to the spinous process of L7. Advance the needle through the skin into the subcutaneous tissue and then through the interspinous ligament (there will be some resistance) and continue slowly until you feel a "pop" as the needle penetrates the ligamentum flavum. You will feel a loss of resistance as the epidural space is entered. If during placement of the needle you contact bony structures, partly withdraw the needle and redirect it caudally or cranially, walking off the adjacent bones to find the intervertebral space.* There are two commonly used methods to confirm correct placement of the needle, loss of resistance and a hanging drop. *With the former method, apply pressure to the syringe plunger as you advance the needle until you feel a "pop" and a sudden loss of resistance as the needle passes through the ligamentum flavum and enters the epidural space. For the hanging drop method, place a drop of saline or the drugs to be injected into the hub of the needle. As the needle penetrates the epidural space watch for the liquid drop to be aspirated into the space due to the subatmospheric pressure within the vertebral canal.* This technique can only be used with the animal in sternal recumbency; use the technique described where a loss of resistance is felt when the animal is in lateral recumbency. *If blood is detected in the needle hub, suggesting that the needle has inadvertently pierced a venous sinus, remove the needle and use a new one for the epidural. Inject slowly and smoothly to avoid excessive cranial spread and an irregular block.* It is possible for the dural sac to be punctured during an epidural; however, dural puncture is more common in cats than in dogs because in dogs the dural sac ends at the level of L6–L7, whereas in cats it ends at S1. *If the dural sac is penetrated, withdraw the needle to the epidural space.*

An **epidural catheter** can be placed to provide longer term analgesia. The Touhy needle is required for catheter placement because the catheter is passed through this needle. *Place the catheter in a sterile fashion with the animal in sternal recumbency. Use the same landmarks as for the single needle injection described previously. Place the Touhy needle into the epidural space, directing the curved needle bevel cranially to assist in catheter placement; tip the needle hub caudally to help in catheter placement. Once in the space, attach an adapter to the needle hub to provide rigidity to the catheter. Remove the needle stylet and thread the epidural catheter through the needle. Once the catheter is at the needle tip, apply slight pressure if required to advance the catheter past this point. Advance the catheter to the desired level. Once the catheter is in place, carefully withdraw the needle over the catheter, keeping hold of the catheter at its point of entry into the skin to avoid displacement as the needle is removed. If desired, tunnel the catheter subcutaneously away from the point of entry to provide additional fixation and minimize catheter contamination. Aspirate the catheter to ensure there is no blood or cerebrospinal fluid present. Connect a bacterial filter, primed with local anesthetic, to the catheter adapter. Secure the catheter in place with a transparent dressing and adhesive.*

Then slowly inject the anesthetic agents into the epidural space (in the awake animal slow injection is necessary to prevent vomiting). If the catheter cannot be advanced, remove it and the needle together; do not remove the catheter with the needle in place as the catheter could be sheared off and lost in the patient. Resistance to injection will be greater than through the needle because the catheter has a narrower diameter. *Confirm correct catheter placement by ultrasound, radiography, or fluoroscopy. When removing the catheter, grasp it close to the point of entry and gently pull it out. Do so in a sterile fashion (wear sterile gloves and use sterile scissors) so that the tip can be cultured. Make sure the whole catheter has been removed.*

NOTE Warn owners that it has been reported that hair regrowth at the epidural site may be delayed after an epidural has been performed.[33]

Coccygeal epidurals can be done to provide analgesia and relaxation to the perineum, penis, urethra, colon, and anus without loss of motor function to the rear limbs by blocking the pudendal, pelvic, and caudal nerves. Lidocaine has been used in this block to provide analgesia and pain management, as well as assist with catheterization of the obstructed feline urethra. This block could also be used for analgesia for dystocia, tail amputations, or degloving injury and other perineal procedures.[34] *Place the cat in sternal recumbency with the area over the sacrum and first coccygeal vertebra clipped and sterilely prepped. Inject between the first and second coccygeal vertebrae, which is the most mobile joint caudal to the sacrum. Determine the injection site by moving the tail. Use a 25-gauge, 1-inch (25 mm) needle to penetrate the skin at the midline, then direct the needle at a 30- to 45-degree angle and advance it through the interarcuate ligament/ligamentum flavum until you feel a "pop" when the ligament is penetrated. If you encounter bone, redirect the needle or withdraw it slightly. Aspirate and then inject 0.1 to 0.2 mL/kg of 2% lidocaine. Ensure there is minimal resistance to the injection. Withdraw the needle and observe the tail for relaxation. Administer a second dose of lidocaine if the first attempt was unsuccessful.*

ACUPUNCTURE AND ELECTROACUPUNCTURE

Although the appeal of acupuncture as a pain-relieving therapy is increasing in veterinary surgical practice, there remains some reticence among surgeons to accept acupuncture as a viable treatment modality; this reticence persists despite numerous experimental and clinical studies demonstrating both specific biological effects of acupuncture and measurable clinical benefit. Most of these studies have been performed in laboratory animals and humans with painful conditions, but much of the knowledge from this literature can be applied to veterinary surgical practice.[35–38] One of the barriers to integrating acupuncture into modern surgical practice is a commonly held perception that it is based on archaic principles, rather than contemporary medical science. Although the Traditional Chinese Veterinary Medical (TCVM) terminology and mechanistic explanations are indeed based on an antiquated system of understanding, the physiologic principles and rationale for clinical application of acupuncture as a pain-relieving modality can be couched in contemporary medical terms. One of the frustrating aspects of learning how to use acupuncture in modern surgical practice relates to the nomenclature used to describe the acupuncture points; the acupuncture points are found along specific conceptual pathways—meridians or channels—that traverse the patient's body. Because these pathways and respective points are named according to an ancient medical system, they may not make inherent sense to veterinary surgeons. For instance, there are several gallbladder points around the hip joint.

Although acupuncture has been around for thousands of years, many of the mechanisms by which acupuncture is thought to exert beneficial physiologic effects have only recently been elucidated, and this is due mainly to advances in neuroimaging and molecular biology techniques. Although the actual names of the acupuncture points along their respective meridians may cause some confusion, the majority of these points and their respective meridians line up with the PNS. Others correspond to known fascial planes of the body. Some believe that acupuncture signals may also follow vascular routes. It is possible that signals are transmitted through a variety of anatomic scaffolds, but it is likely that the nerves play a prominent role in all the scenarios described.[35,38–41] In general the entire body, including the CNS and the viscera, is accessible via the PNS. Classification of acupuncture points is also based on the location of nerves associated with those points (Box 13.6).

Acupuncture includes manual acupuncture or "dry needling" (DN), aquapuncture (injecting a sterile liquid into an acupuncture point), and electroacupuncture (EA). Aquapuncture may have a greater therapeutic effect than DN; presumptive mechanisms include enhanced stimulation of the injected acupuncture point via spatial distortion of the injected substance and pharmacologic effects of the injected substance. It is generally believed that clinical effects of EA are more potent and longer lasting than DN or aquapuncture. The vast majority of experimental and human clinical literature supports the use of EA as the most likely permutation of this treatment method to exert a measurable and lasting physiologic and clinically appreciable effect on pain alleviation. In short, the authors' recommendation is to employ EA routinely during acupuncture sessions rather than DN alone.[42–44]

An acupuncture point can be thought of as an anatomic unit consisting of free nerve endings, small arterioles, venules, lymphatics, and mast cells. There is some evidence that acupuncture points may be thought of as larger than "points" and similar to receptive regions or fields in the vicinity of the point. Acupuncture points are usually physically in areas of surface depressions and physiologically in cutaneous regions typified by low electrical resistance and high electrical conductivity.[38,45]

The effects of acupuncture on pain relief include local, segmental (spinal cord level), and suprasegmental mechanisms. EA

BOX 13.6 Classification of Acupuncture Points Based on the Location of Nerves Associated With Those Points

Type I (motor points): located where major nerves penetrate muscles. They are the most common and comprise nearly 70% of all acupuncture points.
Type II: located where nerves intersect on the dorsal and ventral midlines.
Type III: located where superficial nerves branch.
Type IV: located where nerves penetrate tendons (e.g., Golgi tendon organs).

BOX 13.7 Peripheral (Local) Physiologic Effects of Acupuncture, in Particular Electroacupuncture, That Contribute to Alleviating Pain

- Induction of release of endogenous opioids from lymphocytes, macrophages, and granulocytes into tissue. These opioids then suppress the propagation of nociceptive signals by acting at receptors of the peripheral nerves in the tissue.
- Activation of sympathetic nerve fibers, which leads to increased levels of endogenous opioids in the region. Some of this effect is via adrenergic receptor activation of inflammatory cells, which causes them to release β-endorphin into the tissue.
- Sympathetic nerve fiber activation also leads to increased expression of specific intracellular adhesion molecules in blood vessels of inflamed tissue. These adhesion molecules promote migration of neutrophils and mononuclear cells that contain β-endorphin and met-enkephalin.
- Increased levels of cannabinoid CB2 receptors in tissue, which leads to upregulation of endogenous local opioids.
- Decreasing levels of local inflammatory cytokines, including tumor necrosis factor-α, interleukin 1β, and interleukin 6. This is also believed to involve endogenous opioids.
- Inhibition of cyclooxygenase-2 and prostaglandin E2 production.

BOX 13.8 Antinociceptive Effects at the Spinal Level Induced by Acupuncture

- Dampening of glutamate receptor activity in spinal cord dorsal horn neurons, via increasing endogenous opioids, noradrenaline, and serotonin levels.
- Increased serotonin levels in the spinal cord accentuate the ability of gamma-aminobutyric acid (GABA) to inhibit pain signal transmission.
- Inhibition of spinal glial cell activation, thereby decreasing astrocyte and microglial-derived pain-promoting cytokines (interleukin 1β, interleukin 6, tumor necrosis factor-α, cyclooxygenase-2, and prostaglandin E2).
- Blocking of substance P release in spinal cord gray matter (substance P promotes nociceptive signals and activates glial cells).
- Upregulation of nociception/orphanin FQ (N/OFQ) receptors in the spinal cord gray matter. N/OFQ is a powerful opioid-related peptide that has potent analgesic properties and is widely distributed throughout the spinal cord. It inhibits C fiber evoked responses and wind-up.
- Increasing spinal cord dorsal horn levels of acetylcholine and dopamine, both of which are believed to inhibit nociceptive signaling.
- Activation of spinal cord δ opioid receptors, leading to reduced cellular GABA reuptake. Increased levels of GABA in the extracellular space enhance its antinociceptive effects.

is more likely to most effectively recruit all three of these mechanisms, in comparison with DN alone. Acupuncture can be thought of as a method of counterirritation. After providing a stimulus to the tissue with either DN or EA, a local reaction ensues that elicits a number of inflammatory and immune responses. Acupuncture, in particular EA, has a number of physiologic effects peripherally (locally) that contribute to alleviating pain. Many of these processes involve endogenous opioids (Box 13.7).[35,38,41,44]

The segmental (spinal) and suprasegmental (brain) effects of acupuncture cannot be completely separated, as they are anatomically and physiologically connected. However, there are a number of antinociceptive effects induced by acupuncture (again, particularly EA) at the spinal level (Box 13.8).[35,37,38,41] Although the mechanisms for suprasegmental effects of acupuncture are not as well understood as segmental effects, they are based on the descending antinociceptive pathway. There is considerable evidence from functional magnetic resonance imaging and positron-emission tomography studies in people, as well as experimental animal models, that specific acupuncture points, when stimulated, will activate specific regions of the brain. This point specificity for stimulation of antinociceptive regions of the brain stem descending pain-modulating pathway is most convincing for limb (vs. trunk) acupuncture points. In addition, activation of such points with a sufficient stimulus will activate the intended brain stem center, without necessarily producing an appreciable segmental effect. By contrast, stimulating an acupuncture point in the dermatomal segment of interest (e.g., a back *Shu* point for thoracolumbar pain) may produce a mainly segmental analgesic response, or a segmental and descending brain stem response, depending on the stimulus intensity (if intense enough, the ascending pathways to brain stem nociceptive centers may also be recruited). These physiologic phenomena are consistent with the typical TCVM recommendations to treat at both local and distal sites. In this way, local, segmental, and suprasegmental effects can be combined for maximum results. Some specific examples of suprasegmental effects of acupuncture (primarily EA) are included in Box 13.9.[38,41,45]

BOX 13.9 Specific Examples of Suprasegmental Effects of Acupuncture (Primarily Electroacupuncture)

- Activation of serotonergic nucleus raphe magnus neurons in the medulla.
- Activation of noradrenergic neurons in the locus ceruleus of the pons.
- Stimulation of the hypothalamus to release β-endorphin.
- Activation of descending neurons of the periaqueductal gray matter of the mesencephalon.

It has also been demonstrated that low-frequency EA (2 to 10 Hz) is more effective for pain control than high-frequency EA (100 Hz).[38,41] However, there is some rationale to combining modes of acupuncture (DN and EA) and different frequencies of EA to produce a greater analgesic effect than would be possible with only one modality or one frequency. There is some evidence that DN may be more effective at mediating analgesic effects through C fibers than EA, with EA mediating analgesic effects mainly through Aβ and Aδ fibers. EA has been shown to cause the release of different mediators of analgesia, depending on the frequency applied. At low frequencies (2 to 10 Hz), endorphins and enkephalins are mainly released. At higher frequencies (50 to 100 Hz), the primary opioid released is dynorphin. At even higher frequencies (>200 Hz), the most prominent neurochemical mediator released is serotonin. In addition, there are other antinociceptive agents released, according to certain applied frequencies. For example, at low frequencies, there are also noradrenergic and muscarinic cholinergic mechanisms that are recruited. At high frequencies, there are muscarinic cholinergic and GABA-ergic mechanisms that are brought into play to help decrease nociceptive signaling. It would appear that endorphins and enkephalins may be the most effective EA-induced mediators of pain (at low-frequency stimulation); however, it is likely that providing other pain-mitigating agents at higher frequencies may have an additive effect.[38,41,46]

Principles of Minimally Invasive Surgery and Imaging of the Surgical Patient

Minimally invasive surgical procedures (e.g., endoscopy) are diagnostic and therapeutic tools that are increasingly expected by veterinary clients. This chapter provides a brief overview of the endoscopic equipment and techniques used in these procedures. Specific techniques (e.g., thoracoscopic pericardiectomy; removal of osteochondritis dissecans [OCD] lesions) are found in the relevant chapters for that system, disease, or condition.

DEFINITIONS AND TERMINOLOGY

Endoscopy is the use of an instrument (i.e., an endoscope) to visualize the interior of an organ or other area that otherwise cannot be examined without surgery. It can be diagnostic or interventional. **Gastroduodenoscopy** is endoscopy of the esophagus, stomach, duodenum, and occasionally the upper jejunum. **Colonoscopy** is endoscopy of the colon. **Ileoscopy** is endoscopy of the ileum and is performed in conjunction with colonoscopy. **Proctoscopy** refers to examination of the anus and rectum. **Bronchoscopy** is endoscopy of the trachea and bronchi, whereas **laryngoscopy** is examination of the pharynx and larynx. **Rhinoscopy** generally refers to placing an endoscope through the anterior nares and examining the nasal passages. It may or may not include using an endoscope to examine the choanae. **Cystoscopy** is endoscopy of the urinary bladder and may include retrograde cystoscopy (i.e., advancing the endoscope through the urethra and into the bladder) or transabdominal placement (i.e., placing the scope through a cannula that has been inserted through the abdominal wall and the bladder wall). **Vaginoscopy** is endoscopy of the vagina. **Laparoscopy** is endoscopy of the peritoneal cavity, whereas **thoracoscopy** is endoscopy of the pleural cavity. **Arthroscopy** is endoscopy of a joint and may be diagnostic but is usually interventional.

Flexible endoscopy uses an endoscope that has a flexible insertion tube designed to look and/or move around corners. The degree of flexibility depends on the instrument, but being able to make bends of 180 degrees or more is typical for most flexible scopes. Flexible endoscopes have a *handle* (where the scope is held by the operator), an *insertion tube* (the part that is inserted into the patient), and an *umbilical cord* (the part that attaches the scope to the light source and video processor). The *biopsy channel* is the passage that allows one to aspirate air or liquids, as well as place instruments through the scope (e.g., biopsy forceps, foreign body retrieval forceps, aspiration tubes, cytology brushes). Almost all flexible endoscopes are now "*immersible,*" meaning they can have their handles placed in water without risk of damage.

Rigid endoscopy uses a plastic or metal scope, which may be solid or hollow. Endoscopic *telescopes* are generally solid (some have a channel in them) and have a lens at the tip of the scope that points at various angles, but the telescope itself cannot bend. Hollow endoscopes often have an *obturator*—a device placed through the endoscope to facilitate insertion of the scope into the organ desired (e.g., esophagus, colon). Rigid endoscopic telescopes are often placed through a *cannula,* which is a metal or plastic tube. A cannula may have a sharp or blunt-tipped *trocar* designed to facilitate penetration into joints, the abdomen, or the chest.

A "*red out*" or a "*white out*" refers to having the viewing tip of the endoscope so close to the surface of what is being examined that one cannot focus on the surface (i.e., a blur occurs) or to having debris on the viewing end of the scope. In double-puncture laparoscopy, thoracoscopy, and arthroscopy, *triangulation* refers to visualizing the tip of the biopsy and operative instruments through the scope to perform various procedures within body cavities or joints.

In arthroscopy, *instrumentation* refers to the insertion of an endoscope, arthroscope, or other tool into the joint. Equipment inserted into the joint through the skin and soft tissue is done so through *portals*. Portals are defined by their use. The scope is inserted through a *scope* or *camera portal,* whereas power and hand tools are inserted through an *instrument portal.* Arthroscopes are always used through *cannulas.* Fluid flowing into the joint is referred to as *inflow* or *ingress;* fluid flowing out of the joint is referred to as *outflow* or *egress*. Repeat arthroscopic examination of a joint that has been previously scoped is referred to as *second-look arthroscopy.*

Minimally invasive osteosynthesis refers to fracture fixation using small skin incisions and techniques designed to limit the deeper soft tissue surgical trauma. **Minimally invasive plate osteosynthesis** refers to reduction and fixation with a plate of any design, without direct surgical exposure of the fracture site, using small skin incisions and subcutaneous or submuscular insertion of the plate. These techniques are discussed in Chapters 32 and 33.

ENDOSCOPY: GENERAL PRINCIPLES, EQUIPMENT, AND TECHNIQUES

Endoscopy is used to biopsy organs, remove foreign objects, examine the interior surface of hollow structures, and perform procedures typically done by more invasive surgery. As such, endoscopy is valuable only when it eliminates the need for more

ABSTRACT

Minimally invasive surgery is a growing field of veterinary surgery. A basic understanding of the techniques and possible indications is critical so that doctors can optimize patient care while minimizing invasive techniques when possible. Sophisticated imaging techniques are now readily available in veterinary medicine. An understanding of the physics associated with these imaging modalities is useful for practitioners and will enhance the clinician's ability to evaluate the images and improve knowledge of clinical indications.

invasive, classic surgery. If tissue samples are inadequate for diagnosis, unacceptable trauma occurs during removal of foreign objects, or mucosal surfaces cannot be adequately examined, then endoscopy ceases to be useful. Unfortunately, endoscopy is sometimes approached more like a "hobby" than an important procedure to be learned and practiced diligently. Flexible endoscopy of the upper gastrointestinal (GI) tract is more difficult to properly perform than is widely appreciated, especially in regard to biopsying the mucosa. If the clinician is not well trained in the first place and/or is not going to perform the procedure often enough to maintain expertise, then it is usually best if patients are referred elsewhere or classic surgery is elected instead. In addition, endoscopic equipment is complex and expensive. It is imperative that the clinician be adequately trained to use the equipment properly to avoid damage and that setup and maintenance of the equipment is thoroughly understood to direct the hospital staff in handling and cleaning of the endoscopy system. It is best if only one or two staff are responsible for maintenance and setting up the equipment.

INDICATIONS

Flexible Endoscopy

The primary use of flexible endoscopy in the alimentary and respiratory tracts in veterinary medicine is to visualize and obtain tissue or cytologic samples of mucosa. Removing foreign objects, dilating strictures, controlling hemorrhage, and inserting tubes are important but less commonly performed procedures (Box 14.1). Tissue sampling (i.e., biopsy or cytology) should almost always be performed in diagnostic procedures regardless of gross mucosal appearance unless there is a specific reason not to biopsy (e.g., coagulopathy, risk of perforation). Tissue samples obtained by flexible endoscopy are usually limited to the mucosa and adjacent submucosa as opposed to the full-thickness samples

BOX 14.1 Primary Indications for Endoscopic Procedures in Dogs and Cats

Gastroduodenoscopy
- Gastric and intestinal biopsy/cytology for diagnosis of infiltrative and lymphatic disorders
- Identification of a mass, ulceration, erosion, lymphangiectasia, or *Physaloptera* infestation
- Identification and removal of foreign objects
- Location of lesions (e.g., ulcer, site of bleeding)
- Placement of a gastrostomy tube
- Removal of polyps causing clinical signs

Esophagoscopy
- Identification and removal of foreign objects
- Diagnosis of esophagitis
- Diagnosis and dilation of strictures
- Identification of hiatal hernia
- Identification and biopsy of tumors

Proctoscopy and Colonoileoscopy
- Biopsy of the rectum, colon, ileum, or cecum looking for infiltrative disorders
- Identification of occult whipworm infestation
- Removal of polyps
- Diagnosis of cecocolic or ileocolic intussusception
- Diagnosis of colonic vascular ectasia

Laryngoscopy
- Identification of laryngeal paralysis, elongated soft palate, or everted lateral saccules
- Location and removal of foreign objects
- Biopsy of a mass

Cystoscopy
- Diagnosis and laser ablation of ectopic ureters
- Biopsy of proliferative lesions in urethra and bladder, especially carcinomas
- Laser ablation of ureteral/trigonal transitional cell carcinoma
- Removal of stones via basket or lithotripsy
- Identification and dilation of urethral strictures
- Injection of collagen into the urethra to control incontinence

Thoracoscopy
- Identification and biopsy of masses and other infiltrative lesions, including lung biopsy
- Assistance in placing chest tubes in animals with severe pyothorax
- Determination of whether thoracotomy is appropriate, and if so, the best approach
- Performance of minimally invasive surgery, such as pericardiectomy, ligation/resection of persistent right aortic arch, thoracic duct ligation

Bronchoscopy
- Identification of lesions (e.g., collapsed trachea, *Oslerus osleri* infestation)
- Bronchoalveolar lavage or brushing of trachea/bronchus for cytology/culture
- Identification and removal of foreign objects
- Identification of lung lobe torsion
- Biopsy of mucosa (e.g., with chronic bronchitis)
- Aid in placement of stents/evaluate stents that were previously placed

Rhinoscopy
- Identification and removal of foreign objects
- Biopsy/cytology of mass lesions and mucosa for infiltrative disorders
- Identification and biopsy of aspergillomas
- Identification of source of epistaxis or chronic nasal discharge

Posterior Nares (Choanal) Examination
- Identification and removal of foreign objects
- Cytology/culture of the caudal nares
- Identification of and biopsy of proliferative disorders
- Identification, dilatation, stenting of nasopharyngeal stenosis
- Identification of nasal mites

Laparoscopy
- Examination and biopsy of abdominal viscera (especially liver and pancreas)
- Determination of whether celiotomy is warranted (e.g., is there evidence of metastasis that means surgery cannot be curative)
- Performance of minimally invasive interventional surgery (e.g., gastropexy, placement of jejunostomy tube, ovariectomy, cryptorchidectomy)

Arthroscopy
- Identification and biopsy of lesions
- Removal of loose bodies (cartilage fragments, bone fragments, torn meniscus)
- Topical management of osteoarthritis: abrasion arthroplasty, microfracture
- Joint lavage for sepsis
- Arthroscopic-assisted fracture repair
- Arthroscopic-assisted joint stabilization

obtained surgically. Assuming good technique, endoscopically obtained samples are adequate for diagnosis in probably more than 90% of patients (personal observation of the author) with gastric or intestinal infiltrative disease (e.g., inflammatory bowel disease, histoplasmosis, neoplasia). Endoscopy cannot reliably diagnose disorders beyond its reach (e.g., focal carcinoma of midjejunum), infiltrates too deep in the wall of the viscera for the biopsy forceps to reach, and lesions consisting of hard, densely fibrotic infiltrates (e.g., scirrhous carcinoma) that the biopsy forceps cannot penetrate.

Cytologic studies from brushings or washes are often diagnostic for disorders such as cancer, parasitic infections, fungal infections, protothecosis, and eosinophilic enteritis. Histoplasmosis has occasionally been diagnosed cytologically when it was missed histologically. However, most idiopathic inflammatory bowel diseases, especially lymphocytic-plasmacytic disorders, cannot be definitively diagnosed cytologically. Washings are especially useful in the respiratory tract to diagnose inflammatory or infiltrative problems, but may be useful if looking for gastric *Ollulanus tricuspis* infestation or duodenal giardiasis.

GI, respiratory, and vaginal hemorrhage are often indications for endoscopy. Endoscopy may help determine if surgery is indicated and ensure that all bleeding sites are located. Intraoperative endoscopy can find bleeding gastric mucosal lesions if the surgeon cannot identify them at surgery; even large ulcers may be missed when the stomach is examined through a gastrostomy incision. Severely hemorrhaging lesions may require endoscopic electrocautery or injection with epinephrine. Endoscopy detects small mucosal lesions (e.g., erosions) indiscernible from the serosal surface.

Placement of esophagostomy, gastrostomy, and enterostomy feeding tubes can be done with or without endoscopy (see pp. 95–101). Endoscopic placement of such tubes is indicated when nonendoscopic apparatus for placement cannot be safely passed through the esophagus (e.g., esophageal stricture, esophageal dilation), when the operator is insufficiently trained with nonendoscopic apparatus, or when endoscopy is already in progress for other purposes. Endoscopic placement of gastrostomy tubes includes insufflation of the stomach, which is advantageous because insufflation helps prevent other abdominal organs from becoming trapped between the stomach and the abdominal wall.

Alimentary tract polyps can be removed endoscopically with endoscopic snares adapted for electrosurgery. However, because rectal polyps are usually found close to the rectum, surgical removal is typically easier and more certain to remove the entire polyp. Endoscopic electrosurgery should only be attempted if the clinician has been trained. Inappropriate use of electrosurgical instruments can damage or destroy the endoscopic equipment and seriously injure the patient.

Endoscopic or fluoroscopic dilation of benign esophageal strictures caused by postesophagitis scarring is preferred to surgical resection. Strictures can recur after either method, but surgery may be associated with greater postprocedural morbidity and mortality and has a higher recurrence rate. Endoscopic and fluoroscopic dilation should not be attempted unless the clinician has been well trained in the various techniques used.

Rigid Endoscopy

Rigid endoscopy can be used for the GI, respiratory, and female lower urinary tracts; peritoneal and pleural cavities; and joints. Indications for rigid endoscopy include many of the same as for flexible endoscopy (see Box 14.1), but rigid endoscopy (especially laparoscopy, thoracoscopy, and arthroscopy) is more often used for interventional procedures compared with flexible endoscopy.

Tissue samples obtained by rigid colonoscopy are invariably better than those obtained with flexible colonoscopy. Rigid biopsy instruments typically procure large, deep colonic or rectal samples that include relatively large amounts of submucosa. Therefore rigid endoscopy is appropriate even when dense, fibrotic, submucosal lesions (e.g., carcinoma, pythiosis) are suspected. This is especially true of proliferative processes in the rectal area where it is imperative to obtain generous amounts of submucosa to allow the pathologist to distinguish benign from malignant processes.

Foreign Bodies

Both rigid and flexible endoscopy are useful in removing foreign objects. Rigid endoscopy is the best way to remove most esophageal foreign objects. Most esophageal, nasal, tracheal, and laryngeal foreign objects—and many gastric and duodenal foreign objects—can be removed endoscopically without undue risk to the patient. Objects out of reach of the endoscope, those that cannot be firmly grasped or trapped by endoscopic devices, and those that may cause severe damage if endoscopic removal is attempted (e.g., linear foreign objects that have been present for several days, objects with sharp edges or points that cannot be covered during removal) should usually be removed surgically.

EQUIPMENT

Flexible Endoscopes

Endoscopes

The equipment needed depends on the type of endoscopy and the body system involved, as well as the species to be examined. Rigid and flexible endoscopes are available in a large assortment of sizes and lengths; both types have advantages and disadvantages (Box 14.2). Flexible endoscopes typically used in veterinary medicine are gastroduodenoscopes, bronchoscopes, colonoscopes, and ureteroscopes. Flexible scopes have a handle, an insertion tube, and an umbilical cord (Fig. 14.1). Bronchoscopes usually have a 2- to 6-mm outer diameter, gastroduodenoscopes a 7.9- to

BOX 14.2 Comparison of Flexible and Rigid Endoscopes

Flexible

- Greater access to more sites in viscus organs
- More expensive than rigid scopes
- Easier to damage/requires training to assemble and clean without damaging
- Requires substantial training to use properly

Rigid

- Less expensive than flexible scopes
- Usually more durable
- Easier to learn to use
- Capable of larger biopsies than with flexible scopes
- Excellent for removing foreign objects and protecting mucosa
- Of the viscus organs, can only access the esophagus, gastric fundus, descending colon, larynx, nose, and trachea
- Can be used in the peritoneal, pleural, and joint spaces

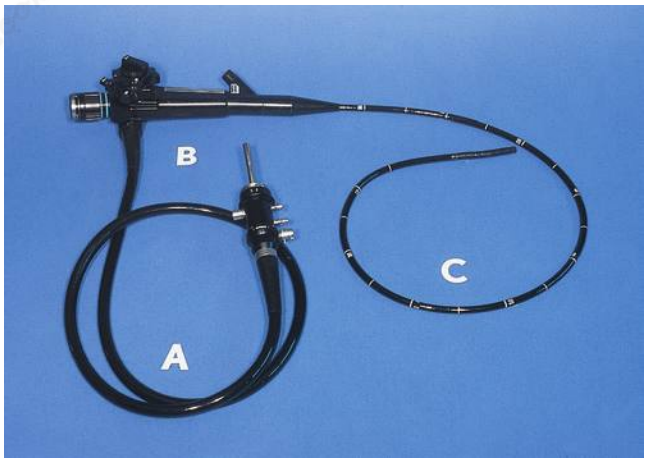

FIG. 14.1 Flexible gastroduodenoscope showing the umbilical cord *(A),* which attaches the scope to the light source; the handle *(B);* and the insertion tube *(C),* which is introduced into the animal.

FIG. 14.2 Detail of flexible biopsy forceps with an ellipsoid, alligator jaw configuration. The upper forceps is used for a 2.8-mm channel, the lower one for a 2.2-mm channel. (From Willard MD. Colonoscopy, proctoscopy, and ileoscopy. *Vet Clin North Am.* 2001;31[4]:657–669.)

10-mm outer diameter, colonoscopes a 10- to 16-mm outer diameter, and ureteroscopes a 2.5- to 3-mm outer diameter. All scopes should have a biopsy-suction channel (usually 2.2 mm in diameter for bronchoscopes, 2.2 to 3.2 mm for gastroduodenoscopes and colonoscopes, 1 to 1.5 mm for ureteroscopes). Gastroduodenoscopes and colonoscopes typically have four-way deflection of the tip of the scope and an air-water channel that is used to insufflate air and wash off the viewing lens; bronchoscopes typically have two-way deflection of the tip and do not have an air-water channel. The insertion tube typically has a working length of 40 to 60 cm in bronchoscopes and ureteroscopes, 100 to 135 cm in gastroduodenoscopes, and 130 to 220 cm in colonoscopes.

The ideal assortment of flexible scopes depends on the expertise of the operator and what procedures are anticipated. Ideally, a bronchoscope (4- to 5-mm diameter), a pediatric gastroduodenoscope (<7.9-mm diameter with a 2-mm channel), and a regular gastroduodenoscope (8.5- to 9.8-mm diameter with a 2.8-mm channel) allow one to perform almost all nonurinary tract flexible procedures. Other flexible scopes that might be considered, depending on ones' needs, are a 1.6-m pediatric colonoscope (helpful in extremely large animals and large, exotic cats) and a ureteroscope for small birds and pocket pets, as well as flexible cystoscopy or rhinoscopy. If one can only have two scopes for both alimentary and respiratory tract work, consider a bronchoscope (4- to 5-mm diameter) and a gastroduodenoscope (8.5- to 9-mm outer diameter with a 2.8-mm channel). If one can only have one scope for respiratory and alimentary tract endoscopy, a 7.9-mm outer diameter pediatric gastroduodenoscope may be the best compromise. If only one scope is possible and it will be used only for alimentary tract endoscopy, an 8.5-mm outer diameter scope with a 2.8-mm channel is preferable.

Biopsy/Cytology Equipment

Biopsy forceps for flexible scopes come in various shapes, sizes, and configurations. The size of the forceps depends on the size of the biopsy-aspiration channel; the larger the channel, the bigger the biopsy forceps that can be used. If possible, a scope with a 2.8-mm channel should be used for most alimentary tract endoscopy in dogs and for cats weighing more than 3 to 4 kg. The tissue sample obtained through a 2.8-mm channel can be more than twice the size of a sample obtained through a 2.2-mm channel. These larger pieces of alimentary tissue often contain the full thickness of the mucosa and some submucosa. Fenestrated biopsy forceps in an ellipsoid, alligator jaw configuration without a needle are widely preferred (Fig. 14.2); however, some endoscopists have other preferences that work for them. Disposable biopsy forceps are widely used in human medicine, but do not necessarily have major advantages in veterinary medicine.

Brushes used to obtain samples for cytology and culture typically consist of a stiff brush in a plastic tube. This brush is manually extended out the tip of the plastic tube once the tip of the brush assembly has been advanced through the endoscopic biopsy channel and is near the tissue to be sampled. Unfortunately, such brush assemblies are easily contaminated as they are passed through the endoscopic channel. There are brush assemblies made for when it is absolutely critical that a noncontaminated sample be obtained (i.e., culture). These brushes consist of an extendable brush that is within an extendable tube that is in yet another tube. The tip of the outermost tube is typically plugged so that there is no chance of contamination when the scope is passed through the biopsy channel of the endoscope. Once the tip of the brush assembly is near the site to be cultured, the innermost tube is extended out the end of the outermost tube, and then the brush is extended out the tip of the innermost tube. Brushes for diagnostic purposes should never be cleaned and reused, as opposed to biopsy forceps, which can be used repeatedly.

Interventional Tools for Flexible Endoscopes

A variety of special retrieval instruments are necessary to reliably remove most commonly encountered foreign objects. The most useful devices are a coin retrieval (W-type) forceps, a shark's tooth forceps (especially useful for firmly grabbing cloth), an alligator jaws, and a 4- or 6-wire basket (Fig. 14.3). The basket should be made of very flexible wire to facilitate passage over and around an object; however, this quality also makes it easier to bend the wire and ruin the basket. Other retrieval devices include wire snares, 3-wire grabbers, magnetic-tip probes, and forceps with nonskid rubber; these instruments are seldom required.

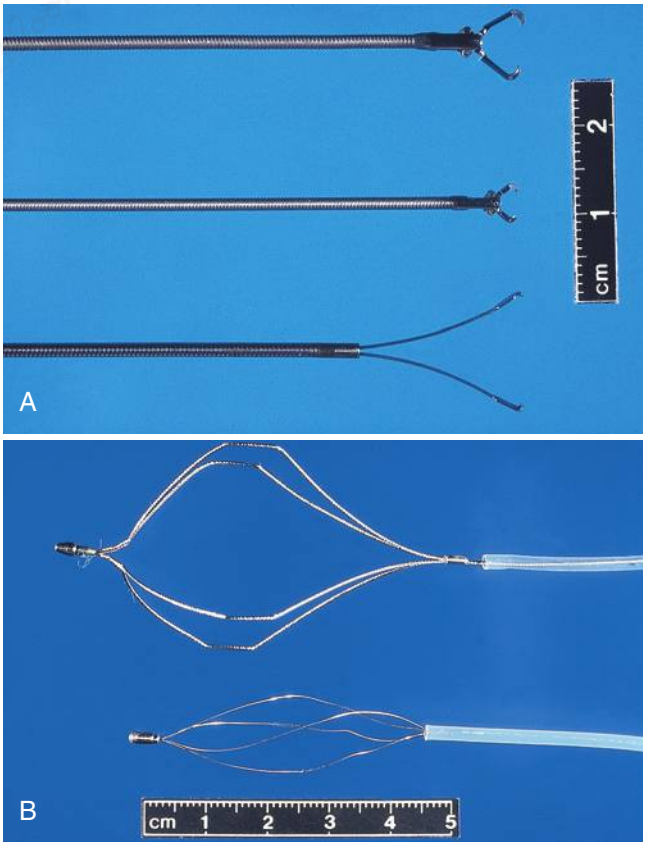

FIG. 14.3 (A) Tips of three commonly used foreign body retrieval forceps. *Top to bottom,* shark's tooth forceps, rat's tooth forceps, and coin retrieval forceps. The coin retrieval and rat's tooth forceps can pass through a 2-mm channel; the shark's tooth forceps requires a 2.8-mm channel. (B) At the top is a 4-wire basket that works well because of the extreme flexibility of the wires. The 4-wire basket below does not open as widely and has wires so firm it is difficult to ensnare the foreign body.

There are various balloons and bougies designed to dilate esophageal strictures. Despite rhetoric that ballooning is superior to bouginage, success is more dependent on the skill and training of the operator rather than the equipment used. Esophageal dilation balloons come in two major configurations: over-the-wire or through-the-endoscope channel. It is important to use these as opposed to a more round balloon, such as is found on endotracheal tubes.

Other equipment includes sheathed needles that allow aspiration or intralesional injection of various lesions through the endoscope. A variety of flexible endoscopic biopsy instruments, snares, knives, biopsy forceps, and probes have electrosurgical capability. The electrosurgical snares are most commonly used because they allow removal of esophageal, gastric, and colonic polyps; they can also be used to make three or four quadrant "cuts" into esophageal strictures to aid in ballooning difficult lesions.

NOTE Use of electrosurgical instruments by untrained individuals can damage or destroy the video processor and cause substantial patient morbidity; therefore they should only be used if the operator is trained in their use.

FIG. 14.4 Tips of two types of rigid biopsy forceps. The upper forceps is a human uterine biopsy forceps, also known as a *clamshell* or *double-spoon forceps*. The lower forceps has a smaller upper punch that fits into a larger lower cup with a shearing action, much like the blades of a scissors. (From Tams TR. *Small Animal Endoscopy*. 2nd ed. St. Louis: Mosby; 1999.)

Rigid Endoscopes

Colonoscopes

Rigid colonoscopes (typically human sigmoidoscopes) and proctoscopes are plastic or metal tubes of variable size and length with an obturator and light source. Air can be insufflated into the colonic lumen with a colonoscope, but not with most proctoscopes. A better examination of the colonic lumen is possible with longer scopes of larger diameter. The minimum recommended working length for colonoscopes is 25 cm, and 35 cm is preferred. Most dogs, except the toy breeds, tolerate a 15-mm outer diameter scope, but a 19- to 25-mm diameter scope should be used whenever possible. Rigid scopes must allow simultaneous viewing of the mucosa and insufflation of air. Unlike flexible scopes, rigid colonoscopes do not allow simultaneous insufflation and biopsy. A suction tube that can be inserted through the lumen is important for removing residual feces and debris. A variety of anoscopes and proctoscopes in different lengths (usually 90 to 120 mm) and diameters (usually 14 to 22 mm) should be available. Biopsy forceps used with rigid colonoscopes and proctoscopes should have a shearing or scissor-like tip that cuts the mucosa (i.e., a small punch that fits into a larger diameter cup) rather than the clamshell or double-spoon tip that grasps and tears tissue (Fig. 14.4). Grasping forceps (such as would be used for esophageal foreign bodies) must be strong and preferably have ridges to aid in obtaining a strong purchase on foreign objects.

Laryngoscopes

Laryngoscopy requires an assortment of various sized rigid laryngoscopic blades in straight and curved configurations. Flexible scopes can be used but are seldom necessary.

Rigid Endoscopy With Special Additional Equipment Needs

Laparoscopy, thoracoscopy, and arthroscopy require an outer cannula (usually with a trocar or obturator), which is inserted into the cavity to be examined, plus a viewing telescope (also responsible for directing light), which is inserted through the cannula into the cavity. The same equipment used for arthroscopy can sometimes be used for cystoscopy and rhinoscopy; however,

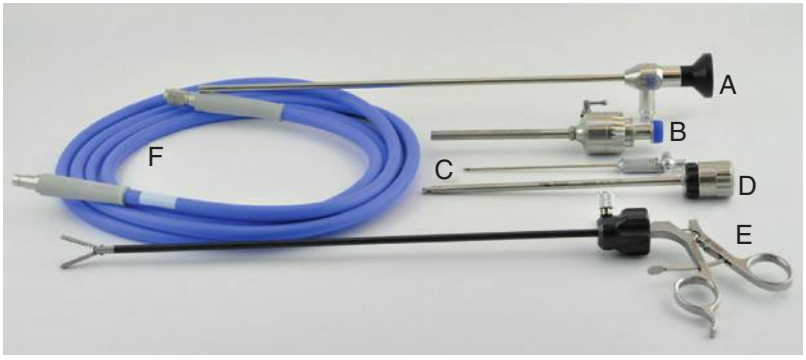

FIG. 14.5 (A) A 5-mm 0-degree autoclavable laparoscope. (B) A 5.5-mm laparoscope sheath with automatic valve and manual valve lever. (C) A 100-mm insufflation Veress needle. (D) A 5.5-mm lacking shielded trocar. (E) A 5-mm 32-cm rotatable grasper with locking handle. (F) A 5-mm fiberoptic light cable.

cleaning and sterilization protocols for these different techniques may vary. Dedicated rigid cystoscopic equipment is also available, and it is often used for rhinoscopy as well.

Laparoscopes/Thoracoscopes

Most telescopes used for laparoscopy and thoracoscopy are 5 to 10 mm in diameter (Fig. 14.5). The larger scopes allow better illumination. There are a variety of angles of view at the tip, ranging progressively from 0 degrees (i.e., looking straight ahead) to 30 degrees (a commonly used telescope that effectively allows one to look behind organs) to scopes that can look back on themselves (i.e., angles of view of 270 degrees or greater). Double- and single-puncture techniques are possible. Double-puncture techniques involve the telescope being placed through one cannula while other instruments (e.g., biopsy forceps, Babcock forceps) are placed through additional cannulas. Some 10-mm diameter telescopes have a channel that allows insertion of an instrument (e.g., biopsy forceps, grasping forceps, scissors) while viewing through the scope. Such scopes are called *operating telescopes* and can be used in single-puncture or double-puncture laparoscopy and thoracoscopy.

There are various modifications of the basic rigid endoscopic techniques, as well as a plethora of one-time use disposable equipment in various configurations, which makes it difficult to succinctly describe how to perform these procedures. Basically, laparoscopy requires a means of insufflating the abdomen (e.g., a Veress needle, a threaded cannula, the Hasson technique), and both laparoscopy and thoracoscopy require a cannula (usually with a trocar or obturator) to insert the telescope into the appropriate cavity. Threaded cannulas are "screwed" into the thoracic or abdominal wall, which eliminates the risk of the cannula inadvertently being withdrawn. The type of biopsy forceps depends on the nature of the biopsy. A liver biopsy is best taken with clamshell or double-spoon forceps (see Fig. 14.4); a biopsy from the pancreas is best accomplished with a punch type of forceps. In general, core needles (e.g., Tru-cut, Becton Dickinson) are only used for the kidney and some masses; they are not recommended for hepatic biopsies unless there is a focal mass (such lesions should generally have been aspirated via ultrasound before endoscopy). Various other forceps (e.g., Babcock), hemostats, aspiration tubes, needle holders, scissors, and so forth should also be available. Electrocautery is particularly important when performing thoracoscopy. Vessel sealing devices (e.g., Ligasure, Medtronic) significantly increase the capabilities and safety of many laparoscopic and thorascopic procedures. Because thoracoscopy is almost always a two-person operation, requiring coordination between endoscopists, video capability is an absolute requirement (as opposed to most other endoscopies in which it is helpful but not critical, the exception being arthroscopy, in which it is also absolutely required).

Cystoscopes

Most cystoscopy is retrograde as opposed to transabdominal, except in cats, in which transabdominal cystoscopy is relatively common. Small-diameter flexible scopes (e.g., bronchoscopes) or rigid telescopes can be used. The rigid telescopes used for retrograde cystoscopy of dogs are usually 10 to 22 Fr in diameter. Cannulas are very useful for rigid cystoscopy because they allow concurrent infusion of a fluid (e.g., physiologic saline) around the telescope during examination, which dilates the urethra and bladder and washes away blood, mucus, and other debris that obscure vision.

Rhinoscopes

Rigid rhinoscopy typically uses the same equipment as cystoscopy and arthroscopy because of the need for small-diameter equipment. The cannulas used for cystoscopy are especially useful because patients presented for rhinoscopy often have mucoid or bloody nasal discharge that obscures visualization. Infusion of cool physiologic saline during the procedure often washes away the mucus, allowing better visualization (as opposed to warm saline, which will dilate vessels and enhance hemorrhage). However, the small size of the nasal cavity in cats and some small dogs limits the use of cannulas because they enlarge the diameter of the instrument being inserted into the nose. Therefore a variety of instruments have been used for rhinoscopy, including flexible and rigid scopes.

Arthroscopes

See later discussion on p. 166.

EQUIPMENT CARE

Endoscopes (especially flexible) are easily damaged. Therefore access to endoscopic equipment should be limited to a few essential individuals, including those who set it up and clean it

BOX 14.3 Basic Principals of Cleaning Flexible Endoscopes[a]

- Perform leakage test *first*
- Aspirate approved detergent through biopsy channels
- Brush biopsy channels and reaspirate
- If appropriate, aspirate disinfectant solution through biopsy channels
- Aspirate distilled water and then alcohol through biopsy channels
- Aspirate air until biopsy channels are dry
- Clean air-water and suction valves
- Lubricate air-water and suction valves
- Flush all water out of air-water channel
- Clean exterior of scope with approved detergent and water/disinfect or sterilize as appropriate
- Clean and dry biopsy and foreign body retrieval forceps

[a]Always see manufacturer's recommendations.

(Box 14.3). When not in use, flexible scopes should be hung vertically on a rack. If it is absolutely necessary to store a flexible endoscope in its carrying case, care must be taken to ensure that the insertion tube is not caught between the edges of the case (a common cause of damage). Newer flexible scopes are immersible, including the handle; however, older fiberoptic scopes can be severely damaged if water penetrates the handle through a seam during the endoscopic procedure or cleaning. Water must not be splashed on the light source or other electronic equipment, and surge protectors should be used. Only water-soluble jelly should be used as a lubricant on a flexible instrument; petroleum-based substances can shorten the life span of the rubber or plastic coverings.

The insertion tube must not be bent into a severe acute angle, especially at the junction of the insertion tube and the handle, lest the outer covering be cracked and leakage ensues. Care must be taken to prevent biopsying the insertion tube when taking a biopsy with the tip of the scope maximally retroflexed. An instrument should *never* be forced through the biopsy channel, especially when the tip of the scope is deflected more than 70 degrees. If fine, rough material (e.g., sand) is aspirated into the biopsy channel, it can tear the channel and cause a leak when a biopsy instrument is inserted. The insertion tube, especially the tip, should not be allowed to strike a hard surface.

NOTE Always use a mouth gag; *never* introduce the insertion tube into the mouth of an unanesthetized animal.

The scope should be cleaned after each procedure, and the manufacturer's recommendations should be followed explicitly. Generally, a leakage test should be performed first because it is much less expensive to repair a leaking scope before water leaks into the insertion tube and damages fiberoptics or electronics. Next, all water should be expelled from the air-water channel, and the suction and biopsy channels should be cleaned with an approved detergent or cleaner. Only chemicals recommended by the manufacturer should be used as disinfectants on a flexible scope. A brush is used to remove adherent material from the biopsy channel. After these channels have been cleaned, alcohol and then air are aspirated through the channels until they are dry. Cleansing and disinfection of flexible scopes is usually adequate; sterilization is rarely necessary unless the patient is suspected of harboring a specific infectious agent (e.g., parvovirus). If sterilization is necessary, use only manufacturer-approved techniques.

NOTE Review the manufacturer's recommendations and be sure to use ethylene oxide caps, if necessary. Never subject flexible scopes to heat and especially not to autoclaving.

Rigid scopes are usually more resistant to damage than flexible equipment and require relatively simple care, such as washing in an approved detergent solution. Care must be taken to avoid hitting or scratching the lenses in the tips of some rigid scopes, such as cystoscopes. Small-diameter rigid scopes (e.g., cystoscopes and rhinoscopes) are easily bent, so care must be taken when handling and storing them. Sterilization of rigid equipment may involve autoclaving (*if* the scope is designated by the manufacturer as one that can withstand autoclaving), but hydrogen peroxide plasma or ethylene oxide sterilization is preferred.

Care of the arthroscope is given on p. 167.

ANTIBIOTICS

Preprocedural administration of antibiotics is not required for routine endoscopies, including cystoscopy and laparoscopy, unless the patient has valvular cardiac defects or prosthetic implants or is severely immunosuppressed. Esophageal ballooning is associated with bacteremia, and prophylactic use of antibiotics was once advocated; however, this is no longer routinely performed. Use of antibiotics after foreign body removal might be reasonable if significant ulceration/laceration has occurred, but this is unproven. Perforation is often, but not always, an indication for surgery.

For antibiotic usage during arthroscopy, see p. 168.

PROCEDURES

Four basic principles apply to most endoscopic procedures:

1. Advance the scope only if you can see where you are going.
2. If you cannot see what is happening, back the scope out a little rather than advancing it, or insufflate a little air or infuse some fluid into the lumen (or both).
3. Unless you need to look at a specific lesion, aim the scope toward the center of the lumen.
4. Do not insert the endoscope into your patient any harder than you would want a physician to insert it into you.

There are few exceptions to these rules. Beware of excessive insufflation of the alimentary tract or abdomen, as both can impair respiration and/or venous return. Using too large a scope can obstruct the respiratory tract. In general, the largest scope that can *safely* be used allows better visualization, larger biopsy samples, and use of better foreign body retrieval devices. The following sections describe selected techniques that might be performed in a variety of locations.

Biopsies

With flexible instruments, the largest biopsy instrument that can safely be used should be chosen. Better samples of alimentary mucosa can usually be obtained if the organ is not excessively distended with air. Samples of grossly normal and apparently diseased mucosa should be taken. Always note the difficulty

involved in taking a biopsy of a particular lesion; some infiltrative lesions (i.e., scirrhous carcinomas and pythiosis) characteristically produce so much dense connective tissue that the flexible biopsy forceps cannot "bite" into the tissue and tear off an adequate piece. Such a finding may be an indication for full-thickness biopsy. Proliferative lesions can exist below the mucosa so that only normal-appearing mucosa is seen overlying a mass effect; in such cases repeated biopsies in the same spot (i.e., "drilling for oil") sometimes allows access to underlying lesions. A biopsy is often best performed when the opened biopsy instrument can be pushed against the mucosa at a near 90-degree angle. In the intestines, the turn and suction technique is often used to achieve such an angle.

Biopsy of Gastrointestinal Mucosa

Advance the biopsy forceps through the channel, then open the jaws of the forceps and withdraw it until the opened jaws are flush with the tip of the endoscope. Flex the tip of the scope so that it is turned into the mucosa at as close to a 90-degree angle as possible; suction air out of the intestine, thereby drawing mucosa into the jaws of the forceps. Advance the forceps into the mucosa until moderate resistance is felt (usually 1 to 3 mm) and close the jaws. Do not advance the forceps so much that the cable on the instrument begins to bow excessively or the tip starts to slide along the mucosal surface. Be sure to straighten the tip of the endoscope before withdrawing the forceps.

At this time, it appears best to routinely obtain at least eight adequate biopsies of the duodenum and two biopsies of each part of the stomach to try to ensure that (1) sporadic and scattered lesions are sampled, and (2) enough tissue samples will be oriented optimally to maximize histologic interpretation. The optimal number of ileal and colonic biopsies is undetermined, but generally eight colonic biopsies and three to four ileal biopsies have been suggested. Intestinal, nasal, and gastric fundus and body mucosa are relatively "soft" and easy to biopsy. Pyloric and antral mucosa are tougher, and the mucosa may need to be grasped more firmly to pull off an adequate-sized piece. Normal canine esophageal mucosa is so tough it is almost impossible to obtain an adequate tissue sample with routine flexible forceps. Normal tracheal mucosa is so thin it is difficult to obtain an adequate sample for histopathologic studies.

Using a needle, carefully retrieve mucosal samples from the biopsy forceps and place them mucosal side up on a plastic histologic cassette sponge, cucumber slice, or piece of formalin-soaked paper without distorting them.

Gastric and nasal mucosa are relatively sturdy, but small and large intestinal mucosa is delicate and must be handled carefully to avoid crush and stretch artifacts.

Place cassette plastic sponge, cucumber slice, or piece of paper with the biopsies on it in a vial of neutral buffered formalin. Do not allow the samples to dry out excessively before they are fixed.

Cytologic Preparations

Make cytologic preparations (i.e., squash preps) by putting a small piece of mucosa between two glass slides.

Press the slides together and then pull them apart either vertically or horizontally. As an alternative, use an endoscopic brush; lightly rub the extended brush against the lesion (do not cause hemorrhage) and then rub it against a glass slide. For cytologic studies of very fibrotic lesions that can be obtained only with rigid forceps, scrape the cut surface of the sample with a scalpel blade and make a squash preparation of the material obtained.

BOX 14.4 Advantages and Disadvantages of Endoscopic Removal of Foreign Objects

Advantages

- Often much quicker than surgery
- Often less stressful to the patient
- Reduced tissue trauma, morbidity, and recovery time

Disadvantages

- Cannot remove all objects
- Can hurt animal with careless technique
- Requires an assortment of expensive foreign body retrieval forceps

Washes

Insert a sterile polyethylene or similar tube through the biopsy channel, position the tip of the tube as desired, instill the solution (usually physiologic saline solution or Hank's buffered salt solution), and apply suction. Do not place the tip of the tube too close to the mucosa and use only modest negative pressure, or you may end up occluding the end of the tube with tissue. As an alternative, aspirate the sample directly through the endoscopic biopsy channel into a trap.

Foreign Body Removal

Each foreign object must be considered individually. An ill-planned endoscopic removal may be more damaging to the patient (e.g., perforate the tract) than the foreign object (Box 14.4). It is also possible to "grab" a foreign object and find that it can be neither removed nor released, necessitating surgery to retrieve the endoscope. There are numerous techniques for foreign body removal, but some basic principles always apply:

1. *Always take a radiograph of the animal shortly before inducing anesthesia.* Some foreign objects that have been present for weeks pass out of reach of the scope just before the procedure is performed. In the same manner, some foreign objects will perforate the organ just a few hours after admission to the clinic. Finding air or water in the thorax or abdomen means that perforation may have occurred, and that the fluid should be analyzed (i.e., looking for evidence of sepsis or inflammation) or perform a contrast radiographic procedure (e.g., contrast esophagram) using an iodide-based contrast agent.
2. *Do not just grab the object and pull.* The object may need to be repositioned to allow the forceps to obtain the best grasp on it. It may also be necessary to reorient the object to make it easier and safer to pull it through the sphincters.
3. *Select the retrieval forceps that allows the firmest grasp on the object.* Rigid retrieval forceps typically allow the tightest grasp on an object.
4. *When an object has been snared, do not pull it out against undue resistance.* Resistance is expected at the lower esophageal high-pressure zone (gastric cardia), the base of the heart, the thoracic inlet, and the cricopharyngeal area. If inappropriate resistance is noted, it is usually better to stop and examine the orientation of the object. The clinician may need to reposition the object or release it and use any of various devices (e.g., hoods, overtubes).
5. *Consider an overtube if there are sharp edges or if you need to dilate the lower esophageal sphincter.*

Postendoscopy Care

Special care is not necessary after routine biopsy of the alimentary or respiratory tracts. Slight hemorrhage is expected after most procedures, especially biopsy procedures. Most hemorrhage is minor or stops spontaneously shortly after the procedure if the coagulation system is normal. Preprocedural coagulation testing is generally done only when (1) there is a reason to suspect the integrity of the coagulation system (e.g., petechiae, spontaneous bleeding, hepatic disease), or (2) laparoscopic or thoracoscopic biopsies will be performed. However, nasal biopsies can be associated with severe hemorrhage, at times requiring ligation of the ipsilateral carotid artery. When laparoscopic biopsy has been performed on a parenchymatous organ (e.g., liver, kidneys), observe the patient closely for 2 to 4 hours to ensure that excessive hemorrhage does not occur (as seen by evidence of progressive hypovolemia). If excessive hemorrhage occurs, either repeat endoscopy or perform surgery to find and stop the bleeding lesion. If excessive hemorrhage continues for an inappropriately long time after routine biopsy, an occult coagulopathy should be considered.

After a foreign object has been removed, the mucosa should be reevaluated for ulceration or perforation, as well as other foreign objects or lesions. If there is any possibility of perforation, radiograph the appropriate body cavity to look for pneumothorax or pneumoperitoneum. Antibiotic regimens effective against aerobic and anaerobic bacteria often are useful in such cases. Such a regimen might be enrofloxacin, 15 mg/kg given intravenously (IV) once daily, plus either ampicillin (22 mg/kg subcutaneously) or clindamycin (11 mg/kg IV) given two or three times a day, respectively. If severe ulceration occurs due to a foreign body, it may be useful to administer either an antacid (e.g., omeprazole [1 to 2 mg/kg] given twice daily) or a gastroprotectant (e.g., Carafate, 0.5 to 1 g given two to four times a day PO), but not both.

It is important to watch for postprocedural dyspnea and/or hypoxia after performing bronchoalveolar lavage in patients with pulmonary disease. In patients that are already marginally oxygenated, it is often best to perform brushings for cytology and culture or a tracheal wash as opposed to a bronchoalveolar wash.

Specialized Interventional Procedures

Other specific interventional procedures (e.g., ballooning benign strictures, intralesional injections, cutting strictures, polypectomy, placing stents, etc.) are discussed under their relevant sections.

ARTHROSCOPY: GENERAL PRINCIPLES, EQUIPMENT, AND TECHNIQUES

The most common arthroscopically performed procedures are fragment removal for diseases such as OCD (see p. 1154) or fragmented coronoid process (see p. 1174), treatment of meniscal injuries (see p. 1227), and assessment of cartilage and intraarticular soft tissue injuries. Other procedures include synovial biopsies, tenotomy (see p. 1169), joint stabilization, and arthroscopic-assisted fracture repair.

INDICATIONS

Arthroscopy may be indicated for either the diagnosis or treatment of joint disease (Boxes 14.5 and 14.6). Arthroscopy is vastly

BOX 14.5 Common Diagnoses With Arthroscopy

Shoulder
Osteochondritis dissecans
Osteoarthritis
Biceps disease
Medial collateral tearing
Lateral collateral tearing

Elbow
Fragmented coronoid process
Osteochondritis dissecans
Ununited anconeal process
Osteoarthritis of the medial compartment

Carpus
Osteoarthritis
Chip fractures

Hip
Osteoarthritis
Labral tearing and avulsion
Tearing of the ligament of the femoral head

Knee
Osteochondritis dissecans
Cruciate disease
Osteoarthritis
Meniscal disease

Tarsus
Osteochondritis dissecans
Chip fractures

BOX 14.6 Common Arthroscopic Procedures

Osteoarthritis treatment: microfracture, abrasion

FCP, Fragmented coronoid process; *OCD,* osteochondritis dissecans.

superior to radiography in the diagnosis of joint diseases because it allows direct visualization of the cartilage and soft tissue structures, provides magnification, and enables biopsy of virtually all structures within the joint. The most significant diagnostic advantage of arthroscopy is the operator's ability to assess the condition of the cartilage surface. Studies have demonstrated that radiology poorly reflects the condition of cartilage in canine osteoarthritis, whereas arthroscopy enables specific grading and determination of the extent of cartilage injury. Arthroscopy also provides more accurate assessment of intraarticular pathology than open surgery because of the magnification, ability to evaluate more of the joint, and the arthroscopic fluid environment, which improves visualization of surfaces and structures.

EQUIPMENT

Arthroscopes are differentiated by diameter (1.9, 2.3, 2.7 mm, and larger), length (short, long), and angle. Arthroscopes in common use in small animal arthroscopy include any of the diameters and lengths listed earlier, with the vast majority having a 30-degree angle (see Fig. 14.5). The diameter applies to the telescope portion alone and does not include the diameter of the arthroscope cannula, which is necessary for use. The selection of diameter is based on the size of the joint and surgeon preference, with larger scopes providing more rigidity and greater field of view and smaller scopes causing less iatrogenic damage and having greater mobility. Most cameras are "three chip" or high-definition and must be used with a specific camera box that processes the image for the television screen. Medical-grade monitors are recommended to provide a bright, clear, and accurate image. Most new light sources use xenon lamps, which provide increased light intensity and higher color temperature than halogen and therefore provide higher visual clarity and color rendition. Xenon light sources are more expensive than halogen but are generally recommended for superior image quality.

Arthroscopy images and videos may be recorded to digital media (i.e., CDs) or stored on a server or picture archive and communication system.

Fluid flow helps maintain joint distention, aids in clearing blood and other debris from the joint, and decreases the risk of contamination. Fluid may be delivered to the joint either by means of gravity or from an arthroscopic pump. Fluid outflow is provided by either a disposable needle, a specific outflow cannula, or through a portal without a cannula.

Arthroscopic therapy is performed with hand instrumentation and a power shaver (Fig. 14.6). These tools are inserted into the joint through an instrument portal that may be used with or without a cannula. Hand instruments include probes, knives, curettes, and forceps. The most commonly used probes are right angled and may have calibration marks for measurement of lesions. Numerous styles of knives and curettes are available for manipulation of soft tissue. The most common forceps used in small animal arthroscopy are graspers for removal of hard or soft tissue and biters for debridement of soft tissue.

FIG. 14.6 Hand instruments for small animal arthroscopy. (A) Grasping forceps. (B) Right angle probe. (C) Microcurette.

Power instruments increase efficiency and enhance the capabilities of the operator. The most common power instrument used is a shaver. These motorized hand tools have numerous tip designs, including burrs, sharp cutters, and aggressive cutters. Additional power instruments include electrocautery and radiofrequency (RF). Electrocautery tips specific for use in arthroscopy are available for some electrocautery generators. Alternatively, cautery may be performed by use of an RF unit. These units, which are available in both bipolar and monopolar designs, have also been advocated for soft tissue ablation and collagen shrinkage. Extreme care must be taken with the use of electrocautery and RF due to the possibility of severe cartilage and soft tissue damage capable with these instruments.

EQUIPMENT CARE

The telescope is the most fragile and expensive portion of the arthroscopy equipment. It may be damaged during the surgery or at any other time by cracking or scratching the lens or by bending. Specific protocols should be established for handling of the arthroscope to prevent any damage. It is advisable to have small cases for each arthroscope that can secure the arthroscope, cannula, and trocars for sterilization and storage. The cases should be sturdy and have a means of securing the instruments within the case. The arthroscope should be placed back in the case immediately after use to prevent damage while the remainder of the surgical table is cleared. Any junctions on the arthroscope, including those between the light post and scope or between the eye piece and telescope, should be checked regularly for tightness. If these junctions become loose, they may permit fluid to leak in, which may impede light or image transmission. Bending of an arthroscope may be evident by the appearance of a black crescent at the periphery of the field of view. Severe bending will result in complete obliteration of the view. If bending occurs, the instrument should be sent to a qualified repair facility rather than attempting to straighten the instrument, which may result in permanent damage.

Arthroscopes should be cleaned by hand with an enzymatic cleaner and distilled water as soon as possible after the procedure to remove blood or other body fluids or tissue. The lens and eye piece may be gently cleaned with a cotton ball and distilled water. The cannulas and trocars are similarly cleaned. Sterilization may be performed by several methods. Nonautoclavable arthroscopes may be sterilized by ethylene oxide gas or hydrogen peroxide plasma, depending on the recommendations of the manufacturer. Newer arthroscopes are autoclavable.

The camera head, with its associated lens and prism, and the cable may be damaged by dropping or mishandling. The camera cord contains relatively delicate wires, and the connection may have fine pins. The camera cord should never be bent or wound too tightly, and the cap should always be placed back on the connector when not in use. Camera heads may be sterilized by autoclave, ethylene oxide gas, or hydrogen peroxide plasma, depending on the manufacturer's recommendations.

The light cable may be sterilized by ethylene oxide gas, hydrogen peroxide plasma, or autoclaving, depending on the manufacturer's recommendations. The light cable is composed of numerous glass fibers that may be broken if the cable is bent or wound too tightly. The fiberoptic cable will also heat up significantly and should never be placed directly against the patient because it may cause burning.

Hand instruments should be cared for using routine cleaning and sterilization techniques. These instruments should be inspected during each use for damage or dull edges. The care of power instruments varies based on the tool and manufacturer.

ANTIBIOTICS

The minimally invasive nature and high volume of fluid flow used with arthroscopy result in a very low risk of infection. Antibiotics are typically administered only on a perioperative basis during these procedures. A first-generation cephalosporin (cephalexin, 22 mg/kg, IV) should be given at induction and discontinued after the procedure.

GENERAL PROCEDURES

The most commonly performed arthroscopic procedures are diagnostic visualization and fragment removal (see Box 14.6). When performing diagnostic arthroscopy, it is critical that a complete and repeatable method to document the procedure be routinely performed using either still or video imaging, or preferably both. For best results, make a short video of the entire joint and then take still images of any abnormal findings. This results in a record of all joints examined while producing a minimum of electronic data. The images are valuable for showing lesions to pet owners and for use as a reference for follow-up evaluation of the case.

Fragment removal varies depending on the joint being treated and the specific disease (Fig. 14.7). The most critical points for successful fragment removal include establishment of suitable joint portals, use of appropriate hand instruments, and development of excellent arthroscopic hand-eye skills. The establishment of suitable portals allows good visualization of the fragment, easy removal and insertion of the instrument, and enhanced ability to manipulate the fragment.

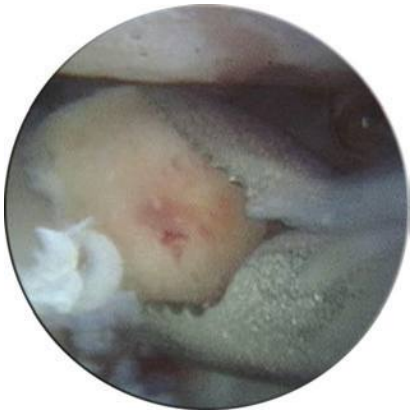

FIG. 14.7 Fragment removal in canine elbow arthroscopy. (From Beale B, Hulse D, Schulz K, Whitney W. *Small Animal Arthroscopy.* Philadelphia: Saunders; 2003.)

SPECIFIC PROCEDURES

Arthroscopy of specific joints can be found in the chapter detailing procedures for conditions affecting that joint. For arthroscopy of the shoulder, see p. 1156; for the elbow, see p. 1177; for the hip, see p. 1211; for the stifle, see p. 1230.

POSTARTHROSCOPY CARE

Because of the minimally invasive nature of arthroscopy, small animal patients undergoing this procedure require little specific postoperative care. Specific instructions depend on the disease being treated and condition of the joint. Arthroscopy portals are generally closed only with skin sutures, although some small portals may require deep closure to limit fluid drainage postoperatively. Regardless of closure method, moderate postoperative drainage from these incisions due to the large volumes of fluid used in the procedure may be seen. Although many animals are administered nonsteroidal antiinflammatory medications for treatment of the primary disease, most patients will not require postoperative analgesics for pain associated with the arthroscopic procedure itself. Exercise restriction is indicated for several days to a week to permit the portals to heal and may be prescribed for longer periods, depending on the underlying disease.

ADVANCED IMAGING

Sophisticated imaging techniques such as computed tomography (CT), magnetic resonance imaging (MRI), and, more recently, positron emission tomography with CT (PET/CT) can be integral parts of the workup of pets with challenging surgical diseases. Since its inception, CT has been used to help resolve complex anatomy. MRI has become the imaging modality of choice for neurosurgery. PET/CT provides important information on both the anatomic location and physiologic function of a variety of diseases. These modalities give the clinician important information on the anatomic or physiologic extent of the disease process.

Medical imaging is no longer just about noninvasive viewing of anatomy. Modern imaging techniques can provide a wealth of information beyond anatomic interpretation. At one end of the spectrum lies pure anatomic imaging; at the other end is pure physiologic imaging. Techniques such as standard planar radiography provide excellent information regarding anatomic structure (especially that of bone), but they do not provide information regarding function of the imaged anatomy. Traditional nuclear medicine (bone scans, thyroid scintigraphy) has provided reliable physiologic imaging and has been commonly utilized in veterinary medicine. Newer modalities such as PET can image glucose metabolism, rates of cell proliferation, and the biodistribution of a drug but do not provide anatomic detail. Hybrid imaging, which provides detail regarding function and anatomy, has become increasingly important in medical imaging. Combining modalities that provide complementary information, such as PET/CT, provide data that are often more useful than the individual information. CT is able to precisely determine anatomy, whereas PET is able to provide information on regional physiology; fusing the two modalities can offer tremendous insight. Other examples of hybrid imaging in use today include excretory urography and upper GI studies, which provide anatomic and limited physiologic information. With ultrasonography, one can look at both anatomy with B-mode and velocity

with Doppler imaging, giving information regarding structure and function.

Physics: Overview

Magnetic Resonance Imaging

Important concepts when considering the physics of MRI is that all living things have magnetic and electrical properties and that magnetism and electricity are interchangeable. MRI is based on the magnetic properties of living tissue, primarily protons of hydrogen atoms. The majority of atoms in the body are hydrogen, principally as a component of water (H_2O), which makes it a particularly useful atom for MRI. The proton has a spin and a charge; because this is a moving electrical charge, it constitutes an electrical current. This electrical current induces a magnetic field; therefore each spinning proton produces a tiny magnetic field.

The basic sequence of events in MRI involves excitation of protons by administering RF pulses, discontinuing the RF pulses, and collecting the RF energy that is released when the protons "relax" to their original energy states; this released energy is converted into an image.

When the RF pulse is discontinued, the protons tend to "relax" back into alignment with the original magnetic field. In addition, the protons will lose phase coherence. As they relax, they release the previously applied energy as radio waves. These radio waves are picked up at different rates and signal intensities, depending on the tissue type releasing the energy. The waves are picked up by receiver coils in the MRI machine, which convert the energy to electrical signals. The computer uses these electrical signals to form an image.

There are two basic types of relaxation of protons (i.e., T1 and T2) that occur concurrently after the RF pulse is stopped; these types of relaxation are related to the return of the displaced net magnetic vector back to the direction of the static magnetic field (the positive z direction-T1 relaxation) and the loss of phase coherence among individual protons (T2 relaxation). Different tissues have different T1 and T2 relaxation times. Different tissues in the body have varying proton densities (i.e., number of hydrogen protons in a given volume of tissue), and the hydrogen protons in different tissues have varying levels of mobility. These tissue differences account for the variation in signal intensities generated by different tissue types in MRI (e.g., fat vs. cerebrospinal fluid [CSF]). The variation in relaxation times between different tissues in the body is far greater than the variation in tissue density, thus soft tissue contrast resolution is superior in MRI compared with CT.

T1 relaxation refers to the return of excited protons to the original energy state of the static magnetic field. Because this represents energy exchange between spinning high-energy protons and the molecular lattice from which they were excited, it is also called *spin lattice relaxation*. Because this energy transfer occurs as the displaced net magnetic vector relaxes back to the z or longitudinal direction, it is also referred to as *longitudinal relaxation*.

T2 relaxation describes energy exchange between the magnetic fields of individual protons before and after the application of an RF pulse. T2 relaxation is also called *spin-spin relaxation*. Because this type of relaxation occurs in a transverse direction (the x-y plane), it is also referred to as *transverse relaxation*. The phenomenon of T2 relaxation is primarily related to the loss of phase coherence among excited protons as they relax back to the equilibrium or ground state.

The time it takes for 64% of the protons in a particular tissue to regain the original energy state following the application of a 90-degree displacing RF pulse is that tissue's relaxation time (T1 or T2). Water has a very long T1 and T2 relaxation time, whereas fat has short T1 and T2 relaxation times. On a T1-weighted image, water (e.g., CSF, edema) will appear dark (hypointense) and fat will appear bright (hyperintense). On a T2-weighted image, water will appear hyperintense and fat will appear slightly less intense when compared with fat in T1-weighted images. Generally, T2-weighted sequences have the most inherent contrast between the various soft tissues, and the majority of pathologic processes will be associated with an increased signal intensity on T2-weighted images. T1-weighted sequences tend to have better anatomic resolution when compared with T2-weighted images.

Besides T1- and T2-weighted sequences, many additional sequences are commonly utilized in MRI. Proton density (PD) sequencing produces an image based on the density of protons within the tissue rather than T1 and T2 decays. The greater the density of protons, the more hyperintense that tissue contrast will be. PD images also tend to have good anatomy resolution. Fluid attenuation inversion recovery (FLAIR) sequences suppress the signal from free water (e.g., CSF) to discern this from tissue-bound water (e.g., edema), which has a considerably shorter T1 value. In neurologic imaging, FLAIR images are particularly helpful in distinguishing infarcts from cystic structures and delineating periventricular lesions as distinct from the neighboring ventricular CSF. Dual echo sequences combine the acquisition of a T2-weighted and PD image and are used to save time during the scanning process. There are two types of fat suppression sequences, the short tau inversion recovery (STIR) and a chemical fat saturation (FAT SAT). The physics behind these two suppression sequences are different. The important clinical difference between the two suppression sequences is that the physics associated with the STIR sequence will also suppress any gadolinium (Gd)-based contrast enhancement. Contrast enhancement can still be appreciated with FAT SAT sequences. It is extremely important to utilize a fat suppression sequence in musculoskeletal MRI to rule out fat deposition rather than a pathologic process within the bone. A fat suppression sequence should be utilized in any clinical situation where signal from fatty tissues needs to be suppressed to discern other neighboring anatomy or to confirm a pathologic process.

Gd-diethylenetriaminepentaacetic acid (DTPA) is a paramagnetic, IV-administered contrast agent used in MRI. Similar to iodinated intravenous contrast administration in CT imaging, Gd-DTPA is used to demonstrate vascularity and abnormalities of the blood-brain barrier. Gd-DTPA shortens both T1 and T2 relaxation times of tissues in which it localizes, leading to greatest signal intensity on T1-weighted images.

All these sequences are seldom done in one MRI exam. Usually several sequences are established for a standard imaging protocol tailored for a specific organ system, such as a brain, spine, generalized musculoskeletal imaging, or a joint-specific protocol (e.g., shoulder or stifle). Each MRI protocol may vary slightly, being made by each specific practice and tailored to that MRI system. Each magnetic resonance (MR) sequence requires an allotment of time to acquire that sequence. In veterinary medicine the patient is under general anesthesia for MRI. Therefore the typical goal with MRI is to have enough sequences and imaging planes to make an accurate diagnosis, without subjecting the patient to unnecessary or repetitive sequences and increased anesthesia time.

There are a number of other MRI sequences that are becoming increasingly utilized in veterinary medicine. These include phase-contrast or cine-MRI and diffusion-weighted imaging (DWI). Phase-contrast or cine-MRI utilizes motion-sensitive pulse sequences to evaluate CSF flow. This type of imaging has potential for application in abnormal CSF flow disorders such as Chiari-like malformation with syringomyelia. DWI is based on MR measurement of the diffusion of intracellular water. With ischemic and inflammatory conditions of the central nervous system (CNS), cytotoxic edema leads to abnormalities of water diffusion (damage to ATPase pumps) that can be visualized via DWI. This mode of MRI is particularly applicable to ischemic/vascular events and inflammatory disorders, as abnormalities can be detected earlier in the disease course compared with conventional (e.g., T2-weighted, FLAIR) MR sequences. A variation of DWI, called *diffusion tensor imaging* or *MR tractography,* is used to evaluate white matter tracts via evaluation of the direction of water diffusion along these tracts.

Computed Tomography

CT utilizes x-rays and computers to provide cross-sectional images of the patient. The final images are composed of many small image squares called *pixels*. The thickness of these image squares (voxels) is determined by the chosen slice thickness. The patient is placed in the opening of the CT gantry. The gantry contains the x-ray tube, x-ray collimators, and x-ray detectors. The x-ray tube and detectors are on opposite sides, and the patient is between them. The collimators control slice thickness. The x-ray tube rotates around an object of interest as x-rays are emitted. As the x-ray beam passes through an object, it is attenuated by tissues in its path. Each tissue attenuates the beam to a different degree. The different attenuating abilities of different tissues, or *linear attenuation coefficients*, provide the basis of tissue contrast for CT. The detector receives the attenuated beam, also called a *projection*, of x-ray photons, and the information is fed into the computer. The projections are reconstructed into a 3D volume by using either purely analytic methods such as filtered back-projection (the most common) or iterative procedures such as expectation maximization. The analytic approaches currently dominate; however, iterative methods perform better with less reliable information and will likely see increased usage as the desire to lower the applied radiation dose becomes more important. The computer assigns grayscale numbers (Hounsfield units) to the tissues that the x-ray beam passed through, based on their linear attenuation coefficients.

The resultant image reflects the different grayscale numbers of different tissue types, and therefore the tissues' respective abilities to attenuate x-rays. As one would expect from conventional x-ray procedures, bone appears white, air appears black, and fluid is somewhere in between (gray). The corresponding Hounsfield numbers for these tissues are +1000, −1000, and 0, respectively.

The human eye can discern approximately 20 shades of gray. The number of shades of gray in the image, as well as the central gray color (above which tissues are brighter, below which they are darker), can be manipulated once the computer receives the image information. Choosing the central gray color, above which tissues appear brighter and below which they appear darker, is referred to as setting the window level (WL). The Hounsfield unit of the tissue of interest is typically chosen as the center of the WL. The number of shades of gray assigned to a particular image represents the window width (WW). A narrow WW is chosen for soft tissue (e.g., brain parenchyma) to improve contrast resolution (the ability to discern differences in composition of tissues in close proximity). A wide WW is chosen for tissues in which good inherent contrast already exists (e.g., air in the frontal sinus region) or when imaging a region where a wide range of tissue densities is displayed (e.g., lung). When imaging brain parenchyma, a WL of approximately 35 and a WW of 150 may be assigned. In contrast, when imaging bony tissue, a WL of 420 and WW of 1500 may be used.

After obtaining CT images of the area of interest, iodinated contrast is often given IV and the patient is imaged. The contrast agent will be distributed through the vascular space and excreted by the kidneys. Contrast is used to demonstrate areas of blood-brain barrier disruption, increased areas of vascularity, delineated blood vessels, and anomalous shunts. As the kidneys excrete the contrast, it quickly concentrates in the urine, which also allows for clear delineation of the ureters.

Advantages of CT over other imaging modalities are numerous. CT provides far superior soft tissue contrast in comparison with conventional radiography. The various soft tissue planes are usually delineated with CT imaging. The cost of CT is typically less than MRI. CT is a more rapid imaging modality than MRI, and the mineralized bony matrix and acute hemorrhage are better visualized with CT versus MRI; these attributes make CT preferable to MRI in acute head trauma patients. Currently available multislice CT scanners are so fast that patients can be imaged in seconds, sometimes only requiring sedation. Other advantages of CT imaging are the ability to alter window settings after data acquisition to maximize tissue contrast. Following the initial data acquisition, modern CT has the ability to form multiple 2D and 3D reconstructed images. With newer CT scanners, these reconstructed 3D images are very detailed and artifacts associated with metallic implants are usually not an issue unless precise quantification near the implant is required. The use of CT for postoperative assessment of implants is very efficient and much more detailed than conventional radiography.

There are several disadvantages of CT compared with MRI. CT involves exposure to ionizing radiation (x-rays), whereas MRI does not. MRI provides far superior soft tissue detail compared with CT. CT is usually adequate for visualizing mass lesions in the brain and spinal cord. However, subtle parenchymal lesions (e.g., inflammatory foci in granulomatous meningoencephalomyelitis), as well as brain (especially brain stem) and spinal cord lesions in very small dogs and cats are much more appreciable on MRI than CT.

Positron Emission Tomography

PET is a form of nuclear medicine, in that it relies on an injected radionuclide for the imaging signal. It is different from traditional nuclear medicine in that it is based on positron emission instead of the more typical single-photon gamma emissions. This difference gives PET several advantages. There are several easily producible positrons emitting isotopes such as fluorine (^{18}F), oxygen (^{15}O), carbon (^{11}C), and nitrogen (^{13}N). It is important to note that these elements are all common to the typical organic compounds found in living things. Unlike isotopes used in nuclear medicine such as technetium-99m (^{99m}Tc), the chemistry of the isotopes available to PET are more accurate surrogates for measurement of the function of living tissue. In addition, the physics of PET allows it to be electronically collimated, whereas single-photon nuclear medicine techniques require physical collimation. This results in better efficiency of several orders of

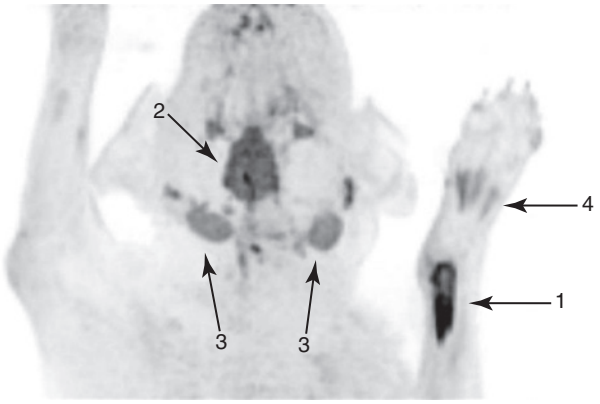

FIG. 14.8 Positron emission tomography imaging of the distal left forelimb and skull of a dog with osteosarcoma of the distal left radius. There is intense uptake of fluorodeoxyglucose (^{18}FDG) in the distal metaphysis and diaphysis of the left radius *(arrow 1)*. There is normal ^{18}FDG uptake in the brain *(arrow 2)* and salivary glands *(arrows 3)*. Mild inflammation in the phalanges of the affected limb is indicated by slightly higher than background FDG uptake *(arrow 4)*.

magnitude. In addition, attenuation correction can be accounted for, resulting in accurately quantified image values. In total, these advantages have led to dramatic changes in the way we view functional physiologic imaging techniques because we are now able to see things that were simply not visible before.

PET relies on positrons to produce an image, but it does not sense them directly.

The application of PET has seen widespread acceptance in human oncology with research applications in neurology and biodistribution for new drug development. In oncology, the primary application is measurement of glucose metabolism with fluorodeoxyglucose (FDG). Imaging of the distribution of FDG gives a good approximation of the overall consumption of glucose (Fig. 14.8). Most cancers are hypermetabolic; thus locating tumors through their glucose metabolism signature has proven very effective.

FDG is one of many PET tracers available that can provide useful information. For example, cells use thymidine during division; thus imaging the cellular use of thymidine using fluorothymidine (^{18}FLT) can be correlated to the rate of cell proliferation. Clearly, for cancers that are growing rapidly, this can be useful information. Knowledge of what parts of the tumor are growing fastest can aid in the development of treatment plans.

PET scanners image the concentration of positron-emitting radioisotopes; therefore any compound that can be labeled can be measured. This feature has had significant impact in the development of new drugs. By labeling a candidate drug with a positron-emitting radioisotope, biodistribution of that drug can be determined without injuring the host. This provides accurate information about dose requirements without the need for large numbers of studies or research animals.

Hybrid Imaging With Positron Emission Tomography/Computed Tomography

From the surgeon's perspective, PET in itself may be interesting, but direct application to surgery is not clearly obvious because reference to recognizable anatomic landmarks is very limited. In fact, the ideal PET scan would show no anatomy at all, only the physiologic parameters of the diseased tissue. The invention of hybrid PET/CT imaging by Drs. Ronald Nutt and David Townsend has allowed correlation of very precise anatomic imaging generated with CT to the functional physiologic information generated with PET, providing an entirely new perioperative surgical planning tool. This application is especially valuable in oncologic surgery, where it may aid the surgeon in obtaining clean margins when resecting a tumor. Although PET/CT is in its infancy in veterinary medicine, its clinical utility will be profound because the state and extent of the disease (the FDG metabolism) is precisely coregistered to the anatomy.

Clinical Applications

As mentioned previously, MRI has become the imaging modality of choice for neurosurgery and the majority of MR studies in veterinary medicine focus on the CNS. The specific clinical applications relating to the CNS are detailed in Chapter 37. In human medicine, the musculoskeletal system is routinely imaged with MRI; it is considered by many to be the most important advanced imaging modality for the assessment of human musculoskeletal injuries and diseases. The advantage of MRI for orthopedics is that it provides an assessment of the entire organ system (e.g., muscles, tendons, ligaments, cartilage, meniscus, joint fluid, fat, and bone). Bone, ligaments, and tendons appear more hypointense on the MR sequences. Many clinicians are hesitant to evaluate bone with MRI because this does not reveal the fine structural detail of the mineralized bony matrix compared with radiography and CT. However, bone is more than a mineralized structure, and MRI is far superior to these other two modalities for evaluating the extent of soft tissue pathology associated with the bone.

Many musculoskeletal MR sequences are reported throughout the literature, some of which focus on a specific tissue type, such as cartilage. The more commonly utilized musculoskeletal sequences include T1-weighted, PD, dual echo, T2-weighted, or PD combined with fat suppression and T1-weighted sequences. One of the most exciting aspects of orthopedic MRI is that the entire articular surface can be imaged. MRI of cartilage in small animals is more challenging because articular cartilage is much thinner in dogs compared with people and large animals (Fig. 14.9). The thinner articular cartilage provides less signal for the MRI, and there is relatively more averaging of the cartilage with subchondral bone and joint fluid.

In musculoskeletal MRI, the terms "bone edema" and "bone bruise" are frequently used to describe a hyperintense lesion on fat suppressed T2-weighted and PD sequences. These lesions are nonspecific and are commonly associated with many types of musculoskeletal injuries and disease processes. When these lesions are evaluated histologically, the findings are quite varied and include inflammatory cells, hemorrhage, hematopoietic cells, necrosis, fibrosis, and edema. A more appropriate term is a "bone marrow lesion."

Although MR allows for superior soft tissue contrast, CT is also a vital imaging modality for the musculoskeletal system. Thinly sliced CT images provide excellent spatial resolution and bony detail, making it the modality of choice to define complex bony anatomy. Some specific examples where this aspect of CT is used frequently include imaging the skull, vertebral bodies, and pelvis following trauma to more fully assess fractures and determine if there is nervous system involvement (Fig. 14.10). Elbows are frequently evaluated with CT to assess for fragmented

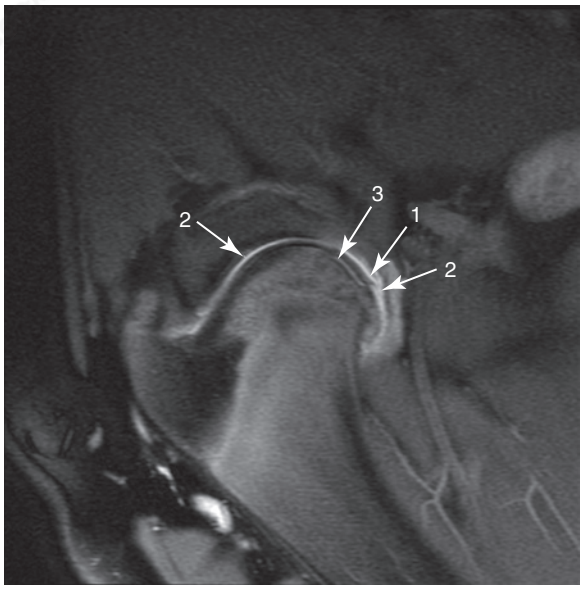

FIG. 14.9 Sagittal magnetic resonance imaging proton-dense, fat-saturated image of the caudal humeral head of a dog with an osteochondrosis lesion. A moderate-sized in situ cartilaginous flap is present *(arrow 1),* which is well delineated by the hyperintense joint fluid *(arrows 2)*. The cartilaginous flap is dorsal to the flattened humeral head *(arrow 3)*.

medial coronoids (Fig. 14.11). MRI of the elbow is also used to assess for coronoid disease and is more sensitive in the identification of cartilaginous coronoid fragments compared with other imaging modalities. CT and MRI are much more accurate and specific in regard to the diagnosis of a fragmented medial coronoid compared with radiography.

For severe angular limb deformities, CT is excellent for presurgical planning. Radiographically, it can be difficult to accurately plan the correctional procedure if the limb deformity is taking place in multiple planes. Not only does CT allow for excellent axial images, modern software can project the limb in all planes and in three dimensions. Additionally, plastic models of the limb can be created from the CT images. These models are highly useful for planning the correctional procedure.

These modalities are also useful for soft tissue surgical planning. The tympanic bullae are frequently evaluated with CT to assess for otitis media and determine whether a bulla osteotomy is indicated. Otitis media is easily recognized on MRI images as a hyperintensity with the bulla on T2-weighted images (Fig. 14.12). Both CT and MRI are useful in the identification and localization of embedded soft tissue foreign bodies, which may or may not be associated with a draining tract. Traditionally, if a draining tract is present, a radiographic fistulogram is performed. Clinically, many fistulograms are of questionable diagnostic accuracy. With MRI, the regional inflammation is readily identified as an atypical hyperintensity on the T2 or PD

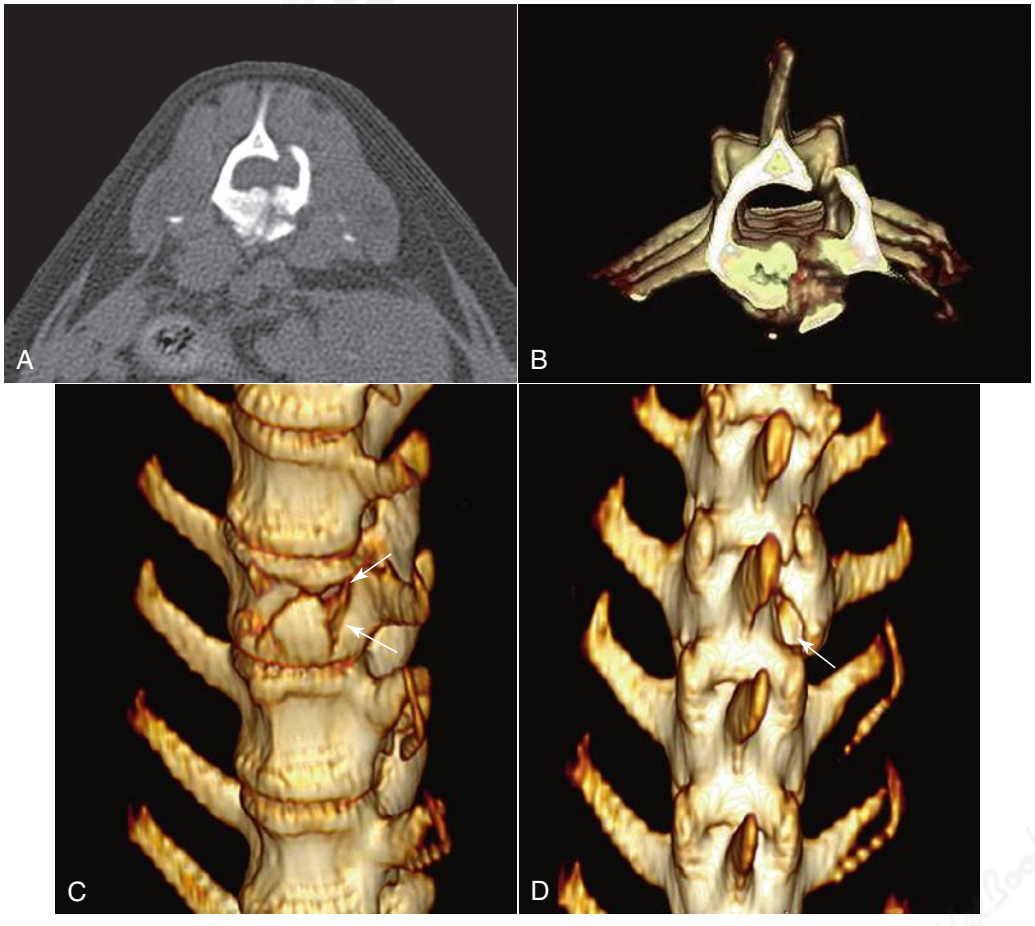

FIG. 14.10 Multiple images of a fractured lumbar vertebral body. (A) Transverse computed tomography image at the level of the fracture site. (B–D) Three-dimensional (3D) surface renderings of the same fracture. (B) A 3D transverse view sliced obliquely to show the extent of the fracture separation. (C) Ventral aspect of the comminuted vertebral body fracture *(arrows)*. (D) Dorsal aspect of the vertebra; note how the left pedicle, part of the lamina, and facet are displaced laterally *(arrow)*. Also note the displaced fracture fragments of the left transverse processes of the two vertebrae, caudal to the vertebral body fracture.

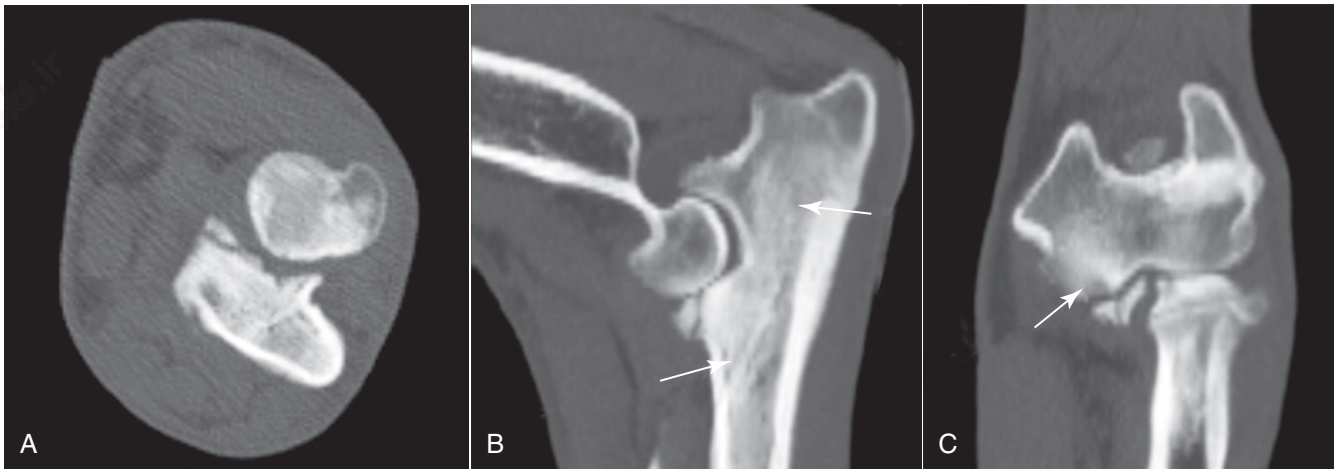

FIG. 14.11 (A) Transverse computed tomography image of a fragmented medial coronoid process (FMCP) (window width = 2000; window level = 400). (B) A sagittal image reformatted at the level of the FMCP. The patient also had concurrent panosteitis *(arrows),* which is best seen on image as sclerosis throughout the proximal ulna. (C) A cranial reformatted image at the level of the FMCP. A small osteochondrosis lesion is present at the medial condyle of the humerus *(arrow).*

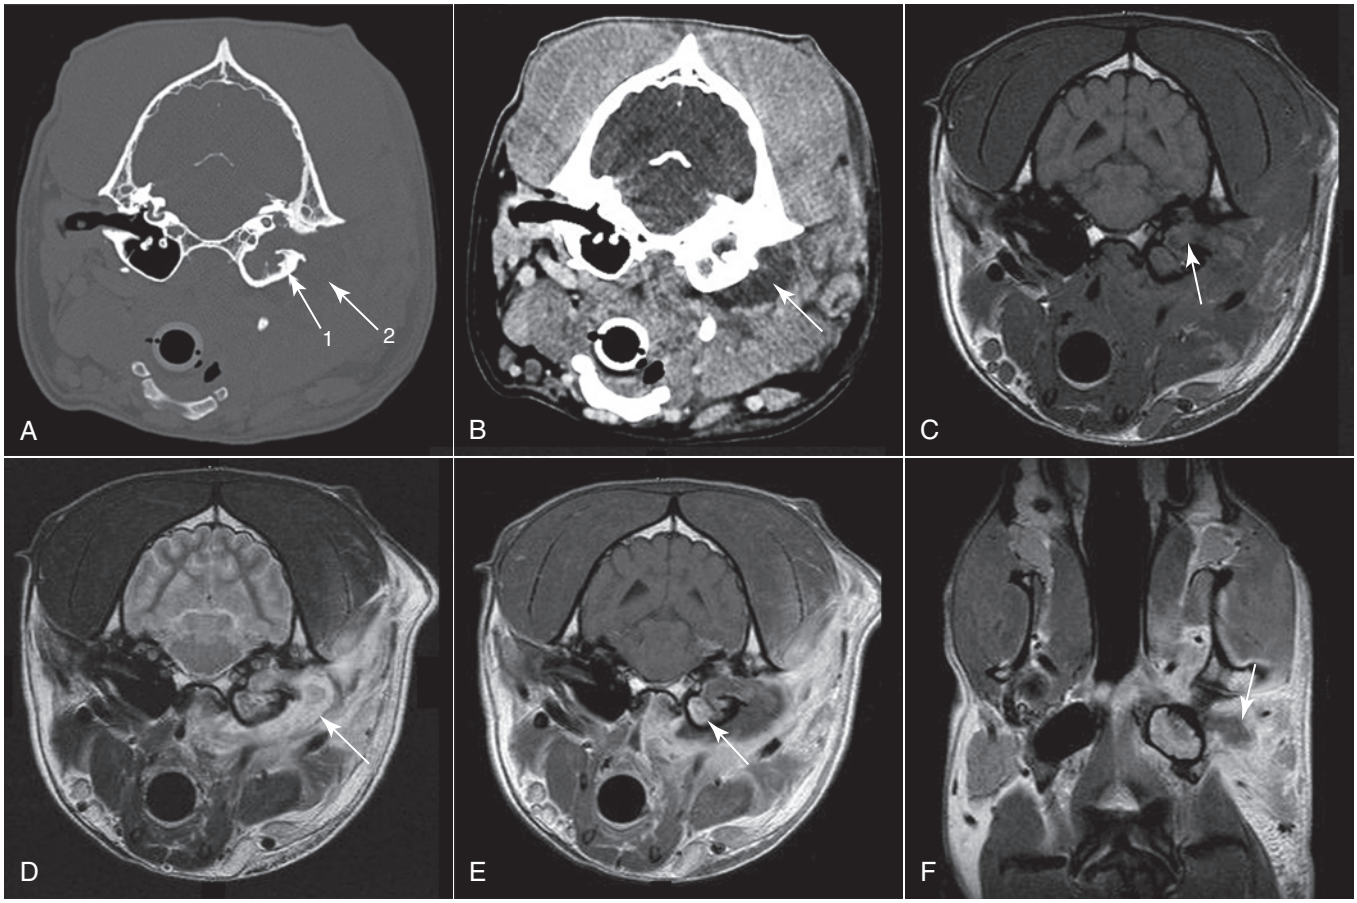

FIG. 14.12 (A) Computed tomography (CT) image set on a bone window (window width [WW] = 25,000; window level [WL] = 480). Note the osseous thickening of the left bulla *(arrow 1),* the soft tissue attenuating material within the bulla, and the more hypoattenuating material closely associated with the left bulla *(arrow 2).* (B) CT image set on a soft tissue window (WW = 300; WL = 30) following administration of contrast. Note the lack of enhancement of hypoattenuating material near the left bulla *(arrow),* but there is enhancement of the tissues surrounding this region. (C–D) Transverse T1- and T2-weighted images of the bulla. Note the improved soft tissue contrast within the left bulla *(arrow)* compared with the CT images. (D) Hyperintensity of the surrounding tissue is characteristic of increased fluid within these tissues *(arrow).* (E) A transverse T1 postcontrast image. Arrow shows contrast enhancement within the bulla. (F) A dorsal T1 postcontrast image at the level of the left bulla. The hyperattenuating tissue on these images correlates with increased vascularity of the tissues. Note how the contrast enhancement is similar to the CT images, especially in the abscessed, nonenhancing region adjacent to the left bulla *(arrow).* These findings are consistent with otitis media with regional abscess formation and cellulitis. The right bulla is unremarkable.

sequences. On CT, the regional inflammation and abscessation can be identified from normal tissues (Fig. 14.13). The appearance of the foreign body depends on its composition. Acquiring images in every plane allows for accurate localization of the foreign body, aiding in the diagnosis and surgical planning.

Vascular diseases may also be assessed with these modalities. Congenital anomalies, such a portosystemic shunt, can be delineated with both CT and MR angiography (Fig. 14.14). Many of these techniques require precise timing to follow the bolus of intravenous contrast through the vessels of interest (Fig. 14.15). Digital subtraction is a technique where a noncontrast image is subtracted from a contrast image to maximize the visibility of the vascular structure. This is more commonly utilized to delineate smaller, less discrete vessels of interest. With MRI, there are several

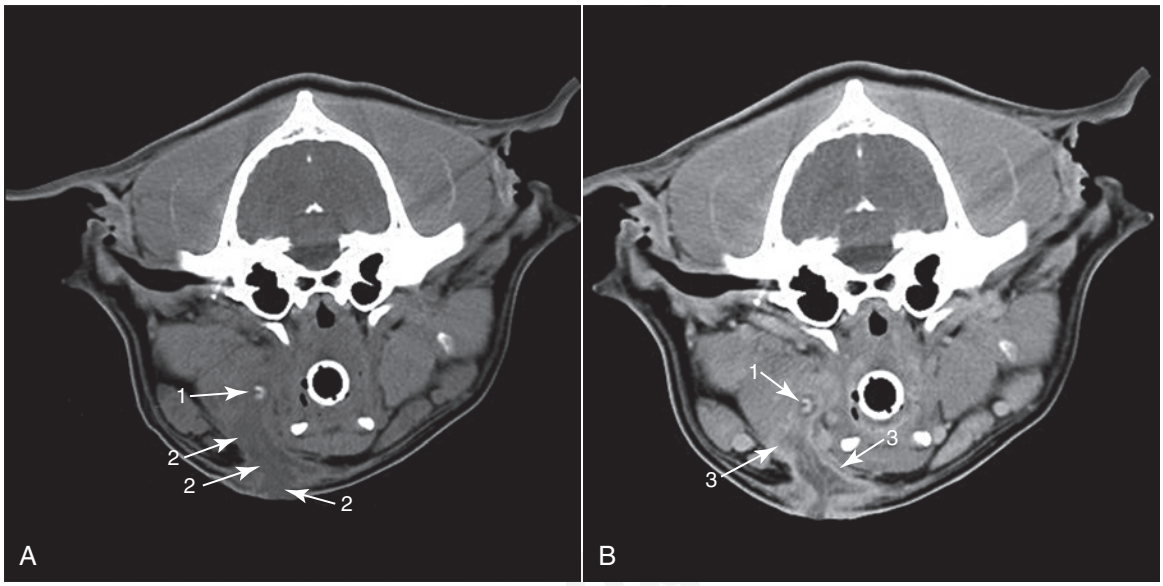

FIG. 14.13 Transverse computed tomography images at the level of the tympanic bulla, (A) before and (B) after administration of contrast, respectively (window width 241:window level 54). A hyperattenuating crescent-shaped foreign body is present in the soft tissues to the right of the endotracheal tube *(arrow 1)*. Heterogeneous soft tissue attenuating material is presently surrounding this structure and extending ventrally to the surface of the skin through the draining tract *(arrows 2)*. Note the contrast enhancement of the soft tissue surrounding the draining tract and foreign body *(arrows 3)*.

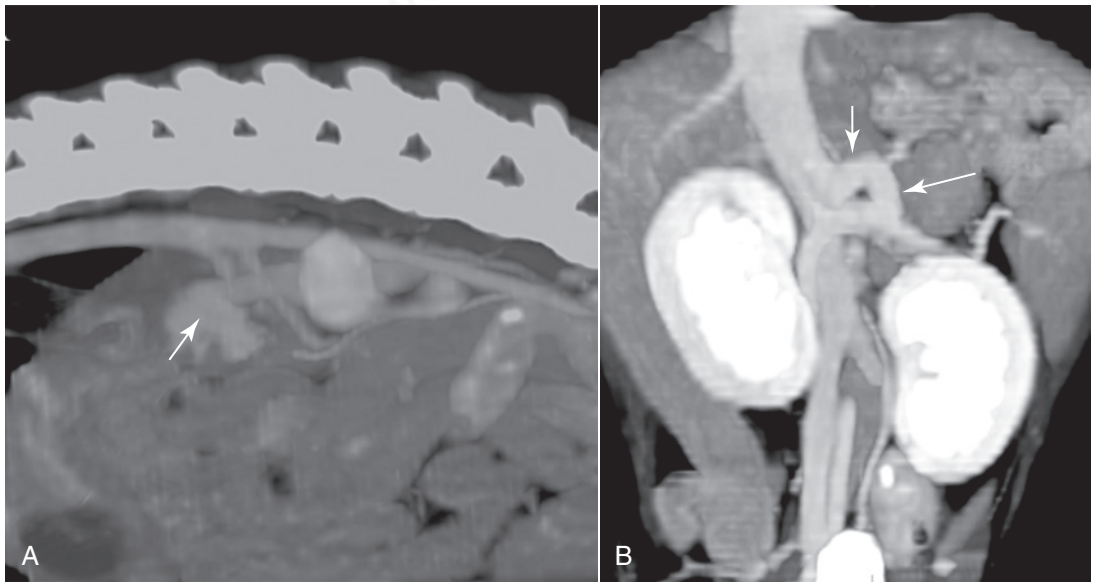

FIG. 14.14 Two-dimensional multiplanar (A) sagittal and (B) frontal reconstructed computed tomography images, centered at the level of a typical portocaval extrahepatic portosystemic shunt (PSS). The PSS is identified by the *arrows* and is an enlarged tortuous vessel connecting the portal vein to the caudal vena cava. imaging techniques that can be utilized to obtain an MR angiogram, many of which do not depend on the administration of intravenous contrast. Some of these techniques will likely be utilized in the future to assess the renal vasculature in feline kidney transplant procedures. Techniques such as TWIST (time-resolved angiography with interleaved stochastic trajectories) allow for a bimodal sampling of MRI K-space in such a way that the temporal resolution can be increased without substantially harming image quality. This means that multiple image frames can be taken quickly and stored so that the precise timing becomes less important. Because intravenous contrast is excreted through the kidneys, CT-based excretory urography is a commonly performed clinical procedure used to aid in the diagnosis of ectopic ureters.

CT is the modality of choice to assess for pulmonary thromboembolism because of its rapid acquisition time. This characteristic also makes it the most clinically applicable modality for the evaluation of other thoracic and thoracic wall diseases, such as lung lobe torsions; to assess for pulmonary metastatic disease when thoracic radiographs are inconclusive; to assess for causes of pleural effusion; and to evaluate the extent of regional neoplasia (Fig. 14.16). Motion causes significant artifacts with both CT and MRI. Motion artifact is more severe with MRI compared with CT; however, the rapid acquisition of modern CT allows for thoracic imaging without the use of gated software. The entire thorax can be imaged in a single breath hold. Any region of motion imaged with MRI requires the use of gated software.

A great example of gated MRI is cardiac MR studies. These studies provide high-resolution cine information that can be used to accurately measure left and right ventricular functional parameters such as ejection fraction and stroke volume. This information can be consistently relied on to provide an estimate of the state of disease in the cardiac muscle. This type of information is often acquired with ultrasound as well, but if performed with MRI, flow quantification of the aortic and pulmonary valves can also be performed. The extent of regurgitation through the valves can be precisely measured over the heart cycle by examining the velocity of the blood flow through the valve. The heart can also be evaluated with high-end modern multislice CT scanners; 128+ slice CTs are sufficiently fast to perform outstanding gated cardiac scans. By using contrast agents, the blood pool and heart muscle itself can be well separated and functional analysis performed. In this way, ejection fraction, stroke volume, and wall-thickening parameters can be computed with great precision. As fast as modern 128+ slice systems are, they do have limitations with high heart rate, namely blurring and edge artifacts. This can complicate the imaging of smaller animals. It is important to note that cardiac gating does not reduce the need for some kind of motion compensation for breathing, and a breath hold significantly reduces artifacts in this type of study. This is not normally a problem because a typical cardiac CT study on a 128-slice system only requires 5 seconds.

Soft tissue surgeons commonly utilize CT and MRI to aid in the planning of complex surgeries, often involving some type of invasive neoplasm. Not only can the tumor be delineated, the major vessels can also be identified. The multiplane reconstructed images, 3D images, and the ability to have plastic models constructed from the imaging data are extremely valuable for the preoperative assessment and planning of these patients. Computed tomographic biopsy procedures are also frequently performed, most commonly of the vertebral bodies and primary pulmonary nodules/masses, which cannot be visualized with ultrasonography (Fig. 14.17).

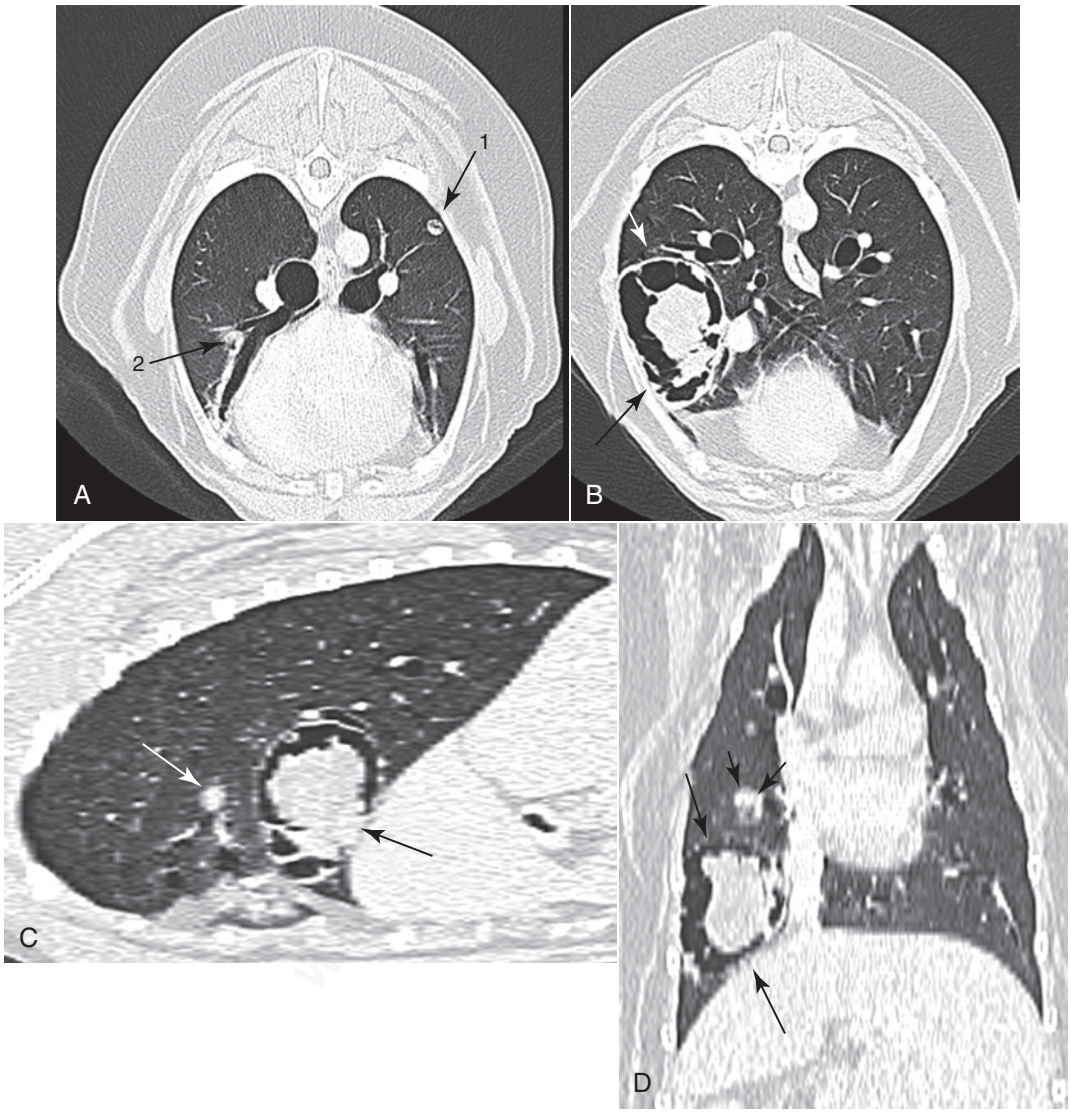

FIG. 14.16 Computed tomography images from a dog with pulmonary neoplasia. All images are post–contrast administration and are set on a lung window (window width = 1500; window level = 600). (A) Two cavitary metastatic lesions cranial to the large primary cavitary lung mass present in (B). One metastatic lesion is present in the peripheral aspect of the dorsal left cranial lung lobe *(arrow 1),* and the other is adjacent to the bronchus of the right middle lung lobe *(arrow 2).* (B) A large cavitary lung mass is present in the peripheral aspect of the right caudal lung lobe *(arrow).* (C) A reconstructed sagittal image of the right hemithorax, which shows the relationship between the metastatic lesion *(white arrow)* and the mass *(black arrow).* (D) A dorsal reconstructed image showing the same relationship as (C), the primary mass *(large arrows)* and metastatic lesions *(small arrows).* The other hyperattenuating structures in the images represent contrast in the pulmonary vessels.

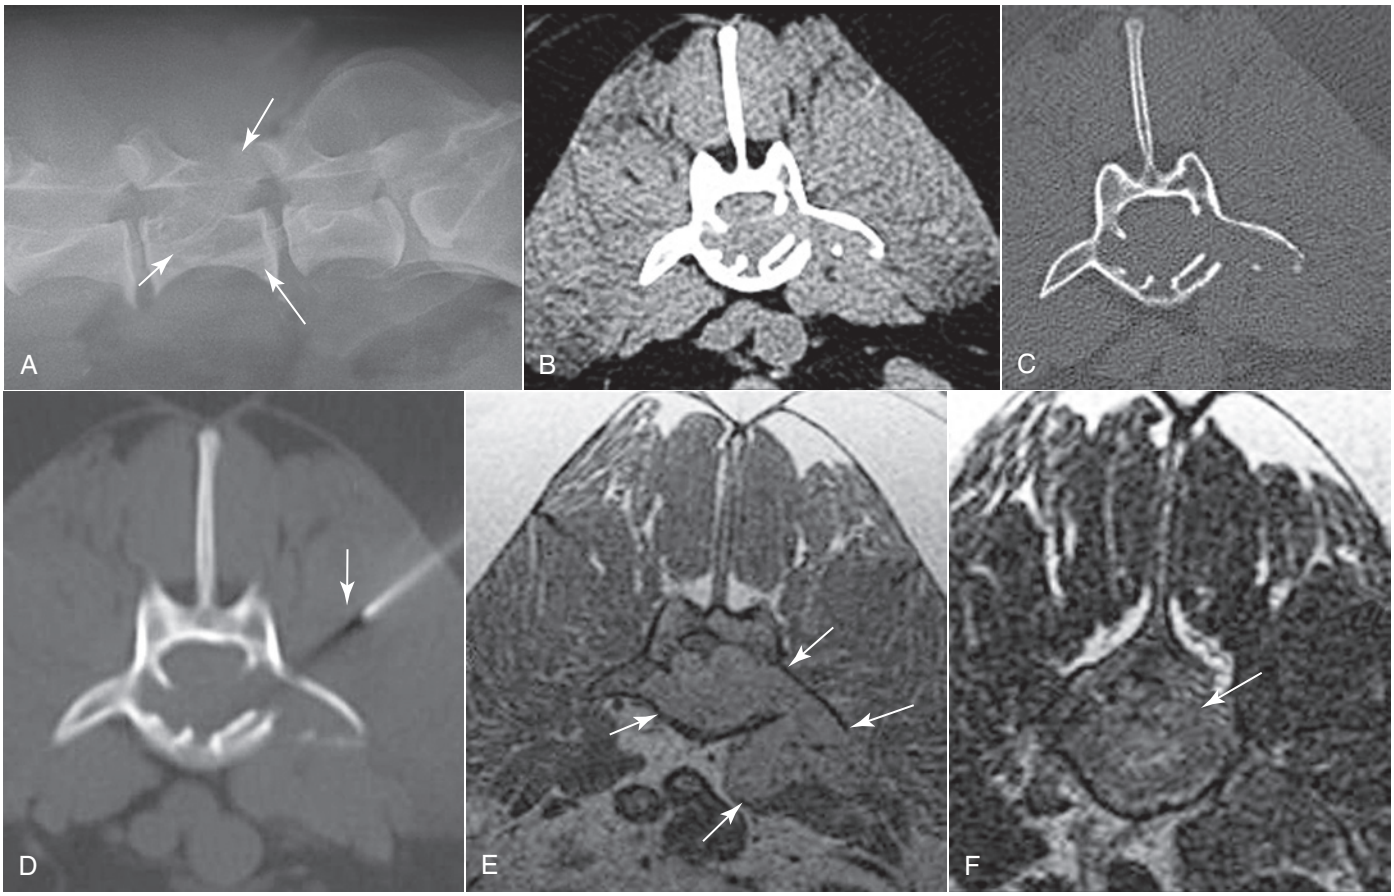

FIG. 14.17 Comparative images of a plasma cell tumor located at the sixth lumbar vertebral body. The computed tomography (CT) images demonstrate the osteolysis better than magnetic resonance imaging (MRI); however, the invasive soft tissue is much more clearly delineated on the MRI. (A) Lateral radiograph of the caudal lumbar region. (B–D) Transverse CT images of L6. (E–F) Transverse T1-weighted and T2-weighted MRI of L6, respectively. (A) Faint radiolucency associated with L6 *(arrows)* indicating the presence of a tumor. (B) Soft tissue window (window width [WW] = 350; window level [WL] = 30). (C) Bone window (WW = 2500; WL = 480). (D) CT biopsy procedure. The linear hyperattenuating structure is the biopsy needle. Immediately distal to the needle is a linear hypoattenuating artifact *(arrow)* caused by the needle. (E) Osteolysis of the lumbar vertebrae and the invasiveness of the tumor *(arrows)*. (F) Invasive nature of the tumor *(arrow)*.

FIG. 14.18 Distal canine femoral osteosarcoma lesion. (A) T1-weighted, postcontrast, fat-saturated sagittal magnetic resonance (MR) image. (B) T2-weighted, fat-saturated cranial MR image. There is an extensive extramedullary component to this mass *(arrow 1)* and a long zone of transition through the femoral diaphysis. (A) demonstrates intramedullary contrast enhancement *(arrow 2);* (B) shows an intramedullary hyperintensity *(arrow 3),* both of which represent the neoplastic invasion of normal intramedullary fat. Normal suppressed bone marrow fat remains present in the most proximal aspect of the femoral diaphysis *(arrow 4).* (Courtesy Dr. Susan Kraft, Colorado State University.)

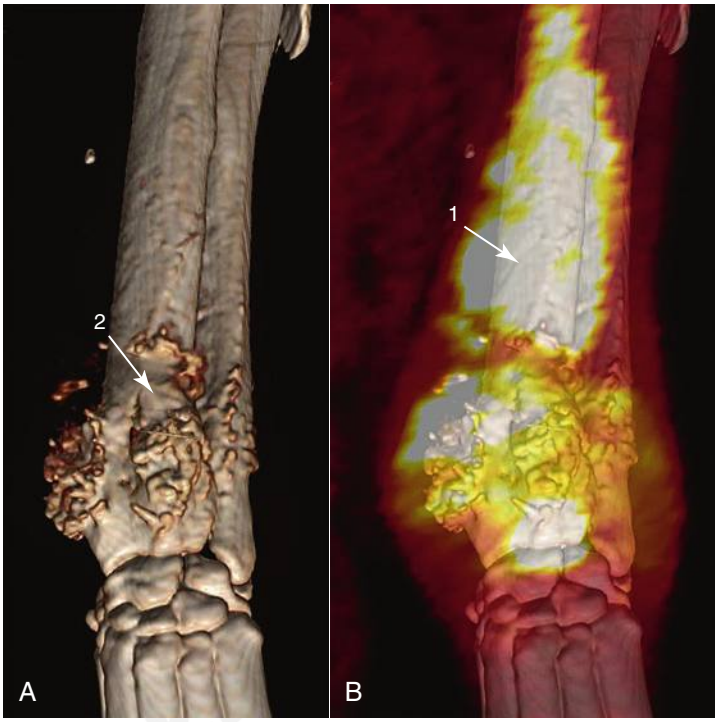

FIG. 14.19 (A) Computed tomography (CT) surface rendering of a canine distal radial osteosarcoma. (B) Positron emission tomography/CT fusion image of the same lesion. The white regions represent the highest uptake of fluorodeoxyglucose (^{18}FDG) (i.e., the highest amount of abnormal physiologic activity). Yellow represents increased cellular uptake of the ^{18}FDG, and red represents normal physiologic or background uptake of the ^{18}FDG. Note how much more extensive the intense physiologic activity *(arrow 1)* of the neoplasm is when compared with the osseous anatomic change associated with the neoplasm *(arrow 2).* This is the same dog as shown in Fig. 14.8, at a later stage of progression.

CT, MRI, PET, and PET/CT have obvious and profound clinical applicability for oncologic surgery. A complete list of clinical examples is beyond the scope of this text. Osteosarcoma is a common tumor in veterinary medicine, and the extent of this neoplasm and the clinical outcome of patients are studied by utilizing radiography, nuclear scintigraphy, and PET/CT. The true extent of this tumor near the cellular level cannot be determined with radiographs or CT. The physiologic changes within the affected tissue may not be significant enough to show an altered physical density that is detectable with CT. MRI delineates the soft tissue changes associated with the tumor and affected bone (Fig. 14.18). Specifically, MRI has been utilized to assess treatment options of osteosarcoma cases, including the use of limb-sparing surgical procedures. PET imaging reveals physiologic changes with great sensitivity and specificity. The fusion of ^{18}FDG PET with CT also shows the physiologic expansion of the osteosarcoma (Fig. 14.19).

In summary, these advanced imaging modalities are key to more fully assessing complex anatomy, tissue vascularity, aberrant vessel formation, and extent of a disease process. As a planning tool for complex surgical procedures, they allow for either anatomic imaging without the superimposition of other anatomic structures or an assessment of the functional physiologic extent of the disease process.

Surgery of the Integumentary System

GENERAL PRINCIPLES AND TECHNIQUES

WOUND MANAGEMENT

SURGICAL ANATOMY

The skin is composed of the epidermis, dermis, and associated adnexa. The outermost layer *(epidermis)* is thin but protective; it is especially thin in areas with abundant hair and slightly thicker in areas without much hair. The thickest epidermis is on the nose and footpads, where it is keratinized. The epidermis is avascular, receiving nourishment from fluid penetrating the deeper layers and from dermal capillaries. The thicker, vascular *dermis* lies deep to the epidermis, which it nourishes and supports. The dermis is composed of collagenous, reticular, and elastic fibers surrounded by a mucopolysaccharide ground substance. Fibroblasts, macrophages, plasma cells, and mast cells are found throughout this layer. The dermis contains blood and lymph vessels, nerves, hair follicles, glands, ducts, and smooth muscle fibers. The hypodermis, or *subcutis*, lies below the dermis.

Musculocutaneous vessels are the primary vessels supplying skin in human beings, apes, and swine; however, dogs and other loose-skinned animals lack musculocutaneous vessels. Musculocutaneous vessels run perpendicular to the skin's surface, whereas vessels supplying canine and feline skin approach and travel parallel to the skin and are direct cutaneous vessels. For this reason, some human pedicle grafting techniques have limited application in dogs and cats. Terminal arteries and veins branch from direct cutaneous vessels and form subdermal (deep) plexus, cutaneous (middle) plexus, and subpapillary (superficial) plexus. The subdermal plexus supplies hair bulbs and follicles, tubular glands, the deeper portion of the gland ducts, and arrectores pilorum muscles. The cutaneous plexus supplies sebaceous glands and reinforces capillary networks around hair follicles, tubular gland ducts, and arrectores pili muscles. The subpapillary plexus lies on the outer layer of dermis, and capillary loops from this plexus project into and supply the epidermis. The capillary loop system is poorly developed in dogs and cats compared with human beings and swine, which is why canine skin does not usually blister with superficial burns.

The subdermal plexus is of major importance to skin viability. In areas where there is a panniculus muscle (cutaneous trunci, platysma, sphincter colli superficialis, sphincter colli profundus, preputialis, supramammarius muscles), the subdermal plexus lies both superficial and deep to it. Therefore surgeons must undermine the fascial plane beneath the cutaneous musculature to preserve the integrity of the subdermal plexus. Where the panniculus is absent, such as in the extremities, the subdermal plexus runs in the deep surface of the dermis, requiring that one undermine well below the dermal surface.

WOUND HEALING

Wound healing is a biologic process that restores tissue continuity after injury. It is a combination of physical, chemical, and cellular events that restore wounded tissue or replace it with collagen. Wound healing begins immediately after injury or incision. The four phases of wound healing are inflammation, debridement, repair, and maturation. Wound healing is dynamic; several phases occur simultaneously. The first 3 to 5 days are the lag phase of wound healing because inflammation and debridement predominate and wounds have not gained appreciable strength. Healing is influenced by host factors, wound characteristics, and other external factors.

Stages of Wound Healing

Inflammatory Phase

Inflammation is a protective tissue response initiated by damage. This phase is characterized by increased vascular permeability, chemotaxis of circulatory cells, release of cytokines and growth factors, and cell activation (macrophages, neutrophils, lymphocytes, and fibroblasts). Hemorrhage cleans and fills wounds immediately after injury. Blood vessels constrict for 5 to 10 minutes to limit hemorrhage, then dilate and leak fibrinogen and clotting elements into wounds. Vasoconstriction is mediated by catecholamines, serotonin, bradykinin, and histamine. The extrinsic coagulation mechanism is activated by thromboplastin released from injured cells. Platelet aggregation and blood coagulation form a clot that ensures hemostasis and provides a scaffold for cell migration. Platelets also release potent chemoattractants and growth factors (epidermal, platelet-derived, transforming growth factors α and β) that are necessary in later stages of wound healing (Box 15.1). Fibrin and plasma transudates fill wounds and plug lymphatics, localizing inflammation and "gluing" wound edges together. Fibronectin dimers within the clot become covalently crosslinked

ABSTRACT

Many cutting-edge modalities are becoming readily available to the veterinary practitioner for management of complicated open wounds, including enzymatic debridement, low-level laser therapy, and negative pressure wound therapy. However, fundamental wound care principles allow for successful management in most wound cases. Good basic wound management allows for rapid healing or provides a healthy wound bed for surgical closure. Principles of open wound care include prevention of further contamination, wound lavage, debridement of devitalized tissue, and appropriate bandage placement and use of wound dressings.

BOX 15.1 Growth Factors Important in Wound Healing

BFGF: basic fibroblast growth factor
EGF: epidermal growth factor
KGF: keratinocyte growth factor; also known as *growth factor 7*
PDGF: platelet-derived growth factor
TGF-α and TGF-β: transforming growth factor
VEGF: vascular endothelial cell growth factor

to fibrin and to themselves in the presence of activated factor XIII, forming a provisional extracellular matrix. This blood clot formation stabilizes the wound's edges and provides limited wound strength. It also provides an immediate barrier to infection and fluid loss and a substrate for early organization of the wound. Scabs form when the blood clot dries; they protect wounds, prevent further hemorrhage, and allow healing to progress beneath their surface. Inflammatory phase cells such as platelets, mast cells, and macrophages secrete growth factors or cytokines, which initiate and maintain the proliferative phase of healing. Inflammatory mediators (i.e., histamine, serotonin, proteolytic enzymes, kinins, prostaglandins, complement, lysosomal enzymes, thromboxane, and growth factors) cause inflammation that begins immediately after injury and lasts approximately 5 days. White blood cells leaking from blood vessels into wounds initiate the debridement phase.

Debridement Phase

An exudate composed of white blood cells, dead tissue, and wound fluid forms on wounds during the debridement phase. Chemoattractants encourage neutrophils and monocytes to appear in wounds (approximately 6 hours and 12 hours after injury, respectively) and initiate debridement. Neutrophils increase in number for 2 to 3 days. They prevent infection and phagocytize organisms and debris. Degenerating neutrophils release enzymes and toxic oxygen products that facilitate breakdown of bacteria, extracellular debris, and necrotic material, and they stimulate monocytes. Monocytes are essential for wound healing; neutrophils are not. Monocytes are major secretory cells synthesizing growth factors that participate in tissue formation and remodeling. Monocytes become macrophages in wounds at 24 to 48 hours. Macrophages secrete collagenases, which remove necrotic tissue, bacteria, and foreign material. They may coalesce and form multinucleated giant cells with phagocytic functions. Macrophages also secrete chemotactic and growth factors. Growth factors (e.g., platelet-derived growth factor, transforming growth factor-α, transforming growth factor-β, fibroblast growth factor, and interleukin-1) can initiate, maintain, and coordinate formation of granulation tissue. Chemotactic factors (e.g., complement, collagen fragments, bacterial endotoxins, and inflammatory cell products) direct macrophages to injured tissue. Macrophages also recruit mesenchymal cells, stimulate angiogenesis, and modulate matrix production in wounds. Platelets release growth factors important for fibroblastic activity. Lymphocytes appear later in the debridement phase than neutrophils and macrophages. They secrete soluble factors that may stimulate or inhibit migration and protein synthesis by other cells. However, they usually improve the rate and quality of tissue repair. Although healing is severely impaired when macrophage function is suppressed, neutropenia and lymphopenia do not inhibit healing or the development of wound tensile strength in sterile wounds.

Repair Phase

The repair phase usually begins 3 to 5 days after injury. Macrophages stimulate DNA and fibroblast proliferation. Cytokines, in concert with extracellular matrix molecules, stimulate fibroblasts in the surrounding tissue to proliferate, express appropriate integrin receptors, and migrate into wounds. Fibroblasts are stimulated by transforming growth factor-β to produce fibronectin, which facilitates cell binding and fibroblast movement. Platelet-derived growth factor and basic fibroblast growth factor are also involved. A tissue oxygen content of approximately 20 mm Hg and slight acidity also stimulate fibroblast proliferation and collagen synthesis. Fibroblasts originate from undifferentiated mesenchymal cells in surrounding connective tissue and migrate to wounds along fibrin strands in the fibrin clot. Fibroblasts migrate into wounds just ahead of new capillary buds as the inflammatory phase subsides (2–3 days). They invade wounds to synthesize and deposit collagen, elastin, and proteoglycans that mature into fibrous tissue. Orientation is initially haphazard, but after 5 days, tension on wounds causes fibroblasts, fibers, and capillaries to orient parallel to the incision or wound margin. Wound fibrin disappears as collagen is deposited. Collagen synthesis is associated with an early increase in wound tensile strength. As the wound matures, there is a notable increase in the ratio of type I (mature) to type III (immature) collagen. The amount of collagen reaches a maximum within 2 to 3 weeks after injury. As the collagen content of a wound increases, the number of fibroblasts and the rate of collagen synthesis decrease, marking the end of the repair stage. The fibroblastic interval of healing lasts 2 to 4 weeks, depending on the nature of the wound. Fibroblast migration and proliferation, collagen production, and capillary ingrowth are delayed if macrophages are absent.

Capillaries invade wounds behind migrating fibroblasts by the process of angiogenesis. Angiogenesis is complex, relying on interaction of extracellular matrix with cytokines that stimulate migration and proliferation of endothelial cells. Stimulus for angiogenesis probably includes macrophage production of mitogenic and chemotactic factors for endothelial cells, and low oxygen tension and increased lactic acid, which affect cytokine production. Basic fibroblast growth factor and vascular endothelial growth factor are specific angiogenic factors. Capillary buds originate from existing blood vessels with columns of capillary endothelial cells migrating toward the site of injury and uniting with other capillary buds or disrupted vessels. New capillaries increase oxygen tension in wounds, augmenting fibroplasia. Mitotic activity in adjacent mesenchymal cells increases as blood begins to flow in new capillaries. Lymphatic channels develop similar to capillary buds but more slowly. Lymphatic drainage of wounds is poor during early healing. The combination of new capillaries, fibroblasts, and fibrous tissue forms bright red, fleshy granulation tissue 3 to 5 days after injury.

Granulation tissue is formed at each wound edge at a rate of 0.4 to 1 mm/day. Unhealthy granulation tissue is white and has a high fibrous tissue content with few capillaries (Figs. 15.1 and 15.2). Granulation tissue fills defects and protects wounds. It provides a barrier to infection, a surface for epithelial migration, and a source of special fibroblasts (i.e., myofibroblasts), which are important in wound contraction. Myofibroblasts are believed to contain proteins (actin and myosin) that contribute to wound contraction. Myofibroblasts are not found in normal tissue, incised and coapted wounds, or tissue surrounding a contracting wound.

FIG. 15.1 An open wound with unhealthy granulation over the right stifle in a 4-year-old Walker Hound.

FIG. 15.2 An open wound on the dorsum of a 9-year-old shih tzu demonstrating healthy granulation tissue and initial stages of epithelialization.

Epithelium is an important barrier to external infection and internal fluid loss. Epithelial repair involves mobilization, migration, proliferation, and differentiation of epithelial cells. *Epithelialization* begins almost immediately (24–48 hours) in sutured wounds with good edge-to-edge apposition because there is no defect for granulation tissue to fill (see Fig. 15.2). Epithelialization begins in open wounds when an adequate granulation bed has formed (usually in 4–5 days). In partial-thickness skin wounds, epidermal migration over the wound surface begins almost immediately from both the wound margins and epidermal appendages, such as hair follicles and sweat glands. Epidermal cells at the margin of the wound undergo a phenotypic alteration that includes retraction on intracellular monofilaments, formation of peripheral cytoplasmic actin filaments, and temporary dissolution of the desmosomes and hemidesmosomes, which release keratinocytes to migrate beneath the eschar at the junction between any remaining necrotic tissue and extracellular matrix of the viable connective tissue. The epidermal cell path of migration is determined by integrins expressed on the membranes of migrating epidermal cells. Chalone, a water-soluble glycoprotein found in the epidermis, inhibits epithelial mitosis in normal tissue but is diminished in wounds, which allows epithelial cells along wound margins to divide and migrate across the granulation tissue. Other growth factors secreted by platelets, macrophages, and fibroblasts may also be involved. Increased basal cell mitotic activity occurs as early as 24 to 48 hours after wounding.

Epithelial migration is random but guided by collagen fibers. Migrating epithelial cells enlarge, flatten, and mobilize, losing their attachments to the basement membrane and other epithelial cells. Basal cells at wound edges develop microvilli and extend broad, thin pseudopodia over the exposed surface of collagen bundles. They develop intracytoplasmic microfilaments and selectively fix antiactin and antimyosin antibodies. Epithelial cells in the layers behind these altered cells migrate over them until they contact the wound surface. Cells continue to slide forward until the wound surface is covered. The migrating cells move under scabs and produce collagenase, which dissolves the base of the scab so it can be shed. Contact on all sides with other epithelial cells inhibits further cell migration (contact inhibition). Initially, new epithelium is only one cell layer thick and fragile, but it gradually thickens as additional cell layers form. After a basement membrane has been established, epithelial cells become plump, develop mitoses, and proliferate, restoring the normal, stratified, squamous epithelium architecture. Some hair follicles and sweat glands may regenerate, depending on the depth of skin damage. Epithelial migration also occurs along suture tracts, which may lead to a foreign body reaction, sterile abscess, scarring, or all of these. Epithelialization of suture tracts can be minimized by early removal of sutures. New epithelium is usually visible 4 to 5 days after injury. Epithelialization occurs faster in a moist environment than in a dry one. It will not occur over nonviable tissue. Epithelial migration is energy dependent and related to oxygen tension. Anoxia prevents epithelial migration and mitosis, whereas hyperbaric oxygen therapy (HBOT) may enhance migration.

Wound contraction reduces the size of wounds subsequent to fibroblasts, reorganizing collagen in granulation tissue and myofibroblast contraction at the wound edge. Contraction occurs simultaneously with granulation and epithelialization but is independent of epithelialization. Wound contraction involves a complex interaction of cells, extracellular matrix, and cytokines. Significant fibroblastic invasion into the wound is necessary for contraction to begin. Centripetal, full-thickness skin edges are pulled inward by contraction, and wounds may be noticeably smaller by 5 to 9 days after injury. The surrounding skin stretches (intussusceptive growth) during wound contraction, and the wound takes on a stellate appearance. Contraction progresses at a rate of approximately 0.6 to 0.8 mm/day. Wound contraction stops when wound edges meet, when tension is excessive, or when myofibroblasts are inadequate. Wound contraction is limited if skin around wounds is fixed, inelastic, or under tension, and it is inhibited if myofibroblast development or function is impaired. Contraction can also be impaired by antiinflammatory steroids, antimicrotubular drugs, and local application of smooth muscle relaxants. If wound contraction stops before granulation tissue is covered, epithelialization may continue and cover the wound.

Maturation Phase

Wound strength increases to its maximum level because of changes in the scar during the maturation phase of wound healing. Wound maturation begins once collagen has been adequately deposited

in wounds (17–20 days after injury) and may continue for years. The cellularity of granulation tissue is reduced as cells die. There is also a reduction in collagen content of the extracellular matrix. Collagen fibers remodel with alteration of their orientation and increased crosslinking, which improves wound strength. Fibers orient along lines of stress. Functionally oriented fibers become thicker. Type III collagen gradually decreases, and type I collagen increases. Nonfunctionally oriented collagen fibers are degraded by proteolytic enzymes (matrix metalloproteinases) secreted by macrophages, epithelial cells, endothelial cells, and fibroblasts within the extracellular matrix. The most rapid gain in wound strength occurs between 7 and 14 days after injury as collagen rapidly accumulates in the wound. Wounds gain only approximately 20% of their final strength in the first 3 weeks after injury. Slower increase in wound strength then occurs, but normal tissue strength is never regained in wounds; only 80% of original strength may be regained. As the number of capillaries in fibrous tissue declines, the scar becomes paler. Scars also become less cellular, flatten, and soften during maturation. Collagen synthesis and lysis occur at the same rate in maturing scars.

Moist Wound Healing

A moist wound environment allows optimal healing. Wound fluid is allowed to remain on the wound, keeping it moist. In a moist environment, debridement is hastened and selective, granulation tissue formation is promoted, and epithelialization is faster. Allowing wound fluid to remain in contact with wounds fosters autolytic debridement by endogenous enzymes that break down necrotic, but not healthy, tissue. Autolytic debridement occurs within 72 to 96 hours under an occlusive bandage. White blood cell phagocytosis decreases bacterial load and removes necrotic debris. White blood cells migrate more readily in a moist environment. Wound fluid also contains cytokines and growth factors that stimulate granulation tissue, angiogenesis, and reepithelialization. Chemotactic factors in wound fluid attract neutrophils and macrophages that secrete additional enzymes, cytokines, and growth factors. Moist wounds limit infections because more white blood cells are found in the wound, and there is improved phagocytosis and a lower pH. Scabs do not form with moist wound healing; therefore white blood cells are not trapped in the scab, and topical medications better penetrate the wound. If the animal is receiving systemic antibiotics, wound fluids may contain antibiotics, which help prevent or control infection. Low oxygen tension under an occlusive bandage stimulates macrophage activity, fibroblast proliferation, and capillary ingrowth. The rate of epithelialization is twice as fast for wounds kept moist with occlusive dressings than for air-exposed wounds. Epithelial cells travel faster and have a shorter distance for epithelialization to occur in moist environments; in air-exposed wounds, migrating epidermal cells must travel beneath a crusted scab and devitalized dermis to reach their destination. Hydrophilic, occlusive, or semiocclusive bandages help keep a wound warm and moist. Increased warmth enhances enzymatic activity. A moist wound is less painful and pruritic, tissues do not desiccate, and scar formation is less. Potential disadvantages of moist wound healing include bacterial colonization (not infection) of the wound surface, folliculitis, and maceration of the wound border.

Host Factors Affecting Wound Healing

Old animals tend to heal slowly, often because of concurrent disease or debilitation. Malnourished animals and those with serum protein concentrations below 1.5 to 2 g/dL may have delayed wound healing and diminished wound strength. Hepatic disease may cause clotting factor deficiencies. Hyperadrenocorticism delays wound healing because of excess circulating glucocorticoids. Animals with diabetes mellitus have delayed wound healing and a predisposition to wound infections. Uremia occurring within 5 days of injury impairs healing by altering enzyme systems, biochemical pathways, and cellular metabolism. Obesity is associated with a higher incidence of postoperative wound infections in human beings. The risk of postoperative wound infection in dogs and cats also increases as the duration of anesthesia increases.

Cutaneous wounds are slower to heal in cats than dogs. Sutured wounds in cats are only half as strong as similar wounds in dogs after 7 days of healing. Cat wounds that are allowed to heal by secondary intention heal slower, produce less granulation tissue (that is more peripherally located), and heal more by contraction of wound edges than dogs.

Wound Characteristics Affecting Wound Healing

Intact surfaces, such as periosteum, fascia, tendon, and nerve sheath, do not support granulation tissue; therefore these surfaces heal slowly when exposed. Fenestration or drilling holes in exposed cortical bone may improve granulation by releasing osteogenic or other factors. Foreign material in wounds (e.g., dirt, debris, sutures, surgical implants) can cause intense inflammatory reactions interfering with normal wound healing. Release of enzymes designed to degrade foreign bodies destroys wound matrix, prolongs inflammation, and delays the fibroblastic phase of tissue repair. Exposure of the wound to antiseptics delays healing and may predispose to infection. Warmth (30°C [86°F]) allows wounds to heal more quickly and with greater tensile strength than if they are at room temperature. A moist wound promotes recruitment of vital host defenses and cells, encouraging wound healing. Bandages help keep wounds warm and moist. Wounds (incisions) created with sharp surgical instruments heal faster and with less necrosis at the wound margin than those made with scissors, electrosurgery, or lasers. Wound infection interferes with the repair phase of healing. Contaminated tissues become infected if invasive bacteria multiply to 10^5 colony-forming units (CFU) per gram of tissue. Development of wound infection depends on the degree of tissue trauma, amount of foreign material present, delay between injury and treatment, and effectiveness of host defenses. Bacterial toxins and associated inflammatory infiltrates cause cell necrosis and vascular thrombosis. Wound exudates can separate tissue layers and further delay healing. Inflammation caused by infection further compromises vasculature, causing additional necrosis.

Healing depends on blood supply, which delivers oxygen and metabolic substrates to cells. Impairment of blood supply by trauma, tight bandages, or wound movement slows healing. Macrophages resist hypoxia, but epithelialization and fibroblastic protein synthesis are oxygen dependent. Collagen synthesis requires 20 mm Hg partial pressure of oxygen (pO_2). HBOT increases tissue oxygen and produces more rapid gains in wound strength. Accumulation of fluid in dead space delays healing because the hypoxic fluid environment of a seroma inhibits migration of reparative cells into wounds. Fluid mechanically prevents adhesion of flaps or grafts to the wound bed.

Recruitment, proliferation, and cellular function in wound healing are controlled by growth factors; proteins synthesized and released by cells are involved in wound healing. Numerous

growth factors have been identified, including platelet-derived growth factor, epidermal growth factor, fibroblast growth factor, and type-transforming growth factor. Platelet-derived growth factors are found in granules, whereas macrophages must be stimulated to synthesize and release growth factors.

Fibronectins are glycoproteins critical to wound healing. They stimulate cell attachment and migration and are found in soluble form in plasma and in insoluble form in connective tissue matrix. Macrophages, endothelium, fibroblasts, and epithelium synthesize and release fibronectin. Fibronectin in the coagulum probably assists initial migration of cellular elements (macrophages and epithelium) into wounds. It binds bacterial cell wall components, collagen, actin, thrombospondin, heparan sulfate, hyaluronic acid, fibrin, cell surface receptors, and other fibronectin molecules. Fibronectin may also be important in providing an early wound-healing matrix and in interlinking cellular and matrix components during healing. Fibronectin in wounds declines as healing nears completion. Proteoglycans are also important in all phases of wound healing. The matrix during cell migration contains elevated concentrations of nonsulfated glycosaminoglycans (i.e., hyaluronate). As wound maturation progresses, more sulfated glycosaminoglycans (i.e., chondroitin sulfate and heparan sulfate) appear.

External Factors Affecting Wound Healing

Radiation therapy (see p. 242) and some drugs delay wound healing. Glucocorticoids depress all phases of wound healing and increase chances of infection. Vitamin A and anabolic steroids may reverse the effects of glucocorticoids on wound healing. Antiinflammatory drugs suppress inflammation but have little effect on wound strength. Aspirin may delay blood clotting. Most chemotherapeutic drugs (e.g., cyclophosphamide, methotrexate, and doxorubicin) inhibit wound healing. Radiation therapy can profoundly inhibit wound healing, depending on dose and time of exposure relative to the time of injury. It reduces the quantity of blood vessels, affects collagen maturation, and causes increased dermal fibrosis. Therefore chemotherapeutic drugs and radiation therapy should be avoided for 2 weeks after surgery. Vitamin A, vitamin E, and aloe vera may promote healing in irradiated wounds. Exposure to pico-tesla electromagnetic field treatment improves strength of sutured wounds and speeds contraction of open wounds in rats. HBOT increases dissolved oxygen in plasma, which stimulates growth of new capillaries; therefore it may be useful for treatment of ischemic wounds. Ultrasonography and phototherapy (low-powered laser) shorten the inflammatory phase of healing and enhance the release of factors that stimulate the proliferative stage of repair. Use of controlled subatmospheric pressure dressings helps remove interstitial fluid, which allows tissue decompression, helps remove tissue debris, and promotes wound healing (see p. 192).

MANAGEMENT OF OPEN OR SUPERFICIAL WOUNDS

Wounds should be covered with a clean, dry bandage immediately after injury or when the animal is brought for treatment to prevent further contamination and hemorrhage (Box 15.2). Life-threatening injuries should be treated and the animal's condition stabilized before further wound management is undertaken. When appropriate during stabilization, bandages should be removed and the wound assessed and classified as either contaminated or infected and as an abrasion, laceration, avulsion, puncture, crush, or burn wound. The "golden period" is the first 6 to 8 hours between wound contamination at injury and bacterial multiplication to greater than 10^5 CFU per gram of tissue. A wound is classified as infected rather than contaminated when bacterial numbers exceed 10^5 CFU per gram of tissue. Infected wounds are often dirty and covered with a thick, viscous exudate.

BOX 15.2 Fundamentals of Wound Management

- Temporarily cover the wound to prevent further trauma and contamination.
- Assess the traumatized animal and stabilize its condition.
- Clip and aseptically prepare the area around the wound.
- Culture the wound.
- Debride dead tissue and remove foreign debris from the wound.
- Lavage the wound thoroughly.
- Provide wound drainage.
- Promote healing by stabilizing and protecting the cleaned wound.
- Perform appropriate wound closure.

Abrasions are superficial and involve destruction of varying depths of skin by friction from blunt trauma or shearing forces. Abrasions are sensitive to pressure or touch and bleed minimally. A *laceration* is created by tearing, which damages skin and underlying tissue. Lacerations may be superficial or deep and have irregular edges. *Avulsion wounds* are characterized by the tearing of tissues from their attachments and the creation of skin flaps. Avulsion injuries on limbs with extensive skin loss are called *degloving injuries*. A *penetrating* or *puncture wound* is created by a missile or sharp object, such as a knife, pellet, or tooth that damages tissue. Wound depth and width vary depending on the velocity and mass of the object creating the wound. The extent of tissue damage is directly proportional to missile velocity. Pieces of hair, skin, and debris can be embedded in wounds. *Crush injuries* can be a combination of other types of wounds with extensive damage and contusions to skin and deeper tissue. *Burns* may be partial- or full-thickness skin injuries caused by heat or chemicals (see p. 237).

Wounds less than 6 to 8 hours old with minimal trauma and minimal contamination can be treated by lavage, debridement, and primary closure. In general, the sooner treatment begins, the better the prognosis. Penetrating wounds should not be primarily apposed without surgical exploration (see p. 243). Severely traumatized and contaminated wounds, wounds older than 6 to 8 hours, or infected wounds should be treated as open wounds to allow debridement and reduction of bacterial numbers. Most wounds are surgically apposed after infection has been controlled; however, some wounds heal by contraction and epithelialization (healing by secondary intention).

NOTE Penetrating wounds, particularly bite wounds, should not be closed primarily without surgical exploration and debridement.

Often sedation or anesthesia is required for initial wound inspection and care. The objective of open wound care is to convert the open, contaminated wound into a surgically clean wound that can be closed. Aseptic technique, gentle tissue handling, and hemostasis are essential. Severely contaminated or infected wounds should be cultured after initial inspection. The area

surrounding the wound should be widely clipped and prepped. The wound may be protected from clipped hair and detergents by applying a sterile, water-soluble lubricant (K-Y Jelly) or by placing saline-soaked sponges in the wound and covering with a sterile pad or towel. As an alternative, the wound may be temporarily closed with sutures, towel clamps, staples, or Michel clips. Hair may be clipped from the wound margin with scissors dipped in mineral oil to prevent hair from falling into the wound. Povidone-iodine or chlorhexidine gluconate skin scrubs are used to prepare clipped skin. The detergents in antiseptic scrubs cause irritation, toxicity, and pain in exposed tissue and may potentiate wound infection. Alcohol is very damaging to exposed tissue and should be used only on intact skin.

Initial wound management begins with removal of gross contaminants and copious lavage using a warm, balanced electrolyte solution, sterile saline, or tap water (500–1000 mL) (Table 15.1). Sterile isotonic saline or a balanced electrolyte solution (lactated Ringer's solution) are the preferred lavage solutions. No one type of fluid has been shown to be preferred in preventing wound infection. Tap water is effective and less detrimental than distilled or sterile water, although it causes some mild hypotonic tissue damage (cellular and mitochondrial swelling). Wound lavage reduces bacterial numbers mechanically by loosening and flushing away bacteria and associated necrotic debris. Lavage may be facilitated by the use of noncytotoxic wound cleansers (e.g., Vetericyn Plus). In general, these cleansers are applied to loosen debris and soften necrotic tissue during bandage changes; they act as a surfactant, disrupting the ionic bonding of particles and organisms to the wound and allowing them to be easily rinsed off with saline or balanced electrolyte solutions. Lavage following application of these cleansers, however, is not necessary. Antibiotics or antiseptics (e.g., chlorhexidine or povidone-iodine; see p. 188) in the lavage solution reduce bacterial numbers; however, these agents may damage tissue. Antiseptics have little effect on bacteria in established infections. However, tris–ethylenediaminetetraacetic acid (tris-EDTA) may be added to lavage solutions to help lyse gram-negative bacteria, such as *Pseudomonas aeruginosa, Escherichia coli*, and *Proteus vulgaris*, and may have synergistic effects with certain systemic antibiotics. Lavaging is preferred to scrubbing the wound with sponges. Sponges inflict tissue damage that impairs the wound's ability to resist infection and allows residual bacteria to elicit an inflammatory response.

Bacteria are effectively removed from the wound surface by high-pressure lavage. Traditionally, a 35- or 60-mL syringe and an 18-gauge needle have been thought to generate approximately 7 to 8 psi of pressure; however, it has been shown that it generates pressures substantially higher than this (18.4 ± 9.8 psi).[1] The most consistent delivery method to generate 7 to 8 psi is a 1-L bag of fluid within a cuff pressurized to 300 mm Hg (Fig. 15.3). Higher pressure (70 psi), generated by pulsatile lavage instruments (i.e., Water Pik, Surgilav, or Pulsavac debridement system), is more effective in reducing bacterial numbers and removing foreign debris and necrotic tissue, but it may drive bacteria and debris into loose tissue planes, damage underlying tissue, and reduce resistance to infection. Bulb syringes or fluid bottles with

TABLE 15.1 Suggested Wound Cleansers

Cleanser	Advantages	Disadvantages
Commercial cleansers (e.g., Vetericyn Plus)	Surfactant breaks the bonds between foreign bodies and the wound surface Convenient	Most ionic surfactants and many nonionic surfactants have been shown to be toxic to cells, delay wound healing, and inhibit the wound's defense mechanisms Expense
Tap water	Availability Low cost Ease of application	Hypotonic Cytotoxic trace elements Not antimicrobial
Balanced electrolyte solution: LRS, Normosol	Isotonic Least cytotoxic	Not antimicrobial
Normal (0.9%) solution	Isotonic	Slightly more acidic than LRS Not antimicrobial
0.05% Chlorhexidine (1 part stock solution to 40 parts sterile water or LRS) or (~25 mL stock solution per liter)	Wide antimicrobial spectrum Good residual activity Not inactivated by organic matter	Precipitates in electrolyte solutions More concentrated solutions are cytotoxic and may slow granulation tissue formation *Proteus, Pseudomonas,* and *Candida* are resistant Corneal toxicity
0.05% Chlorhexidine with Tris-EDTA	Makes bacteria more susceptible to destruction by lysozymes, antiseptics, and antibiotics. Rapidly lyses *P. aeruginosa, E. coli,* and *Proteus vulgaris* Increases antimicrobial effectiveness approximately 1000-fold	Precipitates in electrolyte solutions More concentrated solutions are cytotoxic and may slow granulation tissue formation Corneal toxicity
0.1% povidone-iodine (1 part stock to 100 parts LRS) or (~10 mL stock to 100 mL LRS)	Wide antimicrobial spectrum	Inactivated by organic matter Limited residual activity Cytotoxic at concentrations >1% Contact hypersensitivity Thyroid disorders if absorbed

EDTA, Ethylenediaminetetraacetic acid; *LRS,* lactated Ringer's solution.

FIG. 15.3 Wound lavage of the dog from Fig. 15.1 using 1 L of 0.9% saline in pressure bag, maintained at 300 mm Hg with extension tubing and an 18-gauge needle.

holes made in the cap do not generate enough pressure to remove bacteria and debris adequately.

Debridement

Healing is delayed if necrotic tissue is left in the wound. Devitalized tissue is removed from the wound by debridement. Debridement involves removal of dead or damaged tissue, foreign bodies, and microorganisms that compromise local defense mechanisms and delay healing. The goal of debridement is to obtain fresh clean wound margins and wound bed for primary or delayed closure. Devitalized tissue is removed by surgical excision, autolytic mechanisms, enzymes, wet-dry bandages (see p. 197), or biosurgical methods. The extent of devitalized tissue is usually obvious within 48 hours of injury.

Surgical Debridement

Devitalized tissue should be surgically excised in layers beginning at the surface and progressing to the depths of the wound. This can be done by sharp dissection, electrosurgery, or laser. Bones, tendons, nerves, and vessels must be preserved, but bone sequestra should be removed because they may prevent complete granulation of the wound (especially with metacarpal and metatarsal degloving injuries) and predispose the wound to infection. Muscle should be debrided until it bleeds and contracts with appropriate stimuli. Extensive debridement of subcutaneous tissue should be avoided as it may delay wound healing, particularly in cats, and may place wounds at a higher risk for infection. Contaminated fat should be liberally excised because it is easily devascularized and harbors bacteria, but cutaneous vessels must be spared to maintain the viability of overlying skin.

As an alternative, the entire wound can be excised en bloc if sufficient healthy tissue surrounds the wound and vital structures can be preserved. The danger of surgical debridement is removal of an excessive amount of possibly viable tissue. With penetrating wounds or punctures, it may be necessary to enlarge the wound to assess the extent of injury and allow debridement. Electrosurgery or a carbon dioxide laser can be as effective as sharp surgical debridement of devitalized tissue. They have the advantage of providing simultaneous hemostasis, which helps prevent debridement of normal tissue. Low-level laser therapy (LLLT) has been advocated to stimulate wound healing in chronic wounds by shortening the inflammatory phase and enhancing the release of factors that stimulate the proliferative stage of repair. Increased collagen deposition and endothelial cell, fibroblast, and myofibroblast proliferation are the most significant effects.

Surgical debridement of obviously devitalized tissue is often combined with autolytic debridement (discussed later) to remove surface contaminants and tissue of questionable viability. After surgical debridement, wounds are often treated as open wounds with hydrophilic dressings and bandages. Provision of adequate wound drainage and a viable vascular bed is important to wound healing. The wound should be closed when it appears healthy or when a bed of healthy granulation tissue has formed, unless wound closure by contraction and epithelialization is anticipated.

Autolytic Debridement

Autolytic debridement is accomplished through creation of a moist wound environment to allow endogenous enzymes to dissolve nonviable tissue. It is often preferred over surgical or bandage debridement in wounds with questionable tissue viability, as it is highly selective for devitalized tissue and markedly less painful than other methods of debridement; however, it is a much slower process. Autolytic debridement is accomplished with hydrophilic, occlusive, or semiocclusive bandages (see pp. 195–196), which allow wound fluid to remain in contact with nonviable tissue.

Bandage (Mechanical) Debridement

Dressings that are allowed to dry on the wound, such as wet-to-dry bandages or dry-to-dry bandages, adhere to the wound surface and pull the debris and strip the superficial layers off the wound bed when removed. In addition to mechanical debridement, wet-to-dry wound dressings provide adequate wound protection and coverage, maintain a moist wound environment, and absorb moderate amounts of wound exudates. These dressings are most effective in early stages of wound healing or in the management of wound infection. However, debridement is painful and nonselective, as healthy or healing tissue may be traumatized. Because of these disadvantages, as well as the availability of other methods of wound debridement, these bandages are not recommended by some. However, wet-to-dry bandages are a very economic and effective dressing in the first few days of open wound care.

Enzymatic Debridement

Enzymatic debriding agents are used as an adjunct to wound lavage and surgical debridement. They are beneficial in patients that are poor anesthetic risks or when surgical debridement may damage healthy tissue necessary for reconstruction. Enzymatic agents break down necrotic tissue and liquefy coagulum and bacterial biofilm, allowing better antibiotic contact with wounds and enhanced exposure for development of cellular and humoral immunity; they do not damage living tissue if used properly. Available enzymes do not digest burned skin, necrotic bone, and connective tissue. Enzymes must remain in contact with the wound for an adequate time to produce the desired effect; therefore these products are slow to work and can be expensive. Local tissue irritation may also occur.

Collagenase-based products (e.g., Santyl) are effective for enzymatic debridement and are used in human wounds, specifically decubital ulcers, pressure sores, and burn wounds. More

familiar products to veterinary surgeons, such as Granulex and Accuzyme, among others, are no longer available due to safety concerns.

Biosurgical Debridement

Maggot therapy using greenbottle fly larvae (*Lucilia sericata*) debrides wounds as the maggots secrete proteolytic digestive enzymes into the wound. Sterile medicinal maggots are bred specifically for biosurgery. A single maggot may consume up to 75 mg of necrotic tissue each day. They require an optimal temperature, an oxygen supply, and a moist wound. Maggot therapy is best suited to necrotic, infected, or chronic nonhealing wounds. The maggots remove necrotic tissue, disinfect the wound, and promote granulation tissue formation. Medicinal maggots are applied to the wound at a density of five to eight per square centimeter. A hole is cut into a self-adhesive hydrocolloid dressing that matches the wound dimensions. This dressing is applied to the wound to prevent the maggots from crawling onto intact skin and to absorb wound secretions. The dressing is covered to trap the maggots in the wound, changing absorbent layers as necessary. Maggots are usually applied for two 48-hour cycles each week.

ANTIBIOTICS

Selective use of antibiotics may help prevent or control integument infections after injury or surgery. Minimally or moderately contaminated wounds less than 6 to 8 hours old may be cleaned and closed or treated without antibiotics. Severely contaminated, crushed, or infected wounds, or wounds older than 6 to 8 hours, typically benefit from antibiotic therapy. Contaminated wounds and those with established infection should be cultured before antibiotics are given, and antibiotic selection should ultimately be based on culture and susceptibility testing. Ideally, quantitative bacterial counts should be performed before grafts or flaps are placed over granulating wounds. Reconstruction should be delayed if bacterial counts are greater than 10^5 CFU per gram of tissue.

Systemic antibiotics should be given if there is a high risk of bacteremia or disseminated infection. A broad-spectrum antibiotic should be administered while awaiting culture and antimicrobial susceptibility results. Antibiotic blood levels should be present at the time of surgery when antibiotics are used prophylactically for clean or clean contaminated procedures. Prophylactic antibiotics are optimally given intravenously 30 minutes prior to the surgical incision being made (see Chapter 9). Contamination occurring during surgery is usually limited to the patient's skin flora; therefore drugs effective against gram-positive skin flora, especially *Staphylococci* spp. (see p. 80), should be selected (e.g., 22 mg/kg cefazolin given intravenously).

TOPICAL WOUND MEDICATIONS

Topical Antimicrobials and Antibiotics

Antimicrobial agents and antibiotics eliminate or reduce the number of microorganisms that destroy tissue in a wound. Topical rather than systemic antibiotics are preferred for open wounds. Mildly or moderately contaminated wounds do not benefit from combined topical and systemic antibiotic therapy; however, combined therapy is advantageous in heavily contaminated wounds. Antibiotics applied within 1 to 3 hours of contamination often prevent infection. Benefits of topical drugs should outweigh their cytotoxic effects. Antibiotics used effectively as topical ointments or added to lavage solutions are penicillin, ampicillin, carbenicillin, tetracycline, kanamycin, neomycin, bacitracin, polymyxin, and cephalosporins. Once infection is established, topical and systemic antibiotics have no beneficial effect in preventing suppuration of wounds undergoing closure. Wound coagulum prevents topical antibiotics from reaching effective levels in tissues deep in the wound and also prevents systemic antibiotics from reaching superficial bacteria. These wounds must be debrided to allow antimicrobial access to bacteria.

Advantages of topical antibiotics over antiseptics in wound management include selective bacterial toxicity, efficacy in the presence of organic material, and combined efficacy with systemic antibiotics. Disadvantages include expense, narrower antimicrobial spectrum, potential for bacterial resistance, creation of superinfections, systemic or local toxicity, hypersensitivity, and increased nosocomial infections. Antibiotic solutions are preferable to ointments and powders. Ointments liberate antibiotics slowly and may be occlusive, promoting growth of anaerobic bacteria. Powders act as foreign bodies and should not be used.

Triple Antibiotic Ointment

Triple antibiotic ointment (bacitracin, neomycin, polymyxin) is effective against a broad spectrum of pathogenic bacteria commonly infecting superficial skin wounds. However, its efficacy against pseudomonads is poor. Zinc bacitracin is responsible for enhancing reepithelialization of wounds but can retard wound contraction. Because these drugs are poorly absorbed, systemic toxicosis (nephrotoxicity, ototoxicity, neurotoxicity) is rare. The ointment is more effective for preventing infections and treating mildly infected wounds.

Silver Sulfadiazine

Silver sulfadiazine in a 1% water-miscible cream or ointment (Thermazene, Silvadene) is effective against most gram-positive and gram-negative bacteria and most fungi. It also serves as an antimicrobial barrier, can penetrate necrotic tissue, and enhances wound epithelialization. It is thought to be the drug of choice to treat burn wounds; however, in one study of partial-thickness burn wounds in people, honey dressings were found to be superior to silver sulfadiazine ointment. In vitro toxicity to human keratinocytes and fibroblasts and inhibition of polymorphonuclear cells and lymphocytes has been shown. These wound-retardant effects of silver sulfadiazine are reversed when it is combined with aloe vera. Silver-impregnated dressings are also available and preferred by some due to less discomfort and less frequent bandage changes (see p. 200). Ointments remain effective for up to 3 days, whereas dressings may be left in place for 7 days. Only a small amount of silver is released slowly from its molecular lattice over a sustained period, reducing cytotoxic effects of ionic silver and making it nonstaining, nonirritating, and nonsensitizing while maintaining its antimicrobial effects. These products are also hydrophilic, helping to maintain a moist wound environment and absorbing exudates.

Nitrofurazone

Nitrofurazone (Furacin) has broad-spectrum antibacterial and hydrophilic properties. It has little effect against *Pseudomonas* spp. Its polyethylene base gives it hydrophilic properties, enabling it to draw body fluid from wound tissue, which helps dilute tenacious exudates so they can be absorbed into bandages. Nitrofurazone delays wound epithelialization. It loses some of its antibacterial effects in the presence of organic matter.

Gentamicin Sulfate

Gentamicin sulfate is available as a 1% ointment or powder (Garamycin), but solutions are preferred. Products with an oil-in-water cream base slow wound contraction and epithelialization. It is especially effective in controlling gram-negative bacterial growth (*Pseudomonas* spp., *Escherichia coli*, *Proteus* spp.). It is often used before and after grafting and for wounds that have not responded to triple antibiotic ointment. However, gentamicin in an isotonic solution does not inhibit contraction, and it promotes epithelialization.

Cefazolin

Cefazolin is an effective antimicrobial against gram-positive and some gram-negative organisms. Topical cefazolin (the combined systemic and topical dose should not exceed 22 mg/kg) provides high levels of antibiotic in wound fluid. The drug's minimum inhibitory concentration is prolonged in wounds when it is applied topically compared with systemic administration. Topically administered cefazolin is 95% bioavailable and rapidly absorbed; therefore systemic levels equal wound fluid levels within 1 hour.

Mafenide

Mafenide (hydrochloride or acetate) is a topical sulfa compound available as an aqueous spray most commonly used for burn wounds in humans. It has a broad spectrum against many gram-positive and gram-negative bacteria, including *Pseudomonas* spp., *Clostridium* spp., and methicillin-resistant *Staphylococcus aureus*; it is particularly useful on severely contaminated wounds.

Topical Wound-Healing Enhancers

Many topical agents have been used in the management of open wounds, some with documented benefit and others without. Unfortunately, there is a lack of well-controlled prospective studies in the veterinary literature to determine ideal agents to promote wound healing in dogs and cats.

Aloe Vera

Aloe vera gel is extracted from the aloe vera leaf and contains 75 potentially active constituents. Aloe vera has been used on burns because of its antibacterial activity against *Pseudomonas aeruginosa.* It also inhibits fungal growth. The antiprostaglandin and antithromboxane properties of aloe vera medications are beneficial in maintaining vascular patency and thus helping avert dermal ischemia. Aloe vera medications may also stimulate fibroblastic replication. Aloe vera has the ability to penetrate and anesthetize tissue. Acemannan, a component of aloe vera extract gel, promotes wound healing (see later discussion). It is also found in other preparations. Allantoin, another component of aloe vera extract gel, stimulates tissue repair in suppurating wounds and resistant ulcers by promoting epithelial growth. Use on full-thickness wounds is discouraged because of its antiinflammatory effects. Aloe vera counteracts the inhibitory effects of silver sulfadiazine when the two are combined.

Acemannan

Acemannan is available as a topical wound hydrogel or a freeze-dried gel form. It is indicated for managing superficial and deep partial-thickness burns, lacerations, dermal ulcers, abrasions, and nonhealing wounds. Acemannan is a β-(1,4) acetylated mannan derived from the aloe vera plant that enhances early stages of healing. Acemannan stimulates macrophages to secrete interleukin-1 (IL-1) and tumor necrosis factor alpha (TNF-α), which enhance fibroblast proliferation, neovascularization, epidermal growth and motility, and collagen deposition to form granulation tissue. Acemannan may also bind growth factors, prolonging their stimulating effect on formation of granulation tissue. The freeze-dried form enhances healing over exposed bone and has hydrophilic properties, which help cleanse the wound and reduce wound edema. The most effective time to begin topical application is in the early inflammatory stage of healing with daily application under a bandage, continuing into the repair stage of healing. The greatest effects are seen in the first 7 days of application. Excess granulation tissue can occur, especially with the freeze-dried form, which inhibits wound contraction.

Tripeptide-Copper Complex

Glycyl-L-histidyl-lysine tripeptide-copper complex (Iamin) stimulates wound healing and is a chemoattractant for mast cells, monocytes, and macrophages, which stimulate debridement, angiogenesis, collagen synthesis, and epithelialization. Enzymes involved in collagen crosslinking need copper. The best time to begin tripeptide-copper complex application is the late inflammatory and early repair phases, with treatment continuing into the later repair phase. It has been effective in accelerating wound healing in chronic, ischemic open wounds. Its greatest effect is in the first 7 days of its use. Exuberant granulation tissue may be a problem with this agent.

Maltodextrin

Maltodextrin (Multidex) is a D-glucose polysaccharide; it is available in a hydrophilic powder or gel form containing 1% ascorbic acid for use on contaminated and infected wounds as a wound healing stimulant. It is reported to stimulate healing by supplying glucose for cell metabolism via hydrolysis of its polysaccharide component. Its hydrophilic property draws fluid through the tissue, keeping it moist. Maltodextrin is chemotactic and pulls neutrophils, lymphocytes, and macrophages into the wound. Maltodextrin also has antibacterial and bacteriostatic properties. It reduces odor, exudates, swelling, and infection, and it may enhance early granulation tissue formation and epithelialization. After debridement and lavage, a 5- to 10-mm layer of maltodextrin is applied to the wound and covered with a bandage from the early inflammatory stage into the repair stage of healing. Daily bandage changes, lavage, and reapplication are recommended.

Honey

Honey is an old agent that has seen renewed interest. Proposed benefits include enhancing wound debridement, reducing edema and inflammation, promoting granulation tissue formation and epithelialization, and improving wound nutrition (Box 15.3). It

BOX 15.3 Benefits of Honey in Wound Healing

- Reduces edema
- Reduces inflammation
- Accelerates wound debridement
- Promotes granulation tissue formation
- Accelerates epithelization
- Antimicrobial

has a wide antibacterial effect through its enzymatic production of hydrogen peroxide from glucose, hypertonicity, low pH, inhibin content, and other unidentified components. Honey increases collagen content, accelerates collagen maturation resulting from crosslinking, and maintains optimal pH conditions for fibroblast activity. Honey contains a wide range of amino acids, vitamins, and trace elements, in addition to readily assimilable sugars that stimulate tissue growth. Honey should be used early in the course of wound healing and discontinued once a healthy granulation bed is present. Honey can also be used for treating partial-thickness burns and may have greater wound healing properties than silver-based preparations.

Specific preparations of unpasteurized medicinal honey are recommended for wound care (e.g., Medihoney, Therahoney, Manuka Honey AD). Honey is applied by impregnating sterile gauze, which is then positioned on the wound and covered with a thick, absorbent bandage. Alternatively, it can be applied as a gel or paste and covered with a nonadherent dressing. The wound is rebandaged one to three times a day depending on the amount of strikethrough.

Sugar

Sugar has similar hypertonic and hyperosmolar effects to honey and also attracts macrophages, accelerates sloughing of devitalized tissue, provides a cellular energy source, and promotes formation of a healthy granulation bed. Granulated sugar is applied in a 1-cm-thick layer, and absorbent bandages are placed to absorb the excess wound fluid. The bandage is changed one to three times a day depending on the amount of strikethrough. Alternatively, a sugar paste made of castor sugar, icing sugar, glycerin, and hydrogen peroxide can be used instead of granulated sugar.

Growth Factors

Application of growth factors to stimulate more rapid healing has been investigated. Application of growth factors assumes the wound is deficient in specific growth factors. Knowing which factor is deficient in what amount at what time is nearly impossible in the complex healing process. Evidence indicates that applying single growth factors to wounds is not as effective as the combination of growth factors that the body produces. Allowing these factors to remain on the wound in the wound fluid under an occlusive or semiocclusive bandage is preferred to adding exogenous growth factors. A few growth factors are available commercially, including recombinant human-derived platelet-derived growth factor (Regranex), but efficacy studies in dogs and cats have yet to be performed.

Platelet-derived products. Platelet-rich plasma (PRP) contains a high concentration of platelets and is, therefore, rich in growth factors and cytokines and could be useful in improving wound healing (see Chapter 31). PRP has been evaluated in both equine and canine models with equivocal results. As a result, topical application of autologous PRP is thought to be best utilized in wounds with massive tissue loss or in chronic wounds for a fresh-source of mediators.

Hydrolyzed bovine collagen. Hydrolyzed bovine collagen (Woun'Dres Collagen Hydrogel, Collasate) has hydrophilic properties that help create a moist environment for autolytic debridement in early phases of wound healing and an optimal environment for epithelialization in latter stages. There is little histologic evidence of an inflammatory reaction in dogs. The collagen matrix provided serves as a lattice for ingrowth of fibroblasts, thus facilitating the repair phase of wound healing. It is probably most effective when used in the late inflammatory and early repair phases of healing to accelerate epithelialization.

Chitosan

Chitosan (HemoCon) is a polysaccharide derived from the chitin exoskeleton of shellfish. The active ingredient, glucosamine, is reported to enhance the function of inflammatory cells, growth factors, and fibroblasts to promote formation of granulation tissue and accelerate wound healing. These dressing are hemostatic and antibacterial. Information regarding the use of chitosan in veterinary medicine is limited.

WOUND CLEANSING SOLUTIONS

Wound cleansing solutions should have ideal antiseptic properties with minimal cytotoxicity. They are used primarily in the initial phases of wound management to decrease bacterial load and rid wounds of necrotic tissue and debris. Once the wound is clean, balanced electrolyte or physiologic saline solutions are ideal for irrigating it (see Table 15.1). Tap water (not distilled) is not an ideal wound cleanser, but is acceptable to initially remove dirt and debris when there is severe contamination. Tap water's hypotonicity causes cell swelling, which can cause significant cell destruction and delay wound healing with prolonged use. Antiseptic solutions are used early in wound management to reduce bacterial numbers and reduce chances of infection. They are contraindicated in clean wounds because all antiseptics have some cytotoxic effects and may be more damaging than beneficial to wound healing.

Commercial Wound Cleansers

Read the label carefully when selecting a commercial wound cleanser; many are a combination of agents that are contraindicated for use in wounds because of cytotoxic effects. Some ingredients to avoid include hydrogen peroxide, sodium hypochlorite, and hydrochlorous acid. The cleansing activity of many of the commercially available cleansers depends on a surfactant that breaks the bonds between foreign bodies and the wound surface. Most ionic surfactants and many nonionic surfactants are toxic to cells, delay wound healing, and inhibit the wound's defense mechanisms. An example of an available commercial wound cleanser is Vetericyn Plus.

Chlorhexidine Diacetate

The preferred antiseptic solution for wound lavage is 0.05% chlorhexidine diacetate because of its wide spectrum of antimicrobial activity and sustained residual activity. It has antibacterial activity in the presence of blood and other organic debris, has minimal systemic absorption and toxicity, and promotes rapid healing. A 0.05% solution is created by diluting one part of 2% stock solution with 40 parts of sterile water. Chlorhexidine forms heavy precipitates in electrolyte solutions, but this neither delays wound healing nor interferes with antibacterial activity. More potent solutions may slow the formation of granulation tissue with prolonged wound contact. Residual activity may last as long as 2 days, and effectiveness increases with repeat application. Potential drawbacks of chlorhexidine include resistance to *Proteus, Pseudomonas,* and *Candida,* as well as corneal toxicity.

Povidone-Iodine

A 1% or 0.1% povidone-iodine solution (10% stock solution diluted 1:10 or 1:100, respectively) is used frequently for wound lavage

because of its wide spectrum of antimicrobial activity. Iodine compounds are active against vegetative and sporulated bacteria, fungi, viruses, protozoa, and yeasts. A 0.1% solution is recommended. This concentration kills bacteria within 15 seconds, and there is no known bacterial resistance. Povidone-iodine is a water-soluble, strongly acidic (pH 3.2) iodophor produced by combining molecular iodine with polyvinylpyrrolidone. Frequent reapplication (every 4–6 hours) is required when it is used as a wetting solution because residual activity lasts only 4 to 8 hours, and organic matter (i.e., blood and serous exudate) inactivates the free iodine in povidone-iodine. Iodine absorption through the skin and mucous membranes may cause excess systemic iodine concentrations and transient thyroid dysfunction. The low pH of povidone-iodine can cause or intensify metabolic acidosis when the solution is absorbed. Scrubbing wounds with povidone-iodine detergents damages tissue and potentiates infection. Contact hypersensitivities may occur in as many as 50% of dogs scrubbed with povidone-iodine compounds. Povidone-iodine at 0.5% is cytotoxic to fibroblasts.

Tris-EDTA

Tris-EDTA (disodium calcium salt of ethylenediamine tetraacetic acid buffered with tris [hydroxymethyl] aminomethane) added to lavage solutions increases permeability of gram-negative bacteria to extracellular solutes and leakage of intracellular solutes. Tris-EDTA solution is prepared by adding 1.2 g of EDTA and 6.05 g of tris to 1 L of sterile water. Sodium hydroxide is used to adjust the pH of the solution to 8, and the solution is mixed and autoclaved for 15 minutes. Treated bacteria are more susceptible to destruction by lysozymes, antiseptics, and antibiotics. Tris-EDTA in sterile water rapidly lyses *P. aeruginosa*, *E. coli*, and *Proteus vulgaris*. The addition of tris-EDTA to a 0.01% chlorhexidine gluconate solution increases antimicrobial effectiveness approximately 1000-fold. Antimicrobial synergism against *E. coli* occurs between tris-EDTA and penicillin, oxytetracycline, and chloramphenicol. Similarly, tris-EDTA and gentamicin, oxytetracycline, polymyxin B, nalidixic acid, and triple sulfonamide have synergistic activity against *P. vulgaris*.

Other Solutions

Acetic acid at 0.25% or 0.5% is occasionally used as a lavage solution. Its antibacterial effect is achieved by lowering wound pH. Wound acidification is beneficial in wounds that contain urea-splitting organisms (e.g., *Pseudomonas* spp.); however, resistance to acetic acid may develop. Acetic acid is more cytotoxic to fibroblasts than bacteria. Hydrogen peroxide and Dakin's solution should not be used as wound lavage solutions. Hydrogen peroxide, even in low concentrations, damages tissue and is a poor antiseptic. It is an effective sporicide; therefore it may be beneficial if clostridial spores are suspected. Hydrogen peroxide dislodges bacteria and debris from wounds by effervescent action. Dakin's solution is a 0.5% solution of sodium hypochlorite (1:10 dilution of laundry bleach). It releases free chlorine and oxygen into tissue, killing bacteria and liquefying necrotic tissue. However, even at half or quarter strength, Dakin's solution is detrimental to neutrophils, fibroblasts, and endothelial cells and should not be used as a wound lavage solution.

OTHER WOUND TREATMENT METHODS

Low-level Laser Therapy

Therapeutic LLLT is widely used on open wounds to potentially accelerate wound healing. However, there is potential for cellular damage and delay in wound healing if administered at higher doses or used inappropriately. The exact mechanism is unknown, but LLLT is thought to modulate processes at the cellular level leading to increased protein synthesis and stimulation of cellular growth and cellular differentiation. In a 2016 study in a canine wound model, LLLT increased keratinocyte cellular migration and proliferation at doses of 0.1, 0.2, and 1.2 J/cm^2, whereas exposure to 10 J/cm^2 had the opposite effect.[2] Protocols for the use of therapeutic laser vary widely in the literature (e.g., based on laser type, energy level, duration of exposure, or frequency intervals), making determination of the effectiveness of this modality challenging. For example, a 2015 study in veterinary medicine found no difference in wound healing between acute wounds in dogs treated with LLLT and those treated without.[3] The most consistent recommendation in the veterinary literature is 2 to 6 J/cm^2 once daily for 7 to 10 days for acute wounds and 2 to 8 J/cm^2 once daily for chronic wounds, using a laser with a wavelength range of 630 nm (visible light) to 904 nm (infrared), with between 1 and 15 W of power; however, an optimal delivery protocol has not been determined.[4]

Hyperbaric Oxygen Therapy

HBOT is the inhalation of pure oxygen at a pressure greater than 1 atmosphere, thereby significantly increasing tissue oxygenation. HBOT has been shown to be beneficial in the short-term treatment of chronic, hypoxic wounds in humans.[5] However, data from the use of HBOT in veterinary medicine are lacking.

Pulsed Electromagnetic Field

Experimentally, pulsed electromagnetic field treatment of open wounds enhances wound epithelialization and may promote early wound contraction without adverse effects on perfusion or tensiometric, histologic, clinicopathologic, or electroencephalographic parameters. A pulsed electromagnetic field generates complex multiform pulses of oscillating electromagnetic fields in the ultra-low frequency range (0.5–18 Hz).

ASSESSMENT OF SKIN VIABILITY

Skin circulation may deteriorate for 5 days after surgery because of edema and other factors. Skin viability is clinically assessed by color, warmth, pain sensation, and bleeding. Viability may also be assessed by dyes, transcutaneous oxygen or carbon dioxide, laser Doppler velocimetry, ultrasonic Doppler flow detection, and scintigraphy. Nonviable skin is black, bluish black, or white, and the area may be nonpliable, cool, and devoid of sensation. Normal skin is warm, pliable, and pink with normal capillary refill (difficult to assess) and pain sensation. Areas of questionable viability are often blue or purple, and capillary refill and sensation are poor.

Intravenous injection of vital stains fluorescein (10 mg/kg) or xylenol orange (90 mg/kg) has been used to assess vascular integrity of skin but has not been better than visual observation. Transcutaneous oxygen (pO_2) or carbon dioxide (pCO_2) monitoring allows immediate evaluation for ischemia but requires prolonged, quiet recumbency, and transcutaneous oxygen or carbon dioxide sensors left in place longer than 3 hours may cause superficial burns. Skin generally survives if a transcutaneous pO_2 value of approximately 60 mm Hg is maintained. Transcutaneous pO_2 values of 30 to 60 mm Hg may be associated with partial or complete survival. Transcutaneous pCO_2 values are

lower at the base of skin flaps (approximately 53 mm Hg) than at the apex (approximately 106 mm Hg), where ischemia is most apt to occur. Laser Doppler velocimetry is an indicator of capillary blood flux that may give an accurate assessment of local circulation. Probes must be placed away from major vessels to monitor relative blood flow, volume, and velocity (factors that vary with species, site, and instrumentation). Ultrasonic Doppler flow detection is a noninvasive, inexpensive means of determining blood flow and predicting viability in an area. Two sounds are usually heard with each arterial pulse, but only one sound is heard with proximal occlusion or stenosis. Areas of nonviable tissue may also be identified by evaluating the area with scintigraphy after injection of technetium 99-m methylene diphosphate.

INTEGUMENTARY SURGERY

The fundamental surgical principles for reconstructive surgery are listed in Box 15.4. Incisions made with scalpel blades cause less tissue trauma than those made with scissors, electrosurgery, or lasers. The CO_2 laser is the best-suited laser for skin incisions; it creates wounds that hemorrhage minimally because vessels are sealed. Skin edges should be manipulated atraumatically using skin hooks or fine-tooth forceps. The deep or subdermal plexus must be preserved during dissection and excision to ensure skin survival. It is important to undermine at the level of the subcutaneous fat to prevent transection of the subdermal plexus. To prevent transecting the direct cutaneous arteries that supply the subdermal plexus, dissection should be performed under the cutaneous muscles (panniculus, preputialis, supramammarius, platysma, and sphincter colli muscles) or in the distal extremities in the deep dermal layer. Risk of infection after surgery is diminished by antimicrobial prophylaxis, but is increased by several factors (Box 15.5).

Sutures

Suture acts as a foreign body in wounds. A buried suture greatly reduces the critical number of bacteria required to cause infection because the suture causes direct irritation, harbors bacteria, and generates ischemic islands of tissue. The smallest and fewest sutures possible should be used to close a wound. Approximating sutures should be used to bring tissue edges into anatomic apposition. A 3-0 or 4-0 absorbable suture (e.g., polyglyconate, polydioxanone, poliglecaprone 25, glycomer 631, polyglactin 910) with a swaged taper point needle should be used to close subcutaneous and subcuticular tissue. A 3-0 or 4-0 monofilament, nonabsorbable suture (e.g., nylon, polypropylene, polybutester) with a reverse cutting needle is preferred for most skin sutures. Skin sutures should be placed at least 0.5 cm from the wound margins. Wounds closed with interrupted sutures have less edema, improved microcirculation, and higher initial tensile strength, whereas continuous suture patterns allow for faster wound closure, less use of suture material, and create a better seal across the incision line. Suture tension should just appose edges, as loosely approximated wounds are stronger during the first 21 days.

Staples

Skin staples used to appose skin edges are less time consuming to place than sutures; however, it is more difficult to correctly align skin edges, and staples are less secure than sutures. Additionally, reduced infection and inflammation have been associated with the use of suture material than with stainless steel staples for skin closure. Apply skin staples perpendicular to the incision after aligning and apposing the edges with thumb forceps; then apply moderate pressure before the trigger is compressed (Fig. 15.4). Space staples approximately 5 mm apart.

Absorbable staples composed of polyglycolic-polyglactic acid copolymers have been introduced for subcuticular closure and are meant to replace cutaneous closure by other methods. These staples are degraded by hydrolysis, losing 60% of their holding strength in 14 days and having a tissue half-life of 10 weeks. Subcuticular staples are applied after aligning the skin edges

FIG. 15.4 Proper application of skin staples.

BOX 15.4 Fundamental Surgical Principles for Reconstructive Surgery

- Use strict asepsis in preparation of surgical team, room, and instruments and during surgery
- Handle tissue gently
- Preserve vascularity
- Remove necrotic tissue
- Maintain hemostasis
- Approximate tissue anatomically without tension
- Obliterate dead space
- Use appropriate suture materials and implants

BOX 15.5 Predictive Major Risk Factors for Postoperative Surgical Site Infection

- Increasing American Society of Anesthesiologists' preoperative assessment score ~3
- Increasing duration of anesthesia (~30% increase for each hour)
- Increasing duration of surgery (doubles every 70–90 minutes)
- Increasing number of persons in operating room (1.3 times higher/person)
- Dirty classification of wound site
- No preoperative or intraoperative antimicrobial prophylaxis (6–7 times more likely)
- Increasing duration of postoperative intensive care stay (1.16 times for each additional day)
- Wound drain (foreign materials reduce number of microorganisms required for infection by 10^4)
- Increasing patient weight

with forceps and then firing the stapler in the subcuticular tissue; staples are spaced approximately 1 cm apart. Subcuticular staples incite less inflammation than subcuticular polyglactin 910 sutures or skin staples; therefore they have a less detrimental effect on wound healing.

Tissue Adhesives

Cyanoacrylate tissue adhesives (see also p. 191) may be used in selected procedures to facilitate skin closure or secure drains. They are often used to hold skin in apposition following onychectomy, tail docking, and ovariohysterectomy in population control programs. Adhesives allow a quick cosmetic closure with less risk of infection or scarring when used properly. Initial wound strength is less than sutured wounds (5-0 nylon), but strength at 5 to 7 days is equivalent or greater with adhesives. Sometimes skin sutures and adhesives are used together to reduce the number of sutures used. Of the nonabsorbable tissue adhesives, N-butyl or isobutyl-2 cyanoacrylates (e.g., Vetbond, LiquiVet, GLUture) are preferred over propyl or methyl cyanoacrylates as they are less toxic. These adhesives should not be placed within the wound or incision but rather over the apposed surface to prevent foreign body reactions. An absorbable, sterile, methoxypropyl cyanoacrylate tissue adhesive is available (Tissumend II Sterile). It may be used externally and internally, with trials having been performed on lung, liver, spleen, kidney, and cornea. It has hemostatic properties, enhances healing, is nonreactive, and absorbs via hydrolysis in 60 to 90 days.

Fibrin tissue glues (Tisseel) reduce hemorrhage when vessels are anastomosed, provide a barrier to microleakage, reduce suture line tension following intestinal anastomosis, and have an adhesive effect, improving tensile strength after skin edges are apposed with sutures. Two-component fibrin glues are mainly composed of bovine or human thrombin and concentrated fibrinogen, duplicating the final stages of the coagulation cascade.

Drains

Dead space allows seepage and accumulation of blood and serum in a warm, moist environment that is ideal for bacterial proliferation. Dead space may be eliminated by layered wound closure when adequate tissue is available, by suture obliteration, by compression bandages, or by drainage. Leaving a wound open provides optimal drainage for an animal's injury. Implanting drains allows evacuation of potentially harmful fluids (e.g., blood, pus, and serum) from wounds and helps eliminate dead space. Drains are often necessary for treatment of bite wounds, lacerations, skin avulsions or separations, mastectomies, seromas, and abscesses. Drains may help maintain contact between a flap or graft and its bed. Drains may be either passive or active. Passive drains (e.g., Penrose drains) depend on gravity for fluid evacuation, whereas active drains require a vacuum. Penrose drains are used most commonly to drain subcutaneous spaces. Active drains increase drain efficiency and reduce drain-related infection. They are especially useful in draining deep wounds and after grafting. Negative pressure can be applied to active drains intermittently or continuously; continuous suction reduces chances of drain occlusion with fibrin or blood clots and encourages tissue apposition. Active drains may be open, with an air vent into the wound, or closed. With vented drains (e.g., sump) there is a danger of retrograde contamination of particulate matter and bacteria passing through the air vent into the wound. Filtered vents reduce the risk of contamination. Closed active drains are preferable to Penrose drains (Fig. 15.5).

FIG. 15.5 A closed suction drain is being used to evacuate an abscess between the thoracic wall and scapula.

FIG. 15.6 For proper passive drain placement, a Penrose drain is anchored dorsally in the wound, exits in the most gravity-dependent area, and does not exit the primary incision. Cover exiting passive drains with a small tie-over bandage to absorb wound fluid and minimize ascending infection.

Penrose drains or passive tube drains should be used in clean wounds only if both the exposed end and the wound can be covered with a sterile compressive dressing or bandage. Superficial, passive drains should be secured to the skin at the dorsal aspect of the wound by direct visualization or blind suture placement (Video 15.1). They should be exited through a stab incision at least 1 cm from the primary incision and positioned such that they allow maximum flow by gravity (Fig. 15.6).

For effective drainage of small spaces, a closed suction drain can easily be made using a butterfly catheter and an evacuated tube or syringe (Video 15.2). The syringe adapter is removed from the plastic tubing, and the tube is fenestrated before the drain is placed in the wound (Fig. 15.7). After wound closure, the needle is inserted into the evacuated tube (5–10 mL) to apply suction. As an alternative, the needle can be removed, the tube fenestrated, and the adapter attached to a syringe with suction

FIG. 15.7 A butterfly catheter and Vacutainer tube are used for active closed drainage of small spaces, such as the ear.

applied. Active collection systems should be emptied frequently to maintain constant negative pressure. The collection reservoir is replaced or emptied when it loses negative pressure or fills with fluid. Most collection systems lose pressure as they become more than half full. Initial collection may simply remove air from the wound as the vacuum is established, and fluid drainage may not occur until several reservoir changes. The volume of fluid collected should be measured and recorded.

The smallest diameter and fewest number of drains with the fewest number of exit holes should be used to prevent complications. Drains should not exit or lie directly under the primary incision. No part of the drain should be in contact with haired skin. Secure drains to the skin so they cannot be removed prematurely or allowed to retract into the wound. Drains should be protected with a bandage that is changed before "strikethrough" occurs. Strikethrough is the saturation of a bandage with fluid that wets both inner and outer surfaces. An Elizabethan collar or bucket can prevent self-inflicted drain or bandage damage. The animal should be kept in a clean, dry environment and have limited exercise. Tissue fragments, fibrin, or viscous exudates may cause drain malfunction. Drains are foreign bodies and cause drainage until removed. They should be removed when the discharge is serosanguinous and the volume has diminished to one-fourth or less of the original drainage. Most wound drains can be removed after 2 to 5 days. Closed suction drains placed under grafts are usually removed after 48 to 72 hours, when drainage has diminished. Be careful when removing drains to prevent disrupting the skin–wound bed interface. Apply a bandage after drain removal to absorb any residual drainage and stabilize the wound site.

BOX 15.6 Benefits of Negative Pressure Wound Therapy

- Increases blood flow
- Reduces edema
- Increases rate of granulation tissue formation
- More rapid reduction in numbers of microorganisms
- Removal of exudate
- Greater flap survival

NOTE All drains should be protected by a bandage.

The major disadvantage of drains is that they serve as retrograde conduits for skin contaminants to enter the wound. Drains also impair tissue resistance to infection and may disrupt graft adherence. Drains made from latex incite more inflammatory reaction than those of Silastic or silicone. To prevent incisional dehiscence and herniation, drains should not exit from primary incisions.

Negative-Pressure Wound Therapy (Video 15.3)

Negative-pressure wound therapy (NPWT) is an alternative method of wound drainage that uses open-cell foam and subatmospheric pressure (e.g., VAC, Curato). Medical-grade, open-cell, polyurethane ether foam dressing with pore sizes between 400 and 600 µm fitted with an evacuation tube is cut to the specific wound configuration and placed into the wound defect. Exposed viscera are covered with mesh or omentum, and major vessels with adjacent soft tissue, before the foam is positioned. The wound site is bandaged, and the tubing is connected to a collection reservoir. The reservoir is connected to a vacuum pump, and subatmospheric pressure (125 mm Hg) is applied continuously or intermittently for cycles of approximately 5 minutes on and 2 minutes off. Continuous suction may be less painful and is often applied during the initial 48 hours of use. The foam is changed every 48 hours (except initially after grafting) to prevent tissue ingrowth, and the bandage is changed as necessary. Fluid is pulled from the wound, creating a moist environment and reducing local tissue swelling.

The benefits of NPWT are increased blood flow, increased rate of granulation tissue formation, more rapid reduction in numbers of microorganisms, and greater flap survival following application of this vacuum system (Box 15.6). In addition, this system facilitates readhesion of degloved tissue and healing of chronic wounds, acute wounds, skin flaps, and skin grafts. Complications may include pain, wound margin dermatitis, excessive ingrowth of granulation tissue, and wound desiccation with vacuum loss. Use of NPWT has been shown to accelerate wound healing in both dogs and cats when compared to conventional foam dressings for open wound.[6,7]

Tourniquets

Tourniquets help control hemorrhage of distal extremities, improving visualization and reducing operating time. However, tourniquets should not be used on traumatized limbs or those

FIG. 15.8 Sterile elastic wrap may be used as a short-term tourniquet. An incision made in the elastic wrap allows access to the lesion for excision.

with vascular injury or circulatory compromise. Pneumatic tourniquets with pressures below 300 mm Hg for less than 3 hours should be used. The limb should be elevated for approximately 5 minutes or exsanguinated with a rubber bandage before the tourniquet is applied. Exsanguination is contraindicated with local suppuration, deep venous thrombosis, or neoplasia. Pressure is more evenly applied if two or three layers of orthopedic padding are placed under the tourniquet. The tourniquet cuff should be applied at a point of maximum circumference, where nerves and blood vessels are protected against direct compression. Although of uncertain value, releasing the tourniquet 10 minutes for every hour of inflation has been recommended. For a short-term tourniquet (as an alternative to or in combination with a pneumatic tourniquet), apply sterile elastic wrap (Vetrap). Apply it from the digits proximally without excess tension, and then incise it beginning at the toes to expose the surgical area (Fig. 15.8). Complications of tourniquet use are ischemia, hypoxia, or acidosis of local tissue; neurapraxia; and muscle damage.

WOUND CLOSURE

Wounds may be closed immediately (primary wound closure); within 1 to 3 days after injury, when they are free of infection but before granulation tissue has appeared (delayed primary wound closure); or after the formation of granulation tissue (secondary closure); or they may be allowed to contract and epithelialize (healing by secondary intention). Wounds closed in the presence of contamination, necrotic tissue, excessive tension, or dead space are apt to dehisce, often with the loss of additional tissue because of bacterial toxins and pressure necrosis. If there is any doubt whether a wound should be closed, it is best to leave it open. Factors that affect the decision not to close wounds include the following:

1. *Amount of time that has elapsed since injury.* Wounds older than 6 to 8 hours are initially treated with bandages.
2. *Degree of contamination.* Obviously contaminated wounds should be thoroughly cleansed and initially treated with bandages.
3. *Amount of tissue damage.* Wounds with substantial tissue damage have reduced host defenses and are more likely to become infected; therefore they initially should be treated with bandages.
4. *Completeness of debridement.* Wounds should remain open if the initial debridement was conservative and if further debridement is necessary.
5. *Status of the wound's blood supply.* A wound with questionable blood supply should be observed until the extent of nonviable tissue is determined.
6. *The animal's health.* Animals unable to tolerate prolonged anesthesia are best treated with bandages until their health improves.
7. *Extent of tension or dead space.* If excessive tension or dead space is present, wounds should be bandaged to prevent dehiscence, fluid accumulation, infection, and delayed wound healing.
8. *Location of the wound.* Large wounds in some areas (e.g., limbs) are not amenable to closure.

Primary healing occurs with clean, incised wounds that are held together. Healing is initiated by movement of epithelial cells from the two edges of the wound toward the center that usually meet within 4 to 7 days of the incision. Primary wound closure is infrequently indicated following trauma. It should only be performed if less than 6 to 8 hours (within the golden period) have elapsed since injury; there is minimal tissue contamination, loss, or trauma; the wound is suitably cleaned by lavage and debridement; there is good hemostasis; and there is no tension or dead space. Traumatic wounds contaminated by feces, saliva, purulent exudate, or soil should not be closed primarily. *Delayed primary closure* is indicated for mildly contaminated, minimally traumatized wounds that require some cleansing and debridement or when the wound is older than 6 to 8 hours. Wounds are first lavaged and debrided to control local contamination or infection. These wounds should be treated with bandages after injury and before closure. Delayed primary closure allows staged debridement and maximum wound drainage. The wound should be surgically closed after bandaging and debridement for 3 to 5 days when it appears clean.

Lavage the wound with a balanced electrolyte solution or sterile saline to remove debris and reduce bacterial numbers (see p. 184). Next, thoroughly explore the wound. Anastomose transected tendons in clean wounds (see p. 1283). Primarily appose large motor nerves that are transected sharply and cleanly; otherwise, delay nerve repair for 2 to 3 weeks until the wound has healed. If excessive dead space surrounds a wound, use passive or active (preferred) drains. Appose subcutaneous tissues with 3-0 or 4-0 buried interrupted or continuous approximating sutures (e.g., polydioxanone, polyglyconate, glycomer 631, poliglecaprone 25). Bring the skin edges into apposition with buried walking sutures (see p. 209) or subcuticular sutures (e.g., 3-0 or 4-0 polydioxanone, polyglyconate, poliglecaprone 25). Use approximating sutures in skin (e.g., 3-0 or 4-0 polypropylene, polybutester, or nylon).

Wounds with considerable tissue loss, contamination, or infection, or those older than 6 to 8 hours should be treated as open wounds. Initially, they should be lavaged, explored, and debrided. Tendons, ligaments, and vessels may be damaged beyond repair. Identifiable tendon ends should be tagged. Apply a hydrophilic bandage (see p. 195) that immobilizes the area and promotes formation of a healthy granulation bed. The wounds will initially begin healing by contraction and epithelialization and may heal completely *(healing by secondary intention)*. Healing by secondary intention is often less expensive and results in normal-appearing skin if contraction is complete. Body wounds

are more apt than leg wounds to completely close by secondary intention. Disadvantages of healing by secondary intention include contracture with disfigurement, incomplete healing, and fragile epithelial scars with large wounds. Alternatively, healthy wounds may be repaired by *secondary closure* or by use of a flap or graft. Secondary closure occurs at least 3 to 5 days after injury, after a healthy granulation bed has formed. Granulation tissue helps control infection in the wound and fills tissue defects. Secondary closure is appropriate when the wound is severely contaminated or traumatized, when epithelialization and contraction will not completely close the wound, or when healing by secondary intention is undesirable. Secondary closure involves resecting the granulation bed and skin margins, lavaging the wound, and apposing skin edges. Secondary closure can also be accomplished by resecting skin margins, debriding the surface of the healthy granulation bed, and apposing skin edges over the granulation tissue. Wound closure in the presence of granulation tissue is somewhat difficult because the tissue is thickened and not pliable. Excising the entire granulation bed gives a more cosmetic closure. If secondary closure is not possible, a flap or graft can be applied over the defect. After wound closure, an absorbent, nonadherent bandage should be applied to support the wound and absorb exudate. Bandages should be changed once or twice daily if a passive drain is used; if little drainage is expected and if drains are not used, once every 3 to 4 days may be adequate.

POSTOPERATIVE CARE AND ASSESSMENT

Postoperative wound care should optimize healing and be tailored to the type of wound. Wounds should be evaluated frequently for infection, tension, fluid accumulation, dehiscence, and necrosis. They may be evaluated visually and with ultrasonography, which helps detect and localize fluid accumulation. An ultrasound scan allows monitoring of wound depth and width and identifies blood clots, edematous regions, granulation tissue, scar tissue, epidermis, and eschar. Wounds should be protected with clean, dry bandages. Bandages act as a barrier against exogenous bacteria and support the wound during the first few days after surgery. Healing, sutured wounds become increasingly resistant to bacterial penetration. The patient and its environment should be kept clean, and adequate nutrition should be provided. Analgesics (see Chapter 13) and antibiotics (see Chapter 9) should be used postoperatively as necessary.

Infection may be suspected if the patient has fever, leukocytosis, anorexia, and/or depression. Although these abnormalities can be a normal response to stress and surgery and do not indicate infection, they are generally more exaggerated with infection than with nonseptic inflammation. If infection is suspected, samples should be collected for culture and cytology. If a surgical wound becomes infected, the sutures should be removed and the incision treated as an open wound with appropriate bandages (see p. 201). Topical or systemic antibiotics (see previous discussion) are used to control infection based on the results of susceptibility testing. The wound may be closed after the infection has resolved.

Sutures should be removed from wounds in 7 to 14 days, even though the wound has regained only 20% to 30% of its original strength. Scarring and infection associated with sutures are greater when sutures are left for longer periods. Most complications are prevented by using good surgical and wound management techniques. Potential complications include inflammation, edema, seroma and hematoma formation, drainage, infection, dehiscence, necrosis, granulomas, contracture, and failure to heal.

Seromas are caused by excessive dead space or motion. They are prevented by closing dead space, using drains, and applying bandages to immobilize and support the wound. Seromas are treated by immobilizing the area and applying a pressure bandage. Large seromas may be drained, although this increases the risk of infection. Dehiscence may occur if tissue necrosis occurs, if sutures are placed too close to the margin, if tension exceeds suture strength, if sutures absorb too quickly, or if sutures strangulate and cut through tissue. Dehiscence may also occur secondary to self-trauma, infection, severe cough, hypoproteinemia, hypovolemia, or administration of drugs that interfere with healing. Wounds that dehisce may be allowed to heal by secondary intention or may be debrided and resutured. A *granuloma* is a chronic inflammatory process that may be caused by foreign material. Contracture or excess scar formation occurs most commonly at sites of motion (e.g., elbow or stifle) or body orifices. Contracture limits motion and may be disfiguring. Scar revision or excision is necessary when contracture interferes with activities. Wounds may fail to heal when the area is infected or has been irradiated or when the animal has received chemotherapy or is severely debilitated or malnourished.

BANDAGES

No single type of bandage provides the optimum environment for all wounds or for total healing of a particular wound. Bandages provide wound cleanliness, control the wound environment, reduce edema and hemorrhage, eliminate dead space, immobilize injured tissue, and minimize scar tissue. They also provide comfort, absorb and allow characterization of wound secretions, and give an aesthetic appearance. Bandages keep wounds warm, which improves wound healing and facilitates oxygen dissociation (Box 15.7). Covering wounds with a bandage promotes an acid environment at the wound surface by preventing carbon dioxide loss and absorbing ammonia produced by bacteria. An acid environment increases oxygen dissociation from hemoglobin and subsequently increases oxygen availability in wounds.

Bandages should be comfortable and clean. Uncomfortable bandages annoy patients, who may then mutilate the bandage or wound or both. Pressure should be applied over and distal to wounds, rather than proximal to them, to minimize venous or lymphatic compromise. When outer layers of a bandage become wet, bacteria readily pass from the outer surface and colonize wounds. Wounds bandaged with adherent or nonhydrophilic contact layers are generally unbandaged, inspected, and treated daily; however, wounds with excessive tissue damage, exudate, or established infection may require bandage changes twice or three times daily. Adherent bandages should be changed more frequently if the gauze is saturated with exudate and slides on

BOX 15.7 Desirable Characteristics of Wound Dressings

- Removes exudates and toxic components
- Maintains high humidity at the wound-dressing interface
- Allows gaseous exchange
- Provides thermal insulation
- Relieves pain
- Protects from secondary infection
- Protects from particulate or toxic contaminants
- Allows dressing removal without wound trauma

BOX 15.8 Hydrophilic Contact Layers

- Hypertonic saline
- Calcium alginate
- Polyurethane foam
- Hydrogel
- Hydrocolloid
- Some topical medications

BOX 15.9 Factors in Contact Layer Selection

- Phase of wound healing
- Amount of exudate
- Wound location and depth
- Presence or absence of eschar
- Amount of necrosis
- Presence of infection

BOX 15.10 Factors That May Affect Wound Contraction

Stimulate or Enhance

Acemannan
Tripeptide copper complex
Occlusive hydrogel dressings
Equine amnion
Pulsed electromagnetic field radiation
Adjustable horizontal mattress sutures
Skin stretchers

Inhibitors

Corticosteroids
Silver sulfadiazine
Mafenide acetate
Hydrocolloid dressings
Porcine small intestine submucosa
Thick skin grafts or flaps

the wound during bandage changes. Bandages applied over wounds with healthy granulation tissue and support bandages used to immobilize fractures may need changing only once every 2 to 4 days. Hydrophilic bandages (Box 15.8) are designed to be left on the wound for 3 to 7 days depending on the characteristics of the contact layer and the amount of exudate being produced. Analgesia or anesthesia may be required for initial bandage changes.

WOUND BANDAGING MATERIALS

Bandages have three basic layers: the contact dressing (i.e., primary layer), the intermediate (i.e., secondary layer), and the outer (i.e., tertiary) layer.

Contact (Primary) Layer

The contact layer touches the wound surface and should remain in contact with it during movement. It is used to debride tissue, deliver medication, transmit wound exudate, or form an occlusive seal over the wound. No single dressing will produce the optimum microenvironment for all wounds or for all stages of wound healing on a single wound. The appropriate contact layer is selected based on the phase of wound healing, amount of exudate, wound location and depth, presence or absence of an eschar, and amount of necrosis or infection. The contact layer should also minimize pain and prevent excess loss of body fluids (Boxes 15.7–15.10 and Tables 15.2 and 15.3). It may be adherent or nonadherent, and occlusive or semiocclusive (Table 15.4). *Adherent* contact layers are used for mechanical debridement of necrotic tissue and debris, and for absorption of wound exudates. These dressings are economic and easy to place, but they should only be used on a short-term basis early in the course of wound healing as the wound debridement is nonselective, and normal healing tissue may be damaged when the bandage is removed. They cause pain on removal and serve little purpose in the absence of nonviable tissue. *Nonadherent* contact layers have traditionally been selected when granulation tissue has formed, but current wound care standards recommend use of hydrophilic nonadherent contact layers for all wounds. These products are very absorptive; they create a moist environment to facilitate healing and reduce the frequency of bandage changes (usually once every 3–7 days). Semiocclusive bandages allow air to penetrate and exudate to escape from the wound surface. They are the most commonly used bandages in veterinary medicine. Occlusive bandages are impermeable to air and fluid. They are used on less exudative wounds to keep tissue moist. Semiocclusive bandages are less likely to macerate adjacent normal tissue.

Wet Adherent

A wet adherent contact layer is used when the wound surface has necrotic tissue, foreign matter, or a viscous exudate. Sterile, wide-mesh gauze moistened, not soaked, with 0.9% saline is applied to the wound. Hypertonic saline (see p. 196) may be used as wetting solutions in grossly infected wounds. The wet dressing dilutes wound exudate so that the intermediate layer of the bandage can absorb it. Necrotic tissue and foreign material adhere to the gauze as it dries and are removed from the wound along with the bandage. Wet bandages absorb faster than dry bandages and are more comfortable. Potential disadvantages of a wet adherent contact layer are pain and tissue damage during bandage changes, bacterial proliferation, tissue maceration, and strikethrough (exudate absorption through outer bandage layer). Rewetting the dried dressing with warm saline facilitates removal and reduces pain during bandage changes; however, it also diminishes the mechanical debridement effect.

Dry Adherent

This type of contact layer is infrequently used because it is painful to remove, viable cells may be removed with necrotic debris, and the wound may desiccate. A dry adherent contact layer was primarily used when the wound surface had a large amount of low-viscosity exudate that does not aggregate. With this bandage an absorbent, wide-mesh gauze is used without a cotton filler. Dry gauze absorbs exudate and adheres to necrotic tissue and debris. The bandage is removed after the primary layer has absorbed fluid and debris and then dried.

Adherent Film or Skin Sealant

Transparent liquids are spread in a thin layer over the wound dry, creating a film or bandage that acts as a barrier between the skin or granulating wound and the external environment (e.g., Cavilon No Sting Barrier Film). They are made from natural ingredients, primarily hetastarches and water. These films are generally permeable to water vapor and occlusive to bacteria

TABLE 15.2 Guide to Dressings Based on Purpose

Purpose	Suggested Products
Cleanse wound	Noncytotoxic commercial cleanser; balanced electrolyte or saline solution
Absorb exudate	Absorption beads, pastes, powders, and pads: Alginates Foams Hydrocolloids Hydrogels Composite dressings
Autolytic debridement: cover wound to allow endogenous enzymes in wound fluid to self-digest eschar and fibrinous slough	Same as above, plus transparent films
Chemically debride devitalized tissue	Enzymatic debridement agents: Granulex, live yeast Preparation-H
Add moisture to wound	Hydrogel Hypertonic saline dressing Medicinal honey
Maintain moist wound environment	Hydrophilic ointments Foam Hydrocolloids Hydrogels Transparent films
Fill dead space	Absorption beads, pastes, powders, and tapes: Alginates Hydrocolloid Hydrogel Foam
Reduce swelling to improve perfusion	Hypertonic saline
Prevent contamination	Biguanide-impregnated antimicrobial gauze Occlusive Semiocclusive
Reduce bacterial numbers	Biguanide-impregnated antimicrobial gauze Antibiotics
Cover and protect wound	Nonadherent, hydrophilic dressing with appropriate intermediate and outer bandage layers
Protect surrounding skin from moisture and trauma	Moisture barrier ointments Skin sealants Transparent film dressings Bandage
Reduce odor	Vapor-permeable film or polyurethane foam with activated charcoal

and water. They are nonirritating and do not stain. They prevent skin irritation from exudates, urine, or feces contamination. They may be used alone over wounds or with a bandage. Reapplication is necessary every 3 to 4 days.

Nonadherent

Nonadherent contact layers do not stick to the wound surface, and most are *semiocclusive*. They are used to promote moist wound healing and epithelialization and to prevent wound dehydration while allowing excess fluid to drain, which reduces tissue maceration. These dressings are composed of wide-mesh gauze impregnated with paraffin (Jelonet), petrolatum (Adaptic), petrolatum and 3% bismuth tribromophenate (Xeroform), or other petrolatum-based ointments (Aquaphor, Furacin). Nonadherent dressings are used when wounds have newly formed granulation tissue and some remaining exudate but are not epithelialized. Xeroform, in particular, allows egress of fluid and bacteria from wounds through the mesh. Fibrin from the wound bed causes temporary bonding of the dressing to wounds as the dressing dries. It is inexpensive and associated with low infection rates but is painful to remove. Epithelialization is rapid. Nonadherent dressings without petrolatum (Telfa or Dermacea) have less chance of adherence to the wound and are used once epithelialization begins.

Other types of nonadherent contact layers are *occlusive dressings*. Occlusive dressings are impermeable to air and are used on healthy wounds with minimal exudation during the repair phase of healing. Occlusive dressings accelerate wound epithelialization and collagen synthesis by maintaining a moist wound environment. They require less frequent changes than other types of bandages. Some types of occlusive dressings have a hydrocolloid, adhesive layer (e.g., DuoDerm) (see p. 199). Other occlusive, nonadherent contact layers include polyurethane films, hydrogels, and hydrophilic beads, flakes, powders, and pastes.

Interactive dressings are nonadherent contact layers that create and control a moist wound environment and modulate cellular activity and growth factor release within the wound to facilitate moist wound healing through all phases of healing. These dressings are designed to meet the different environmental stages found in the different phases of wound healing and include, but are not limited to, hydrocolloid, alginate, antimicrobial, and biologic dressings.

Moist wound healing is promoted by incorporating hydrophilic materials that are placed on the wound bed or in the wound cavity. Hydrophilic dressings include hypertonic saline, calcium alginate, polyurethane foam, hydrogel, hydrocolloid, and some topical medications. Hydrophilic materials should not extend onto normal skin to prevent maceration of tissue adjacent to the wound. Barrier ointments or skin sealant adhesive films may be applied adjacent to the wound to prevent maceration if necessary. Some products with adhesive borders designed for people do not adhere around animal wounds well because of higher skin lipid concentrations and rapid hair regrowth. Most nonadherent, hydrophilic contact layers are highly absorbent, requiring bandage changing only every 3 to 7 days. Product costs are higher, but with fewer bandage changes the overall cost is comparable to more frequently changed adherent bandages.

NOTE No single dressing will produce the optimum microenvironment for all wounds or for all stages of wound healing of a single wound.

Hypertonic Saline

Hypertonic saline dressings (Curasalt, Curity) are indicated for infected, necrotic, and heavily exudative wounds and eschars. These dressings are loosely woven gauze impregnated with 20% sodium chloride and should be used in the inflammatory stages of healing during the first few days of wound care. Osmotic action desiccates bacteria and necrotic tissue, and reduces edema,

TABLE 15.3 Guide to Dressings Based on Wound Characteristics

Wound	Objective	Wound Characteristics	Dressing to Consider
Acute mild contamination and tissue damage	Hemostasis, debride, reduce contamination, provide moist environment	Hemorrhaging <6–8 hours old	Calcium alginate Hydrogel, hydrocolloid
Acute moderate to severe contamination and tissue injury	Reduce contamination, debride Provide moist environment	Gross dirt and debris in wound; contusions, avulsions, ischemia, and <6–8 hours old	Hydrogel, hydrocolloid
Exposed muscle, fascia, subcutaneous tissue	Provide moist environment Encourage granulation	Clean wound	Calcium alginate, hydrogel
Necrotic	Promote debridement Provide moist environment Absorb exudates	Dry eschar or slough Excessive exudate and surface devitalized	Hypertonic saline or hydrogel Hydrogel or calcium alginate
Granular	Provide moist environment Encourage granulation	Irregular or incomplete granulation, minimal to moderate exudate	Calcium alginate, hydrogel
Needs epithelialization	Provide moist environment to promote and protect resurfacing	Healthy granulation tissue: pink, smooth Dry, moist	Hydrogel sheet, hydrocolloid Foam

TABLE 15.4 Contact Layer Wound Dressings

Type	Trade Name	Indication	Action
Adherent Dressings			
Wet-dry	—	Inflammatory phase, high-viscosity exudate	Absorbs, debrides, hydrates, disrupts granulation tissue Change daily to 3 times daily
Dry-dry	—	Inflammatory phase, low-viscosity exudate	Absorbs, debrides, disrupts granulation tissue Change daily to 3 times daily
Antimicrobial sponge or roll gauze	Kerlix AMD	All phases	Kills surface bacteria, prevents bacterial penetration of bandage
Hypertonic saline	Curasalt; Curity	Inflammatory and debridement phases Necrotic, infected, heavy exudates	Osmotic action desiccates bacteria and necrotic tissue Nonselective debridement Decreases edema, resulting in increased perfusion Change every 1–3 days, apply only once or twice
Adhesive Dressings			
Semipermeable films	OpSite, Tegaderm, Bioclusive, Bioguard	Low- and high-exudate wounds with granulation tissue Covering for sutured wounds	Adhesive sticks to skin around wound; may have a thin nonadherent contact layer; creates a moist environment Accelerates epithelialization; permeable to water vapor but occlusive to bacteria and water Change every 1–3 days
Skin protectant films	Cavilon No Sting Barrier Film	Skin irritation, chronic wounds, burns, hot spots	Forms a film over surface; protects skin from urine, feces, and tape; allows rapid healing Reapply every 3–4 days
Semiocclusive to Occlusive Nonadherent Dressings			
Calcium/calcium-sodium alginate (pad, ribbon, fiber)	Curasorb, Sorbalgon	Transition from inflammatory to repair phase, heavy exudate; burns; lacerations; incisions; biopsy	Pad forms a gel when absorbing exudate, which cleans the wound; it also is hemostatic and encourages epithelialization and granulation Do not use overexposed tendon, bone, or necrotic tissue Cover with semiocclusive pad Change every 5–7 days
Paraffin or petrolatum impregnated:	Jelonet, Adaptic	Early repair phase, viscous to sanguineous exudate	Increases wound contraction, absorbs bacteria and exudate, delays epithelialization Change every 1–3 days
With 3% bismuth tribromophenate	Xeroform		
Rayon/polyethylene glycol (sheets, gel) or cotton (pad) Perforated polyester film with cotton	Telfa Pads, Dermacea	Early to midrepair phase when epithelialization begins, sanguineous exudate to dry; sutured wounds; minor lacerations	Increases wound contraction, absorbs bacteria and exudate; may promote exuberant granulation Change every 1–3 days

Continued

TABLE 15.4 Contact Layer Wound Dressings—cont'd

Type	Trade Name	Indication	Action
Polyurethane film	Tegaderm, OpSite, Bioguard, Bioclusive	All healing phases. Partial thickness injuries; wounds with granulation tissue and minimal exudate; may use as covering for hydrogel or hydrophilic pastes or powders	Increases epithelialization; may cause tissue maceration and bacterial proliferation Change every 1–3 days
Hydrocolloid (sheet, paste, powder; some are semiocclusive)	Flexicol, Duoderm	Early repair phase; healthy granulation tissue bed with advanced wound contraction and little to moderate exudate; pressure sores; burns; cavity wounds; degloving	Increases epithelialization and comfort; adhesiveness may reduce contraction; use until granulation tissue fills wound; promotes granulation and may cause hypergranulation; gas permeable but has water-impermeable coating or is totally impermeable; if infection develops under dressing, discontinue Change every 2–3 days
Hydrogel (mesh, paste, gel, sachets)	Hydrasorb, Curafil, Curagel, Intrasite Gel, BioDres, Geliperm, Carravet, Tegagel, Nu-gel, Solugel	Inflammatory, debridement, and repair phases; dry, sloughing, or necrotic wounds; abrasions; blisters; superficial wounds Use with minimal exudates	Absorbs fluid; keeps wound moist; permits autolytic débridement; increases collagenase activity in burns Discontinue when granulation tissue fills the wound; may promote exuberant granulation Promotes contraction Can use to deliver topicals: acemannan (Carravet), hyaluronic acid, chondroitin sulfate (Tegaderm), silver, and metronidazole Change bandage every 4–7 days
Foam			
Silicone Foam Also gel dressing	Cavi-Care, CicaCare, Silastic gel	Same as for polyurethane foam	Same as for polyurethane foam May prevent or reduce formation of exuberant granulation tissue
Biologic Dressings			
Collagen	Helix3 CM	Inflammatory to repair phase	Reduces pain, heat, water loss, and contamination; stimulates epithelialization, collagen synthesis, and granulation; increases contraction (amnion); reduces bacterial numbers; controls exudates Provides scaffold Experimental results are mixed
Chitosan	Hemocon, ExcelArrest XT	Hemostasis	Provides a matrix for hemostasis that is also antibacterial
Porcine small intestinal submucosa (SIS)	Oasis Wound Matrix	Repair phase	Absorbable scaffold for tissue ingrowth
Porcine bladder extracellular matrix	ACell Vet, Scaffold	Repair phase	Absorbable scaffold for tissue ingrowth
Silicone membrane and porcine collagen	Biobrane	Early to mid-repair phase when epithelialization begins, sanguineous exudate to dry; sutured wounds; minor lacerations	Increases wound contraction, absorbs bacteria and exudate; transparent and conforms, but may adhere
Miscellaneous Dressings			
Activated charcoal	Actisorb	Debridement to repair phase with severe infection	Adsorbs bacteria and reduces odor Provides moist wound healing Prevents formation of exuberant granulation
Silver impregnated	Acticoat, Silvercel, Silvasorb, Actisorb, Algidex AG, Aquacel	Inflammatory to repair phase with high bacterial load; burns	Reduces bacteria; strips facilitate drainage Change every 3–4 days
Maltodextrin: powder or gel	Multidex, Algidex AG	Debridement; slow-healing wounds	Cleanses and promotes healing in contaminated and infected wounds; hydrophilic; chemotactic to white blood cells; yields glucose to promote healing; antibacterial and bacteriostatic

resulting in improved perfusion. These dressings quickly convert necrotic wounds to moderately exudating and granulating wounds. Debridement is nonselective, so use is limited to one or two applications; these dressings are usually followed with placement of alginate, hydrogel, or foam dressings once granulation tissue has begun to form. Hypertonic saline bandages should be changed at least every 24 hours to prevent saline dilution and wound desiccation.

Hydrogel

Hydrogels, or water polymer gels (e.g., Hydrosorb), are modified crosslinked polysaccharide formulations (gelatin or polysaccharide)

available as gels, dry or hydrated sheets, or impregnated gauze. They are hydrophilic and swell when interacting with aqueous solutions; they contain approximately 90% to 95% water when hydrated. Gels are moisture retentive, nonadherent, nonocclusive, and highly comfortable, providing a cool, soothing effect and some pain relief. These dressings are highly absorptive, creating a moist wound environment that promotes debridement, granulation, and epithelialization. They are used to treat dry, sloughing, or necrotic wounds and abrasions, lacerations, burns, and minor skin irritations. Hydrogels are very effective in hydrating a wound, and they increase collagenase activity to facilitate autolytic debridement and promote granulation. They may be used as a vehicle for antibiotics or other antimicrobials, including metronidazole, silver sulfadiazine, and acemannan. Dressings should be cut to the size of the wound to prevent maceration of adjacent tissue. An outer bandage is used to secure the dressing to the wound surface. Bandages are changed every 4 to 7 days.

Hydrocolloids

Hydrocolloids (e.g., Flexicol) are biocompatible hydrophilic polymers, such as sodium carboxymethylcellulose or hydroxyethylcellulose with pectins and gelatin or embedded in an elastic mesh. They may be occlusive or semiocclusive adhesive pads (not to wound bed), pastes, or powders. Pads consist of an inner (often adhesive) layer of thick absorbing hydrocolloid and an outer, thin, water-resistant, bacterial-impervious, polyurethane film. They are flexible and highly absorbent and adhere to both wet and dry tissue. Wound exudates are absorbed, and the hydrocolloid swells, forming a gel on the wound surface. The gel expands, filling the wound cavity, keeping it moist. Hydrocolloids maintain a moist wound environment, promote autolytic debridement, and insulate the wound bed. They increase epithelialization and comfort, but adhesiveness to surrounding tissue may reduce contraction and cause hypergranulation. Dressings are useful on partial- or full-thickness wounds with clean or necrotic bases, including pressure sores, minor burns, or granulating wounds with necrotic tissue, but they are not intended for heavily exudative or infected wounds. Hydrocolloid pads should extend 2 cm beyond the wound onto normal skin that may be protected with a skin sealant to prevent maceration. Cavitary wounds should be loosely packed with a filler agent to fill dead space before applying a hydrocolloid pad. The hydrocolloid dissolves as it absorbs fluid, forming a yellow-colored fluid. Bandage changes are typically needed every 3 to 5 days, when exudates begin to leak or the dressing loosens. Wound inspection is difficult as the pads are not transparent. Use of these dressings should be discontinued if infection develops under them.

Some hydrocolloid dressings have an adhesive layer and are occlusive (e.g., DuoDerm). The hydrocolloid adheres to skin around the wound, and the dressing over the wound interacts with the wound fluid to create a nonadherent, occlusive hydrocolloid gel. These dressings are used on wounds with an established granulation tissue bed, advanced contraction, minimal fluid production, and initial epithelialization. The wound should first be lavaged and dried. The hydrocolloid dressing then is warmed between the palms to make it soft and pliable. The dressing is cut to an appropriate size and shape to cover the wound, and the protective film is removed. The dressing is applied with light pressure until it adheres to the skin. Adherence is a problem in dogs and cats but may be improved by clipping the hair adjacent to the wound. It may be necessary to apply a light intermediate and outer bandage layer to hold the hydrocolloid dressing in place over mobile areas. The dressing is removed after 2 to 3 days when the outer surface of the hydrocolloid feels like a fluid-filled blister or if leakage occurs. The gel is lavaged or wiped from the wound, and a new dressing is applied. Wounds dressed with hydrocolloid contact layers are less painful and epithelialize more rapidly than wounds covered by semiocclusive, nonadherent dressings; however, wound contraction is reduced. The dressings are not transparent, which makes wound monitoring difficult.

Calcium Alginate

Calcium alginates (e.g., Curasorb, Sorbalgon) are nonocclusive, nonadhesive, hydrophilic, moisture-retaining dressings. They are classified as fibrous dextranomers. Calcium alginate products are derived from salts of alginic acid obtained from the algae *Phaeophyceae*, found in seaweed, forming pads, ropes, ribbons, or packing whose fibers are either calcium sodium alginate or pure calcium alginate. Calcium alginate is used as a hemostatic agent for lacerations, postoperative wounds, donor sites, nasal sinuses, or dental alveoli; a formulation in combination with zinc improves this ability. Calcium alginate is used as a wound filler or dressing that stimulates granulation in wounds after they have been debrided, and increases epithelialization. These dressings also absorb moderate to large amounts of exudate (20–30 times its weight in fluid) and are appropriate during the inflammatory or repair phases of healing for wounds. Ion exchange with the exudates causes a biodegradable viscous hydrogel to form on the surface of the wound. The released calcium ions and a phospholipid surface promote the activation of prothrombin in the clotting cascade. Placement of calcium alginate dressings overexposed muscle, tendon, bone, or dry necrotic tissue is not recommended. Bandages are changed every 1 to 5 days depending on the amount of wound exudates.

Foams

Polyurethane foam dressings (e.g., Copa, Permafoam) are highly absorbent, hydrophilic dressings with a nonadherent contact surface. Some have adhesive borders to adhere to normal adjacent skin. They are highly conforming, vapor permeable, and an effective barrier to bacterial penetration. These dressings are designed to protect and cushion a variety of wounds, especially those in difficult areas. Products vary in conformability, permeability, and absorbency. They maintain a moist wound environment, support autolytic debridement, and promote epithelialization; therefore they are appropriate for partial- or full-thickness wounds with small to moderate amounts of exudates, moist necrotic wounds, or clean granulating wounds. The foam pads are easy to apply and can be cut to fit the wound dimensions. The foam should be wetted with saline or medications if the wound is mildly exudative, or it can be used with another contact layer to prevent adherence. Dressing changes are recommended every 1 to 5 days depending on wound exudation.

Antimicrobial (Polyhexamethyl Biguanide) Gauze Dressings

Sterile gauze sponges, roll gauze, or nonadherent pads impregnated with polyhexamethyl biguanide (Kerlix AMD sponge or roll, Telfa AMD nonadherent dressing) may be used alone or on top of another contact layer. Polyhexamethyl biguanide is a polymeric biguanide with antimicrobial action against gram-positive and gram-negative bacteria. Susceptibility to biguanides varies among bacterial species, with greater efficacy noted against gram-positive bacteria. Polyhexamethyl biguanide is rapidly bactericidal at high concentrations, causing disruption of bacterial

cytoplasmic membranes with leakage and precipitation of cell contents. It is tissue compatible and does not have any apparent negative effects on wound healing. It is similar to chlorhexidine and is used in contact lens solutions, disinfectants, antiseptics, and other products to control bacterial growth. Dressings impregnated with polyhexamethyl biguanide resist bacterial colonization on wounds and have prolonged local activity. Environmental bacteria are inhibited from penetrating the bandage to gain access to the wound, and bacteria on the wound are inhibited from contaminating the environment. Both gauze sponges and rolls are available. Premoisten the gauze if it is used as a packing material.

Other Antimicrobial Dressings

Dressings impregnated with iodine, chlorhexidine acetate, activated charcoal, antibiotics, and silver are also available to aid in the prevention and control of infection. Iodine is found in crosslinked polymerized dextran dressings. As the dressing hydrates in the moist wound environment, elemental iodine is released to exert an antibacterial effect and to interact with macrophages to produce TNF-α and IL-6. The slow release is designed to maintain adequate levels of active iodine for approximately 48 hours.

Silver-impregnated dressings (e.g., Acticoat) release silver from the dressing over time to kill bacteria. Bacterial susceptibility includes *E. coli, Klebsiella pneumoniae, P. aeruginosa, Streptococcus* spp., and *Staphylococcus* spp., including methicillin-resistant *Staphylococcus aureus*. These dressings are most effective during the inflammatory and repair phases of wound healing, and they are of great benefit in the management of burn wounds (see p. 237). Numerous forms of silver-impregnated dressings are available, as silver is often combined with other agents (e.g., alginate [Silvercel], activated charcoal [Actisorb], hydrogel [Silvasorb], maltodextrin [Algidex AG], and foam [Aquacel Ag Foam]).

Activated charcoal dressings (Activate, Actisorb) provide a moist wound healing environment, absorb bacteria, prevent exuberant granulation tissue formation, and may reduce wound odor. They are intended for heavily infected wounds during the debridement phase to the repair phase of wound healing.

Antibiotic-impregnated collagen sponges are used in human surgery to treat or prevent surgical site infections. CollaRx is made from denatured type 1 bovine collagen impregnated with gentamicin. In addition to its antibacterial effects, these sponges exert a hemostatic effect by causing the adhesion and aggregation of platelets and bridge proteins. The fully biodegradable material releases high levels of antibiotic at the implant site, whereas serum levels remain below toxic levels.

Bioactive Dressings

Bioactive dressings are composed of materials that originate from living tissue. Bioactive dressings include those derived from fibroblasts by tissue cell cultures, artificial skin derived from keratinocytes, and extracellular matrix dressing derived from the submucosal layers of the porcine small intestine or urinary bladder, as well as biologic dressings such as skin grafts, amniotic membrane, and peritoneum. Biologic dressings may serve as contact layers on wounds with minimal exudate.

Collagen dressings (Helix3 CM) are derived from bovine or swine material and rendered nonantigenic as a result of enzymatic purification. They are available in sheets, particles, pastes, or gels. They are believed to accelerate wound repair by the provision of a matrix for cellular migration. They are used most often on large avulsion wounds as a scaffold for tissue ingrowth. Extracellular matrix scaffolds have an angiogenic effect and recruit stem cells to migrate into the acellular scaffold to reconstruct and remodel severely damaged or missing tissue.

Porcine small intestinal or urinary submucosa (Oasis Wound Matrix, ACell Vet Scaffold) can be used as a wound dressing to provide a biocompatible, absorbable scaffold for tissue ingrowth.

Chitosan dressings (Hemcon Patch or Bandage, ExcelArrest XT) are derived from the chitin, a natural polysaccharide from the exoskeleton of shellfish. This biodegradable dressing provides an antibacterial barrier; however, its primary use is for hemostasis.

Biobrane is a temporary wound dressing composed of an ultrathin, semipermeable silicone membrane bonded to a flexible, knitted nylon fabric with pores. The two layers are covalently bonded to porcine collagen peptides to increase wound adherence. Biobrane is flexible and stretches to conform to the area. It is incorporated into the wound and is therefore comfortable. The wound can be seen through the dressing, and minimal fluid collects. The dressing is removed when epithelialization is complete or infection is detected. This dressing's primary use is for superficial and partial-thickness wounds.

Transparent Vapor-Permeable Films

Transparent film dressings (e.g., OpSite, Tegaderm, Bioguard, Bioclusive) are thin, transparent, moisture-retentive dressings made of polyurethane. They are comfortable, water resistant, and allow wound inspection without dressing removal. They are adhesive to dry skin but nonadhesive to wounds. They are semipermeable, transmitting oxygen, water vapor, and carbon dioxide, but occlusive to water and bacteria (e.g., *Pseudomonas, Staphylococcus,* and *E. coli*). Drainage collects under the membrane. The moist environment accelerates healing. Uses include superficial or partial-thickness wounds with few or no exudates and dry, necrotic eschars to provide a moist autolytic debridement. They are not used on infected or exudative wounds or thin, fragile skin. They may be used during the entire healing period. They are applied so they extend at least 2 cm beyond the wound margins. Applying a skin sealant on intact surrounding skin before dressing application helps prevent maceration and skin stripping. They do not adhere well to areas with skin folds or unshaved hair and are better suited to people than animals. Adherence can be improved around the perimeter with vapor-permeable film spray.

Intermediate (Secondary) Layer

The intermediate layer of a bandage is an absorbent layer that removes and stores deleterious agents (e.g., blood, serum, exudate, debris, bacteria, and enzymes) away from the wound surface. Bacterial growth is retarded if the bandage allows fluid evaporation and exudate becomes concentrated. The intermediate layer should have capillarity for absorption and should be thick enough to collect fluid. The intermediate layer also pads the wound from trauma, splints the wound to prevent movement, and holds the contact layer against the wound. Absorbent cotton, combine roll, or cast padding may be used. Enough pressure must be applied during application of this layer to eliminate spaces between the wound and contact layer and between the contact layer and intermediate layer. Such spaces allow fluid to accumulate, which promotes tissue maceration; however, excessive compression impairs absorption and interferes with blood supply and wound contraction. The outer layers of the intermediate layer can be

made nonabsorptive by applying petrolatum, which inhibits environmental fluid from reaching the wound.

Outer (Tertiary) Layer

The tertiary layer holds the other bandage layers in place and protects them from external contamination. Roll gauze or surgical adhesive tape are used for the outer bandage layer. Porous tape allows fluid evaporation and promotes dryness, but it allows surface bacteria to contaminate the wound when it becomes wet. Conversely, wound bacteria can migrate through taped bandages and contaminate the environment. Using antimicrobial roll gauze (Kerlix AMD sponge or roll) to compress the intermediate bandage layer helps control bacteria on the wound surface and helps prevent environmental organisms from migrating through the bandage to the wound. Waterproof tape protects the wound from environmental fluids but creates an occlusive bandage that may lead to tissue maceration. It should be used only in areas predisposed to getting wet (e.g., the feet), and it often is used in combination with porous tape. Elastic adhesive tapes (e.g., Elastikon) apply pressure, conform to the area, and immobilize it. Support rods or splints may be incorporated into the outer layer of the bandage if additional immobilization is required. Custom-made or modified garments (e.g., VetGood Protective Medical Pet Suit, Suitical Recovery Suit, Surgi Snuggly, Surgi-Sox, DogLeggs) can be used to protect or replace the tertiary layer of bandages applied to the body or head. Elizabethan collars, side or body bars, and tape hobbles are commonly used to prevent the patient from chewing on the bandage.

TYPES OF BANDAGES

When applying bandages, appropriate materials of adequate width should be used to prevent a tourniquet effect. Porous materials allow air to circulate and moisture to escape. All bandages should be applied as smoothly as possible to prevent ridges and lumps, which may cause irritation and skin necrosis. Each turn of the bandage should overlap the previous turn by 50%. It is sometimes advantageous to unroll elastic tapes and allow them to relax before encircling a body part to prevent application of excessive pressure. Owners must be instructed on proper bandage care. Bandages should be evaluated frequently for signs of slippage or strikethrough. The surface of all bandages should be kept clean and dry. Patients should be observed for discomfort, swelling, hypothermia, skin discoloration, dryness, or odor, which may indicate that the area has been bandaged improperly. Bandages applied too tightly impair circulation and damage soft tissue. Digits should be exposed when extremity bandages are applied to allow sensation and circulation to be monitored. Loose bandages cause pressure sores or slippage. Patients should be restrained from chewing at the bandage, and exercise should be limited to short leash walks. When the patient is outside, bandages should be covered with a plastic bag or other waterproof material to protect them from dirt and moisture. The waterproof material should be removed within 30 minutes to prevent excess accumulation of moisture under the bandage.

Signs of pain (i.e., excessive licking or chewing at the bandage) and swelling may indicate an ill-fitting bandage, which should be replaced to prevent serious complications. Bandages that apply too much or uneven pressure, especially over bony prominences, may lead to ischemia and pressure necrosis. If deep tissues are affected, amputation of a limb may be necessary. Skin grafting or flaps may be necessary to reconstruct more superficial injuries.

Tie-Over Bandages

The contact and absorbent layers of a bandage can be held in place with a tie-over bandage when the wound is in an area inaccessible to standard bandaging techniques (e.g., hip, shoulder, axilla, or perineum) (Fig. 15.9).

Place several sutures (e.g., 2-0 nylon, 0 nylon, or polypropylene) in the skin surrounding the wound, tying them with a loose loop. Apply an appropriate contact layer and an intermediate bandage layer on the wound. Hold these layers in place by lacing sterile gauze or umbilical tape through the loose skin sutures. As an alternative, staple long strands of suture 2 to 3 cm from the wound edges around the periphery of the wound, then tie or clamp these sutures over the bandage to hold it in place. Cover the area with an outer bandage layer if possible (Fig. 15.10).

Stabilizing Bandages

Stabilizing bandages help immobilize fractures to minimize further tissue damage during transport for definitive fracture fixation. These bandages are heavily padded and are often referred

FIG. 15.9 (A) A large open wound on the lateral thigh of a 6-year-old Greyhound. (B) A tie-over bandage is used to manage the wound.

FIG. 15.10 Apply several sutures or skin staples with loose loops around the periphery of wounds to create a tie-over bandage in areas inaccessible to standard bandaging techniques. Apply the primary and secondary bandage layers, then hold the tertiary layer in position by lacing umbilical tape or heavy suture through the loose skin sutures or staples.

to as Robert Jones bandages (see p. 981 for application technique). After fracture fixation with splints, external fixators, or internal fixation, stabilizing bandages may be used to support injured tissue, reduce swelling, and treat open wounds. The type of wound and condition of the tissue determine the type of bandage applied to the wound.

Postoperative or Closed Wound Bandages

Bandages may be applied to areas without an open wound to absorb fluid from a drain or incision line, to support the incision, to compress dead space, to apply pressure, or to prevent trauma or contamination. These bandages improve the patient's comfort by supporting wounds.

Place a nonadherent, absorbent dressing over the incision line and several layers of wide-mesh, absorbent gauze over drains. Determine the thickness of the intermediate layer based on the amount of drainage expected. Be sure to use adequate padding over the end of the drain to prevent strikethrough. Assess the character and amount of drainage with each bandage change.

Incisions expected to have minimal drainage may be protected from environmental contaminants with a nonadherent absorptive pad, which is incorporated into an adhesive polyurethane film dressing.

Pressure Bandages

Pressure bandages facilitate control of minor hemorrhage, edema, and excess granulation tissue. Direct application of a glucocorticoid ointment to the wound may help control excess granulation tissue. The more convex the surface, the greater the pressure exerted by the dressing on the tissue.

Apply an absorbent, nonadherent contact layer over the area of hemorrhage or excess granulation tissue. Use a thick, absorbent intermediate layer and elastic adhesive tape for the outer bandage layer. Wrap the elastic tape carefully to prevent excess pressure, which can impair arterial, venous, and lymphatic circulation and cause tissue necrosis or nerve damage. Check for discomfort, swelling, hypothermia, dryness, or odor, which may indicate that the area has been bandaged too tightly. Remove the bandage within 24 hours if it was applied to control hemorrhage.

FIG. 15.11 Pressure relief bandage applied over the greater trochanter in a dog. The bandage is made from a firmly rolled towel that is cut, taped, and applied over the bony prominence.

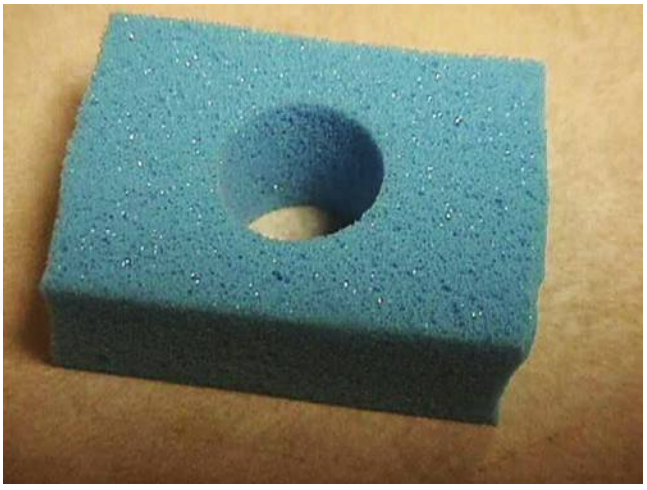

FIG. 15.12 A hole has been cut through this foam sponge to distribute pressure around a pressure sore or wound.

Pressure Relief Bandages

Bandages designed to prevent pressure over an area (usually a bony prominence) are used to treat or prevent pressure sores (see p. 246). Preventing pressure encourages healing over bony prominences. Most pressure relief bandages use a doughnut-shaped bandage, foam, or pipe insulation (Fig. 15.11) to distribute pressure around rather than over the wound. The bandage should be large and thick enough to prevent pressure over the bony prominence. A circular opening may be created in the bandage and used to treat the wound without removing the entire bandage.

A doughnut-shaped bandage may be created from cast padding, medium-density foam sponge, or a small towel (Figs. 15.11 and 15.12). *Create a doughnut-shaped bandage by rolling a towel or cloth into a tight cylinder, securely taping it to maintain the roll, and forming it into an appropriately sized circle. Create a doughnut-shaped bandage from cast padding by folding several layers together and cutting a hole in the center to accommodate the bony prominence or to surround the wound. Create a doughnut opening in thick foam by cutting a hole in the center to accommodate the bony*

prominence or to surround the wound. Center the doughnut-shaped bandage over the lesion or bony prominence and secure it to the skin with tape so that it does not slip.

These bandages may be difficult to maintain in position, and taping directly to the skin may cause skin irritation. Pipe insulation bandages are usually used to protect the olecranon. *Create bandages from foam rubber pipe insulation tubes by splitting the tube and cutting a hole where the bony prominence will lie. If necessary, use two or three thicknesses of pipe. Stack and tape the pieces of pipe together. When using the bandage over the olecranon, first pad the cranial surface of the radiohumeral joint with cast padding to prevent joint flexion and to keep the dog from lying in sternal recumbency. Then tape the cast padding and pipe insulation in place. Use a spica type of bandage (see the discussion on bandaging extremities below) if necessary to hold the bandage in position. When using the doughnut to redistribute pressure from a wound, first apply the contact and intermediate layers of the bandage, then incorporate the doughnut in the outer bandage layer.*

BANDAGING TECHNIQUES

Bandaging the Thorax and Abdomen

The thorax and abdomen are often bandaged to cover wounds, surgical incisions, or drainage devices. These bandages should be applied firmly, but without constricting the chest or abdomen. Abdominal pressure bandages are occasionally used when abdominal hemorrhage is suspected. Their effectiveness lasts only 1 to 2 hours, and they should be removed within 4 hours. When placing an abdominal pressure bandage, bandage layers should be applied firmly. A rolled towel can be placed along the midline to reinforce the bandage before tape is applied.

Apply a nonadherent contact layer over the incision or wound. Hold the contact layer in position with combine rolls, cast padding, or cotton. Use padding, gauze, and tape rolls 3 to 6 inches (7–15 cm) wide and wrap the padding circumferentially around the torso with slight pressure. Overlap each wrap by approximately one-half to one-third the width of the roll. Increase the thickness of the intermediate layer with increasing amounts of expected drainage. Reduce rostral or caudal slipping of the bandage by wrapping the intermediate and outer bandage layers between the legs and over the shoulders or hips in a crisscross fashion. Encircle the torso with one wrap of bandage material, then direct the bandage from the right inguinal area (axillary area) to the left perineal area (shoulder area). Encircle the torso again and continue across the right perineal area (shoulder area), through the left inguinal area (axillary area), to the left flank (thorax). Repeat the crisscross pattern several times. Also reduce slippage by adhering 0.5 to 1 inch (1–3 cm) of tape to the hair. Do not wrap the bandage so tightly that thoracic expansion is inhibited. Hold the intermediate layer in place with elastic tape gauze or stockinette. Cut a length of stockinette (3 inches [7.5 cm] for cats and small dogs; 4–6 inches [10–15 cm] for medium and large dogs) slightly longer than the length of the body from head to rump. Cut small holes in the stockinette to accommodate the legs. Place the stockinette over the head, and pull the front legs through the leg holes before rolling the stockinette caudally. Pull the hind legs through the leg holes. Secure the bandage with tape. In male dogs, cut a hole in the bandage to accommodate the prepuce or divert urine with a catheter to keep the bandage dry.

Bandaging the Head

Most head bandages are placed to protect an ear that has been traumatized or has surgical incisions (Fig. 15.13). Similar bandages can be used to cover the eye. Head bandages may interfere with breathing if they are applied too snugly or with neck flexion. A properly applied bandage should allow insertion of the fingers between the bandage and the chin to allow room for neck flexion without airway obstruction. If the bandage is too tight, an incision can be made partway across the bandage under the chin. Leaving one ear out of the bandage helps to keep the bandage from sliding. Extreme caution should be used when removing the bandage to prevent laceration or amputation of the pinna. Commercial products are available (e.g., Surgi-Sox Aural Compression Bandage, DogLeggs).

FIG. 15.13 A head bandage is being used to manage multiple head and neck bite wounds in a 5-month-old German shepherd. The tape muzzle was placed to manage maxillary and mandibular fractures.

Apply 1-inch (3 cm) porous tape directly to the edge of the pinna to form a stirrup (see Fig. 17.23). Fold the ear over an absorbent pad or gauze sponges onto the dorsum of the head, and wrap the tape around the head to secure the ear in position. Using a similar technique, pad and place the opposite pinna over the first pinna if indicated. Place a nonadherent contact layer over an incision or place gauze sponges over the end of a passive drain. Hold the pinna and contact layers in position with 2- to 3-inch (5–7.5 cm) cast padding or cotton roll. Encircle the head, passing the rolls of bandage material cranial and caudal to the opposite ear unless both ears are immobilized. Starting under the chin, wrap loosely and overlap each wrap by approximately one-third the width of the roll. Cover this intermediate bandage layer with overlapping wraps of elastic gauze or stockinette. To prevent slippage, secure the bandage in position with elastic tape attached to the skin and hair at the cranial and caudal edges of the bandage. If it will be necessary to medicate the ear, cut holes in the bandaging over the external acoustic meatus.

Bandaging the Extremities

A soft, padded extremity bandage is used to cover abrasions, lacerations, or incisions and can be modified to accommodate splints for joint or bone immobilization. Modifications of the basic padded bandage may be necessary to allow immobilization, prevent slippage, or protect digits. Immobilization is accomplished by placing a spoon splint, molded thermoplastic splint, fiberglass splint, or aluminum rods between the intermediate and outer bandage layers. These materials may sometimes replace the outer layer. It is important to ensure adequate padding at the ends of the splint material to

prevent skin irritation. Placing additional padding over possible pressure points under a splint or bandage increases the pressure on these points when compressed; therefore it is better to use a doughnut pad to redistribute the pressure to a larger area surrounding the pressure point (see Figs. 15.11 and 15.12).

Begin by applying a 1-inch (2.5 cm) porous tape stirrup to the dorsal and ventral or medial and lateral surfaces of the paw (Fig. 15.14A). Extend stirrups 3 to 8 inches (7.5–20 cm) beyond the digits to help prevent the bandage from slipping distally. If necessary, use a loose layer of elastic gauze to help secure the stirrups. Insert small pledgets of cotton or other absorbent material between the digits and the metatarsal-metacarpal pads and digital pads. Apply an appropriate contact layer over the wound (see p. 195). Snugly apply cast padding around the paw beginning at the level of the second and fifth digital pads. Wrap obliquely so that the third and fourth digits protrude slightly beyond the bandage (see Fig. 15.14B). Overlap the cast padding (2- to 3-inch width [5–7.5 cm]) one-half to two-thirds of its width as it is advanced up the leg. Continue the bandage to the proximal radius and ulna (tibia and fibula) or above the elbow (stifle), depending on the site of the injury. Use enough padding to create the bulkiness necessary for protection. Snugly wrap elastic gauze (2- to 3-inch width [5–7.5 cm]) over the cast padding to conform the padding to the limb, overlapping each turn by one-half the width of the material. Separate the tape stirrups and attach them to their respective sides of the bandage (see Fig. 15.14C). Apply an outer layer of elastic tape (2- to 3-inch width), overlapping one half the width with each turn (see Fig. 15.14D). Avoid overstretching the tape to prevent compromising limb circulation. Check exposed digits three and four frequently for swelling, coolness, and discomfort; remove the bandage and evaluate the limb if these signs are observed.

Eliminate pressure from digital pad injuries by using a triangular piece of medium-density foam cut to the size of the carpal or tarsal pad or a medium-density foam doughnut to protect carpal or tarsal pad injuries (see Fig. 15.12). Placing a solid foam pad outside the intermediate bandage layer before the outer tape layer is placed helps to relieve pressure from the digits. Similarly, place the doughnut before applying the outer bandage layer.

Slippage can be prevented by extending the bandage to encircle the shoulder and thorax (hip and caudal abdomen), creating a spica-type of bandage (Fig. 15.15). This bandage immobilizes the shoulder or hip in addition to the more distal joints and often incorporates splint material. The intermediate and outer bandage layers crisscross cranial and caudal to the affected limb and caudal and cranial to the contralateral limb (as described on p. 206) for abdominal and thoracic bandages. The bandage is reinforced with splint rod, fiberglass casting tape, or thermoplastic splint material if fractures are to be temporarily stabilized or if additional wound immobilization is desired.

Temporary immobilization of injuries below the elbow or stifle can also be accomplished by applying a Robert Jones bandage or a modified Robert Jones bandage. A Robert Jones bandage is a large, bulky bandage that provides stabilization by applying compression to a thick cotton layer (see p. 981). A modified or light Robert Jones bandage has much less cotton padding, making it less bulky. Modified Robert Jones bandages are used to reduce limb edema after surgery.

Onychectomy, digit amputation, or pad reconstruction may benefit from a bandage to protect the digits and reduce hemorrhage. In these cases, stirrups should be applied laterally and the digits covered with gauze sponges or a nonadherent contact layer.

Reflect layers of 2-inch (5 cm) cast padding from dorsal to ventral and then ventral to dorsal over the end of the paw (Fig. 15.16A). Extend the cast padding in a spiral pattern to the midradius and midulna (tibia and fibula). Leave the proximal ends of the tape stirrup exposed to aid bandage removal. Cover the cast padding with elastic gauze. Fold the tape stirrups to their respective sides. Cover the bandage with tape from the distal extremity to the proximal hair (see Fig. 15.16B).

PRINCIPLES OF PLASTIC AND RECONSTRUCTIVE SURGERY

SKIN TENSION AND ELASTICITY

Reconstructive surgery is commonly performed to close defects that occur secondary to trauma, to correct or improve congenital abnormalities, or after removal of neoplasms. A variety of reconstructive procedures are available; it is important to select the appropriate technique or techniques to prevent complications and avoid unnecessary cost. Although large lesions, particularly those on the trunk, often heal by contraction and epithelialization (see p. 181), wound closure may be preferable. Large or irregular defects can sometimes be closed using relaxing incisions or "plasty" techniques (e.g., V-to-Y plasty, Z-plasty). Large defects or those on the extremities may require that tissue be mobilized from other sites. Pedicle flaps are tissues that are partly detached from the donor site and mobilized to cover a defect (see p. 217); grafts involve the transfer of a segment of skin to a distant (recipient) site (see p. 232). Careful planning and meticulous, atraumatic surgical techniques are necessary to prevent excessive tension, kinking, and circulatory compromise. The amount of skin available for transfer varies between sites on the same animal and between breeds. Little skin can be mobilized in the extremities, whereas advancing adjacent tissue can often close large defects over the trunk. The character of the recipient bed influences the choice of reconstructive technique. Properly developed and transferred local flaps can survive on avascular beds, whereas grafts and distant flap transfers require vascular beds (i.e., healthy granulation tissue, muscle, periosteum, and paratenon).

Hirudiniasis, or the attachment of leeches to skin, can help in reconstructive and microvascular surgery. Leeches are recommended only for tissues with impaired venous circulation. The medicinal leech is *Hirudo medicinalis*. After a blood meal, a leech can go for months without eating. Leeches produce a small bleeding wound that mimics venous outflow. The leech eats an average of 5 mL of blood, but blood oozes from the wound for 24 to 48 hours after the leech detaches because of anticoagulants and vasodilator substances introduced into the wound. There is a significant risk of infection with *Aeromonas hydrophila* when leeches are used.

TENSION LINES AND TENSION RELIEF

The location of the wound, elasticity of surrounding tissue, regional blood supply, and character of the wound bed should be considered when planning reconstructive surgery. Grasping and lifting the skin in the proposed flap or graft area and allowing it to retract spontaneously assesses skin tension and elasticity. Evaluating the amount of tension that can be tolerated by tissue is subjective. Apposing incision edges under too much tension causes incisional discomfort and pressure necrosis, resulting in sutures "cutting out" and partial or complete incisional dehiscence.

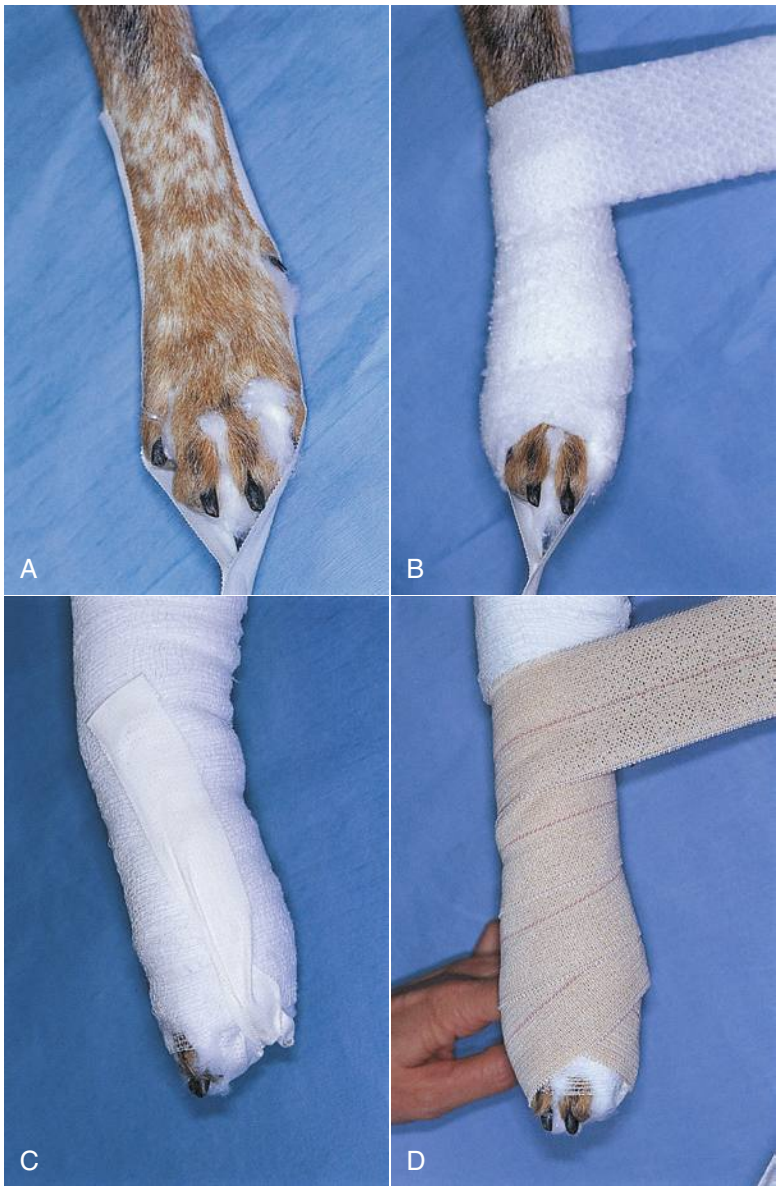

FIG. 15.14 (A) For a leg bandage, apply a 1-inch (2.5 cm) porous tape stirrup to the dorsal and ventral or medial and lateral surfaces of the paw. Insert an absorbent material between the digits and the metacarpal or metatarsal and digital pads. (B) Apply cast padding or cotton over an appropriate contact layer, overlapping wraps by one-half to two-thirds the width of the roll. Keep the third and fourth digits exposed. Conform the padding to the limb by applying elastic gauze. Apply a splint for greater immobilization between the padding and elastic gauze (optional). (C) Fold the tape stirrups over the gauze. (D) Apply an outer layer of 2- to 3-inch-wide (5–7.5 cm) elastic tape, overlapping one-half of the width of the tape with each turn.

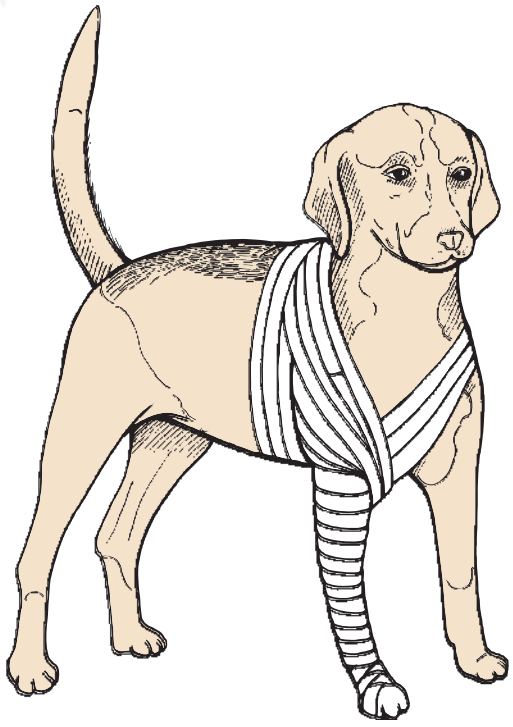
Methods of reducing tension include undermining wound edges, selecting appropriate suture patterns, and using relief incisions, skin stretching, and tissue expansion. In addition, the animal is always positioned for surgery, such that mobile skin is not pinned against the table; using pads and flexing the appropriate joints accomplish this. If these methods do not allow primary apposition, wounds may be allowed to heal by secondary intention or may be reconstructed with flaps or grafts.

Tension Lines

Tension lines are formed by the predominant pull of fibrous tissue within the skin. General lines of tension have been mapped in animals, but breed, conformation, gender, and age variations occur (Fig. 15.17). Tension causes incised skin edges to separate and widens linear scars (Fig. 15.18). Incisions should be made parallel to tension lines. Incisions and wounds along tension lines heal better, faster, and with more aesthetic results, whereas those made across tension lines tend to gape. Incisions made at an angle to tension lines take a curvilinear shape. Incisions made across tension lines require more sutures for closure and are more likely to dehisce than those made parallel to tension lines. Traumatic wounds should be closed in the direction that prevents or minimizes tension. Wound edges should be manipulated before closure to determine which direction the suture line should run



FIG, 15.15 For proximal extremity lesions, continue the bandage up the leg, around the chest or abdomen, and between the legs to create a spica-type bandage.

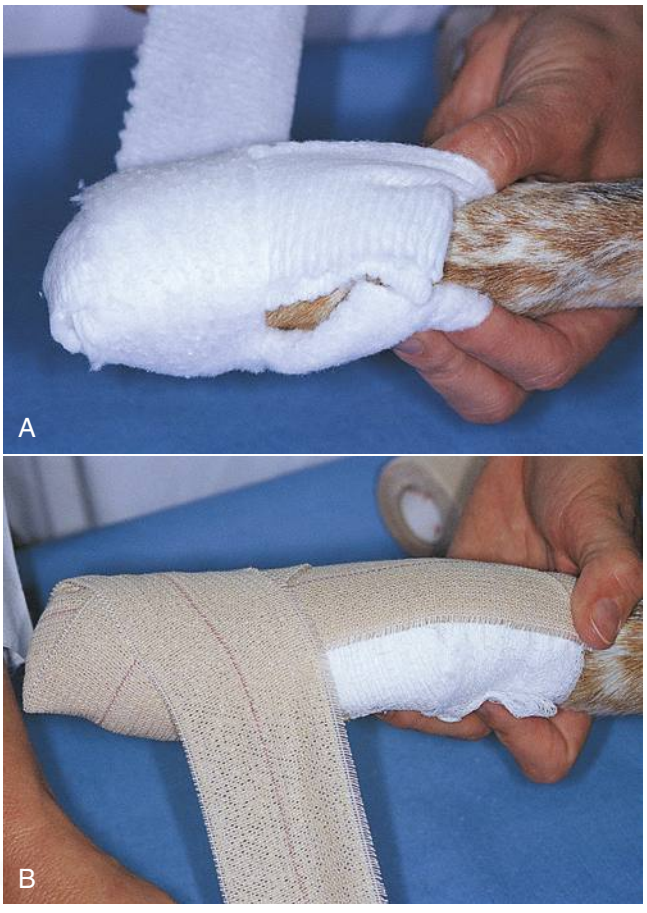


FIG. 15.16 A paw bandage is placed in a manner similar to a leg bandage, except that the digits are covered. (A) After placing stirrups and the contact layer, reflect cast padding over the digits from dorsal to ventral and then ventral to dorsal. Then wrap the padding around the distal limb. (B) Conform the bandage to the limb with elastic gauze and secure the bandage with elastic tape in a similar fashion.

to minimize tension (Fig. 15.19). If tension is minimal, a wound should be closed in the direction of its long axis. The direction of closure should prevent or minimize the creation of "dog ears," or puckers, at the ends of suture lines.

Tension Relief

Skin is undermined by using scissors to separate the skin or panniculus muscle (or both) from underlying tissue. Undermining skin adjacent to a wound is the simplest tension-relieving procedure. It releases skin from underlying attachments so that its full elastic potential can be used as it is stretched over the wound. Skin should be undermined deep to the panniculus muscle layer to preserve subdermal plexus and direct cutaneous vessels that run parallel to the skin surface (Fig. 15.20). Where there is no panniculus muscle layer (middle and distal portion of the extremities), the skin should be undermined in the loose areolar fascia deep to the dermis to preserve the subdermal plexus. Elevated skin should include a portion of the superficial fascia with the dermis to preserve the direct cutaneous arteries. In areas where skin is closely associated with an underlying muscle, a portion of the outer muscle fascia should be elevated with the dermis rather than dissecting these structures. Prevent subdermal plexus injury by using an atraumatic surgical technique, including cutting skin with a sharp scalpel blade instead of scissors and avoiding crushing instruments (e.g., Allis tissue forceps). Brown-Adson thumb forceps, skin hooks, or stay sutures should be used to manipulate skin. Tissue layers are separated by repeatedly inserting Metzenbaum scissors with the blades closed, opening the blades, and then withdrawing the scissors in an open position. Tissue is snipped with the scissors as necessary. As an alternative, the partly opened scissors can be advanced along the cleavage plane without snipping. While undermining, determine if tension relief is adequate by periodically attempting to approximate the skin edges.

Bleeding is usually insignificant during undermining. Excessive bleeding may be controlled with electrocoagulation or ligation; however, skin tension and bandaging usually control hemorrhage and prevent seromas. Undermining areas near wound margins associated with delayed wound closure requires that the epithelialized skin edge be separated from the granulation tissue. The skin should be excised with a scalpel blade at the junction of normal skin and new epithelium. The incision should be continued through the granulation tissue at the normal cleavage line of subcutaneous fascia, deep to the subdermal plexus. Wound closure under excessive tension, rough surgical technique, and division of direct cutaneous arteries interfere with cutaneous circulation and may cause skin necrosis, wound dehiscence, or infection. Surgical manipulation of recently traumatized skin should be minimized until circulation improves. Resolution of contusions, edema, and infection indicates improved skin circulation.

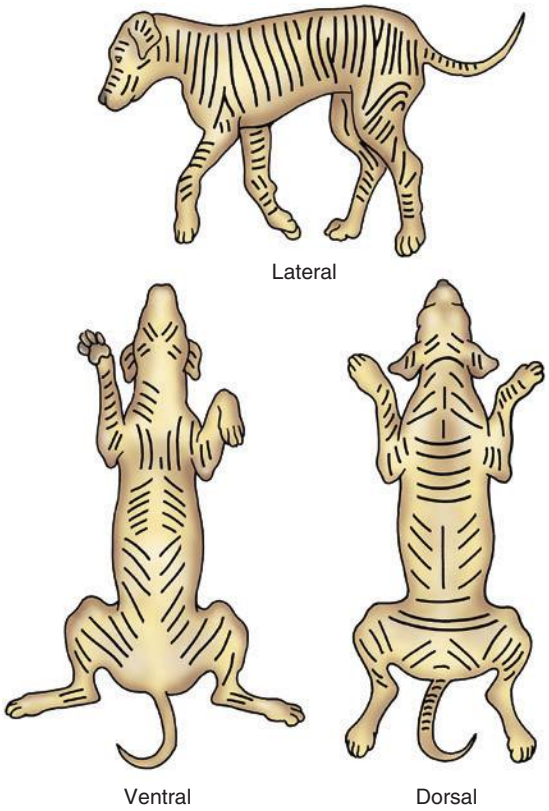

FIG. 15.17 Approximate skin tension lines in dogs. (Modified from Irwin DHG. Tension lines in the skin of the dog. *J Small Anim Pract*. 1966;7:595.)

Skin Stretching and Expansion

Skin stretching and expansion is a technique used in reconstructive surgery that takes advantage of the skin's ability to stretch beyond its natural or inherent elasticity, by the processes of mechanical creep and stress relaxation, when continuous tension is applied. During this process, dermal collagen fibers are stretched, and tissue fluid is slowly displaced from around collagen fibers, which are straightening and compacting longitudinally in the direction of the stretching force. Skin can be prestretched hours to days before surgery to allow closure with less tension at the time of the procedure. Presuturing, adjustable sutures, skin stretchers, and skin expanders are used in this technique (Fig. 15.21). Presuturing is performed 24 hours before surgery to prestretch the skin. Lidocaine, sedation, or general anesthesia is administered

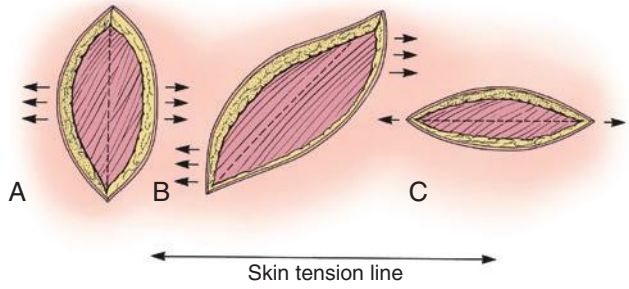

FIG. 15.18 Incisions made across tension lines. (A) Perpendicular or (B) oblique incisions gape and require more sutures for closure than incisions that (C) parallel skin tension lines.

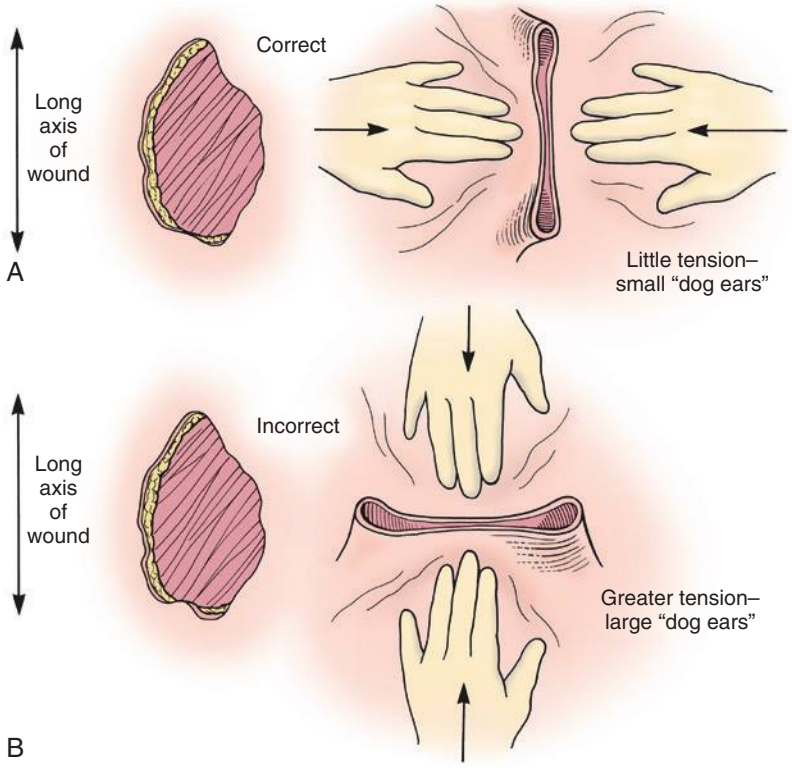

FIG. 15.19 Wound edges should be manipulated to determine the direction of least tension and minimal "dog ear" formation. (A) Wound edges showing little tension and small dog ears. (B) Wound edges showing greater tension and large dog ears.

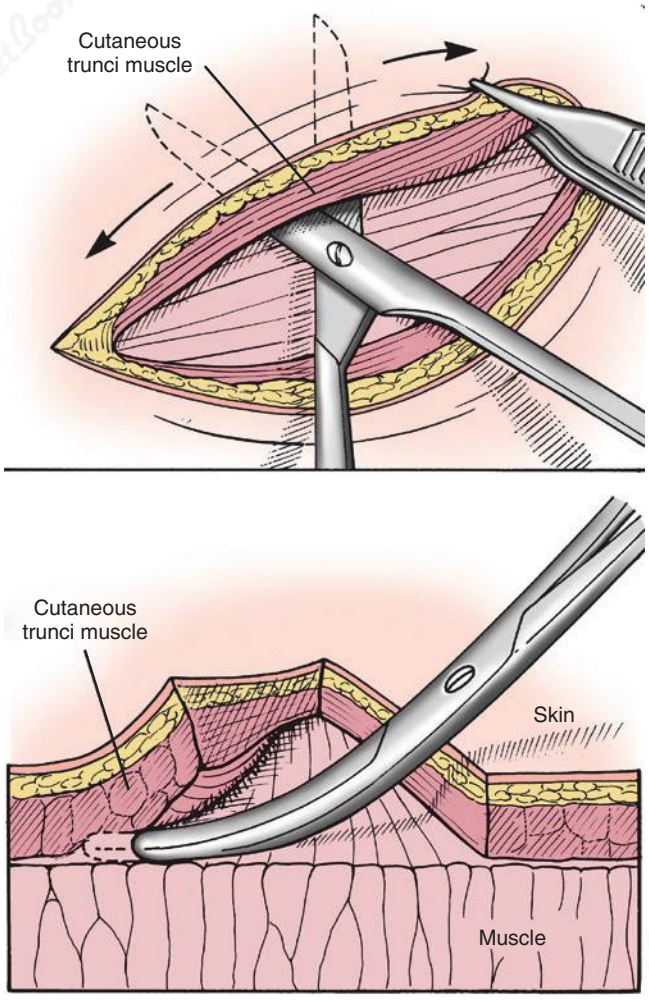

FIG. 15.20 Before wound closure, use scissors to undermine skin and subcutaneous tissue or skin and panniculus muscle and to separate them from the underlying tissue.

before suture placement to relieve discomfort. Tension sutures (interrupted Lembert or vertical mattress sutures of 2-0 or 0 monofilament, nonabsorbable suture material) are placed to imbricate skin on apposing sides of the lesion (see Fig. 15.21). Sutures are placed 3 to 5 cm from the proposed incision site. The sutures exert their effect primarily on healthy skin immediately adjacent to the proposed surgical site, and they are not adjustable. Presuturing is effective only in areas where elastic skin is limited (i.e., extremities). An adjustable horizontal suture can be used to stretch skin over a wound gradually. This is a continuous intradermal suture (2-0 to 3-0 nylon, polypropylene, or polybutester) anchored at one or both ends with a button secured on the skin surface with a split shot fishing weight. On succeeding days, traction on the suture advances the wound edges over the wound, and new weights are applied to maintain tension. These sutures are used primarily on limb wounds in which the wound edges cannot initially be apposed.

Skin stretchers (e.g., X-Banders) are a noninvasive device capable of stretching skin both adjacent to and distant from the surgical site. More skin can be stretched or recruited using this technique than by presuturing or tissue expanders. Skin stretchers are most effective on the neck and trunk. Self-adherent skin pads with a thin coat of additional cyanoacrylate adhesive are applied to clipped, clean, dry skin adjacent to and distant from the surgical site, depending on the amount of stretching needed. Pads are placed 1 to 2 cm from the wound margin with their long axis perpendicular to the direction of skin tension. Elastic connecting cables are attached to pads on one side of the wound and stretched before they are attached to the pads on the opposite side of the wound. An additional row or tier of pads and cables can be placed more distant from the wound if further skin recruitment is required. The cables are adjusted every 6 to 8 hours to generate the optimal high-tension load to accelerate skin stretching or deformation. Sufficient skin may be recruited within 24 to 48 hours, although 96 hours may be required. Pads are peeled from the skin or removed with glue solvent before surgery. Little or no undermining is generally required after skin stretching. Skin stretchers are also used before removal of a mass or after surgery when incisions are closed under excessive tension. Application of a skin stretcher helps alleviate tension and prevent dehiscence (see Fig. 15.21). Pads are generally removed 3 to 5 days after surgery.

Tissue expanders are inflated in subcutaneous tissue to stretch overlying skin, allowing creation of larger flaps for closing defects. They are beneficial in overcoming tissue shortage and obtaining skin with desirable qualities. Tissue expanders reduce dermal thickness and temporarily increase epidermal mitosis. Subcutaneous fat and muscle adjacent to the tissue expander atrophy, and neurapraxia may occur. Tissue expanders have an inflatable bag and reservoir made of silicone elastomer. Although expensive, they are available in various sizes and shapes (e.g., Integra). Careful planning is required for optimal expansion and reconstruction. The base of the expander should approximate the size of the donor site. The incision for insertion of the expander should be made parallel to tension lines at the leading edge of the future flap, or skin adjacent to the site will be inappropriately stretched. The device is placed subcutaneously and inflated with saline. Rapid expansion requires intermittent intraoperative short-term inflation of the expander. It involves inflating the expander for 2 to 3 minutes, deflating and letting the tissue rest for 3 to 4 minutes, and then repeating the cycle two or three times before creating a flap. Gradual expansion involves injecting to a given pressure or volume at intervals spanning days to weeks (usually every 2–7 days). Inflation at injection is continued until the skin feels tense or looks blanched or until discomfort is perceived. When the tissue is sufficiently stretched to allow reconstruction, the device is removed and a skin flap is created to close the defect. Complications of tissue expanders include pain, seroma formation, scar widening, infection, dehiscence, skin necrosis, and implant failure, and they should not be used in previously irradiated tissue. Axial pattern flaps (see p. 222) are preferable to tissue expanders for large wound reconstruction.

SUTURE PATTERNS

Subdermal Sutures

Subdermal fascia is strong and tolerates tension better than subcutaneous tissue or skin. Sutures placed in subdermal or subcuticular tissue reduce tension on skin sutures and bring skin edges into apposition. These sutures also reduce scarring. For subdermal and subcuticular sutures, 3-0 or 4-0 polydioxanone, poliglecaprone 25, or polyglyconate suture on a cutting needle with a buried knot is used.

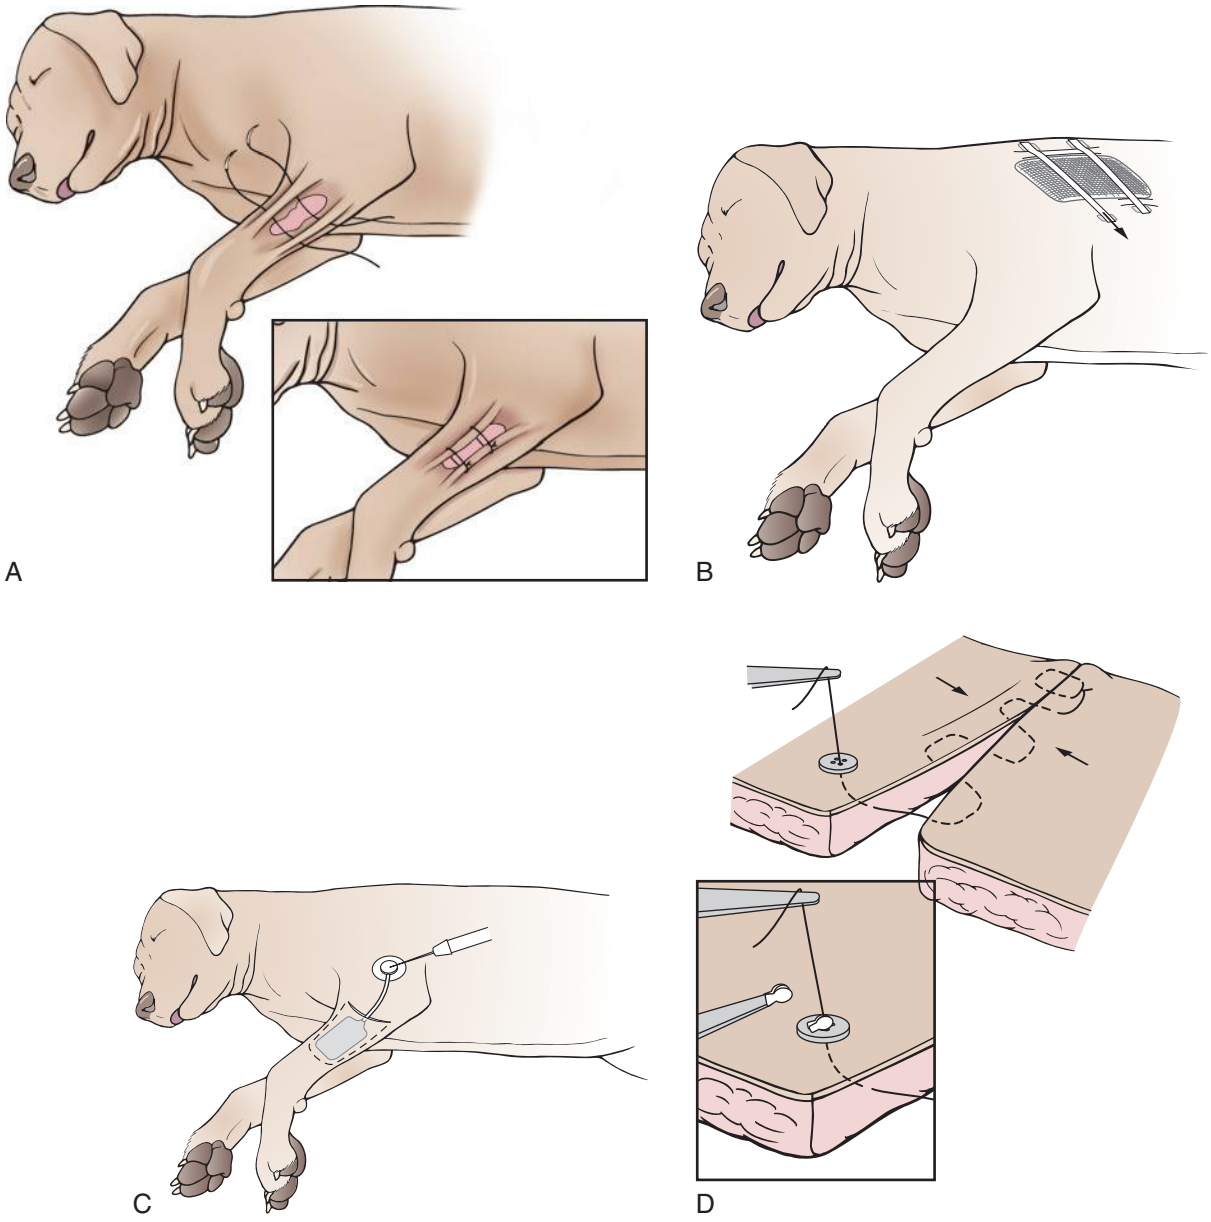

FIG. 15.21 Methods for recruiting skin to close wounds under tension include (A) presuturing, (B) skin stretchers, (C) inflatable tissue expanders, and (D) adjustable sutures.

Walking Sutures

Walking sutures move skin across a defect, obliterate dead space, and distribute tension over the wound surface. Skin is advanced toward the center of the wound by placing rows of interrupted, subdermal sutures beginning at the depths of the wound. The suture (e.g., 2-0 or 3-0 polydioxanone, poliglecaprone 25, or polyglyconate) should be placed through fascia of the body wall at a distance closer to the center of the wound than the bite through the subdermal fascia or deep dermis (Fig. 15.22). Walking sutures do not penetrate the skin surface. Tying the suture advances skin toward the wound center. Walking sutures are placed no closer than 2 to 3 cm apart. Successive rows of walking sutures further advance the skin toward the center of the wound. Sutures are placed on both sides of the defect to advance undermined skin toward the center. The number of walking sutures should be minimized to prevent creating subcutaneous loculi or compromising circulation. Subdermal and skin sutures are used to complete wound closure.

External Tension-Relieving Sutures

External tension-relieving sutures help prevent sutures from cutting out, which occurs when pressure on skin within the suture loop exceeds the pressure that allows blood flow. Pressure is reduced by spreading it over a larger area of skin. Placing sutures farther from the skin edge or using mattress or cruciate sutures helps disperse pressure. Other suture patterns that help relieve tension include alternating wide and narrow bites using simple interrupted sutures or placing pulley sutures, such as "far-near-near-far" or "far-far-near-near" patterns. The standard tension-relieving suture for the skin is called the *vertical mattress*

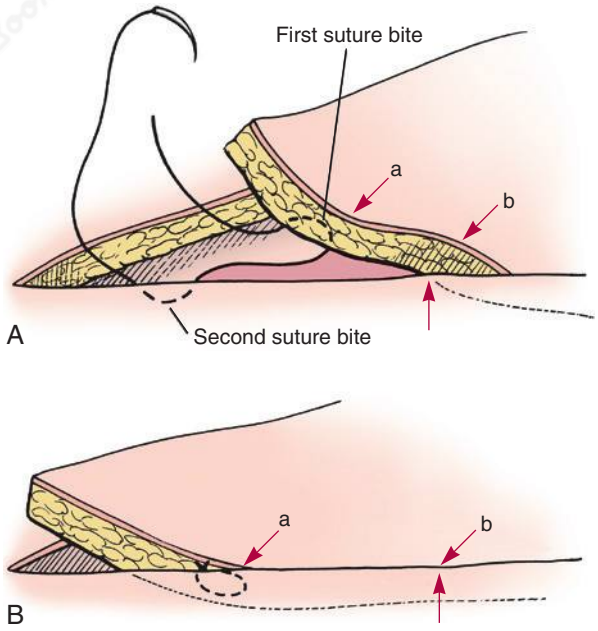

FIG. 15.22 Use walking sutures to advance skin toward the center of the wound. (A) Place the suture through the fascia of the body wall at a distance closer to the center of the wound than the bite through the subdermal fascia or deep dermis. (B) Note that the distance from *a* to *b* increases because of skin stretching when the suture is tied.

suture. A tension-relieving row of vertical mattress sutures should be placed 1 to 2 cm away from the primary row of sutures apposing the skin edges. The vertical mattress sutures (2-0 to 0 polypropylene, polybutester, or nylon) are placed while the skin is approximated with towel clamps or skin hooks before apposition of the skin edges with approximating sutures (e.g., 3-0 or 2-0 polypropylene, polybutester, or nylon). Tension-relieving vertical mattress sutures can usually be removed by the third day after surgery, when collagen fibers have reorganized and fibrin has stabilized the wound edges. Horizontal mattress sutures with or without rubber tubing stents may be used; however, they have a greater potential for impairing local cutaneous blood flow to the skin edges.

PREVENTION OF "DOG EARS"

"Dog ears," or puckers, may be prevented or corrected at the end of a suture line by unequal suture spacing or by resecting a small ellipse or triangle of skin. Placing sutures close together on the convex side of the defect and farther apart on the concave side of the wound may prevent dog ears (Fig. 15.23A). Dog ears may be corrected by outlining with an elliptic incision, removing redundant skin, and apposing the skin edges in a linear or curvilinear fashion (see Fig. 15.23B). As an alternative, the dog ear may be incised in the center to form two triangles; one triangle should be excised and the other used to fill the resultant defect (see Fig. 15.23C–D), or both triangles may be excised and the edges apposed, creating a linear suture line (see Fig. 15.23E). Thin, elastic skin is less prone to the formation of dog ears than thick skin. Many dog ears flatten without excision.

RELAXING INCISIONS

Relaxing incisions, or incisions made near a defect to allow apposition of skin edges, are beneficial in allowing skin closure around fibrotic wounds or over important structures, or before radiation therapy after extensive tumor excision. They are rarely indicated except on distal extremities, around the eyes and anus, or to cover tendons, ligaments, nerves, vessels, or implants.

Simple Relaxing Incisions

Relief incisions heal by contraction and epithelialization in 25 to 30 days. Some relaxing incisions surrounded by loose elastic tissue can be closed primarily after the wound is approximated.

Begin undermining at the edge of the defect at the point of maximum skin tension and continue until the edges can be apposed under tension. Close the wound and make a relaxing incision at the point where undermining stopped or where tension lines are observed (Fig. 15.24A). Begin the incision at the point of maximum skin tension and extend it as necessary to relieve excess tension. If necessary, make the relief incision before skin closure. Place a nonadherent pad over the relief incisions and suture line, followed by a padded bandage. Initially, change the bandage every 1 or 2 days.

Multiple Punctate Relaxing Incisions

Multiple punctate relaxing incisions are small, parallel, staggered incisions made in skin adjacent to a wound to allow closure with reduced tension (see Fig. 15.24B). *Undermine skin around the wound, and place a continuous subdermal suture pattern. Tighten the suture, starting at one end of the incision and working toward the other end. If the skin edges do not appose in an area, make a small incision approximately 1 cm long in adjacent skin on either side of the wound, approximately 1 cm from the wound. If excessive tension persists, make a second row of incisions 0.5 to 2 cm lateral to the first row. Tighten the suture to appose the wound edges; continue the procedure along the length of the wound. Place skin sutures to appose the original wound, then place a nonadherent bandage. Change the bandage daily during the early stages of healing and less often as healing progresses.*

Tension-relieving incisions heal by secondary intention. Multiple punctate relaxing incisions are more cosmetic than single relaxing incisions but provide less relaxation and have a higher risk of causing significant circulatory compromise.

V-to-Y Plasty

V-to-Y plasty is a type of relaxing incision that provides an advancement flap to cover a wound. It is used to close chronic, inelastic wounds or wounds that would distort adjacent structures if closed under tension. It is commonly used in eyelid surgery. A V-shaped incision is made approximately 3 cm from the wound (see Fig. 15.24C). The original wound is closed after undermining skin (see Fig. 15.24D). The V relief incision is closed in the shape of a Y. Closure is begun at the ends of the V until tension develops (see Fig. 15.24E). The remainder of the relief incision is closed as the stem of the Y (see Fig. 15.24F).

Z-Plasty

Z-plasty is a technique that lengthens or relaxes an incision. The Z may be incorporated into the wound, or a separate Z may be made adjacent to the wound to facilitate closure with less tension. The central limb of the Z is the wound or primary incision. The

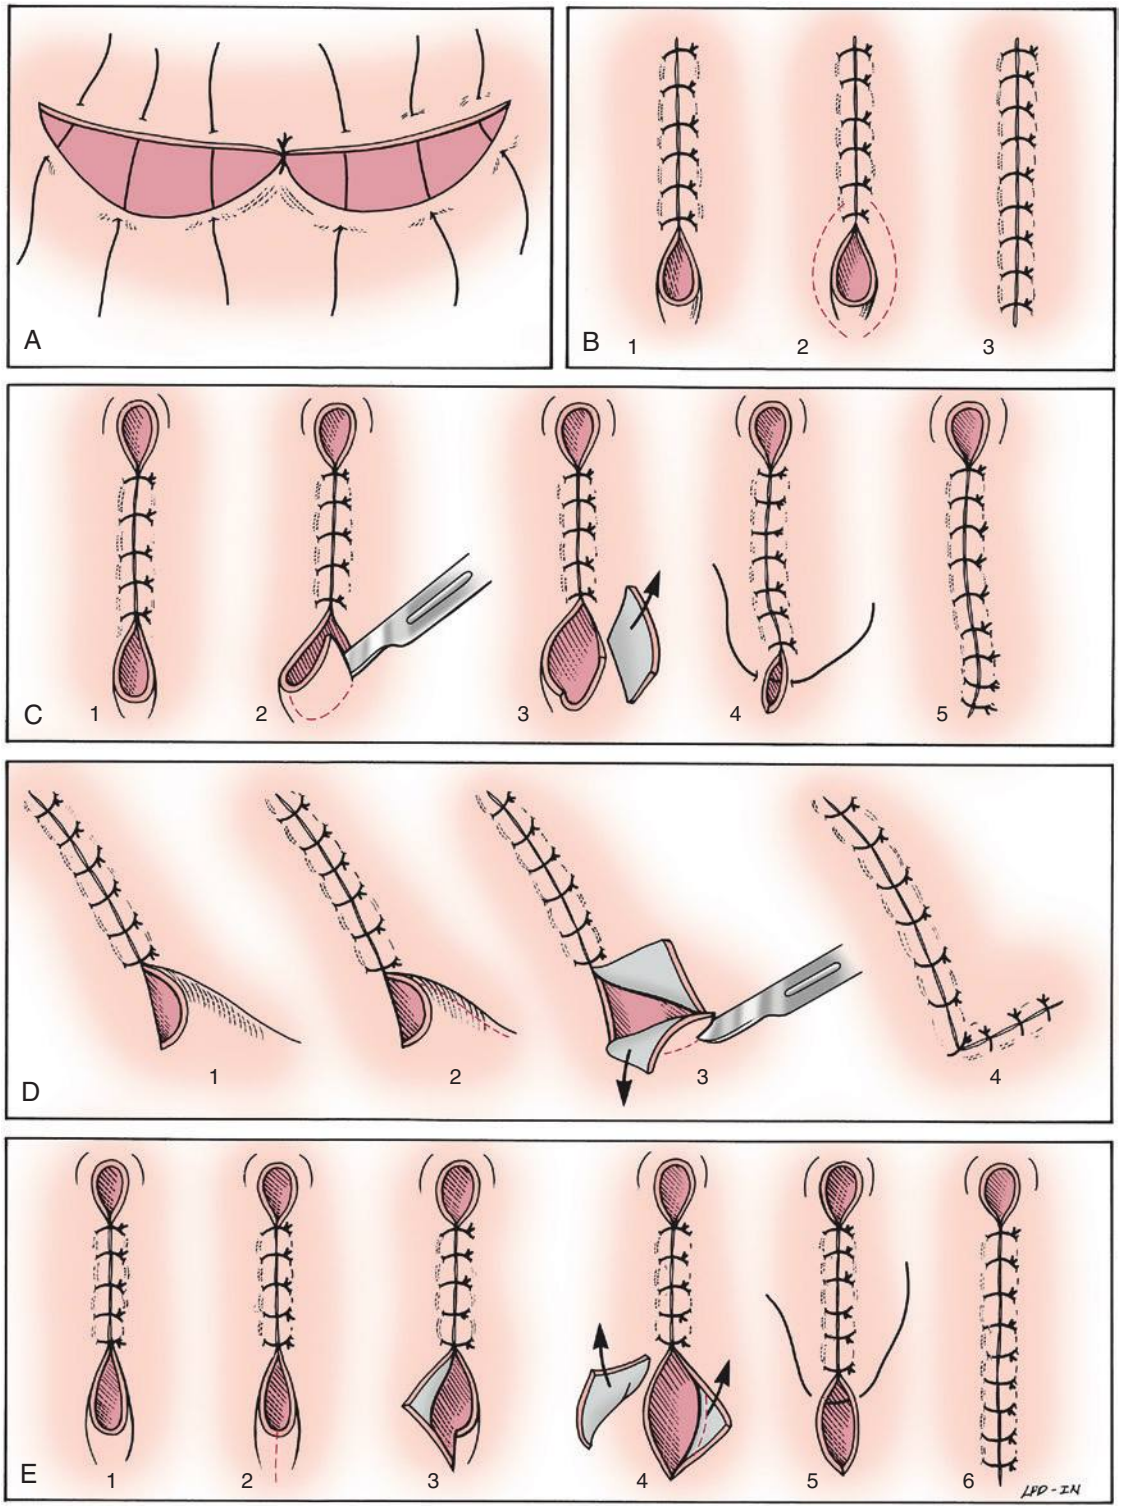

FIG. 15.23 Prevent or correct "dog ears" or puckers at the end of suture lines by (A) using unequal suture spacing or by (B) resecting an elliptic segment of skin, or (C–D) one large triangle, or (E) two smaller triangles of skin.

two arms of the Z are made the same length as the central limb (see Fig. 15.24G). The angles of the Z can vary between 30 degrees and 90 degrees, but 60 degrees is advised. Larger angles give more length gain (45 degrees gives approximately a 50% increase; 60 degrees approximately a 75% increase). Length is gained along the original central limb of the Z when the flaps of the Z are transposed (see Fig. 15.24H). A Z-shaped incision is made with the central arm of the Z parallel to the direction length as needed. The flaps are undermined before transposition and suturing (see Fig. 15.24, *inset*).

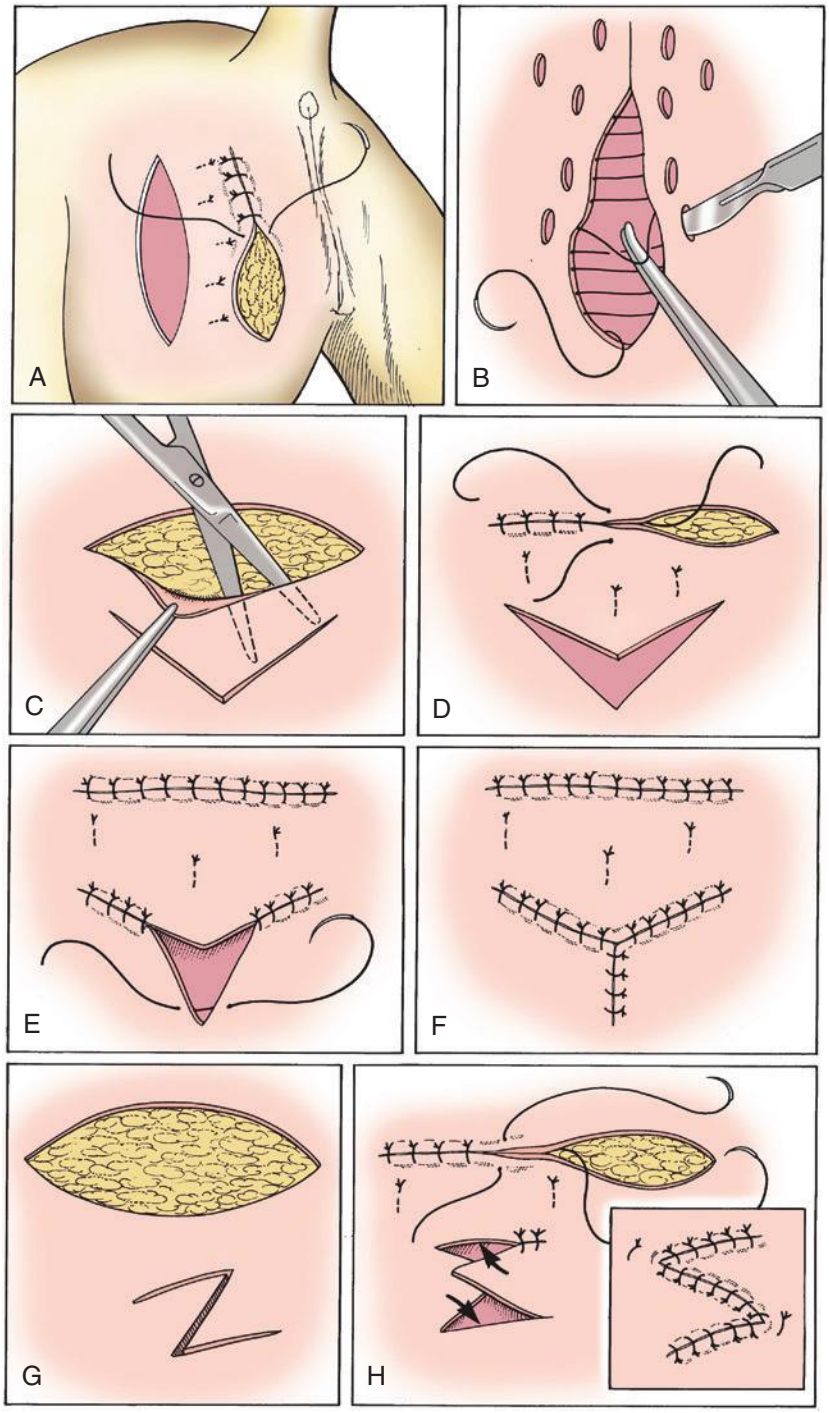

FIG. 15.24 Make relaxing incisions near the defect to allow skin apposition. (A) After undermining the skin, unilateral or bilateral simple relaxing incisions are made adjacent to the wound. (B) After preplacing a continuous subcuticular suture pattern, multiple punctate incisions are made parallel to the wound. (C–F), V-to-Y plasty provides an advancement flap to cover the wound. (G) and (H), A Z-plasty can be made adjacent to or involving the wound to allow wound closure.

SKIN BIOPSY

Skin biopsies are required to diagnosis some dermatologic problems, skin infections, and tumors. With chronic dermatitis, biopsy is sometimes useful only to rule out other disorders such as neoplasia. Secondary skin infections should be eliminated before biopsy, if possible. Biopsies of chronic skin abnormalities should include multiple samples of representative lesions. Usually, biopsy of abnormal skin is sufficient, but samples of normal skin are helpful for comparison when evaluating scaling disorders, primary seborrhea, depigmenting or hyperpigmenting lesions, and alopecia.

Clip the hair, carefully leaving approximately 0.25 inch (5–6 mm), and avoid inflicting skin trauma. When the primary problem is dermatologic, and not infectious or neoplastic, do not scrub or disinfect biopsy sites because this may adversely affect the pathologist's interpretation. Scrubbing may interfere with identification of the type of keratin and presence of surface crust, scales, microorganisms, or parasites. *Mark the lesions by circling or drawing a 2- to 3-cm line in the direction of the hair growth with an indelible marker. Perform the biopsy with a sharp 6- or 8-mm biopsy punch and a small, sharp-sharp scissors or scalpel blade for cutting the specimen from the subcutaneous tissue. Hold the skin taut around the biopsy site with the thumb and forefinger. Place the punch perpendicular to the skin surface with the lesion in the center. Rotate the punch in one direction while applying moderate pressure until a pop is felt or to the hub of the punch. Apply gentle pressure for hemostasis. Grasp and gently retract the specimen with small tissue forceps; then transect the attached subcutaneous tissue. Blot blood from the specimen, and place it on a tongue depressor or cardboard marked with the direction of hair growth to prevent curling. Appose skin edges (3-0 or 4-0 monofilament nonabsorbable suture) with a single suture.*

Alternatively for bullae, nodules, or deep lesions, make a wedge or elliptic-shaped incision around the lesion or at the junction of normal and abnormal tissue with a scalpel blade. Laser biopsies are not advised as laser-induced artifacts may make small specimens nondiagnostic.

Specimens of tumors can be obtained by incisional, excisional, or needle core biopsies. *Unlike specimens collected for dermatologic disorders, clip the hair and prepare it for aseptic surgery. Perform incisional biopsies such as skin biopsies using a punch or elliptic incision through both normal and abnormal tissue. Perform needle core biopsies using a TruCut biopsy instrument with samples taken from peripheral and central areas of the mass.*

Excisional biopsies are described later and should include all previous biopsy incisions, punctures, and needle tracts. *Immediately after collection, place samples in fixative (10% neutral buffered formalin) to preserve their integrity. Make sure the pathologist can orient the specimen correctly and if necessary mark with ink or sutures. Provide a gross description of the lesion because evidence of erythema is lost in the fixative.* It is usually wise to also submit tissue for bacterial and/or fungal culture.

REMOVAL OF SKIN TUMORS

Before a tumor is removed, skin tension and elasticity should be assessed, but excessive tumor manipulation should be avoided. The direction of skin tension lines, shape of the excision, and method of closure should be planned before surgery. A large area should be clipped and aseptically prepared for surgery, especially if there is a chance that skin flaps may be needed for closure. Excision of skin tumors should include the tumor, previous biopsy sites, and wide margins of normal tissue in three dimensions (i.e., length, width, and depth). For benign tumors, remove the tumor and 1 cm of normal tissue; for malignant tumors, a margin of more than 2 to 3 cm may be necessary for complete local excision (Fig. 15.25). These margins are taken in all dimensions, including the deep margin if feasible. Induration of the periphery of the lesion resulting from a fibroplastic host response may help identify the gross limits of the tumor. The margin distance should be greater for aggressive, infiltrative tumors (i.e., mast cell tumors, melanomas, squamous cell carcinomas, soft tissue sarcomas, feline mammary adenocarcinomas, hemangiopericytomas, infiltrating lipomas). Tumor invasion is affected by the type of surrounding tissue. Tissue easily infiltrated by tumor cells (i.e., fat, subcutaneous tissue, muscle, and parenchyma) should be resected with the tumor. Cartilage, tendon, ligaments, fascia, and other collagen-dense, vascular-poor tissues are resistant to neoplastic invasion and therefore are often spared during resection. Excision of infiltrative or aggressive tumors should extend at least one fascial layer below the detectable tumor margins. Radical tumor excision (i.e., removal of an entire compartment or structure, amputation, or lobectomy) is indicated for poorly localized tumors or those with high-grade malignancy.

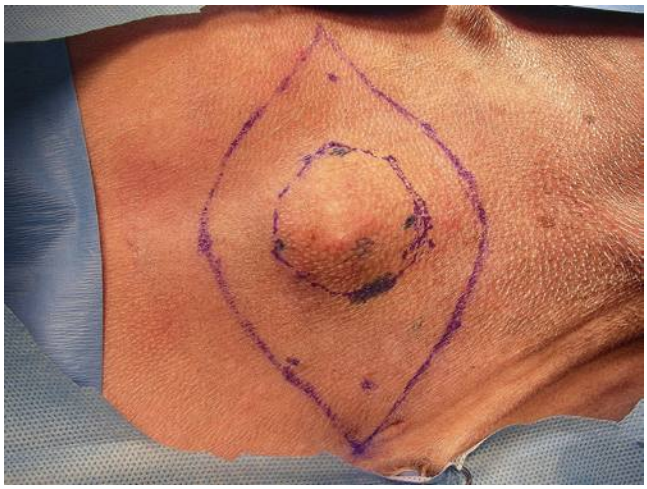

FIG. 15.25 A surgical marker was used to delineate a 2- to 3-cm margin for excision of a malignant tumor involving the skin and subcutaneous tissues.

NOTE Excision of infiltrative or aggressive tumors should include greater than 2 to 3 cm of "normal" tissue around the lesion. Extend the dissection at least one fascial layer below the detectable tumor margins.

Perform resections as atraumatically as possible to protect adjacent tissue and to prevent tumor seeding. Use a length-to-width ratio of 4:1 when making elliptic incisions around a tumor to minimize dog ear formation. As the ellipse is started through all layers (skin, subcutaneous tissue, and fascia or muscle), place a suture through them to maintain alignment and prevent retraction of one layer from the others. When removing multiple masses from the same animal, first remove lesions believed benign and change instruments and gloves (and drapes if necessary) after removal of each mass to prevent spreading tumor cells from one site to another. Ligate the blood supply as early as possible to prevent systemic spread of tumor cells or substances (e.g., histamine and heparin). Irrigate the wound bed after tumor incision. Aspirate or biopsy regional lymph nodes to stage the disease. Replace tumor-contaminated (or possibly contaminated) instruments, drapes, and gloves before wound closure. If radiation therapy is anticipated, mark resection margins within the wound using metallic staples to facilitate planning radiation therapy. Mark tumor margins with sutures or dyes and submit all resected specimens for histologic evaluation. Place the sample in approximately 10 parts formalin to 1 part tissue.

Adequate fixation with 10% neutral, buffered formalin requires that specimens be less than 5 to 10 mm wide. Identification of the tumor type is imperative in determining the appropriate postoperative therapy and the prognosis.

NOTE Local tumors most often recur because the surgical margins for the original tumor were inadequate; be sure to mark tumor borders.

CLOSURE OF IRREGULAR SKIN DEFECTS

Although it is advisable to remove skin lesions with an elliptic skin incision to facilitate closure, some lesions cause irregularly shaped defects because of their size or location. Skin elasticity and tension lines should be assessed before excision and closure.

Circular Defects

Circular excision of lesions saves the most normal skin compared with other excision patterns. Skin tension lines may convert defects of other shapes into circular defects. Circular defects are difficult to close because dog ears tend to develop. They may be closed using a variety of techniques. The linear, combined V, and bow tie techniques are preferred. Conversion of a circular defect by a fusiform or elliptic excision with a 4:1 length-to-width ratio resects more skin than may be necessary (156%). The linear technique may be used for small defects when skin edges can be apposed without the formation of large dog ears. Sutures are placed parallel to the direction of skin tension lines, beginning at the center of the defect. The dog ears at each end of the suture line are excised and the remaining defects apposed (Fig. 15.26A).

The combined V technique is used when skin apposition causes dog ears and limited skin is available for reconstruction. This technique does not remove additional normal skin. Two equilateral triangles are designed on opposite sides of the circular defect with the central axis 45 degrees from the long axis (tension lines) of the defect. The sides of each triangle are incised such that the vertex of the V points to the longitudinal axis of the defect. The skin flaps are rotated and sutured to convert the

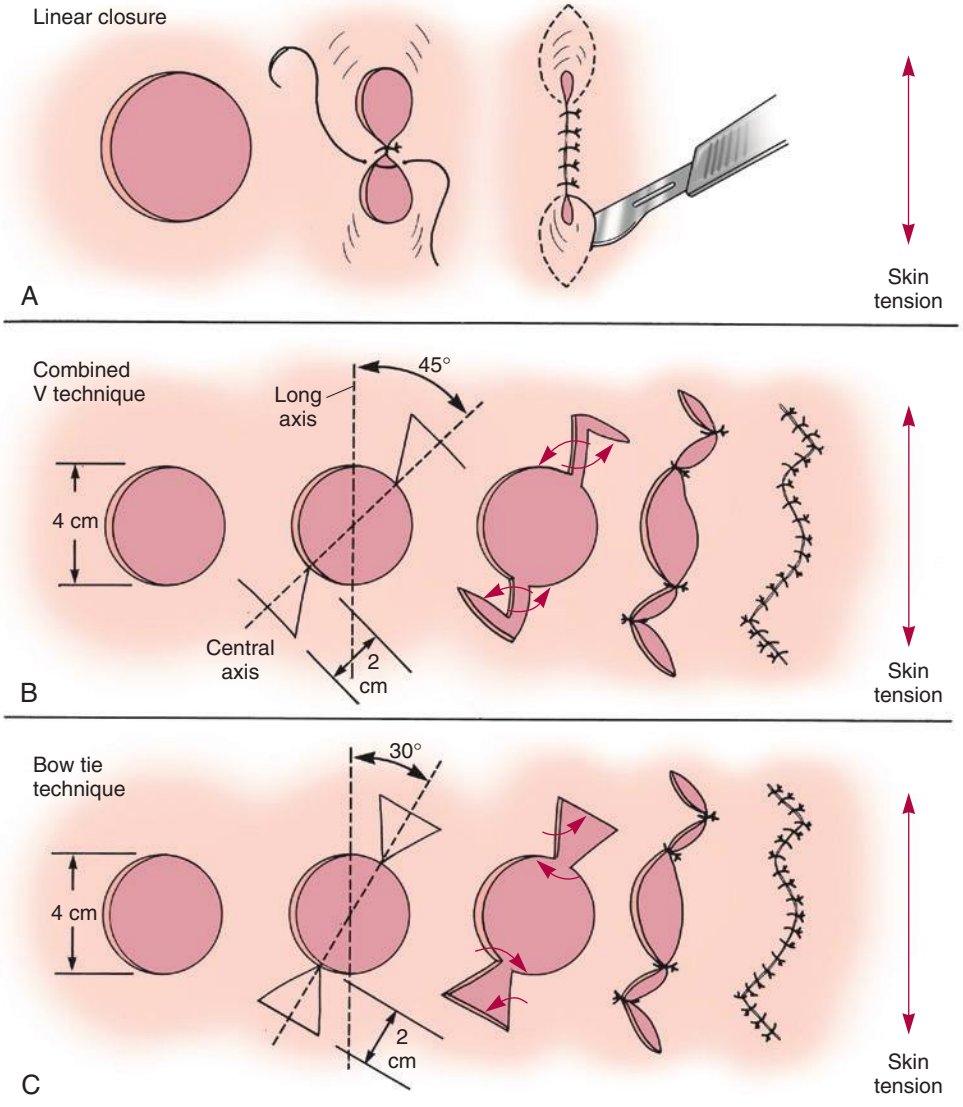

FIG. 15.26 Closure of small circular defects. (A) Use a linear closure if the skin edges can be apposed without creating large "dog ears." (B) Use a combined V technique when limited skin is available for reconstruction. (C) Use a bow tie technique when abundant skin is available.

circular defect into a smaller, irregular fusiform defect. Edges of the converted defect are apposed with approximating sutures (see Fig. 15.26B). The bow tie technique is used when skin apposition results in large dog ears and abundant skin surrounds the defect. This technique removes 36% additional skin. Two equilateral triangles are removed from opposite sides of the circular defect, with the central axis of each triangle 30 degrees from the long axis of the skin tension lines. The flaps are transposed and sutured into their new positions to shorten the sides of the original circle and transform the shape of the defect (see Fig. 15.26C).

Triangular Defects

Triangular lesions may be closed by shifting local tissue or rotating flaps. A simple closure technique is to begin at each point of the triangle and suture toward the center of the defect to create a Y-shaped suture line (Fig. 15.27A). A rotational flap is a semicircular or three-quarter circular flap of skin that is rotated about a pivot point into the defect (see Fig. 15.27B). Rotational flaps are used when skin is available on only one side of the defect or when moving skin from one side of the defect results in distortion of adjacent structures (i.e., near the eye or anus). Bilateral rotational flaps are used when little movable skin is available, but it is movable on two sides of the defect. Flaps should be sufficiently large (approximately 4:1 length-to-width ratio) to prevent tension on surrounding tissue. If tension is noted, a backcut into the base of the flap may ease tension and allow the flap to move by a combination of rotation and transposition (see Fig. 15.27C). Tension may also be relieved by removing a small triangle of skin (Burow's triangle) at the end of the semicircle opposite the defect.

Square and Rectangular Defects

Square or rectangular defects may be closed using centripetal, unilateral, or bilateral advancement flaps or rotational flaps. Centripetal closure begins with suture closure at each corner of the defect and advances toward the center to form an X suture line (Fig. 15.28A). This technique should be used when skin is available on all four sides of the defect. A unilateral or single-pedicle advancement flap should be used to close defects with mobile skin on only one side and in the same plane as the defect. Parallel incisions are made from two corners of the defect at least as long as the width of the defect, and skin is undermined and advanced over the defect (see Fig. 15.28B). If necessary, relaxing incisions are made at the base of the flap. An H-plasty or a double-pedicle advancement flap is used to close large defects that have mobile skin available on two sides of the defect (see Fig. 15.28C). A rotational or transposition flap is used to cover defects that have mobile skin on only one side of the defect and available skin in a plane different from that of the defect (see Fig. 15.28D). These flaps become effectively shorter with increasing rotation. They should be longer than the defect to achieve adequate coverage without tension. The width of the flap base should at least equal the width of the defect. The diagonal from the pivot point of the flap to the farthest corner of the defect should be equal to the diagonal from the flap's pivot point across the flap. A dog ear forms at the base of the flap opposite the pivot point.

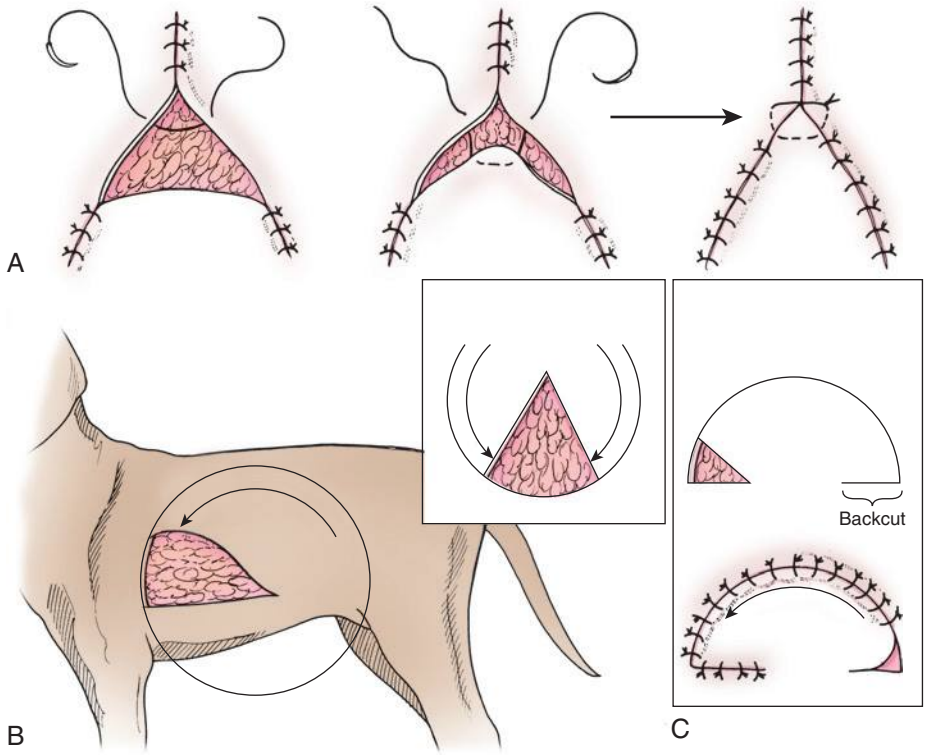

FIG. 15.27 Repair of triangular defects. (A) Close the defect as a Y by beginning at each point and suturing toward the center. (B) Create one or two rotational flaps at the defect edge. (C) A backcut or excision of Burow's triangle may be necessary to relieve tension at the base of the flap.

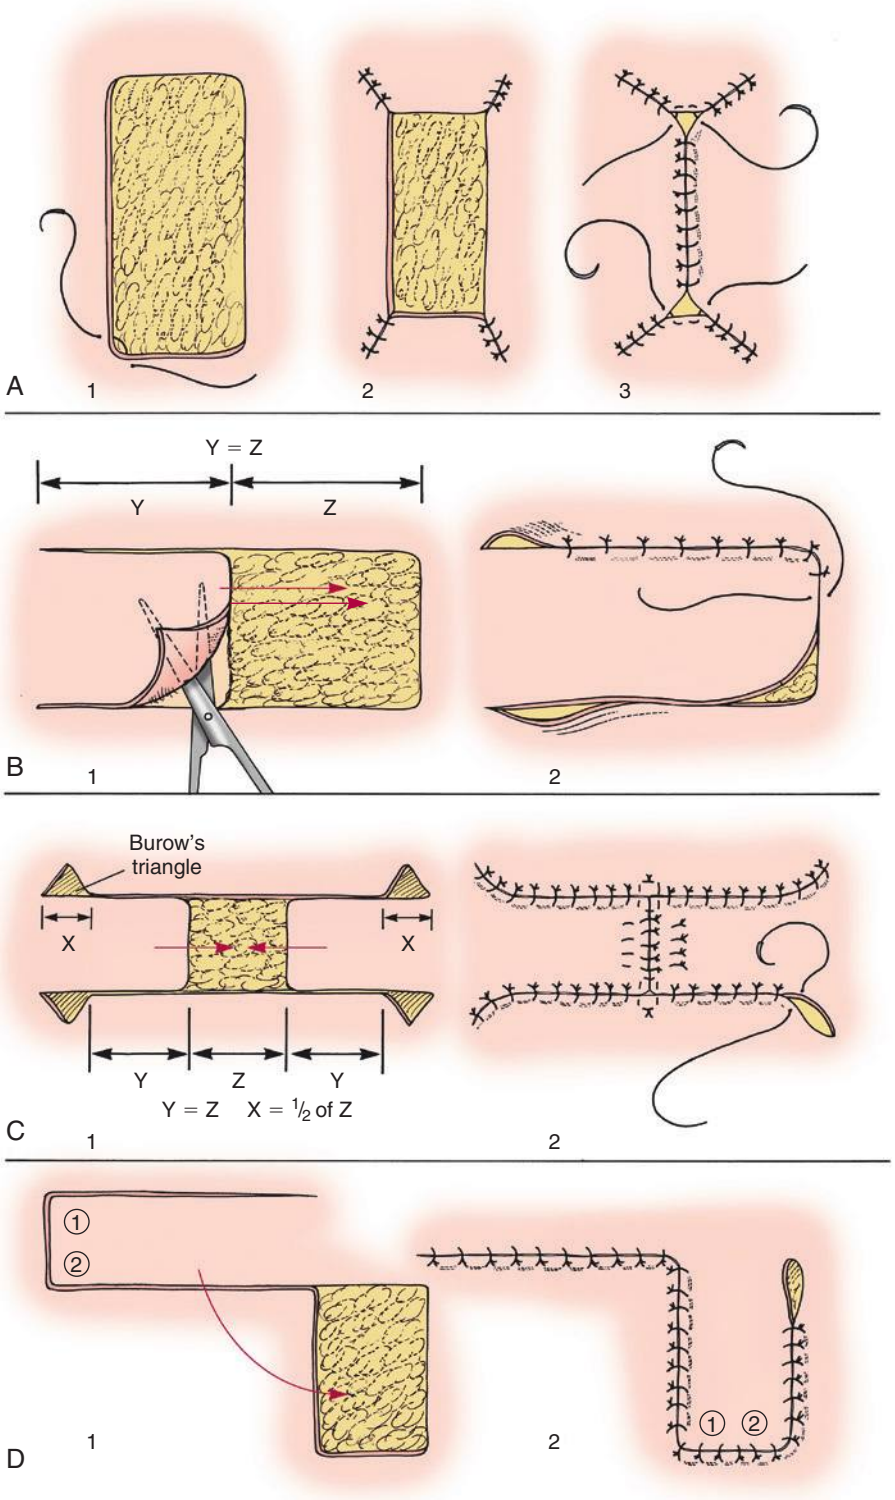

FIG. 15.28 Repair of square or rectangular defects. (A) Close from the corners and advance to the center to form an X suture line. Use a (B) unilateral or (C) bilateral advancement flap to close defects with mobile skin on only one or two sides of the defect. (D) Use a rotational or transposition flap to cover defects with mobile skin in a plane different from the defect.

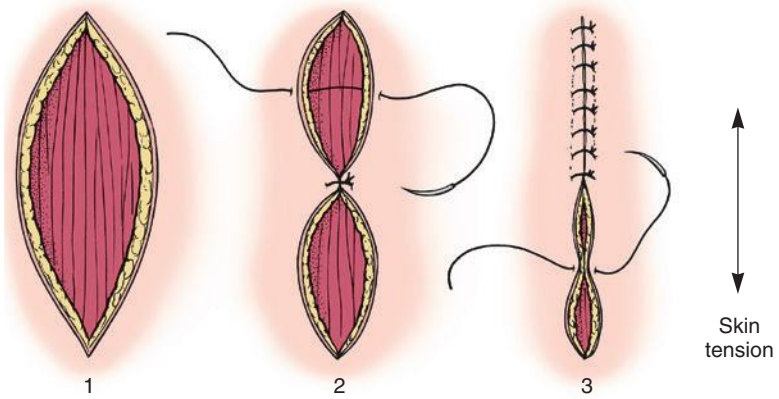

FIG. 15.29 Close fusiform defects *(1)* by placing the first suture across the widest part of the wound. Continue to divide each segment of the defect in half with subsequent sutures *(2* and *3).*

Fusiform Defects

Fusiform, or elliptic, defects are closed by first placing a suture across the widest part of the defect. Continue to divide each remaining segment in half with subsequent sutures to achieve a linear closure without dog ears (Fig. 15.29).

Crescentic Defects

In crescentic defects, one side is longer than the other. These defects are closed beginning at the midpoint. Each remaining segment is divided in half with subsequent sutures, and sutures on the convex side are spaced closer together than sutures on the concave side. Dog ears are removed as necessary (Fig. 15.30).

PEDICLE FLAPS

Pedicle flaps are "tongues" of epidermis and dermis that are partly detached from donor sites and used to cover defects. The base, or pedicle, of the flap contains the blood supply essential for flap survival. Pedicle flaps often allow immediate coverage of a wound bed and prevent the prolonged healing, excessive scarring, and contracture associated with healing by secondary intention. They can be classified in various ways based on the location, blood supply, and tissue formation. A specific flap may be classified in more than one way. Most flaps are called *subdermal plexus flaps*; however, those with direct cutaneous vessels are called *axial pattern flaps.*

Flaps that remain attached to the donor bed by only the direct cutaneous vessels and subcutaneous tissue are called *island flaps.* Flaps created adjacent to the defect in loose elastic skin are termed *local flaps. Interpolation flaps* are rectangular flaps that are rotated into a nearby rather than adjacent defect. Those created at a distance from the defect are *distant flaps,* which usually require multiple-stage reconstruction. Flaps that include tissue other than skin and subcutaneous tissue are called *compound* or *composite flaps* and may include muscle (myocutaneous), cartilage, or bone.

Increasing the width of a pedicle flap does not increase the surviving length of the flap. However, narrowing the base of the pedicle by backcut techniques increases the possibility of necrosis. The base of flaps should be slightly wider than the width of the flap body. Multiple small flaps may be preferable to a large flap if circulation is questionable. Delaying flap transfer 18 to 21 days after initial creation may improve circulation and survival in ischemic flaps (delay phenomenon). Flaps must be fixed to the edges of the recipient bed with no tension to allow revascularization and healing. Donor sites should have enough skin to permit primary closure and skin transfer to the recipient site. Donor sites with excessive motion and stress should be avoided.

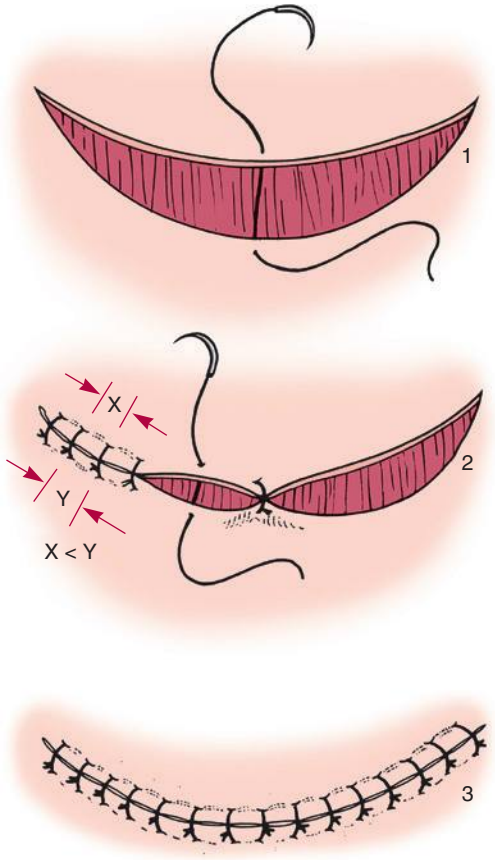

FIG. 15.30 Close crescent defects by *(1)* beginning at the midpoint and dividing each segment of the defect in half with subsequent sutures *(2* and *3).* Space sutures closer on the convex than the concave aspect of the defect.

Reconstruction should be planned so that the color and direction of hair growth after transfer of flaps or grafts to the recipient site are similar to those of the donor site.

Hyperbaric oxygen treatment or NPWT may improve survival of the flap or graft. Hyperbaric oxygen treatment consists of breathing 100% oxygen in a chamber where pressure is maintained at greater than 1 atmosphere absolute or greater than sea level pressure. HBOT hyperoxygenates hypoxic tissue, stimulates fibroblasts, and enhances tissue revascularization. NPWT also increases blood flow and is associated with greater flap survival (see Box 15.6).

Venous congestion in a flap may be suspected if the flap becomes dusky or bluish in color, if capillary return is quicker than normal, and if rapid or dark bleeding occurs in response to a needle prick. Venous congestion may lead to failure of the flap or graft.

ADVANCEMENT FLAPS

Advancement flaps are local subdermal plexus flaps. They include single-pedicle, bipedicle, H-plasty, and V-Y advancement flaps (see Figs. 15.24, 15.27, and 15.28). Flaps are formed in adjacent, loose, elastic skin that can be slid over the defect. An advancement flap is developed parallel to lines of least tension to facilitate its forward stretch over a wound. It does not bring additional loose skin to the wound. Advancement flap stretching is opposed by retractive forces that may lead to dehiscence.

ROTATIONAL FLAPS

Rotational flaps are local flaps that are pivoted over a defect with which they share a common border. They are semicircular and may be paired or single. They may be used to close triangular defects without creating a secondary defect. A curved incision is created, and the skin is undermined in a stepwise fashion until it covers the defect without tension (see Fig. 15.27).

TRANSPOSITION FLAPS

Transposition flaps are rectangular, local flaps that bring additional skin when rotated into defects. A Z-plasty is a modified transposition flap (see Fig. 15.24G and H). Ninety-degree transposition flaps are aligned parallel to the lines of greatest tension to obtain the bulk of the flap required to cover the defect. The donor site is easily closed because minimal tension lines are perpendicular to the suture line. The width of the flap equals the width of the defect (see Fig. 15.28D). The length of the flap is determined by measuring from the pivot point of the flap to the most distant point of the defect; the length decreases as the arc of rotation increases past 90 degrees because of kinking and skin folding. Dog ears occur but flatten with time.

Other useful transposition flaps include the forelimb fold and flank fold flaps (Figs. 15.31–15.34). The size and length of skin fold flaps vary with body conformation and which three of the four flap attachments are severed. The four attachments are medial and lateral attachments to the upper limb and dorsal and ventral attachments to the trunk. Often a margin of the defect to be closed serves as one of the incisions. Skin fold flaps can be harvested bilaterally to close large axillary and sternal or inguinal wounds. Creation of these flaps begins by grasping the loose skin extending from the elbow to the body wall or flank to determine the amount of skin that can be harvested as a flap. Symmetric lateral and medial incisions are first outlined and then made. These incisions are connected with a crescentic incision made proximal to the elbow (stifle). The flap is elevated from the triceps or quadriceps, transposed, and sutured to the prepared wound bed. The donor site is apposed after flap transposition. Other elbow or flank fold flap configurations can be created for coverage of defects involving the lateral thorax, abdomen, hip, stifle, shoulder, or elbow by severing either the dorsal or ventral body wall attachments (see Figs. 15.32 and 15.34). The flank fold flap supplied by the lower branches of the ventral branch of the deep circumflex iliac artery can be considered an axial pattern flap. Similarly, if the elbow fold flap includes the lateral thoracic artery, it should be considered an axial pattern flap as well. A novel transposition flap can be created from scrotal skin after prescrotal castration and positioned in the perineum and thigh.

INTERPOLATION FLAPS

A variation of the transposition flap, the interpolation flap differs in that it lacks a common border with the wound; this leaves an area of interposed skin between the donor bed and the recipient wound. The flap is created in the same way as a transposition flap except that the length of the interpolation flap must include the length of the intervening skin segment (see Fig. 15.28). The subcutaneous tissue on the segment of flap overlying the intervening skin is left exposed. After approximately 14 days, this redundant segment of the flap is resected and the incised edges are sutured. As an alternative, a bridge incision can be made connecting the donor and recipient beds to facilitate flap transfer, which eliminates the need for a second surgical procedure.

POUCH AND HINGE FLAPS

Pouch flaps (bipedicle flaps) and hinge flaps (single-pedicle flaps) are direct, distant flaps useful for reconstructing lower extremity skin defects, although axial pattern or mesh grafts are more commonly used. Reconstruction using the pouch or hinge flap requires three stages: (1) debridement and granulation, (2) flap creation and healing, and (3) flap release. After a healthy bed of granulation tissue has formed, the skin on the limb and ipsilateral thoracoabdominal area is prepared for aseptic surgery. The limb is positioned along the animal's side, and two parallel dorsoventral incisions are made at locations that allow complete coverage of the defect (Fig. 15.35A).

Create a flap 1 to 2 cm wider than the defect to accommodate elastic contraction and stretching of the flap. Undermine the flap beneath the cutaneous trunci muscle, and place the foot within the pouch. Appose skin at the wound edges with the edges of the flap using interrupted approximating sutures (e.g., 3-0 or 4-0 polypropylene, polybutester, or nylon). Place three to four interrupted sutures through the skin of the flap into the granulation tissue to immobilize the flap over the defect. Place two or three retaining or tension-relieving sutures through the skin adjacent to the flap on the limb and body wall to help prevent the limb from shifting ventrally and placing tension on the flap. Bandage the limb against the body for 14 days, and change the bandage every 3 to 4 days. As an alternative, cut an access window in the bandage over the flap, allowing evaluation and wound care without removal of the entire bandage. Place a patch bandage over the access window between treatments. Release the limb from the pouch by making two horizontal incisions (dorsal and ventral) an appropriate distance from the paw to allow coverage

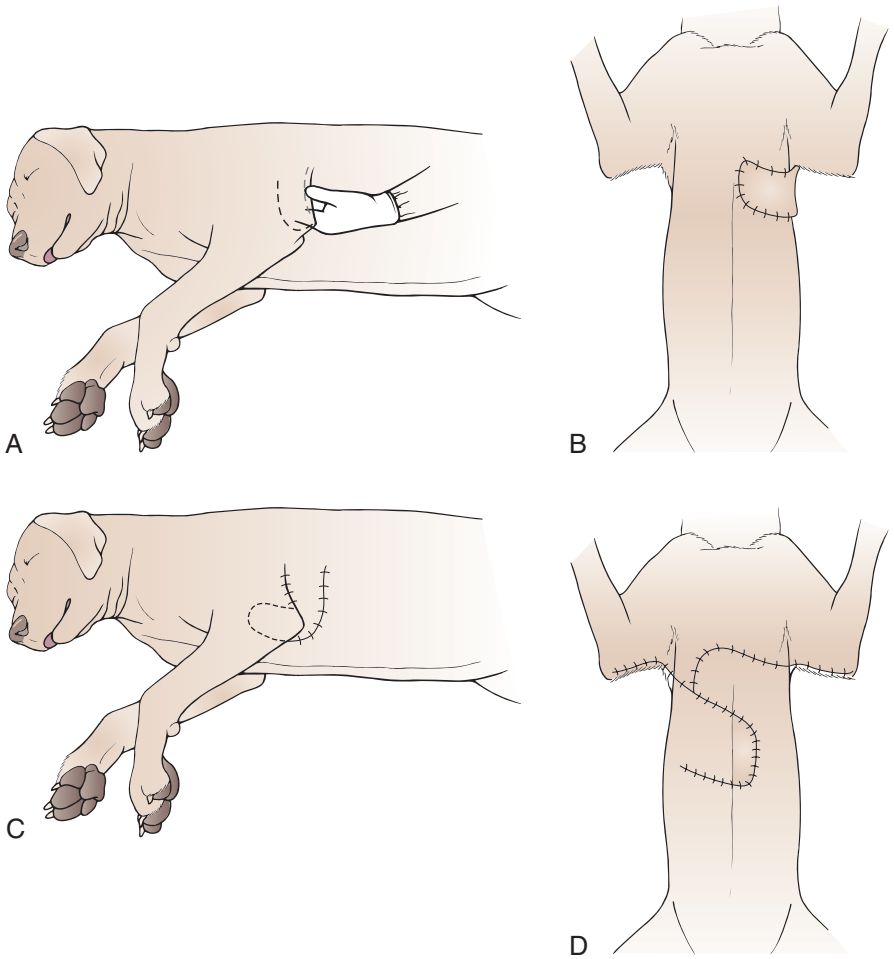

FIG. 15.31 The forelimb skin fold is harvested to close axillary or sternal wounds. (A) Grasp loose skin from the elbow to the body wall to determine the amount of skin that can be harvested. Dashed lines indicate incisions to create lateral and medial skin incisions to define the width of the flap, then connect the incisions with a crescent-shaped incision proximal to the elbow. (B–C) Elevate, transpose, and suture the flap into the wound, then close the donor site. (D) Create bilateral flaps to close larger wounds.

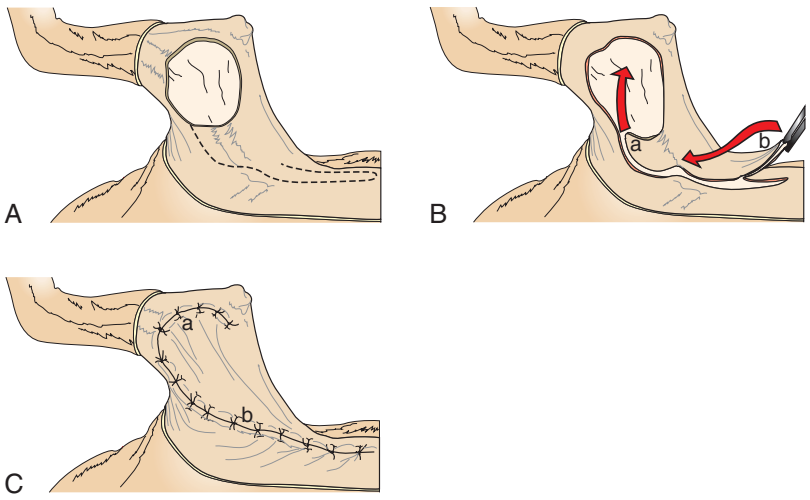

FIG. 15.32 This elbow fold flap is created to close a defect on the medial aspect of the proximal forelimb. (A) The dashed line indicates the incision of the ventral body wall attachment of the fold. (B) The flap is elevated and prepared for transposition. (C) The flap is sutured into position, and the donor site is closed.

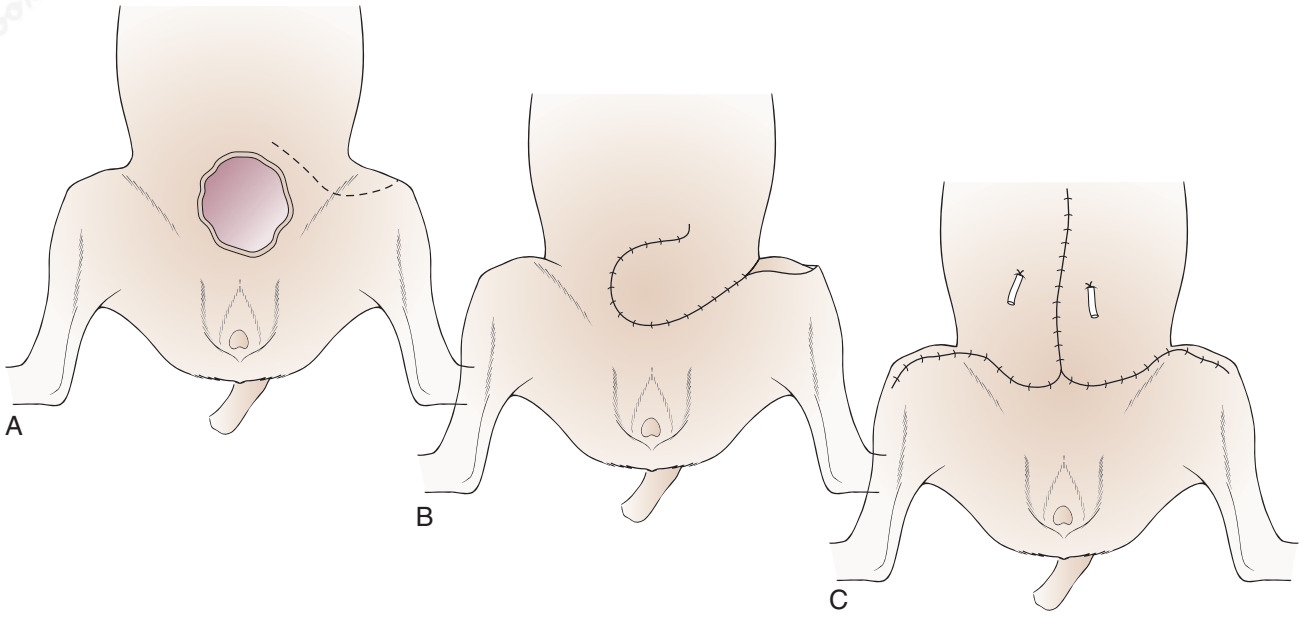

FIG. 15.33 The flank skin fold is harvested to close inguinal wounds. (A) Loose skin from the flank is incised to create a flap *(dashed line).* (B) Create lateral and medial skin incisions to define the width of the flap; then connect these incisions with a crescent-shaped incision proximal to the stifle; transpose and suture to defect. (C) Create bilateral flaps to close larger wounds.

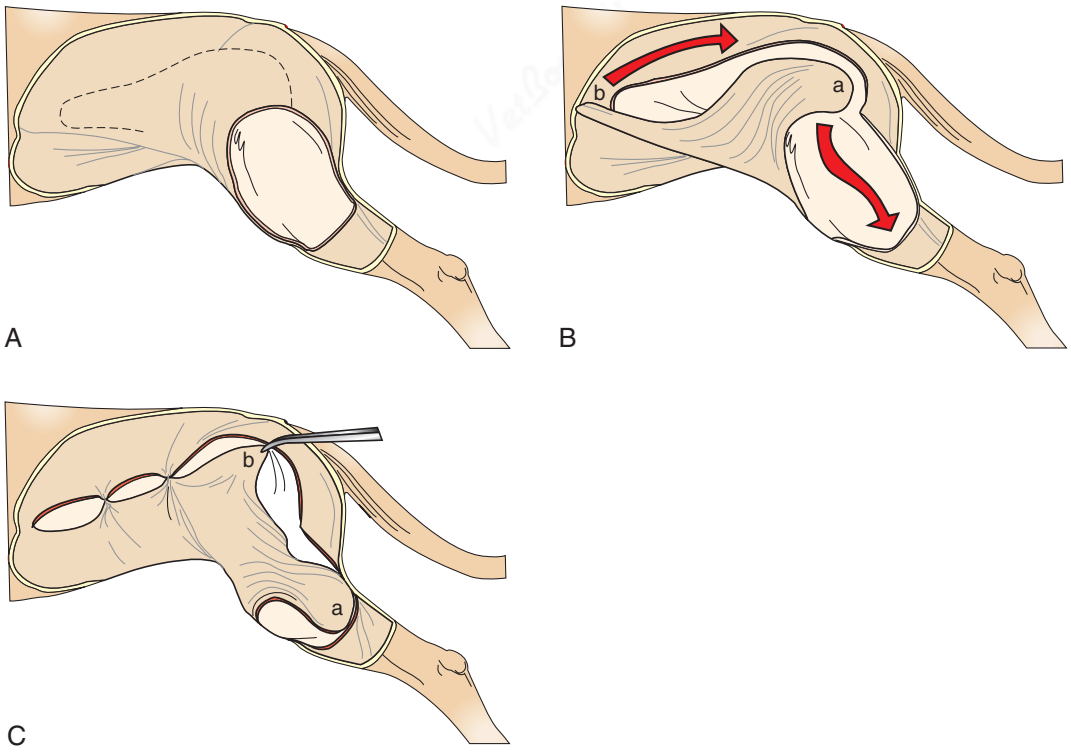

FIG. 15.34 A flank fold flap is used to close a defect on the lateral thigh. (A) The dashed line indicates the incision of the dorsal body wall attachment of the flank fold. (B) After creating the flap, the most dorsal aspect is transposed to the most distal aspect of the defect. (C) The flap and defect are closed.

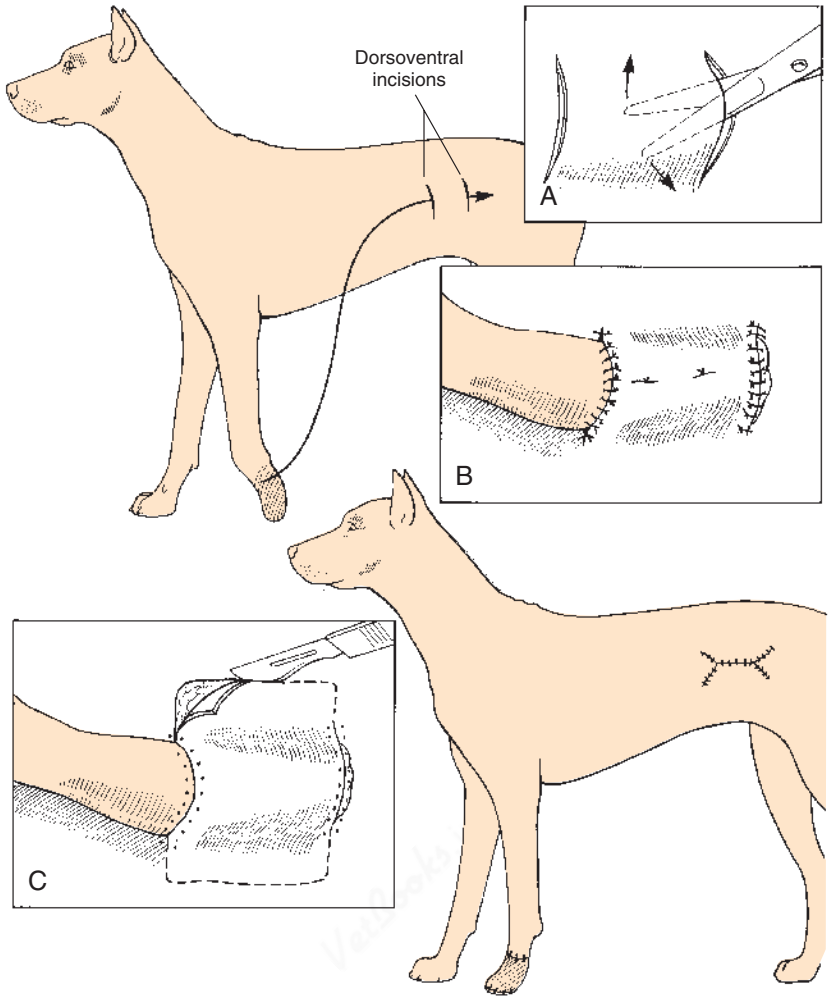

FIG. 15.35 Pouch flap. (A) Make two parallel dorsoventral incisions and undermine skin to create a pouch. (B) Position the limb inside the pouch and suture the edges of the defect to the flap. (C) After 2 to 3 weeks, release the limb and cover the remainder of the defect. Make two horizontal incisions to free the flap, then suture it to the remaining edges of the defect. Close the donor site.

of the palmar aspect of the defect (see Fig. 15.35B). Delayed release of the flap by dividing the pedicles in stages encourages flap survival.

Incise half of the lower pedicle, followed by release of the remaining half in 2 to 3 days. Two days later, begin delayed division of the upper pedicle in a similar fashion. Lavage the medial aspect of the paw to remove exudate and debride if necessary. Trim freed flap edges and suture to the opposing wound border with each division. Lavage the donor site and close with interrupted approximating sutures (e.g., 3-0 to 4-0 polypropylene or nylon) (see Fig. 15.35C).

Although this technique is successful in covering distal extremity skin defects, some animals may not tolerate the limb being positioned against the body wall, and temporary joint stiffness and muscle atrophy may occur.

TUBED PEDICLE FLAPS

A tubed pedicle flap uses a multistage procedure to "walk" an indirect, distant flap to a recipient site. The tube is made wider and longer (2–3 cm) than the recipient bed because these tubes contract as a result of decreased elasticity and fibrosis before transfer.

To create the tube, make two parallel incisions through the skin in an area where remaining skin can be reapposed without excess tension (Fig. 15.36A). Undermine skin between the two incisions. Suture incised edges of the flap together with approximating sutures (e.g., 3-0 or 4-0 polypropylene or nylon), creating a tube attached at both ends. Appose the edges of the donor site with approximating sutures (e.g., 3-0 or 4-0 nylon or polypropylene). After 18 to 21 days, transect one end of the tube and transpose it to the recipient bed. Transection can also be done in stages; half of the tube is incised and resutured in place, then 2 days later the remainder of the tube is transected and then transposed.

As an alternative, transpose the end of the tube nearer the donor site, and transect the other end of the tube and transpose it over the defect (see Fig. 15.36B) after an additional 18 to 21 days. Incise the tube and unroll it as needed to cover the defect, and suture the edges of the tube to the edges of the defect (see Fig. 15.36C). Appose skin edges at the tube's origin. Transect the remaining end of the

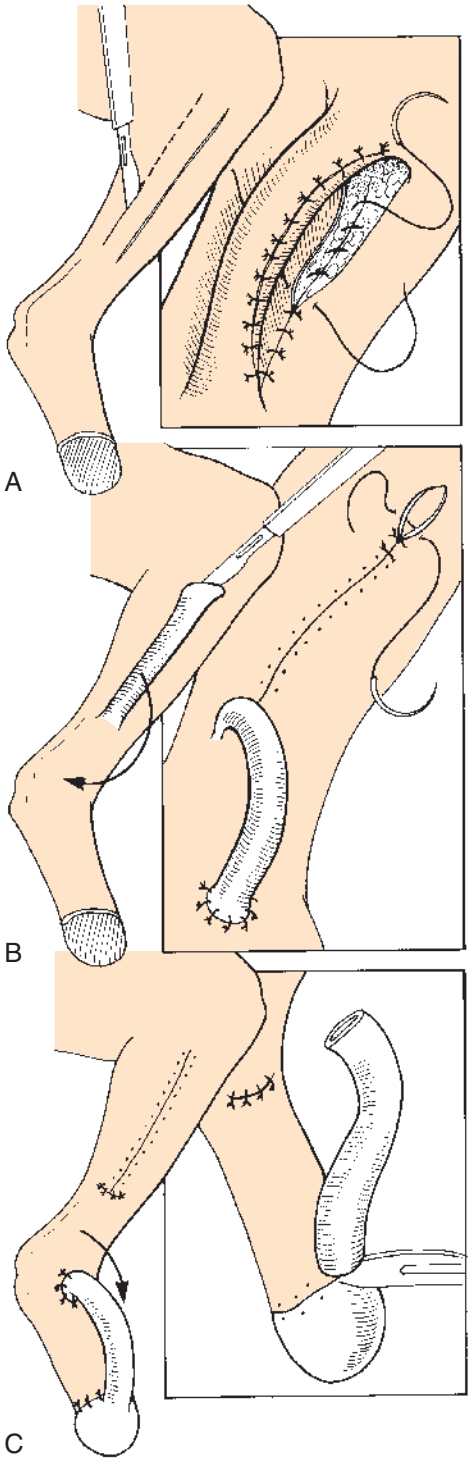

FIG. 15.36 Tubed pedicle flap. (A) Make two parallel incisions in mobile skin. Create a tube by suturing the edges together and appose the donor site. Note: The tube may need to be created more proximally on the limb than illustrated so that the skin is sufficiently mobile to close the donor site defect. (B) Approximately 3 weeks later, advance the tube toward the defect by severing one end of the tube and suturing it nearer the defect. (C) After another 3 weeks, sever the other end of the tube and use it to cover the defect or advance it closer to the defect.

tube after 18 to 21 days to complete coverage of the defect if necessary. The disadvantage of this technique is the number of stages and time required to accomplish wound closure.

AXIAL PATTERN FLAPS

Axial pattern flaps are pedicle flaps that include a direct cutaneous artery and vein at the base of the flap. The terminal branches of these vessels supply the subdermal plexus. They have better perfusion than pedicle flaps with a circulation from the subdermal plexus alone. Axial pattern flaps are elevated and transferred to cutaneous defects within their radius. They are usually rectangular or L-shaped flaps. Axial pattern flaps have been described using the caudal auricular artery branches, the superficial temporal artery, the omocervical artery (superficial cervical), the thoracodorsal artery, the lateral thoracic artery, the superficial brachial artery, the cranial superficial epigastric and caudal superficial epigastric arteries, the deep circumflex iliac artery, the genicular artery, and the lateral caudal arteries as direct cutaneous arteries in dogs (Fig. 15.37). Although similar flaps can be created in cats, only the thoracodorsal, caudal superficial epigastric, caudal auricular, superficial cervical, superficial temporal artery axial pattern, and reverse saphenous conduit flaps have been evaluated. Axial pattern flaps require careful planning, measuring, and mapping on the skin surface to minimize errors. Positioning is important to ensure that skin and underlying landmarks are in normal anatomic position. Limbs are placed in relaxed extension, and thoracoabdominal skin is grasped, lifted, and allowed to retract spontaneously to normal position before the flaps are outlined. Axial pattern flaps can be modified to create island arterial flaps by severing the cutaneous pedicle but preserving the direct cutaneous artery and vein. Island flaps have the potential for use as a free flap for transfer and microvascular anastomosis.

Axial pattern flaps are used most commonly to facilitate wound closure after tumor resection or trauma. The survival rate for axial pattern flaps is approximately twice that for subdermal plexus flaps of comparable size. Axial pattern flaps also provide durable, full-thickness skin that can be transposed primarily without the need for a vascular bed or postoperative immobilization. Complications include wound drainage, partial dehiscence, distal flap necrosis, infections, and seroma formation. The cosmetic results are good. Although historically the outcome following wound closure using axial pattern flaps has been reported as good to excellent, a 2015 retrospective study of 73 dogs reported good to excellent outcomes in 64%, with complications occurring in 89%.[8]

Caudal Auricular Axial Pattern Flap

The sternocleidomastoideus branches of the caudal auricular artery and vein may be used to reconstruct ipsilateral or contralateral defects involving the head and neck. The sternocleidomastoideus branches are located between the lateral aspect of the wing of the atlas and the vertical ear canal and are directed caudodorsally. The caudal auricular artery is located approximately 1 cm caudal to the base of the scutiform cartilage of the pinna (a palpable depression at the midpoint between the base of the ear and the wing of the atlas).

Position the forelimb in relaxed extension so that the scapula is perpendicular to the trunk. Outline the flap with the base centered over the lateral aspect of the wing of the atlas (see Fig. 15.37). Draw a caudal incision line parallel to the base at a point rostral

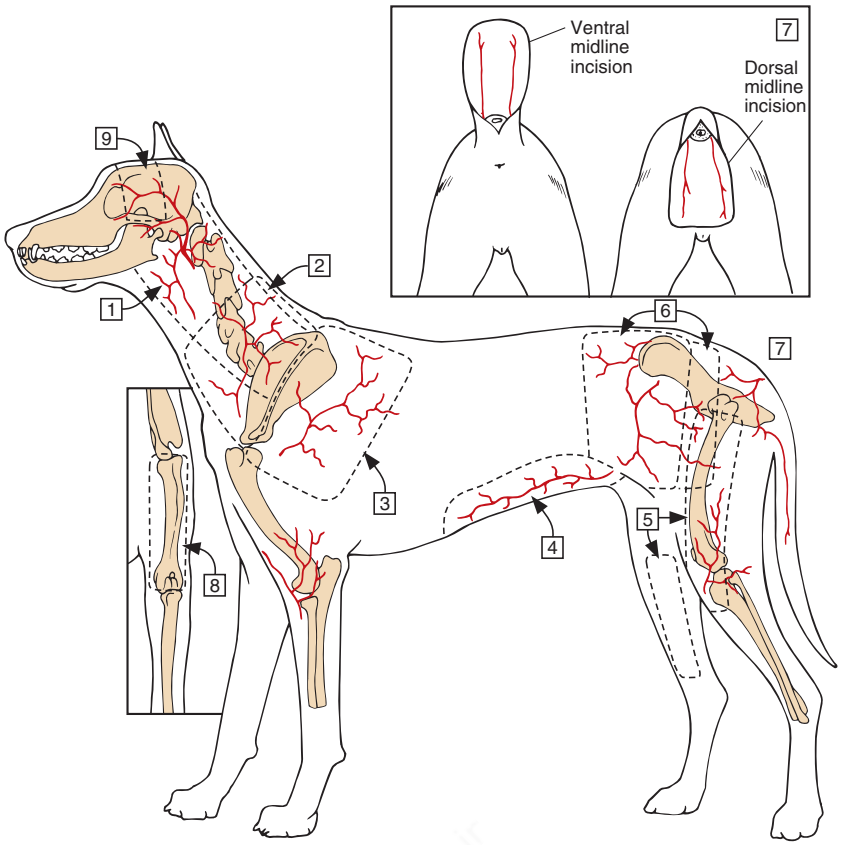

FIG. 15.37 Direct cutaneous vessels used in axial pattern flaps. *1,* Caudal auricular; *2,* omocervical; *3,* thoracodorsal; *4,* caudal superficial epigastric; *5,* medial genicular; *6,* deep circumflex iliac; *7,* superficial lateral caudal *(inset); 8,* superficial brachial *(inset)*; *9,* superficial temporal. Dashed lines outline anticipated flaps corresponding with each direct cutaneous vessel (neither a cranial superficial epigastric flap nor a reverse saphenous conduit flap is shown).

to the scapular spine, which will provide a flap long enough to cover the defect. Then draw dorsal and ventral lines that connect the base and the caudal incision line at a width that allows closure of the donor site. In cats, the dorsal border is nearer the dorsal midline. The width of the flap approximates that of the central third of the lateral aspect of the cervical area.

Incise the dorsal, ventral, and caudal lines and elevate the flap deep to the platysma (sphincter colli superficialis) muscle until the sternocleidomastoideus branches of the caudal auricular artery are identified. Rotate the flap into the defect, place drains, and appose skin edges. If there is interposing skin between the donor and recipient sites, make a bridge incision to connect the sites or partly tube the flap to span the interposing skin.

Superficial Temporal Artery Axial Pattern Flap

A cutaneous branch of the superficial temporal artery allows formation of an axial pattern flap that can be used to cover defects involving the face and head, especially the maxillofacial area. This flap is also used in oral reconstruction after partial maxillectomy. The superficial temporal artery lies in a subcutaneous position at the base of the zygomatic arch and extends rostrally along the zygomatic arch.

Position the animal in ventral recumbency. Mark the base of the flap caudally at the caudal aspect of the zygomatic arch and rostrally at the lateral orbital rim. Outline the flap by making two parallel lines; extend one line from each of these points dorsally and laterally to the middle of the dorsal orbital rim of the contralateral eye. Limit the width of the flap to the orbits and ears. Connect the parallel lines (see Fig. 15.37). Incise the outlined flap and elevate it with the frontalis muscle, which is a thin muscle overlying the temporalis muscle. Transpose the flap. Eliminate dead space with Penrose or closed suction drains and close the defects.

Omocervical Axial Pattern Flap (Superficial Cervical Axial Pattern Flap)

Omocervical axial pattern flaps are used for defects involving the face, head, ear, shoulder, neck, and axilla. By making a bridging incision between the angle of the jaw and the cranioventral edge of the donor site and creating a parapharyngeal tunnel, a staged, extended flap can be passed into the mouth to reconstruct oronasal defects caudal to the third premolar. They incorporate the superficial cervical branch of the omocervical artery and associated vein. Vessels originate adjacent to the prescapular lymph node at a site corresponding to the cranial shoulder depression and course dorsally just cranial to the scapula.

Position the patient in lateral recumbency with the forelimb in relaxed extension perpendicular to the trunk. Draw a line over the scapular spine to identify the caudal incision. Draw the cranial incision line parallel to the scapular spine at a site equal to the distance between the scapular spine and the cranial shoulder depression at the cranial edge of the scapula. Extend the lines to and continue along the dorsal midline. Extend the flap to the

FIG. 15.38 A thoracodorsal axial pattern flap has been tubed and applied over an elbow wound.

contralateral scapulohumeral joint if necessary. As an alternative, create a right-angle design incorporating the skin over the dorsal aspect of the opposite scapula. Large omocervical flaps may require ligation of the opposite omocervical direct cutaneous artery and vein. Incise the outlined flap and undermine deep to the sphincter colli superficialis muscle. Transpose the flap. Eliminate dead space with Penrose or closed suction drains and close the defects.

Thoracodorsal Axial Pattern Flap

Thoracodorsal axial pattern flaps are preferable to omocervical flaps because they are more robust. They are used to cover defects involving the shoulder, forelimb, elbow, axilla, and thorax (Fig. 15.38). In cats, the thoracodorsal flap extends to the carpus. In dogs, distal limb coverage depends on the body conformation and limb length. The flap is based on a cutaneous branch of the thoracodorsal artery and associated vein located at the caudal shoulder depression at a level parallel to the dorsal border of the acromion.

Position the patient in lateral recumbency with the forelimb in relaxed extension perpendicular to the trunk. Outline the flap by drawing a line over the scapular spine to mark the cranial incision (see Fig. 15.37). Draw the caudal incision line parallel to the scapular spine at a site approximately twice the distance from the acromion to the caudal shoulder depression. Extend the lines to and continue along the dorsal midline. Create an L flap for extended coverage by extending the dorsal incision line by approximately 50% and creating a parallel incision line beginning at the approximate midpoint of the caudal incision line. Incise the outlined flap and undermine deep to the cutaneous trunci muscle. Transpose the flap. Create a tube or make a bridge incision as needed for distant transposition. Eliminate dead space with Penrose or closed suction drains and close the defects.

NOTE Flaps extended ventral to the contralateral scapulohumeral joint usually survive. Development of long thoracodorsal axial pattern flaps may require division of the opposite cutaneous branches of the thoracodorsal artery and vein.

Lateral Thoracic Axial Pattern Flap

The lateral thoracic axial pattern flap is similar to the thoracodorsal flap, but smaller with a less extensive approach. It is used to cover the elbow. The lateral thoracic artery extends from the caudal aspect of the shoulder joint running horizontally and slightly ventrally on the lateral thoracic wall ventral to the thoracodorsal artery. It arises from the axillary artery close to the caudal border of the first rib. Deep branches supply the axillary lymph node, the ventral portion of the latissimus dorsi muscle, and part of the deep pectoral muscles. More superficial cranial branches to the elbow skin fold supply this axial pattern flap. The distribution of this vessel varies slightly between breeds.

Position the patient in lateral recumbency with the forelimb in relaxed extension perpendicular to the trunk. Palpate the caudal aspect of the shoulder joint and identify the origin of the thoracodorsal artery (see the previous discussion) to estimate the location of the lateral thoracic artery in a more ventral location. Draw the flap with the ventral border along the dorsal border of the deep pectoral muscle and the dorsal border parallel to this line with the artery in the center. Incise along these lines extending toward but not including the second mamma. Connect the parallel lines caudally, undermine the flap deep to the cutaneous trunci, and transpose up to 90 degrees to cover the defect. Place a closed suction drain, secure the flap to the defect, and appose the donor site.

Superficial Brachial Axial Pattern Flap

Superficial brachial axial pattern flaps are used to cover defects involving the antebrachium and elbow. These flaps depend on a small branch of the brachial artery located 3 cm proximal to the elbow (superficial brachial artery).

Position the patient in dorsal recumbency with the leg suspended in an elevated position. Outline the flap by drawing parallel to the humeral shaft two lines that extend dorsally and gradually converge at or below the greater tubercle. Center the base of the flap over the anterior third of the flexor surface of the elbow. Elevate the flap to the base, being especially careful to preserve the subdermal plexus, superficial brachial vessels, and cephalic vein. Rotate the flap into the defect, place drains, and appose skin edges. Flap length and survival preclude use of this flap to cover wounds in the carpal area.

Caudal Superficial Epigastric Axial Pattern Flap

The caudal superficial epigastric axial pattern flap is a versatile flap that is used to cover defects involving the caudal abdomen, flank, prepuce, perineum, thigh, and hind leg (Fig. 15.39). In cats, the flap extends over the metatarsal area. In dogs with long bodies and short limbs, it may extend to or below the level of the tibiotarsal joint. The flap includes the three to four caudal mammary glands and is supplied by the caudal superficial epigastric artery and associated vein that pass through the inguinal ring.

Position the patient in dorsal recumbency. Outline the flap with the ventral midline as the location of the medial incision. In male dogs, incorporate the base of the prepuce. Mark a parallel lateral incision at a distance equal to the distance from the mammary

FIG. 15.39 A caudal superficial epigastric axial pattern flap has been harvested and applied over a distal limb wound.

teats to the midline. Determine the number of mammary glands to include in the flap based on the size of the defect. Create the flap by connecting the two parallel lines between the first and second or second and third glands with a crescent-shaped incision. Undermine the flap at the level of the external abdominal oblique aponeurosis, deep to the supramammarius muscle. Make the flap wider as needed to cover the defect if abundant loose, elastic skin is available for closure. Transpose the flap, place drains, and appose skin edges.

NOTE Concurrent ovariohysterectomy is recommended as transposed glands remain functional. Mammae may be resected later if their appearance is objectionable.

Cranial Superficial Epigastric Axial Pattern Flap

The cranial superficial epigastric axial pattern flap is smaller and less versatile than the caudal superficial epigastric axial pattern flap; however, it can be quite useful for closure of large skin defects overlying the sternum. The flap is kept small because these vessels are short, and some flap necrosis is expected. The flap may include mammary glands three, four, and possibly five. In males, the flap ends cranial to the prepuce. Although there is some variability, the cranial superficial artery penetrates the medial aspect of the rectus abdominis muscle at the junction between the second and third mammary glands. Cranial and caudal superficial epigastric artery anastomoses occur between or near the third and fourth mammary glands. The positioning and creation of the flap are similar to those for the caudal superficial epigastric flap. The base of the flap is located in the hypogastric region, where the cranial epigastric vessel enters the skin lateral to the abdominal midline, and a few centimeters caudal to the cartilaginous border of the ventral thorax (xiphoid process).

Outline the flap with the ventral midline as the location of the medial incision. Mark a parallel lateral incision at a distance equal to the distance from the mammary teats to the midline. Determine the number of mammary glands to include in the flap based on the size of the defect. Create the flap by connecting the two parallel lines between the fourth and fifth glands or caudal to the fifth gland with a crescent-shaped incision. Undermine the flap at the level of the external abdominal oblique aponeurosis, deep to the supramammarius muscle. Ligate branches of the caudal superficial epigastric artery as necessary. Transpose the flap, place drains, and appose skin edges. Create an island flap by making a crescent-shaped incision between the second and third mammary glands. Use caution during dissection and manipulation to prevent trauma, kinking, or stretching of the cranial superficial epigastric vessels.

Deep Circumflex Iliac Axial Pattern Flap

The dorsal branch of the deep circumflex iliac vessel is used in flaps to cover defects involving the caudal thorax, lateral abdominal wall, ipsilateral flank, lateral lumbar area, medial or lateral thigh, greater trochanter, and pelvic area. The dorsal and ventral branches of the deep circumflex iliac artery originate at a point cranioventral to the wing of the ilium.

Position the patient in lateral recumbency with the hind limb in relaxed extension perpendicular to the body. Outline the flap by first drawing a line midway between the cranial border of the wing of the ilium and the greater trochanter. For the cranial incision, draw a second line parallel to the first line and equal to the distance from the iliac border to the caudal line Extend the lines to the dorsal midline and create an L extension, if needed, to cover the defect (see Fig. 15.37). Incise the outlined flap. Elevate the flap below the level of the cutaneous trunci muscle. Transpose the flap, place drains, and appose skin edges. The ventral branch of the deep circumflex iliac artery is used in flaps to cover defects of the lateral abdominal wall and as an island flap for pelvic and sacral defects.

Make the reference lines as for the previous flap. Draw the caudal incision line extending distally cranial to the border of the femoral shaft. Extend the cranial incision line down the flank and thigh region parallel to the caudal flap border. Connect the two lines above the patella. Elevate the flap below the level of the cutaneous trunci muscle. Incise the outlined flap. Transpose the flap, place drains, and appose skin edges. The flank fold flap is a variation of the ventral deep circumflex iliac axial pattern flap (see p. 218) developed for transposition into inguinal defects.

Genicular Axial Pattern Flap

Genicular axial pattern flaps are used to cover defects involving the lateral and medial tibia and potentially the tibiotarsal joint. These flaps are dependent on the short genicular branch of the saphenous artery and medial saphenous vein.

Position the patient in lateral recumbency. Mark a point 1 cm proximal to the patella and 1.5 cm distal to the tibial tuberosity (see Fig. 15.37). Extend these two points dorsally parallel to the femoral shaft, ending at the base of the greater trochanter. Connect the parallel lines dorsally. Incise the outlined flap. Elevate the flap and rotate it to cover the defect. Place drains and appose skin edges. Although circulation is usually sufficient, this is not a robust flap.

Reverse Saphenous Conduit Flap

Reverse saphenous conduit flaps are used for defects at or below the tarsus (Fig. 15.40). They are created by ligating and dividing the vascular connection between the femoral artery and vein and the saphenous artery and medial saphenous vein. Reverse blood flow occurs because of anastomoses between the cranial branch of the saphenous artery and the perforating metatarsal artery (via medial and lateral plantar arteries), the cranial branch of the lateral saphenous vein, and other venous connections with the cranial and caudal branches of the medial saphenous veins distal to the tibiotarsal joint. Preoperative angiography ensures the presence and function of the saphenous artery, medial saphenous vein, and femoral artery and vein.

Position the patient in lateral recumbency with the affected limb down. Roughly outline the flap by marking a line across the central

FIG. 15.40 (A) A reverse saphenous conduit flap is being harvested and (B) applied over a wound on the distal limb.

third of the inner thigh at or slightly above the level of the patella. Make parallel lines 0.5 to 1 cm cranial and caudal to the branches of the saphenous artery and medial saphenous vein. Make the transverse incision as marked to expose the saphenous vessels and nerve. Ligate and transect the saphenous artery and medial saphenous vein at their junction with the femoral artery and vein. Extend the incisions distally as marked in a slightly converging fashion. Undermine deep to the saphenous vessels by elevating a portion of the medial gastrocnemius muscle fascia with the flap. Ligate and divide the peroneal (fibular) artery and vein. Do not elevate the flap beyond the anastomosis between the cranial branch of the medial saphenous vein and the cranial branch of the lateral saphenous vein. Rotate or partly tube the pedicle transfer to the defect. As an alternative, make a bridge incision between the donor site and the wound. Place drains and appose the defects.

Lateral Caudal Axial Pattern Flap

The lateral caudal arteries of the tail may be used to reconstruct areas involving perineum and caudodorsal trunk defects. The largest source of skin is from the proximal third of the tail. The tail skin may also be used as a tube flap to cover defects on the hind leg. The lateral caudal vessels are bilateral and are located in the subcutaneous tissue of the tail. The lateral caudal arteries arise from the caudal gluteal arteries and have several anastomotic branches with the median caudal artery. Use of this flap requires tail amputation. In a retrospective study of 13 dogs, all flaps ultimately healed with no long-term complications.[9] Four dogs had wound complications, but only one of these dogs required surgical revision.

Make a dorsal midline incision along the length of the tail to cover dorsocaudal defects (see Fig. 15.37). Make a ventral midline skin incision to cover defects on the hind leg. Dissect the subcutaneous tissue from the deep caudal fascia, preserving the right and left lateral caudal arteries and veins. Amputate the tail at the third or fourth caudal intervertebral space (see p. 253). Transpose the skin flap over the defect, place drains, and appose skin edges.

COMPOSITE FLAPS

Flaps composed of skin with muscle, bone, or cartilage are termed *composite flaps*. The pinna has been used as a composite flap to cover maxillofacial defects. Numerous myocutaneous flaps, with or without attached bone segments, have been used to facilitate reconstructive surgery.

Myocutaneous and Muscle Flaps

Muscle flaps with overlying skin (myocutaneous flaps) or without skin (muscle flaps) may be created to facilitate herniorrhaphy, to cover soft tissue defects, to contribute circulation to fractures, and to combat infection. They should be used only when reconstruction with local flaps (see p. 217), axial pattern flaps (see p. 222), or free grafts (see p. 232) is not feasible. These flaps must be sufficiently large to cover the defect and have an easily accessible and constant dominant vascular supply. Donor sites should be easily closed. Muscles in dogs and cats that may be sacrificed without loss of function include the cutaneous trunci, gracilis, trapezius, sternohyoid, sternothyroid, deep pectoral, anconeus, ulnaris lateralis, humeral head of the flexor carpi ulnaris, sartorius, semitendinosus, rectus femoris, cranial tibial, long digital extensor, and portions of the latissimus dorsi.

Myocutaneous Flaps

Myocutaneous flaps described in the veterinary literature include latissimus dorsi, cutaneous trunci, gracilis, semitendinosus, and trapezius muscles. These muscles are superficial, allowing easy access and elevation, and have direct cutaneous arteries exiting the muscle surface to supply overlying skin. A vascular pedicle sufficient to maintain circulation is required to facilitate flap rotation into defects. Increased rotation may impair circulation and require that the flap length be reduced. Distant transfer of gracilis, latissimus dorsi, transverse abdominis, and some trapezius flaps is possible with microvascular anastomosis.

NOTE Development of myocutaneous flaps requires the presence of direct cutaneous arteries exiting the muscle surface to supply the overlying skin.

Platysma Myocutaneous Flap

The platysma muscle is a well-developed muscle originating from the middorsal tendinous raphe of the neck and skin. It courses longitudinally toward the mouth over the parotid and masseter to the lips and ventrally to the midline. The platysma myocutaneous flap used to cover defects involving the head and neck is identical to the caudal auricular axial pattern flap (see p. 222).

Latissimus Dorsi Myocutaneous Flap

The latissimus dorsi muscle is a flat, triangular muscle overlying the dorsal half of the lateral thoracic wall. It originates from thoracolumbar fascia of the thoracic and lumbar spinous processes and from muscular attachments to the last two or three ribs. The aponeurosis of the latissimus dorsi inserts on the major teres tuberosity of the humerus. The muscle flexes the shoulder, drawing the limb caudally. The ventral portion of the muscle is supplied by branches of the thoracodorsal artery (dorsal and lateral thoracic arteries), which penetrate the muscle and supply the cutaneous trunci muscle and skin. Intercostal arteries supply segmental branches to the dorsal portion of the latissimus dorsi muscle and the overlying cutaneous trunci muscle. Latissimus dorsi myocutaneous flaps are bulky because they contain the cutaneous trunci muscle and skin, subcutaneous fat, and latissimus dorsi muscle. They are best suited for thoracic defects, although they may be used for forelimb defects. Anatomic landmarks are the ventral border of the acromion, adjacent caudal border of the triceps muscle, head of the last rib, and distal third of the humerus that corresponds to the axillary skin fold (Fig. 15.41).

With the patient in lateral recumbency and the forelimb in relaxed extension perpendicular to the trunk, plan and outline the flap with a marking pen.

Draw a line from the caudal border of the triceps muscle to the vertebral attachment of the last rib. Draw a parallel line caudodorsally from the axillary skin fold and connect them to outline the flap (see Fig. 15.41). Incise skin and extend the incision through the underlying latissimus dorsi muscle. The muscle flap equals the size of the skin flap. Elevate the latissimus dorsi and skin as a unit. Isolate, ligate, and divide the lateral intercostal vessels deep to the latissimus muscle. Identify and preserve the thoracodorsal artery and vein. Transpose the flap to the desired location without occluding the thoracodorsal vessels. If necessary, make a bridge incision or partial tubing of the flap for transposition. Place a closed suction drain at the donor site and beneath the flap at the recipient site. Secure the flap in position and close the donor site.

The latissimus dorsi may be used alone as a muscle flap; it is harvested in a similar manner without the skin for this purpose.

Cutaneous Trunci Myocutaneous Flap

The cutaneous trunci muscle arises from the pectoralis profundus and forms a thin leaf covering most of the dorsal, lateral, and ventral walls of the abdomen (see Fig. 15.41). It is more closely associated with skin than underlying structures. Blood supply is from small muscular branches and direct cutaneous arteries supplying the overlying skin. The cutaneous trunci overlying the latissimus dorsi muscle receives two to four short, direct cutaneous branches of the thoracodorsal artery caudal to the border of the triceps muscle. Elevating the cutaneous trunci muscle with skin helps preserve the subdermal plexus. Cutaneous trunci myocutaneous flaps are more pliable and elastic than latissimus dorsi myocutaneous flaps and are preferred for forelimb flaps.

Plan and outline the flap in the same way as for a latissimus dorsi myocutaneous flap. Incise the skin as outlined, but do not extend the incision beyond subcutaneous tissue between the cutaneous trunci and latissimus dorsi. Elevate the cutaneous trunci by dissecting the loose subcutaneous tissue. Ligate and divide branches of the proximal lateral intercostal direct cutaneous vessels. Transpose the flap to its desired location without occluding the thoracodorsal vessels. If necessary, make a bridge incision or partial tubing of the flap for transposition. Place a closed suction drain beneath the flap at recipient and donor sites. Secure the flap in position and close the donor site.

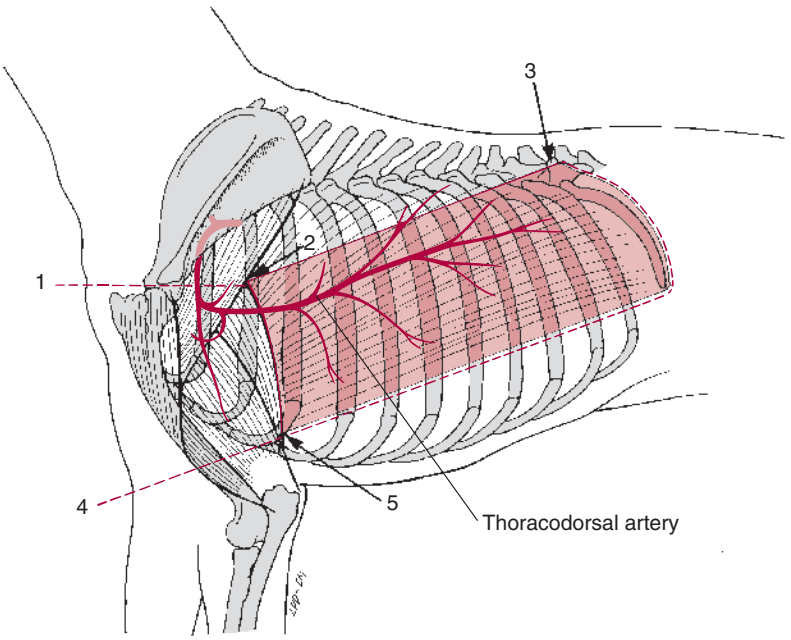

FIG. 15.41 Landmarks for the latissimus dorsi and cutaneous trunci myocutaneous flaps. *1,* Ventral border of the acromion; *2,* adjacent caudal border of the triceps muscle; *3,* vertebral attachment of the last rib; *4,* distal third of the humerus; and *5,* axillary skin fold. To construct the flaps, draw a line from *2* to *3* and a second parallel line from *5.* Incise and connect the two parallel lines dorsally.

Trapezius Osteomyocutaneous Flap

Trapezius osteomyocutaneous flaps are generally used for defects in the neck, cranial thorax, or proximal thoracic limb; however, they may be transferred to distant sites with microvascular anastomosis. The trapezius is a thin, triangular muscle divided into cervical and thoracic parts. The cervical part of the trapezius is overlapped by the cleidocervicalis muscle and the thoracic part by the latissimus dorsi muscle. The muscle originates from the median raphe of the neck and supraspinous ligament from the level of the third cervical vertebra to the ninth thoracic vertebra and inserts on the scapular spine. It acts to elevate and abduct the forelimb. Lameness and scapular fractures may occur when this flap is used. Only the scapular spine, and not the scapular body, remains viable. The bone in this flap is weak and should be used as a source of osteogenesis rather than support. Dorsal, caudal, and cranioventral borders of the flap are 2 cm ventral to the dorsal midline, 2 cm caudal to the scapular spine, and a line between the acromion and transverse process of the third cervical vertebra, respectively.

Make a triangular skin incision over the cervical part of the trapezius muscle (Fig. 15.42). Incise the origin of the cervical part of the trapezius on the dorsal midline. Dissect the incised trapezius from the cleidocervicalis and omotransversarius muscles, preserving the attachment to the scapular spine and the prescapular branch of the superficial cervical vascular pedicle. Dissect the caudal half of the supraspinatus muscle from its attachment on the scapular spine and body. Incise the deltoideus and thoracic part of the trapezius attachments to the scapular spine. Dissect the cranial half of the infraspinatus from the scapular spine and body. Create a bone flap using an air-powered burr or saw. Dissect the medial attachments of the subscapularis and serratus ventralis muscles from the bone flap. Elevate the osteomusculocutaneous flap and transfer it to the recipient site, preserving the prescapular branch of the superficial cervical vascular pedicle. Place a closed suction drain at the donor site and close the defect with approximating sutures (for muscle, use 2-0 or 3-0 polydioxanone or polyglyconate suture; for subcutaneous tissue, use 3-0 or 4-0 polydioxanone or polyglyconate suture; for skin, use 3-0 or 4-0 nylon or polypropylene suture). Apply a bandage over the donor and recipient sites for support and fluid absorption.

Muscle Flaps

Muscle flaps may be transposed beneath skin to fill defects, repair hernias, and treat paralysis. Many muscles have been used to facilitate adjacent visceral repair and to fill defects. The use of muscle in reconstruction is limited by the tissue available and the surgeon's imagination. Muscles are capable of contributing circulation to areas of ischemia caused by trauma or radiation therapy. They may also provide support, facilitate return of function, improve cosmesis, and reduce wound contamination and sepsis. The latissimus dorsi may be used with or without a cutaneous flap to cover thoracic wall defects (see previous discussion). The muscle flap may be used with mesh or other implants to give support and is sutured to adjacent muscle or fascial planes. The transversus abdominis muscle has been used to facilitate

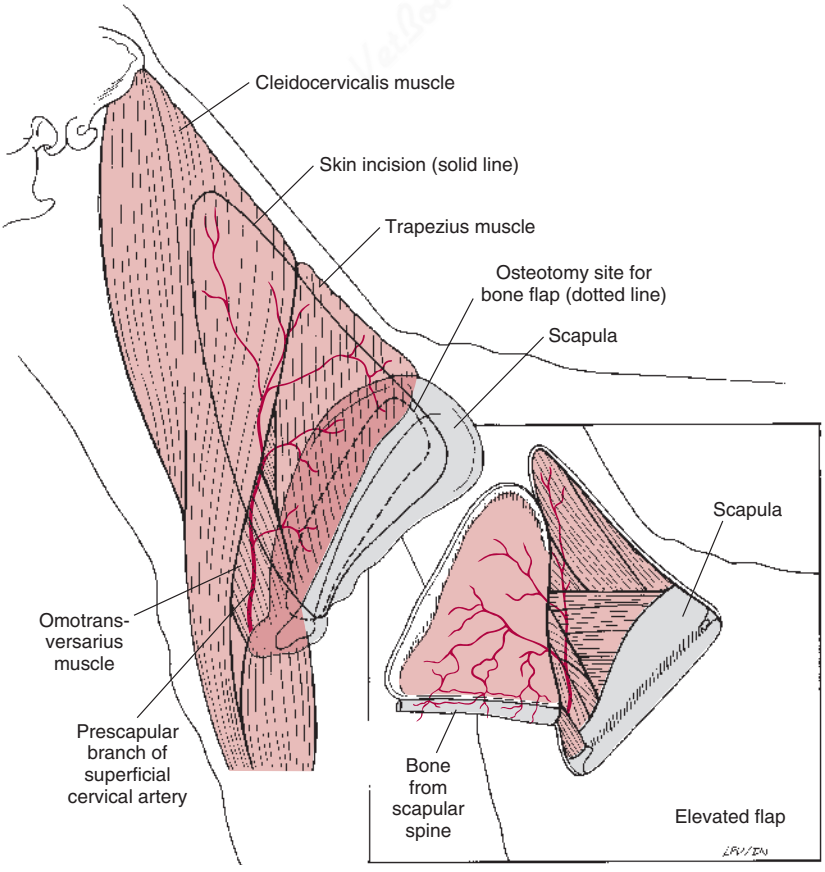

FIG. 15.42 Outlined trapezius osteomyocutaneous flap for regional reconstruction. The inset shows the flap ready for relocation.

repair of the diaphragmatic hernia. The internal obturator, superficial gluteal, and semitendinosus muscles have been used in perineal hernia repair (see p. 496). Caudal abdominal hernias or defects can be reinforced with pectineus or sartorius muscle flaps. Esophageal repair may be facilitated by use of intercostal, diaphragm, sternocephalicus, or sternothyroideus muscles (see p. 374). The sternohyoideus and sternothyroideus muscles may be used to cover laryngotracheal defects. Biceps femoris or deep gluteal muscle flaps are sometimes used to cushion the femoral head and neck ostectomy site (see p. 1213). Reconstruction of distal antebrachial, carpal, and metacarpal injuries can be assisted by transposition of the humeral head of the flexor carpi ulnaris. The semitendinosus has been used to reconstruct tibial defects.

External Abdominal Oblique Muscle Flap

The external abdominal oblique muscle is elastic and mobile and may be used to facilitate repair of defects in the abdominal wall or caudal thoracic wall. This flap may be used to fill defects larger than 10 × 10 cm in medium-size dogs. The external abdominal oblique muscle is a long, flat muscle covering the ventral half of the lateral thoracic wall and lateral abdominal wall. Its fibers are directed caudoventrally. It is divided into a costal part arising from the fifth to thirteenth ribs and a lumbar part arising from the last rib and the thoracolumbar fascia. It has a wide aponeurosis that inserts on the linea alba and cranial pubic ligament and contributes to the external rectus fascia, external inguinal ring, and prepubic tendon. The cranial branch of the cranial abdominal artery supplies the middle zone of the lateral abdominal wall and is accompanied by the cranial hypogastric nerve and satellite vein. The deep branch of the deep circumflex artery anastomoses with the cranial and caudal abdominal arteries and is the main supply to the caudodorsal fourth of the abdominal wall. It is accomplished by a satellite vein and joined by the lateral cutaneous femoral nerve.

Make a paracostal skin incision from the level of the epaxial muscles to the ventral midline, beginning 5 cm caudal to the 13th rib. Identify and divide the lumbar fascial edge of the external abdominal oblique muscle, leaving a 0.5- to 1-cm margin of fascia along the muscular edge (Fig. 15.43). Undermine the lumbar external abdominal oblique muscle. Identify and preserve the neurovascular pedicle (branches of the cranial abdominal artery and cranial hypogastric nerve and satellite vein) in a craniodorsal location caudal to the 13th rib. Divide the dorsal fascial attachment and sever the lumbar external abdominal oblique muscle at the level of the 13th rib. Transpose the flap to an adjacent defect. Overlap the defect with the flap, and suture the inner fascial surface with 2-0 polydioxanone or polyglyconate using a simple interrupted pattern. Place a closed suction drain and appose the defect edges.

Cranial Sartorius Muscle Flap

Cranial sartorius muscle flaps are used to repair prepubic tendon ruptures or femoral hernias when tissue trauma, retraction, and fibrosis preclude adequate anatomic reapposition. This type of flap may also be used to cover femoral trochanteric ulcers. In dogs, the sartorius muscle consists of two long, flat, straplike muscles on the craniomedial surface of the thigh. In cats, the sartorius muscle has only one belly and an origin and insertion similar to that of the dog. The feline sartorius muscle has one

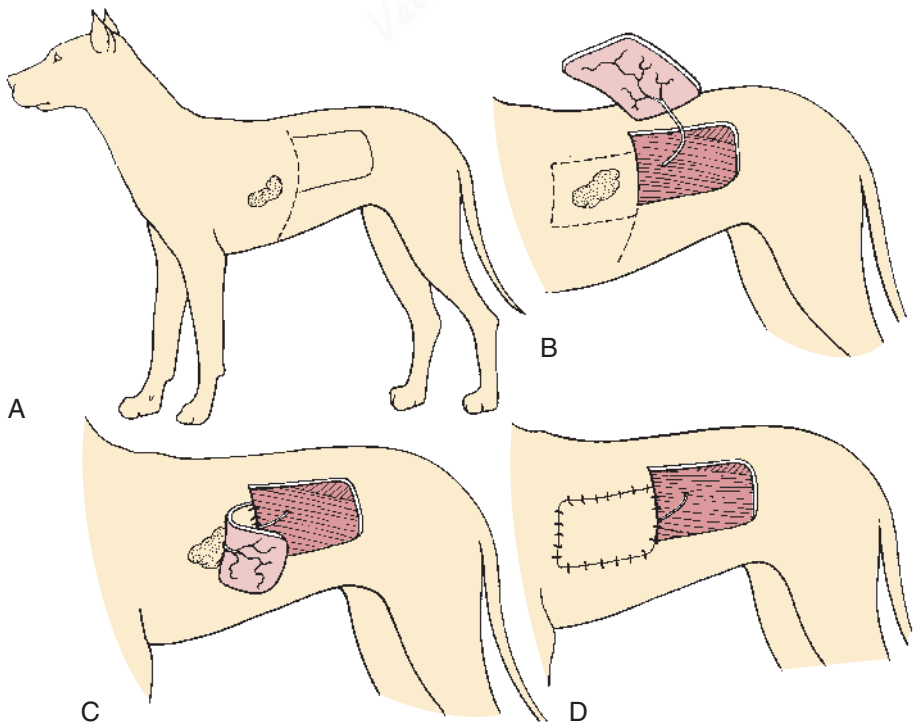

FIG. 15.43 An external abdominal oblique flap is created to reconstruct defects involving the caudal thorax or abdominal wall. (A) Make a paracostal incision from the epaxial muscles toward the ventral midline, beginning 5 cm caudal to the 13th rib. (B) Incise the lumbar fascial edge of the external abdominal oblique muscle and undermine it, preserving the neurovascular pedicle. (C–D) Transpose and suture the muscle over an adjacent defect.

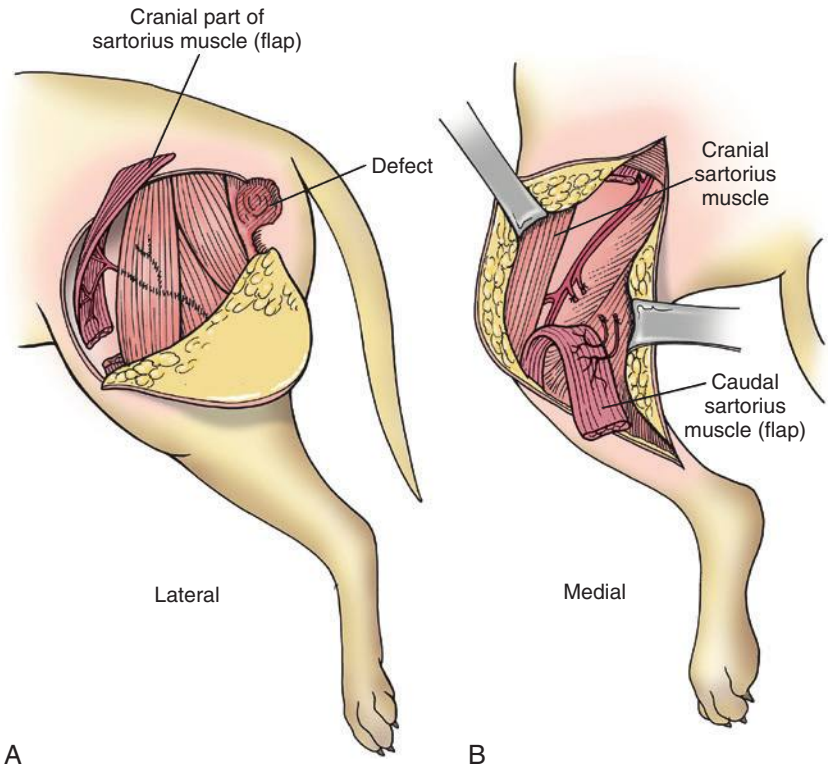

FIG. 15.44 (A) Use a cranial sartorius muscle flap to reconstruct prepubic tendon ruptures, femoral hernias, or femoral trochanteric ulcers. (B) Elevate a caudal sartorius muscle flap to cover defects over the tibia or metatarsus.

or more large vascular pedicles entering either the origin or insertion of the muscle and other smaller pedicles. In dogs, the origin of the cranial part of the sartorius is the crest of the ilium and the thoracolumbar fascia. The cranial sartorius inserts on the patella with the rectus femoris of the quadriceps. A single major vascular pedicle, branches of the femoral artery and vein, enters the proximal one-third of the muscle caudally. The muscle acts to extend the stifle and flex the hip.

Incise the skin of the medial thigh over the cranial sartorius extending to the inguinal region, and dissect subcutaneous tissue to expose the muscle (Fig. 15.44A). Isolate the muscle by blunt and sharp dissection from the caudal sartorius and quadriceps femoris muscles and other tissue. Transect the muscle distally at its insertion on the tibia and elevate it to its vascular pedicle, which enters the proximal one-third of the muscle caudally. Rotate the flap up to 180 degrees into adjacent defects. As an alternative, create an island muscle flap by subperiosteal elevation of the muscle's ilial origin. Suture muscle borders to adjacent fascial planes to cover the defect with absorbable suture material (e.g., 2-0 or 3-0 polydioxanone, poliglecaprone 25, or polyglyconate). Place a closed suction drain in the donor and recipient sites, and close the defect or defects.

Caudal Sartorius Muscle Flap

Caudal sartorius muscle flaps can be rotated distally to cover defects over the tibial or metatarsal area. These flaps may facilitate fracture repair when healing is impaired by osteomyelitis or poor circulation. Preoperative angiography ensures that the saphenous artery is not the primary source of circulation to the traumatized area and distal extremity. The caudal sartorius muscle originates from the cranial ventral iliac spine and adjacent ventral border of the ilium. It inserts on the cranial border of the tibia in common with the gracilis muscle. The caudal sartorius muscle has a segmental blood supply with a dominant vascular pedicle off the saphenous artery and medial saphenous vein at the distal third of the muscle belly. It acts to flex the hip and stifle.

Make a skin incision on the medial aspect of the thigh along the length of the caudal sartorius, and dissect subcutaneous tissue to expose the muscle (see Fig. 15.44B). Transect the caudal sartorius muscle approximately 4 cm distal to its origin on the ilium. Double ligate and transect the saphenous artery and medial saphenous vein where they join the femoral artery and vein. Prevent traumatizing the saphenous vessels in the medial tibial region and along the caudal border of the muscle. Transect the caudal sartorius near the tibial crest for complete mobilization. This creates an island muscle flap dependent on the saphenous artery and medial saphenous vein. *Extend the skin incision and further mobilize the vascular pedicle as needed. Transfer the flap to the desired location and secure. Place a closed suction drain and close the defects at the donor recipient sites.*

Flexor Arpi Lnaris Muscle Flap

The humeral head of the flexor carpi ulnaris muscle is useful for reconstructing injuries involving the tissues of the antebrachial, carpal, or metacarpal areas. The humeral head of the flexor carpi ulnaris lies cranial to the ulnar head of the flexor carpi ulnaris except distally, where the tendon lies caudally. The origin of the humeral head is the medial epicondyle of the humerus; its insertion is the accessory carpal bone. The blood supply to the proximal portion of the muscle is from varying pedicles of the recurrent ulnar, ulnar, and deep antebrachial arteries. A vascular

pedicle from the caudal interosseous artery enters the distal end of the humeral head on its deep face near the accessory carpal bone. There are intramuscular anastomoses between the proximally coursing branches of the caudal interosseous artery and the descending branches of the ulnar and deep antebrachial arteries. The action of the flexor carpi ulnaris is to flex the carpus.

Incise along the caudolateral aspect of the antebrachium from just below the elbow extending 1 to 2 cm distal to the accessory carpal bone to expose the muscle. Incise the antebrachial and carpal fascia to identify the humeral head lying between the ulnar head of the flexor carpi ulnaris caudally and the ulnaris lateralis laterally. Transect the distal tendon of the ulnar head to completely expose the humeral head. Dissect the fascial attachments of the humeral head and transect at the junction of the proximal and middle third of the muscle (Fig. 15.45). Make a bridge incision to the wound and rotate the muscle medially or laterally into the wound. Appose the muscle to the surrounding viable tissue, and place drains as needed. Apply a moist, nonadherent bandage over the exposed muscle if the wound is not immediately covered with skin.

Temporalis Muscle Flap

Temporalis muscle flaps are used to close orbitonasal defects or to improve cosmesis after orbital exenteration. The temporalis muscle is fan shaped and arises from the temporal fossa, inserting on the mandibular coronoid process. The temporal and masseter muscles fuse between the zygomatic arch and the coronoid process. The temporal branches of the superficial temporal artery, cranial deep temporal artery, and caudal deep temporal artery supply the temporalis muscle. The blood supply enters the muscle near its narrow insertion on the mandible and runs in a ventrodorsal direction, paralleling the muscle fibers. The muscle closes the mandible in conjunction with the masseter and medial pterygoid muscles.

Make a cranial to caudal incision centered over the orbit to expose the temporalis muscle (Fig. 15.46). Preserve the superficial temporal artery. Dissect and transect the temporalis fascia from the zygomatic arch. Incise and subperiosteally elevate the desired portion of temporalis muscle. Rotate the flap around its insertion to the recipient site, resecting the zygomatic arch and lateral orbital ligament as needed. Secure the flap over the defect with approximating sutures (e.g., 2-0 or 3-0 polydioxanone, poliglecaprone 25, or polyglyconate). Obliterate dead space with a closed suction drain and close cutaneous defects routinely.

OMENTAL FLAPS

Omental flaps may be used to cover soft tissue defects, contribute to circulation and drainage, enhance healing, control adhesion, and combat infection, similar to muscle flaps. Although less durable than muscle flaps, they stimulate formation of granulation

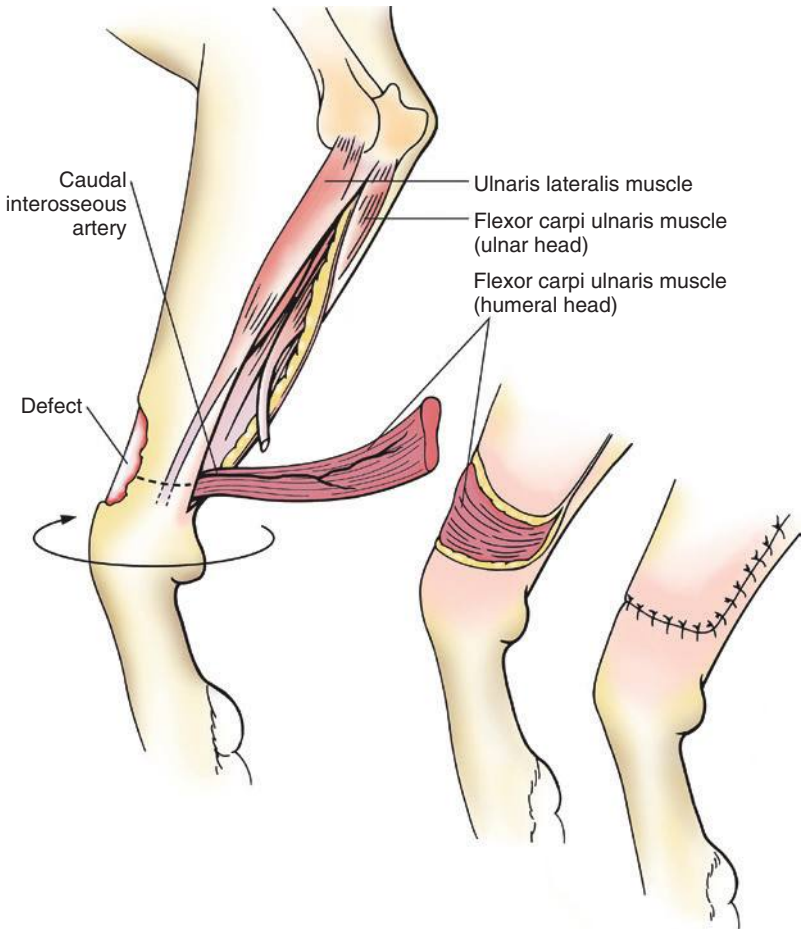

FIG. 15.45 Use a flexor carpi ulnaris flap with the caudal interosseous vascular pedicle entering the muscle on the deep surface near the tendon of insertion to cover wounds in the antebrachial, carpal, or metacarpal areas.

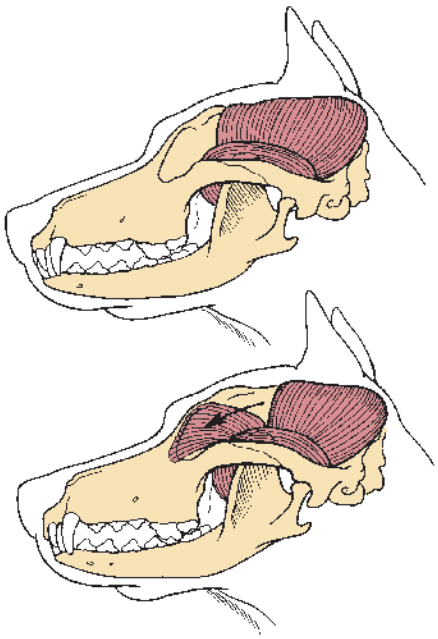

FIG. 15.46 Use a temporalis muscle flap to close orbitonasal defects.

tissue to allow earlier wound closure with skin flaps or grafts. They are especially useful for chronic nonhealing wounds involving the thorax, abdomen, and inguinal and axillary areas and can be used for facial and distal extremity wounds if extended omental lengthening or microvascular transfer is used. In dogs and cats, the omentum is a thin, double sheet of mesothelium that folds on itself in the caudal abdomen. It attaches ventrally to the greater curvature of the stomach and dorsally to the pancreas and spleen. The omental blood supply is from peripheral vessels of the right and left gastroepiploic arteries.

Two methods may be used to mobilize the omentum. One involves creating a vascular pedicle involving either the right or left gastroepiploic artery; the other involves releasing the omentum from the pancreas and then lengthening it with an inverted L-shaped incision. Both methods require a ventral midline celiotomy. The multiple vessel ligations required for the former technique increase the risk of hematoma formation, which may affect omental flap viability.

Create a vascular pedicle based on either the right or left gastroepiploic artery by ligating the segmental gastric arteries as they leave the gastroepiploic artery and enter the greater curvature of the stomach. Ligate either the right or left gastroepiploic artery, depending on which side of the body the omentum is needed. Incise additional attachments to the pancreas and spleen, and ligate vessels as necessary to harvest an appropriate length of omentum for transposition.

*To perform the other lengthening technique, retract the dorsal omental leaf cranially and exteriorize the spleen. Release the dorsal leaf from the pancreas using sharp dissection, and ligate or cauterize vessels as encountered. Ligate and transect the one or two vessels originating from the splenic artery close to the spleen. Extend the dorsal leaf caudally, unfolding the omentum. Begin the inverted L-shaped incision on the left side just caudal to the gastrosplenic ligament (*Fig. 15.47*). Double ligate and transect omental vessels when encountered as you extend the incision across one-half to two-thirds of the omentum's width. Continue the incision caudally, parallel to the remaining omental vessels, along two-thirds the length of the omentum. Ligate or cauterize vascular branches as encountered. Rotate the omentum caudally to fully extend the pedicle.*

After the omentum has been mobilized, make a small incision (2–3 cm) through the lateral abdominal wall near the wound or several centimeters from the celiotomy for distant wounds. Create a subcutaneous tunnel to the wound, transpose the omentum through this tunnel, and secure it to the wound with interrupted absorbable sutures. Take care when handling and transposing the omentum to keep it warm and moist and to prevent occlusion of remaining omental vessels to maintain its viability.

Possible complications after omental transposition include seroma formation, herniation through the omental exit hole, and flap necrosis.

MICROVASCULAR FLAP TRANSFER

Specialized training and equipment are necessary to successfully perform microvascular transfers. The required equipment includes an operating microscope with good optics, 9-0 to 11-0 suture material, approximating and atraumatic vascular clamps, microscissors, jeweler's forceps, ophthalmic needle holders, vessel dilators, and coupling devices. Most axial pattern skin flaps and muscle flaps can be used for microvascular transfer if vessels in the flap are large enough and if vessels of similar size are available near the wound bed. Peripheral angiography of the recipient site is advised to ensure that recipient vessels are present and functioning. Recipient vessels that have been used clinically for free flap transfer include the ulnar artery and cephalic vein in the forelimb; the cranial tibial artery and the dorsal branch of the medial saphenous vein or the plantar branch of the medial saphenous artery and its vena comitans in the hind leg; and the left infraorbital and superior labial arteries for palatal reconstruction. Anastomosis of recipient vessels should occur outside the area of trauma.

Once the location of the vascular pedicle has been identified during creation of the flap, magnifying loupes and the operating microscope are used to identify and isolate the vessels. Vessel clamps are applied, and the vessels are ligated and transected proximal to the clamps. At the recipient bed, the wound undergoes final debridement, and the vessels are identified and isolated in a similar manner. End-to-end anastomosis is preferred to end-to-side anastomosis because it is technically easier. Vessel ends are irrigated with heparinized saline, and excessive periadventitial tissue is removed. Arteries and then vein are anastomosed. Failure of flap transfer occurs if vessels are kinked or if they thrombose.

SKIN GRAFTS

Skin grafts are the transfer of a segment of free dermis and epidermis to a distant recipient site. They may be full thickness (epidermis and entire dermis) or partial thickness (epidermis and a variable portion of the dermis). They are used for defects that cannot be reconstructed by direct apposition or skin flaps (usually limb and large trunk defects). Skin graft survival depends on absorption of tissue fluid and revascularization. *Autografts* (grafts from the same animal) are most useful; however, *allografts* (grafts from the same species, also called *homografts*) and *xenografts* (grafts from different species, or heterografts) that

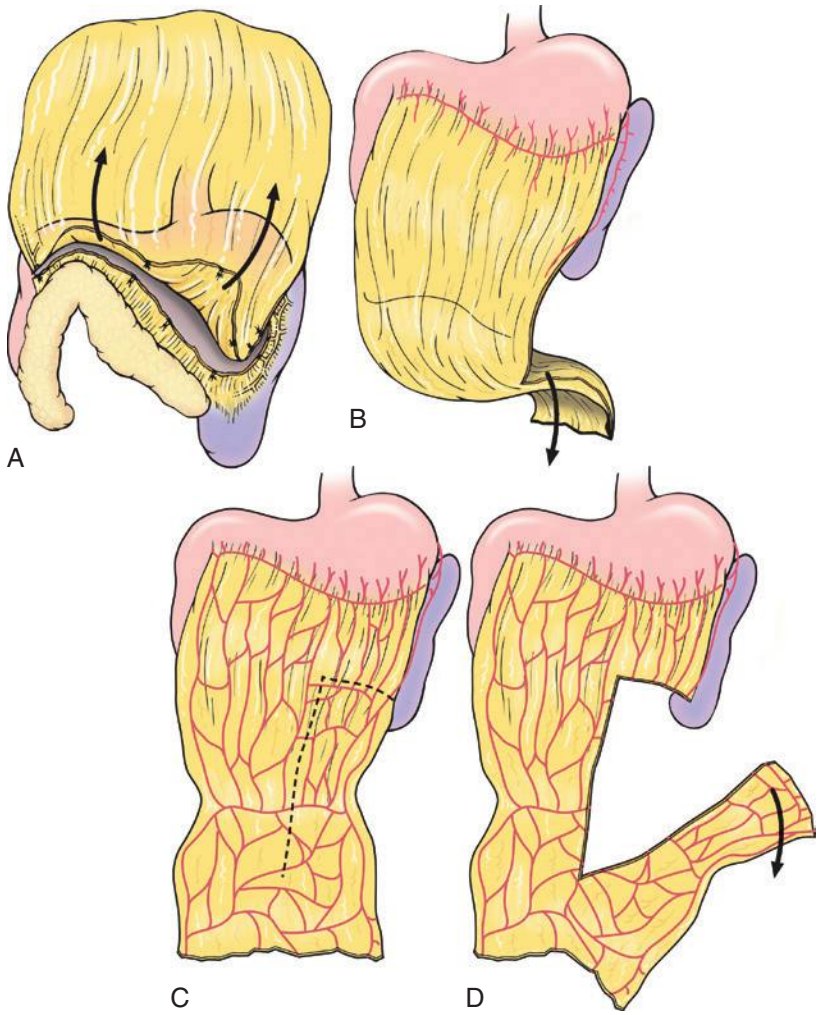

FIG. 15.47 Omental extension. (A) Exteriorize the omentum and spleen, then retract the dorsal leaf cranially and free it from its pancreatic attachments. (B) Extend the dorsal leaf of the omentum caudally. (C) Make an inverted L-shaped incision just caudal to the gastrosplenic ligament. (D) Rotate the left side caudally to achieve full extension.

are eventually rejected may be used to temporarily cover and protect large burned or denuded areas. Making templates of the defect and graft and drawing reference lines on the skin are helpful in planning reconstruction.

Successful graft healing, or graft "take," is dependent on the establishment of arterial connections and adequate drainage. This must occur by the seventh or eighth postoperative day, or the graft will die. The graft bed must supply adequate vasculature for the graft. Healthy granulation tissue or a fresh, clean wound free of infection and debris may serve as the graft bed. Healthy muscle, periosteum, and peritenon can support a skin graft. Bone, cartilage, tendon, and nerve that are denuded of their overlying connective tissue do not support grafts. Poor graft take occurs over avascular fat, crushing injuries, infected tissue, irradiated tissue, old or hypertrophic granulation tissue, and chronic ulcers. Chronic granulation tissue should be excised to allow new granulation tissue to form before grafting (approximately 4–5 days). The surface of healthy granulation tissue may be debrided by excising a thin layer (0.5–2 mm) with a blade or by rubbing with a gauze sponge before grafting. If bleeding persists, hemorrhage may be controlled with pressure or pinpoint electrocoagulation. The graft bed should be covered with moistened sponges while preparing the graft. A graft adheres to its bed by fibrin contraction soon after being placed. Fibrous tissue forms after fibroblasts, leukocytes, and phagocytes invade the area. The strength of graft adherence increases as fibrous tissue forms; by the tenth postoperative day, a firm union has occurred. Good graft contact with the graft bed is essential to adherence and graft take. To achieve good contact, the graft bed must be free of debris and irregularities. Immobilizing the graft with sutures and bandages minimizes graft movement over the wound and facilitates adhesion. Use of subatmospheric pressure drainage (see p. 192), which improves graft contact with the recipient bed and drainage, is being advocated to facilitate graft survival. Improperly applied or wrinkled bandages or those that apply excess pressure or abrade the graft can result in graft necrosis. Bandages should be well padded and bulky to restrict limb motion.

Plasmatic imbibition initially nourishes the graft and keeps the graft vessels dilated until the graft revascularizes. Capillary action pulls the fibrinogen-free, serum-like fluid and cells from the graft bed into the dilated vessels of the graft. Absorption of hemoglobin products gives the graft a bluish black color. The absorbed fluid

diffuses into the interstitial tissue of the graft, causing edema; edema reaches its maximum at 48 to 72 hours after grafting. As venous and lymphatic drainage improves, fluid is taken away from the graft, and the edema regresses. Anastomosis of graft vessels with graft bed vessels of similar sizes *(inosculation)* may begin within 1 day of grafting. Vascular buds from the graft bed follow the fibrin scaffold to meet preexisting severed graft vessels. Vascular anastomoses form, and blood flow to the graft begins. Initially blood flow is sluggish and disorganized, but it improves and approaches normal by the fifth or sixth day. Fluid accumulations (i.e., seroma or hematoma) inhibit inosculation. Grafts may also be revascularized by the ingrowth of new vessels from the bed into the graft. New vessels form by endothelial sprouting and anastomosis with another sprout or formed vessel. Vascular sprouts may be found within the lower layers of the graft in 48 to 72 hours. New vascular connections remodel, differentiate, and mature until a system of arterioles, venules, and capillaries forms. New lymphatic vessels develop in the graft and establish lymphatic drainage by the fourth or fifth postoperative day.

Fluid accumulation within or under the graft and movement of the graft prevent good vascular connections from developing between the graft and the bed. A nonadherent, hydrophilic bandage should be placed immediately after grafting and left undisturbed for 24 to 72 hours to facilitate graft immobilization, fluid absorption, and graft adhesion, and to protect the graft from trauma. The frequency of bandage changes depends on the wound and varies from daily to every 3 to 4 days for at least 3 weeks. Grafts are pale when initially placed in a wound. They appear black and blue during the next 48 hours. The dark colors fade and a light reddish tinge appears by 72 to 96 hours. The entire graft should be red 7 to 8 days after surgery if graft survival is complete. Normal color gradually returns by the fourteenth day. Persistently pale areas are avascular and will undergo necrosis and slough. Black coloration indicates dry ischemic necrosis. Do not resect areas of questionable viability.

The most common causes of graft failure are separation from the graft bed, infection, and movement. They cause graft failure by disrupting the delicate fibrin bonds that bind the graft to the bed. Without adherence, revascularization and organization are impossible. Hematoma or seroma formation under the graft is a common cause of graft failure. Fluid mechanically separates the graft from its bed, impairing nutrition and revascularization. Meticulous hemostasis during graft bed preparation helps prevent hematomas and seromas. Nonexpanded mesh grafts, closed suction drainage, and vacuum-assisted drainage (see pp. 191 and 236) are the best methods of facilitating drainage. Mesh grafts have an advantage of not requiring placement of a tube that may disrupt graft adhesion and healing. Vacuum-assisted drainage has an advantage of promoting good contact between the graft and the recipient bed, and continuous drainage. The initial bandage change is recommended 24 to 72 hours after grafting to detect and drain fluid accumulation under the graft. The danger of fluid accumulation is greater than the risk of moving the graft during bandage manipulations. Infection is detrimental to graft survival because bacteria may cause dissolution of fibrin attachments or produce sufficient exudate to lift a graft from the recipient bed. Plasminogen activators and proteolytic enzymes released by bacteria disrupt the fibrin seal. β-Hemolytic streptococci and pseudomonads produce large amounts of plasmin and proteolytic enzymes. *Pseudomonas* spp. also produce elastase, which breaks down elastin; elastin adheres to fibrin, facilitating graft adhesion.

Donor site skin should have hair the same color, texture, length, and thickness as the hair surrounding the recipient site. The donor site should have enough skin to allow closure without tension after graft removal. Hair follicles may be damaged during graft harvesting and preparation or by poor graft revascularization. Removal of subcutaneous tissue may damage the base of hair follicles and reduce hair regrowth. Hair regrowth is usually noticed within 2 to 3 weeks after grafting; however, hair color may be altered after grafting. Split-thickness grafts result in sparse hair regrowth. Hair regrowth with strip, punch, and expanded mesh grafts is patchy. Full-thickness sheet grafts and nonexpanded mesh grafts result in the best hair regrowth and cosmetic appearance.

Reinnervation of grafts depends on the type and thickness of the graft, the amount of scar tissue formation, and the innervation of surrounding tissue. Return of sensation is greatest in flaps, less in full-thickness grafts, and least in split-thickness grafts. Reinnervation occurs from the margins of the graft. Pain is the first sensation to return, followed by touch, and last, temperature discrimination.

Full-Thickness Skin Grafts

Full-thickness skin grafts include the epidermis and entire dermis. They are indicated to cover large defects on flexor surfaces, thus preventing contracture and distal extremity defects (Fig. 15.48). After healing, full-thickness grafts resemble normal skin in hair growth, color, texture, and elasticity. They become pliable, movable, and durable. Full-thickness grafts take to the wound bed equally as well as split-thickness grafts. The disadvantages of full-thickness grafts include planning, tedious removal of subcutaneous tissue, and areas of nonviability. Full-thickness grafting techniques include meshes, plugs, strips, and sheets of skin.

Sheet Grafts

Sheet grafts are indicated to prevent contracture of defects on the distal aspect of the limbs and over flexor surfaces. They should be used only over uninfected granulation beds and when minimal fluid production is expected because fluid accumulation or drains prevent graft adhesion. Sheet grafts are less flexible, less expansive, and less conforming than mesh grafts. The donor site is the skin of the lateral thoracic wall, back, shoulder, or other areas with abundant skin. The lateral thoracic wall is the preferred donor site because the skin is relatively thin and well haired.

Aseptically prepare the surgical sites. Debride, lavage, and control hemorrhage in the graft bed before placing the graft. Make a pattern of the defect using a sterile towel or paper template. Using the pattern of the defect as a guide, harvest a segment of skin approximately 1 cm larger than the pattern from the donor site with the hair oriented in the proper direction. Excise all subcutaneous tissue from the graft with a scalpel blade during harvest or it will interfere with revascularization (Fig. 15.49). As an alternative, excise the graft, stretch it, and fix it to a piece of stiff cardboard or drape it over the index finger, and then remove subcutaneous tissue with a Metzenbaum scissors. Keep grafts moist by periodically submerging them in a bowl of saline or lactated Ringer's solution; this also rinses off fat fragments and helps identify remaining subcutaneous tissue. Keep the donor site moist with saline-soaked sponges while placing the graft. Place the graft in the defect with the hair properly oriented and with uniform contact with the recipient bed. Overlap the skin edges with the graft to ensure complete wound coverage and to prevent the skin edges from curling underneath. Tack the

FIG. 15.48 (A) Injuries involving the distal extremities commonly require grafting. Grafts should be applied over healthy granulation tissue. (B) A full-thickness sheet graft has been applied over the wound.

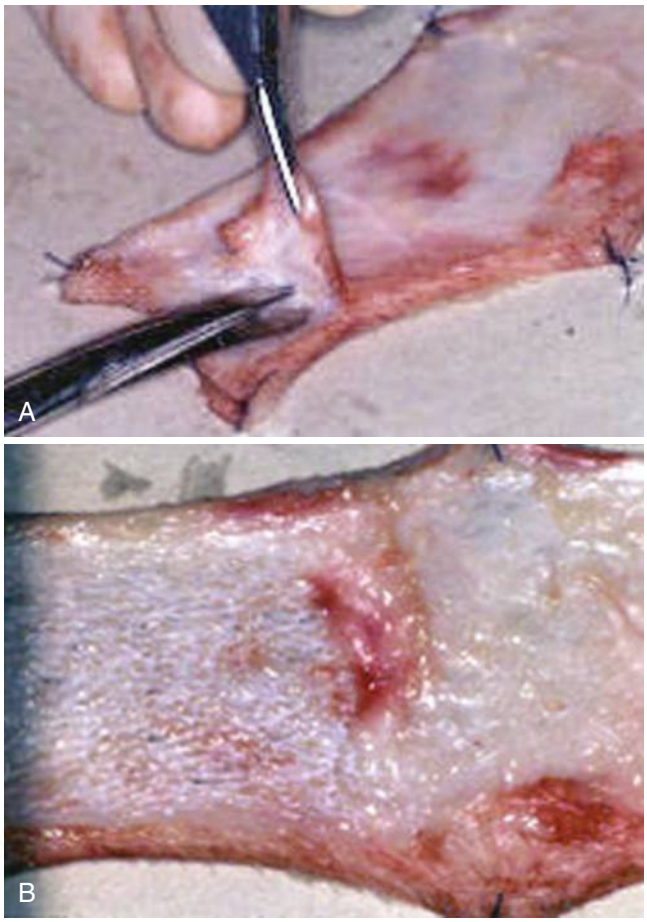

FIG. 15.49 (A) Subcutaneous tissue being removed from a full-thickness skin graft. (B) Close-up view of graft after subcutaneous tissue has been removed to expose hair follicles.

graft in position with interrupted sutures. Place a closed suction drain beneath the graft or make one or more stab incisions to promote drainage. Appose the edges of the graft and wound with staples or simple interrupted or continuous sutures (e.g., 3-0 or 4-0 nylon or polypropylene) placed 3 to 4 mm apart. Close the donor site by undermining and apposing wound edges or using a pedicle flap. Bandage the graft site with a nonadherent, hydrophilic, absorbent bandage that restricts the patient's motion. Change the evacuation tube as needed. Change the bandage, evaluate the graft 24 to 48 hours after surgery, and continue rebandaging as needed for 21 days. Where the graft overlaps skin edges, it will necrose and peel off when sutures are removed at 7 to 10 days.

Plug, Punch, or Seed Grafts and Strip Grafts

Plug, punch, or seed grafts and strip grafts are placed in a prepared granulation tissue bed. They are indicated for limb wounds and wounds with low-grade infection or irregular surfaces. They are best used on smaller wounds in areas not subjected to excessive wear or external trauma. These grafts are difficult to immobilize after implantation. The initial bandage change after surgery is delayed for 3 to 5 days to prevent displacing the grafts. Wounds that are parallel to the long axis of the limb lend themselves to strip grafting. Plugs and strip grafting are easy to perform and require no special equipment. However, excessive bleeding from the graft bed may float plugs out of the recipient site or delay revascularization. The cosmetic appearance is poor because of epithelial scarring and sparse hair growth, which result because the wounds heal by epithelialization from each graft and wound edge.

Prepare the graft bed by debriding and treating it as an open wound for several days. Harvest plugs of skin from the donor site with a 5- or 6-mm biopsy punch or tent the skin with a bent hypodermic needle or curved suture needle and resect a small piece of tissue. Harvest 5-mm-wide strips of skin freehand for strip grafting. Remove subcutaneous tissue from the dermis (see Fig. 15.49). For plugs, make small, slitlike pockets in the granulation tissue (2–4 mm deep, 5–7 mm apart), almost parallel to the wound surface. Insert a plug in each pocket after controlling hemorrhage, holding it in position with gentle pressure for 1 to 2 minutes. As an alternative, cut holes in the granulation tissue with a 4-mm skin biopsy punch (approximately 2 mm smaller than the punch used for harvesting the graft), approximately 1 to 2 cm apart, and insert the skin plugs into these holes. Make grooves 2 mm wide and 3 to 5 mm apart for strip grafting. After hemorrhage has been controlled, lay a skin strip in each groove and anchor it with an interrupted suture at each end. Bandage and splint the graft site with nonadherent, hydrophilic, absorbent materials. Excise and reappose the donor site or treat it as an open wound with bandages. Change the graft bandage 3 to 4 days after surgery, taking care not to dislodge any of the grafts. Rebandage the area as needed until healing is complete. Bandages should be bulky and restrict motion.

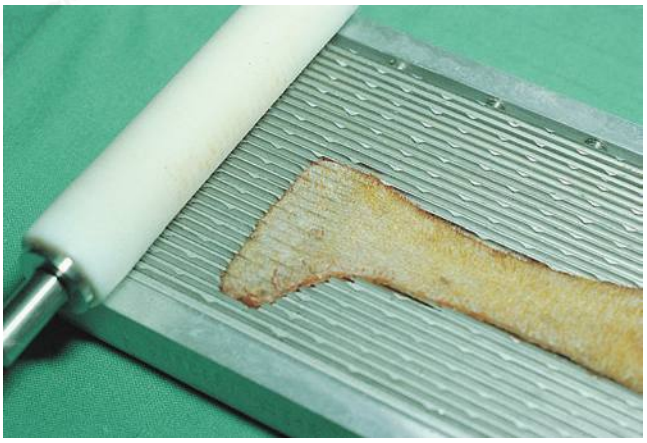

FIG. 15.50 After a skin graft has been harvested, it can be meshed (dermal side down) using a mesh graft expansion unit.

FIG. 15.51 Skin grafts may be meshed by making small, full-thickness incisions through the graft. The incisions are aligned in parallel rows.

Mesh Grafts

Mesh grafts may be either full-thickness or split-thickness grafts in which parallel rows of staggered slits have been cut. Meshing a sheet graft allows drainage, flexibility, conformity, and expansion. The degree of expansion is directly related to the length of the slits; longer slits equal greater expansion. As the graft is expanded, it shortens in the perpendicular plane. A sheet graft is meshed with a special mesh graft expansion unit (Fig. 15.50) or freehand (Fig. 15.51). Freehand slits are made in a sheet graft when it is fixed to cardboard after subcutaneous tissue has been removed. Slits are made with a No. 11 or No. 15 scalpel blade and should be approximately 5 to 15 mm long and 2 to 6 mm apart and oriented in staggered rows. Mechanically meshed grafts are more expansible because they expand in more than one direction; those meshed with freehand slits expand in only one direction.

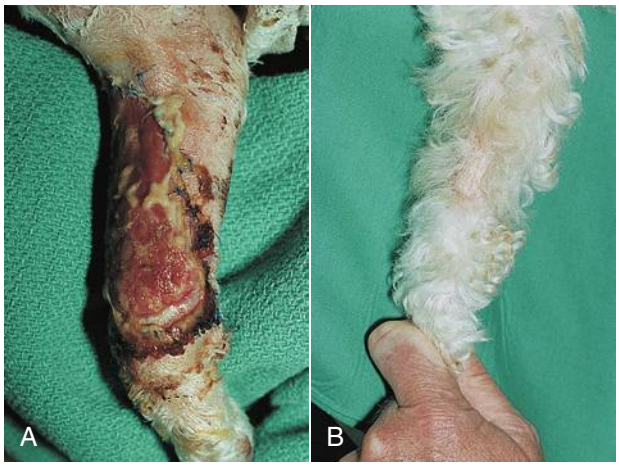

FIG. 15.52 (A) Skin graft in Fig. 15.40 at 6 days; note partial graft loss. (B) Cosmetic appearance after 100 days is good.

Cosmesis is improved if the slits are placed parallel to the skin tension lines.

A nonexpanded, full-thickness mesh graft is recommended for most grafting needs as it may be used under a wide range of circumstances, has a high success rate, and has a good cosmetic appearance. Meshing allows a graft to conform and adhere to irregular surfaces and allows placement on graft beds with exudation or blood. Meshing allows drainage, which facilitates graft adherence. The cosmetic appearance is as good as that with sheet grafts (Fig. 15.52). Survival is 90% to 100% when grafts are applied on healthy granulation beds and managed properly. Expanded mesh grafts are indicated when donor sites are limited and defects are large. They should be cut longer than the defect to account for shortening with expansion. A diamond-shaped pattern with tufts of hair between epithelial scars results when a mesh graft is expanded. This may not be cosmetically acceptable.

NPWT has been used in both clinical and experimental studies in dogs and cats with increased graft uptake and better overall outcomes.[6,10–12]

Split-Thickness Skin Grafts

Split-thickness skin grafts are composed of epidermis and a variable thickness of dermis. Feline skin is too thin for split-thickness grafting. Graft taken with split-thickness grafts is similar to that with full-thickness grafts. Split-thickness grafts are less durable and more subject to trauma than full-thickness grafts, and hair growth may be absent or sparse. In addition, the graft may appear scaly. Hair regrowth at the donor site of thick split-thickness grafts may also be sparse if the site is allowed to heal as an open wound rather than being resected. Skin of the lateral thoracic wall, back, shoulder, or another area with abundant skin may be used as the donor site. However, the flexibility of the abdominal wall and the irregularity of the thoracic wall make graft harvesting difficult. The relatively firm, flat surface over the epaxial muscles lateral to the dorsal spinous processes, lateral thigh, and arm muscles are better sites for harvesting skin.

Aseptically prepare the surgical sites. Debride, lavage, and control hemorrhage in the graft bed before placing the graft. Harvest the split-thickness graft with a dermatome or freehand. Inject sterile saline subcutaneously under the donor site to elevate the skin, and

reduce contour irregularities. If using a dermatome, lubricate the skin surface with sterile mineral oil or water-soluble gel. Pull the skin in opposite directions over the donor site to make it taut. Harvest the graft. Using a scalpel, make a partial-thickness incision perpendicular to the skin surface. Then, holding a modified safety razor almost parallel to the skin surface, begin cutting. Place stay sutures in the cut edge of the graft to apply traction while cutting. Change blades as they become dull. Place the graft on the bed with hair growth oriented in the proper direction. Overlap the wound edges with the graft by 2 to 4 mm. Anchor the graft in place with interrupted sutures or skin staples. Irrigate under the graft with saline or thrombin. Apply a nonadherent, absorbent bandage with a splint to immobilize the area. Use a tie-over bandage if necessary. Holes inadvertently perforating the graft will allow drainage and eventually heal. *After harvest and grafting, excise the donor site and close it or manage it as an open wound with bandages. Perform the first bandage change 24 to 48 hours after surgery. Drain the area if a seroma or hematoma has formed by making a small incision in the graft and aspirating. Expect the graft overlapping the skin to necrose. Rebandage the area and change the bandage only as needed because movement of the graft bed interferes with revascularization.*

NOTE Increased pain is expected when the graft site is managed as an open wound; however, the wound will reepithelialize in approximately 3 weeks and additional split-thickness grafts can be harvested from the same site if necessary.

Stamp Grafts

Stamp grafts are square patches of split-thickness skin applied to a granulating wound. The graft bed and graft are prepared and managed in the same manner as for other split-thickness grafts. The graft is cut into patches ranging from 5 mm^2 to 25 mm^2. Patches are spaced 1 to 10 mm apart in graft bed depressions. These grafts are particularly susceptible to movement and easily displaced by bandages.

SURGICAL MANAGEMENT OF SPECIFIC SKIN DISORDERS

BURNS AND OTHER THERMAL INJURIES

Burns occur when heat energy is applied at a faster rate than tissue can absorb and dissipate it. Fires, electric heating pads, hair dryers, scalding water, steam, hot cooking oil, exhaust systems, and hot pipes are common sources of thermal burns in domestic animals (Fig. 15.53). The extent of injury is influenced by the temperature of the heat source, duration of contact, and tissue conductance. In humans, temperatures above 45°C (113°F) can cause coagulation necrosis and irreversible skin damage; a temperature of 70°C (158°F) for only 1 second causes a full-thickness burn. A transition zone separates completely devitalized tissue from uninjured tissue. The area in direct contact with the heat coagulates; cellular proteins denature and blood vessels coagulate. The transition zone is characterized by reduced blood flow, intravascular sludging, and potentially reversible tissue damage. Progressive dermal ischemia may occur in this area because of release of vasoactive substances (e.g., thromboxane A_2, histamine, leukotrienes, prostaglandins, oxygen free radicals), tissue edema, desiccation, and bacterial invasion. The transition zone is surrounded by an area of hyperemia where minimal damage occurs and healing is complete. It can be difficult to determine the burn depth and area of involvement as the depth of injury is not uniform and the skin surface is often leathery and covered by dry coagulum. Eschar is the residue of skin elements that have been coagulated by the heat. It is composed almost entirely of tough, denatured collagen fibers. Scabs contain dead cells and flimsy fibrin and, unlike eschar, are not a strong protective covering.

FIG. 15.53 A 360-degree thermal burn of the distal tibia in a 2-year-old cat. The limb was trapped in a double-pipe radiator. Note the pale appearance of the skin and distinct lines of demarcation proximally and distally.

Superficial *(first-degree)* burns affect only the epidermis. The area is painful, thickened, erythematous, and desquamated. Healing occurs rapidly (within 3–6 days) by epithelialization from stratum germinativum or adnexal dermal structures. Unlike human skin, canine skin does not act as an organ for heat dissemination; therefore dogs do not have the rich superficial vascular plexus that humans do. For this reason, dogs show less erythema with superficial burns than humans. Superficial partial-thickness burns are moist, blanch with pressure, and are sensitive to pain. They usually heal within 3 weeks because of epithelialization from deeper portions of the skin appendages. Healing is usually complete and occurs without grafting.

Deep partial-thickness *(second-degree)* burns cause major destruction of the dermis. The only remaining adnexal epithelium is in the upper layers of the subcutaneous fat. Subcutaneous edema and notable inflammation occur, and the hair does not epilate easily. Progressive damage during the first 24 hours results from the heat of injury and the release of proteolytic enzymes, prostaglandins, and vasoactive substances. Although these burns frequently heal without grafting, healing takes months, and scarring may be extensive. Healing occurs by reepithelialization from deep adnexa and wound margins. The burn must be protected against trauma and contamination while healing. Ineffective therapy may allow a second-degree burn to progress to a third-degree burn, especially if bacterial infection occurs.

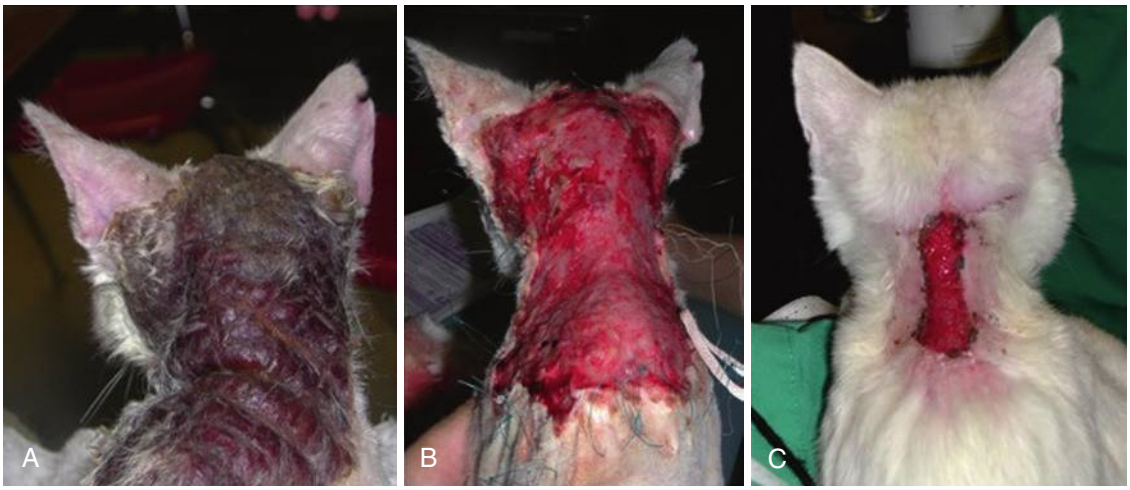

FIG. 15.54 (A) This 6-month-old cat has a thick eschar after receiving a burn of unknown etiology or duration. (B) The eschar was surgically excised and the wound debrided to fascial tissue. (C) The wound healed by second intention to a wide scar on the back of the neck.

Full-thickness *(third-degree)* burns form a dark brown, insensitive, leathery eschar (Fig. 15.54A). All skin structures are destroyed, and hair epilates easily. Third-degree burns are less painful than first- or second-degree burns as nerves have been destroyed. Superficial vascular thrombosis and deep vascular permeability cause subcutaneous edema and necrosis. Healing occurs by contraction and reepithelialization unless the wound is reconstructed. Some indication of injury depth may be obtained by elevating the eschar. First- and second-degree burn eschars split when elevated and bent to reveal underlying epidermis or dermis; third-degree burns may not split, or the split may extend to subcutaneous tissue. Early eschar removal is important as a necrotic eschar quickly becomes colonized on its deep surface and serves as a nidus of infection.

Burns that extend beyond the dermis are sometimes classified as *fourth-degree burns.* They have the same characteristics as third-degree burns but with additional tissue damage extending into the muscle and bone. Healing by secondary intention or reconstruction is usually required.

Burn wounds are sterile or colonized only by superficial bacteria during the first 24 hours. The large volume of dead tissue provides an excellent medium for bacterial growth, and occlusion of local blood supply impairs delivery of humeral and cellular defense mechanisms and systemic drugs to the wound. Superficial bacteria proliferate and invade the deeper tissue under the eschar within 4 to 5 days of injury. Initially, most organisms are gram-positive cocci, but by 3 to 5 days, the wound is colonized with gram-negative bacteria, typically *Pseudomonas* spp. Early removal of eschar and application of topical antibiotics are necessary to minimize the progression of damage.

Burns frequently cause shock and multiple organ failure due to fluid loss, fluid shifts, electrolyte imbalances, protein losses, myocardial depression, increased peripheral vascular resistance, and increased blood viscosity. Cardiac abnormalities, immunosuppression, anemia, renal failure, hepatic failure, and disseminated intravascular coagulation sometimes occur. More severe systemic signs are associated with large burn surface areas. Respiratory distress may occur from smoke inhalation (corrosive gases and chemical irritants), thermal burns of the upper airway, and carbon monoxide and cyanide poisoning. Smoke inhalation causes pulmonary edema with vascular congestion, interstitial edema, and atelectasis. Pneumonia often occurs several days after smoke inhalation.

Burns from contact rather than fire may not be immediately recognized. Moisture and flattening of the hair coat may be noted a few days after injury. This is rapidly followed by hair and skin loss, which makes demarcation of the burn area obvious. Burns may be prevented during surgery by using circulating warm water pads or bags inflated with circulating warm air (42°C [107.6°F] or lower) rather than electrical wire element pads. Thermal burns may also be caused by gloves or bottles filled with hot water. Anesthetized or hypothermic animals are particularly susceptible to burns from hot water bottles because of reduced circulation associated with vascular constriction. The longer the exposure, the greater the risk of burns. Burns may also be prevented by properly grounding patients when using electrosurgical units.

Treatment

The first priority in treating burns is to minimize tissue loss by administering first aid and preventing shock. Prevention of septic complications by good wound management is the next priority. Meticulous care immediately after injury to ensure adequate perfusion, hydration, and wound protection from trauma and infection may prevent progression of tissue damage and allow salvage of injured tissue. Early wound debridement and reconstruction are important to minimize morbidity. Cooling affected areas immediately after thermal injury (within 2 hours) may limit extension of tissue destruction. The area should be lavaged with cold water, or cold packs should be applied to the wound; however, it is important to prevent systemic hypothermia. Analgesics should be given as necessary to alleviate pain (see Chapter 13). Vital signs, mental status, hematocrit, total protein, urine output, central venous pressure, electrolytes, blood gases, and daily body weight should be monitored.

The size of the burn area can be estimated by measuring the area of burned skin with a metric ruler, dividing that area by the animal's total surface area (Table 15.5), and multiplying by 100. As an alternative, a rough estimate can be gained using the rule of nine: each forelimb of the animal represents approximately

Total body surface area = $weight^{0.425} \times height^{0.725} \times 0.007184$ ($m^2 = kg^{0.425} \times cm^{0.725} \times 0.007184$) or Total body surface area = $0.1 \times weight\ (kg)^{2/3}$.
From Swaim SF. *Surgery of traumatized skin: management and reconstruction in the dog and cat.* Philadelphia: WB Saunders; 1980.

9% of the total body surface area (TBSA); each rear limb is 18% (two nines); and the dorsal and ventral thorax and abdomen are each 18%. Animals with partial-thickness burns involving less than 15% TBSA require minimal supportive therapy, whereas those with burns involving more than 15% TBSA require emergency supportive care. Euthanasia should be considered for those with burns involving more than 50% TBSA. Shock doses of lactated Ringer's solution or hypertonic saline solution should be administered to minimize and reverse signs of shock. The amount of isotonic fluid required during the first 24 hours may be estimated using the formula 3 to 4 mL/kg per percentage TBSA burned. Hypertonic saline solutions are beneficial in reducing total fluid requirements, limiting edema, and increasing cardiac output. Hypertonic saline (4 mL/kg bolus) plus lactated Ringer's solution (1 mL/kg per percentage TBSA burned) may be administered. When giving hypertonic saline, the serum sodium concentration should not exceed 160 mEq/L. Nonprotein colloid solutions (i.e., dextran 70, hetastarch) given in the early postburn period (16–24 hours after injury) may improve survival and reduce edema formation (see p. 33). Administration of protein colloids (i.e., fresh-frozen plasma or albumin) to hypoproteinemic patients should be delayed for 8 to 12 hours to allow the stabilization of membrane permeability and increased lymph return that reduces protein loss. Protein colloids given within the first 8 to 12 hours are lost into the burn wound and worsen edema formation. Dogs with partial-thickness burns involving 20% TBSA may lose 28% of their plasma volume during the first 6 hours. Transfusions (i.e., whole blood and packed red blood cells) may be necessary in anemic patients.

Respiratory distress should be treated by giving oxygen (mask, nasal insufflation, tracheostomy tube) and bronchodilators. The half-life of carbon monoxide is reduced with oxygen therapy. Continuous positive pressure ventilation may be necessary in some animals. Tracheostomy (see p. 842) and mechanical ventilation are indicated in patients with upper airway swelling or severe tracheobronchial secretions. The trachea and bronchi should be suctioned if necessary. Systemic antibiotics should be administered if bronchopneumonia occurs (see p. 888).

Aggressive nutritional support counters the increased metabolic demand and protein losses that occur in burn patients (see Chapter 10). Animals with moderate to severe wounds should be fed a high-protein, high-calorie diet. Early enteral feeding is important in preventing gastroduodenal ulceration. Proton pump inhibitors should be given if gastroduodenal ulceration is suspected (see p. 429).

Burn Wound Management

Removal of dead tissue is essential to the control of sepsis and promotion of a viable vascular bed suitable for surgical closure. Necrotic tissue may be debrided from burn wounds with dissection, autolytic, bandage, enzyme, or biosurgical techniques (see p. 185). Autolytic, enzymatic, and biosurgical debridement spare viable tissue that may be removed by surgical excision or bandages, but results vary; the best results are obtained with endogenous or exogenous enzymes on a moist, pliable eschar. Loose and obviously devitalized tissue in partial-thickness burns may be removed with scissors, hydrotherapy, or gauze sponge abrasion. With full-thickness burns, sharp excision to muscle fascia is necessary (see Fig. 15.54B). Early burn excision is recommended to minimize secondary infections and systemic effects (e.g., endotoxins and blood loss). Application of NPWT may prevent progression of partial-thickness burns by reducing edema and improving circulation.

Small burn wounds can be excised and closed primarily (Fig. 15.55). Closure is achieved by skin advancement or skin flaps. Larger wounds may be allowed to heal by contraction and epithelialization, or they may be grafted. Healing by secondary intention may take months or may be incomplete, and the resulting scar may be cosmetically unacceptable (see Fig. 15.54C). For these reasons, many large burns are debrided, allowed to form a healthy granulation bed, and then reconstructed using rotating skin flaps, axial pattern flaps, tissue expansion, or grafts. Early wound closure reduces wound management and secondary infection, and it shortens hospitalization. Scars are fragile and may erode and bleed easily. Squamous cell carcinomas occasionally occur in burn scars.

Numerous wound dressings have been evaluated specifically for burn care, and although most dressings have a beneficial effect on wounds, silver sulfadiazine delivers the best protection against wound colonization and infection. Silver sulfadiazine is bactericidal with activity against gram-positive and gram-negative bacteria and *Candida* spp. However, aloe vera is associated with

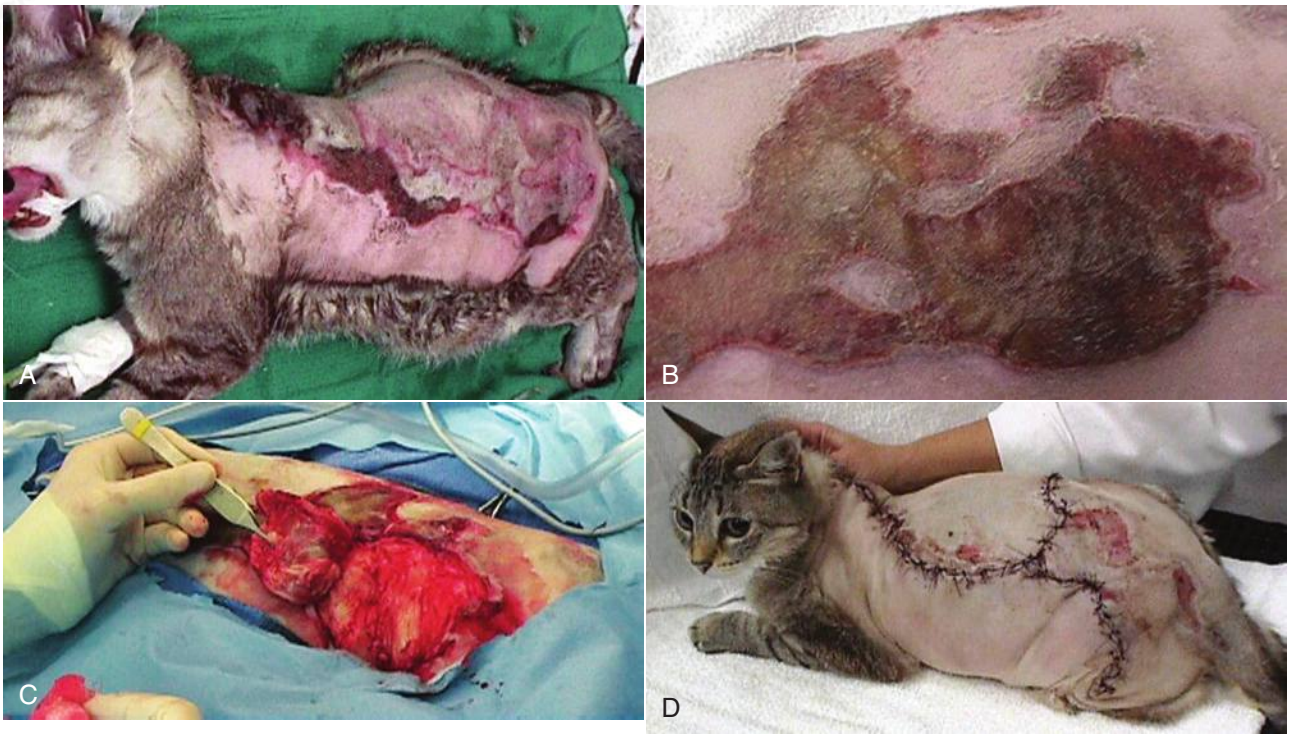

FIG. 15.55 (A) This cat received a thermal burn several days before presentation. (B) Close-up appearance of an area of the burn showing varying degrees of discoloration and a distinct line of demarcation. (C) The eschar is being surgically removed, exposing the subcutaneous tissue. (D) Postoperative appearance after excision and flap advancement to close the defect.

faster rates of reepithelization in partial-thickness burns. Paraffin gauze dressings have been shown to be associated with short healing times in superficial burns, and silver-based dressings are of most benefit in deeper burns. Alginate silver (e.g., Silvercel, Algidex AG) is an advanced wound dressing that combines the antimicrobial properties of silver with the absorptive wound management properties of calcium alginate and polyurethane foam; application to partial-thickness burns is associated with decreased pain scores and overall good wound outcome. Nanocrystalline silver dressings (Acticoat) have stronger antibacterial activity and are associated with less pain and reduced frequency of bandage changes.

Estimate the burn depth and calculate the size of the burn in relationship to the TBSA obtained from a weight conversion chart (see previous discussion and Table 15.5). Clip the wound and surrounding hair before gently lavaging with an antiseptic solution (e.g., 0.05% chlorhexidine diacetate). Cover the wound with a topical aloe vera compound or silver sulfadiazine (see p. 186), and then apply a hydrophilic bandage. After the first 24 hours, apply water-soluble, 1% silver sulfadiazine cream (Thermazene, Silvadene) to the wound once or twice daily or a slow-release silver sulfadiazine dressing (SilvaSorb) once every 3 to 7 days (see p. 200). Alternatively, apply medicinal honey to the wound (see p. 187). Bandage the wound, and aseptically manage it during subsequent bandage changes performed at intervals appropriate for the contact layer and amount of exudation (see Boxes 15.7–15.10 and Tables 15.2, 15.3, and 15.6). Medicinal honey bandages may require bandage changes several times daily. Remove the proteinaceous gel from the surface of the wound during bandage changes and before reapplication of topicals. Use gentle hydrotherapy to remove debris and clean the wound.

TABLE 15.6 Suggested Burn Wound Bandage Contact Layer

Eschar present—needs softening and debridement	Hypertonic saline or hydrogel dressing with silver sulfadiazine and biguanide-impregnated gauze
Eschar gone—needs further debridement	Hydrogel or hydrocolloid dressing and biguanide-impregnated gauze
Eschar gone—needs granulation	Hydrogel or calcium alginate and biguanide-impregnated gauze
Needs epithelialization	Polyurethane foam pad and biguanide-impregnated gauze

ELECTRICAL INJURIES

Electrical burns occur when current touches one point on the body, with or without an exit point. Chewing on electrical cords is the most common cause of electrical injury in small animals. Resistance to electrical current flow is greatest in bone and least in nerves (from greatest to least resistance, the order is bones, fat, tendon, skin, muscle, blood, and nerve). Low-voltage electrical current (<1000 V) follows the path of least resistance, which is usually along blood vessels. Low-voltage burns char tissue at the initial site, which decreases conductivity and limits further current flow, minimizing further injury. The initial contact point with high-voltage currents (>1000 V) negligibly decreases conductivity; therefore injury is extensive. Tissue necrosis occurs from vascular thrombosis and release of vasoactive substances. Tissue damage may be massive because of deep extension of the generated heat.

Immediate death can result from respiratory paralysis or ventricular fibrillation, and tetany can result in spinal fractures.

Animals are often found collapsed in a tonic state with an electrical cord in the mouth. The body stiffens from contraction of striated muscles while receiving the electric current. Generalized tonoclonic activity with vomiting and defecation can also occur. If the animal survives, the tonic state resolves when the cord is removed from the mouth, although the animal may be weak and ataxic for a short period. Burns primarily occur on the lips, gums, palate, or tongue. These areas initially may appear charred, pale gray, or tan. Edema develops after 1 to 2 days. The extent of injury may not be apparent for 2 to 3 weeks. Pulmonary edema frequently occurs shortly after electrocution, causing dyspnea and moist rales.

Treatment

Affected patients should be examined frequently for pulmonary edema. Pulmonary edema may be treated with oxygen therapy, diuretics (i.e., furosemide, 2.5–5 mg/kg IV or IM every 1–4 hours as needed, or as a constant-rate infusion [CRI] at 0.66–1 mg/kg per hour), terbutaline, vasodilators (e.g., nitroprusside or nitroglycerine: these are potentially dangerous drugs; the reader is referred to a medical text for more information in using them), and aminophylline (5–10 mg/kg given intramuscularly or intravenously three times a day: IV administration should involve diluted drug given over 30 minutes). Terbutaline is generally preferred over aminophylline because the latter may cause vomiting, diarrhea, anxiety, or nervousness. IV administration in particular can cause tachycardia, arrhythmias, and central nervous system excitement and/or seizures. Caution should be used when giving aminophylline to dogs with seizure disorders because antiseizure medications (see Chapter 39) can lessen its effectiveness. It should be used cautiously in animals with hypothyroidism, liver or kidney disease, or congestive heart failure. Ventilatory support is needed if there is no response to medication.

Repair of damaged tissue should be delayed until the full extent of the injury is known. Technetium scans of muscle are helpful in determining viability. Minor burns may be allowed to heal by secondary intention. Oronasal fistulae must be repaired (see p. 346). Large lip wounds should be repaired to prevent oral drying and improve cosmesis.

FROSTBITE

Severe or prolonged cold may cause necrosis of exposed tissue. The extremities (i.e., ear, tail, scrotum, mammary glands, digits, and flank folds) are most commonly affected because of the sparse hair coat and poor peripheral circulation in these areas. Frozen tissue is pale, hypoesthetic, and cool. Thawed viable tissue is hyperemic, painful, and scaly. Nonviable tissue undergoes dry gangrene or mummification and sloughs. Superficial injuries involve skin and subcutaneous tissue, whereas deep injuries extend beyond the subcutaneous tissues. Ice crystals form in intracellular and extracellular spaces, causing cell damage and death.

Treatment

The affected body parts should be rapidly rewarmed in warm water (39°C–42°C [102°F–107.6°F]) for approximately 20 minutes to improve circulation. Affected areas become erythematous and edematous, form large vesicles, and are often painful, necessitating analgesics (see Chapter 13). Topical aloe vera or silver sulfadiazine should be applied to the affected areas. Bandages are used to prevent self-trauma. Conservative therapy should be continued until viable tissue can be distinguished from nonviable tissue (i.e., 3–6 weeks). Necrotic tissue should then be debrided and the area reconstructed if necessary. Healing may be complete beneath the mummified tissue.

FIG. 15.56 A chemical burn in a 6-year-old Border collie.

CHEMICAL INJURIES

Chemical burns from strong acids or alkalis or special chemicals destroy tissue by denaturing proteins or interfering with cell metabolism. The mechanism of injury is usually a direct chemical reaction rather than actual thermal injury, although thermal damage can result from an exothermic reaction (Fig. 15.56). Mechanisms of injury include oxidation, reduction, corrosion, dehydration, denaturation, and vesication. The severity of injury depends on the type of chemical and its strength; the volume involved, the contact time, and the depth of penetration; the chemical's mechanism of action; and the total area of contact. Corrosives (i.e., sodium-containing drain and oven cleaners, and phenol disinfectants) denature proteins, causing erosion and ulceration. Dehydrating chemicals (e.g., sulfuric and hydrochloric acids) desiccate tissue, and oxidizing agents (e.g., chromic acid, hypochlorite, and potassium permanganate) coagulate protein. Denaturizing agents (e.g., picric acid, tannic acid, acetic acid, formic acid, hydrofluoric acid) fix or stabilize tissue by the formation of salts. Vesicants (e.g., dimethyl sulfoxide, cantharides, halogenated hydrocarbons, gasoline) liberate tissue amines (histamine, serotonin) causing blisters.

Treatment

Resultant burns should be flushed with large volumes of water immediately after chemical exposure to remove the chemical and prevent further injury. Dry chemicals should be dusted off before irrigation. Flushing dilutes the chemical and dissipates the heat of chemical reactions. Do not immerse the area in water as this may spread chemical damage. After flushing with water, neutralizing agents, if used, are applied with gauze sponges, which are loosely wrapped over the area for 20 minutes. Attempting to neutralize alkaline injuries with acidic solutions (and vice versa) is dangerous and may lead to thermal injury from the resulting exothermic reaction. The animal should be prevented

from licking the wound to prevent chemical burns of the tongue, oropharynx, and esophagus. Antimicrobials and bandages should be applied as described for thermal burns (see p. 237). Early debridement may prevent further chemical penetration and tissue destruction, but excessive tissue removal should be avoided.

Alkali

Lye (sodium hydroxide), cement (calcium, sodium, and potassium hydroxide), and many detergents produce saponification of fat and liquefaction necrosis of tissues, leaving them with a soapy feel. Irrigation should continue until the soapy texture is gone. Some alkalis (e.g., the common fertilizer anhydrous ammonia) penetrate the skin quickly and may require extensive irrigation for many hours.

Acid

Acids cause destruction by cell dehydration and production of acid albumins. Irrigate exposed skin with large volumes of water. Muriatic acid and sulfuric acid should be neutralized with soap before flushing. Hydrofluoric acid (risk in petroleum factories, glass etching, air condition cleaning, and chemical manufacturing) must be neutralized to stop penetration; irrigate with aqueous benzalkonium chloride or apply calcium gluconate gel, which precipitates residual fluoride ion. If pain persists, 10% calcium gluconate should then be injected into and around the lesion (0.5 mL/cm^2). Early local excision and grafting is indicated if pain continues or to prevent continued tissue damage. Calcium ions trapped as calcium fluoride may lead to hypocalcemia if hydrofluoric acid burns are extensive.

Special chemicals include phenol, phosphorus, and petroleum products such as gasoline and tar. Phenol has an anesthetic effect on the skin and is not water soluble. It is rapidly absorbed through the skin and may cause central nervous system depression, hypothermia, hypotension, intravascular hemolysis, and death. A lipophilic solvent (e.g., polyethylene glycol, propylene glycol, glycerol, vegetable oil) is used to cleanse the area. White phosphorus is used in insecticides, fertilizers, and incendiaries. It is lipophilic and is converted to phosphoric acid on contact with tissue. Its high penetrability may lead to systemic toxicity, causing damage to the liver and kidneys and depressed calcium levels. Phosphorus particles can also ignite when in contact with the air. Therefore copious lavage followed by wet soaks to prevent ignition is recommended. Rinsing the area with dilute 0.5% to 1% solution of copper sulfate results in the formation of a blue-gray cupric phosphide coating over the residual phosphorus particles to help prevent ignition and identify particles. An ultraviolet light can also be used to identify particles for removal. Gasoline's hydrocarbons act as a fat solvent and can damage skin, leading to absorption and systemic toxicity, causing multiorgan injury. Tar products cause thermal injuries. Cold water is used to cool the material, which is then dissolved and removed with a petrolatum-based ointment. If a petrolatum solvent is used, the burn may absorb it, leading to toxicity.

SKIN REACTIONS TO RADIATION THERAPY

Radiant energy from roentgen ray tubes, radioactive elements, luminous bodies, fluorescent substances, or the sun may cause injury. In animals, radiation injury is usually a consequence of external beam radiation therapy to cure or control various tumor types (Fig. 15.57). Effects of radiation therapy on normal tissue are related to the energy of the ionizing radiation, number of fractions given, total dose, and time elapsed following radiation. There are four degrees of radiation injury: (1) cutaneous erythema, (2) superficial epidermal (dry) desquamation, (3) moist desquamation from loss of basal layers of epidermis, and (4) necrosis with dermal destruction and irreversible ulceration. Cutaneous erythema occurs during the first week of therapy as a result of dilation of capillaries and increased vascular permeability. Superficial epidermal or dry desquamation occurs with doses less than 30 Gy and is characterized by pruritus, scaling, and increased melanin pigmentation. Moist desquamation occurs with doses greater than 40 Gy, being characterized by discomfort, bullous formation, epidermal sheds, edema, and fibrin exudates. Reepithelialization will occur within 10 days with moist desquamation if the wound does not become infected. Ulcers associated with moist desquamation often heal after therapy but recur. Higher doses of radiation lead to dermal destruction and irreversible ulceration.

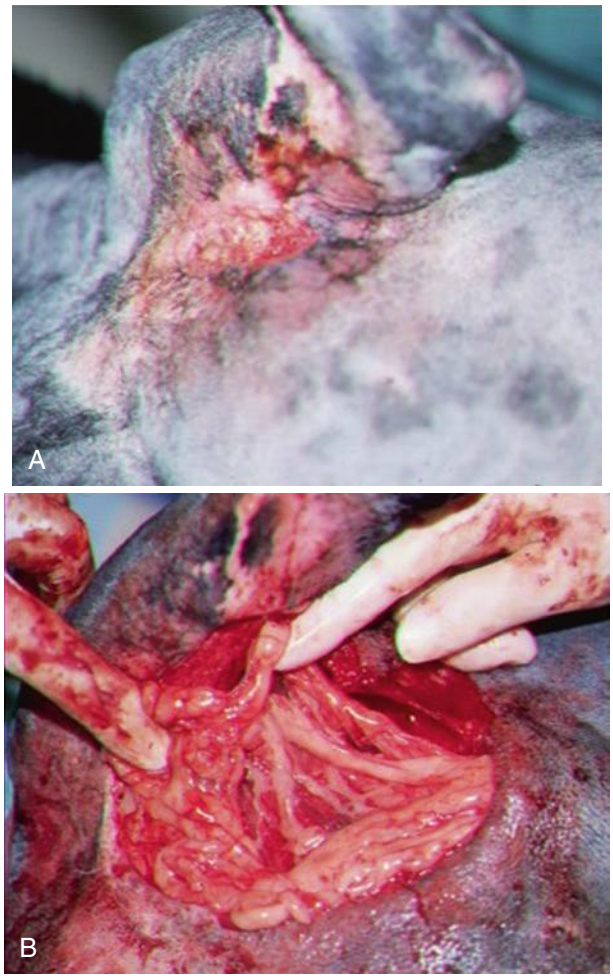

FIG. 15.57 (A) Acute tissue effects in the axilla of a 10-year-old mixed breed dog following full course radiation therapy. (B) Omentum was utilized to aid reconstruction and healing of the injury.

Radiation injury may also be classified as early (acute) or late (chronic) changes. Early (i.e., acute) injury is characterized by the development of edema, erythema, tenderness, and desquamation in the irradiated area within 1 to 4 weeks of radiation therapy. The skin may be either moist or dry. Acute injuries are due to

depletion of rapidly dividing cells, occurring in renewing tissues, such as mucosa, epidermis, hair follicles, and sebaceous glands. Late (i.e., chronic) injury occurs in nonrenewing tissue, such as bone, nerves, and sometimes skin. Late injury is marked by dryness, pigmentation, induration, loss of pliability, atrophy or thinning, telangiectasia, keratosis, a decrease in adnexal structures, ulceration, progressive fibrosis, and a progressive decrease in circulation. Capillaries dilate and decrease in number and arteries sclerose as fibrous tissue increases and skin elasticity is lost. These changes are slow and progressive. Late injury may become evident weeks to years after radiation therapy. Radiation impairs soft tissue healing by (1) microvascular obliteration, (2) excessive fibrosis, and (3) disruption of cellular proliferation. Proliferating microvasculature, epithelial cells, fibroblasts, and myofibroblasts are damaged. After 1 year, the epidermis is thin, dry, and semi-translucent; hair follicles and sebaceous glands are usually absent. Much of the collagen and subcutaneous adipose tissue are later replaced by atypical fibroblasts and dense fibrous tissue that may cause induration of skin and limit movement. Eccentric myointimal proliferation of small arteries and arterioles may progress to thrombosis or complete obstruction. Ischemic ulcers are often a consequence of these vascular changes. Chronic changes to skin make it thin, hypovascular, extremely painful, and easily injured by slight trauma or infection. Irradiated tissue cannot tolerate the same degree of bacterial contamination as normal tissue, and antibiotics are not delivered in effective concentrations because of compromised microcirculation. The goal of treatment is to transform the chronic wound into an acute wound state.

NOTE When excising tissue that has been irradiated, be sure to submit all excised tissue for histologic examination.

Incision into previously radiated tissue should be avoided because healing is inhibited. Avoid or minimize surgical manipulations that may further compromise tissue. If surgery is to follow radiation therapy, it should be performed 2 to 8 weeks after therapy when radiation inflammation is subsiding and tissue circulation is still sufficient for healing.

Treatment

For acute radiation effects in the skin, treatment involves keeping the area clean, applying topical medications (hydrogel containing acemannan, silver sulfadiazine, or aloe vera cream), and preventing self-mutilation. *Cleanse the area with normal saline or a mild soap solution and rinse thoroughly to prevent irritation. Apply hydrophilic topicals that absorb water and act as mild lubricants.* Sometimes protective ointments or gels are applied to protect dry lesions. *Reduce itching with colloidal oatmeal bath (Aveeno Bath), cornstarch, or topical corticosteroid creams.* Moist desquamation injuries may also benefit from astringent soaks, antibiotics, and moisturizers. *Avoid any products with alcohol or menthol because they remove natural lipid and worsen the skin's reaction.* Experimentally, growth factors, orgotein, topical vitamin C, nonsteroidal antiinflammatory drugs, and helium-neon lasers have been used to treat acute radiation injuries. *Apply hydrophilic bandages to provide a moist wound-healing environment (see Box 15.8).* Most acute injuries heal within 10 to 14 days after conclusion of radiation therapy.

For chronic radiation injury, debridement of ulcers should be conservative, removing only necrotic tissue. Evaluating bleeding edges is not a reliable method of determining viability. Continual assessment and debridement are necessary to avoid removing tissue that will heal. Use topical antibiotics on irradiated wound beds after debridement because this tissue may have decreased resistance to infection and poor regional vascularity, leading to unreliable delivery of systemic antibiotics to the wound. Complete excision of all irradiated tissue may be necessary with chronic radiation wounds. Submit all excised tissue to determine if neoplasia is present. Wound closure is most successful when vascularized myocutaneous, cutaneous, muscle, or omental flaps are used (see Fig. 15.57B). Flaps are created outside the irradiated area and transposed over the wound. Healing by secondary intention and free grafts are apt to fail because of impaired vascularity. HBOT may improve healing by increasing the oxygen gradient in the wound or damaged tissue. Consider using NPWT devices (see p. 192), and apply hydrophilic bandages to encourage optimal healing (see Box 15.8).

ANIMAL BITE WOUNDS AND ABCESSES

Bites inflicted on one animal by another may be provoked or unprovoked. Bites often cause crushing, tearing, and avulsion injury that is more severe to the underlying tissue than is apparent from the often minor-appearing skin laceration or puncture (Fig. 15.58). This is because canine and feline skin is freely movable, and the bite pressure is high (150–450 psi). The most commonly affected sites are the neck, limbs, head, chest, shoulder, abdomen, and perineal regions. Multiple wounds are common. Mortality associated with bite wounds is less than 10% and is more common with thoracic bite wounds. Mortality is generally due to either infection or concurrent trauma; the wound is contaminated with the attacker's oral flora, as well as bacteria, hair, and other debris from the skin and environment. Devitalized tissue, dead space, compromised blood supply, and serum accumulate, creating a prime environment for bacterial growth. This type of environment is synergistic to anaerobic bacterial growth. Wound infection is common if treatment is delayed. Cat bites are more likely to become infected than dog bites.

FIG. 15.58 Multiple bite wounds on the antebrachium of a 1-year-old Staffordshire terrier.

BOX 15.11 Normal Oral Flora of Dogs and Cats

Gram-Negative	Gram-Positive
Pasteurella multocida	*Bacillus* spp.
Enterobacter aerogenes	*Corynebacterium* spp.
Escherichia coli	*Staphylococcus aureus*
Pseudomonas fluorescens	*Staphylococcus epidermidis*
Acinetobacter calcoaceticus	*Staphylococcus saprophyticus*
Caryophanon spp.	*Streptococcus* spp.
Neisseria spp.	*Actinomyces* spp. (anaerobic)
Moraxella spp.	
Mycoplasma spp.	

Common aerobic isolates from bite wounds include *Pasteurella multocida*, *Staphylococcus* spp., *Enterococcus* spp., *Bacillus* spp., and *E. coli*; common anaerobic isolates include *Clostridium* spp. and *Corynebacterium* spp. (Box 15.11). Severe infections may occur after inoculation with *Mycobacterium* or *Sporotrichosis* organisms.

Culture all wounds and identify organisms present and their antimicrobial susceptibility. Initial antibiotic therapy before susceptibility data are available is based on whether organisms identified are gram-positive or gram-negative. Cephalosporins and penicillins are appropriate for many wounds as they have a good spectrum of activity and enter wound sites quickly when given intravenously. A single subcutaneous injection of cefovecin (8 mg/kg) repeated at 14-day intervals as necessary can be effective in naturally occurring wounds and abscesses in dogs and cats. Consider fluoroquinolones if gram-negative organisms are identified. Metronidazole or clindamycin can be administered if an anaerobic infection is suspected.

Manage bite wounds by clipping and scrubbing a wide area around the wound followed by copious lavage and cleaning of the wound (see p. 184). Explore full-thickness punctures and lacerations to remove debris and devitalized tissue and to determine the extent of the injury.

Penetration of the abdominal or thoracic cavity necessitates exploration of the cavity to identify and treat concurrent visceral injury. Ultrasonography and radiographs may help evaluate the wounds, but they may severely underestimate the amount of body wall or internal trauma.

Most external wounds should be managed with bandages (see p. 201) to optimize drainage and allow autolytic debridement. After 3 to 5 days, most acute wounds will be healthy enough for delayed primary closure with or without placement of passive or closed suction drains. More chronic bite wounds may require bandaging for a longer period. These wounds are closed secondarily (after the appearance of granulation tissue) or allowed to heal by secondary intention.

Closure of severely contaminated, infected, or traumatized wounds and sealing or healing of punctures often cause abscessation. *Treat abscesses by first clipping and aseptically preparing a wide area around the swelling or draining tract. Then, using aseptic technique, open the abscess by lancing or enlarging the tract's opening. Obtain cultures. Thoroughly lavage the abscess cavity, and debride necrotic tissue. Place a drain or leave the wound open to facilitate drainage and apply a bandage.*

NOTE Treat bite wounds with hydrophilic bandages for 3 to 5 days to minimize wound complications.

BOX 15.12 Snakebites: Key Points

Pit Vipers: Copperhead, Cottonmouth Water Moccasin, Rattlesnake

- Characteristics: Triangular heads with facial pits between eyes and nostrils, elliptic pupils, hollow fangs
- Usually bitten during spring and summer months
- Most commonly bitten on head; sometimes neck and legs
  - Verify bite by identifying two fang marks
  - May be bitten more than once
- Signs: Swelling, depression, tachypnea, bleeding punctures, petechial/ecchymotic hemorrhages, cardiac arrhythmias
- Expect: Leukocytosis, hemolytic anemia, thrombopenia, echinocytosis, abnormal coagulation, elevated fibrin split products

Treatment

- Supportive care: Fluids and analgesics; ± antiinflammatories, antihistamines, antibiotics ± oxygen, blood products, hetastarch, antiarrhythmic drugs
- Antivenom: Expensive and of uncertain value
- Wound: Mobilize; clip, aseptically prepare, and lavage wound; debride necrotic tissue

Do not use tourniquets, suction, or an incision to remove venom!

SNAKEBITE

Snakebites can cause severe local tissue damage and systemic effects. Snake venom is an extremely complex mixture of enzymes, proteins, and peptides; venom composition varies between species, individual snakes, and the bite itself. Venomous snakes in the United States include the Crotalidae (pit vipers) and Elapidae (coral snakes) subfamilies. The Crotalidae subfamily includes the copperhead, cottonmouth water moccasin, and rattlesnake. Pit vipers have a triangular head with facial pits between the nostrils and eyes, and vertically elliptic pupils (Box 15.12). Their fangs are hollow, retractable teeth (hinged) near the rostral maxilla. Coral snakes, along with many nonpoisonous snakes, have round heads, no pits, and round pupils. Coral snakes have small fangs that are fixed in the cranial maxilla. Their short fangs allow them to hang from the animals they bite. Nonvenomous snakes have teeth but no fangs.

Coral snake venom is primarily neurotoxic and hemolytic, causing moderate tissue reaction and pain at the puncture sites. There is a delay of several hours before the onset of systemic signs, which worsen gradually over 18 hours. The effects may last 7 to 10 days. Neurotoxicity caused by coral snake venom is characterized by central nervous system depression, vasomotor instability, and muscle paralysis. Coral snake envenomation may cause lethargy, tremors, ptosis, dysphonia, incoordination, and hematuria. Larger doses may cause vomiting, salivation, defecation, and generalized parasympathetic stimulation, followed by paralysis and death. The primary cause of death is respiratory paralysis.

Crotalid (pit viper) venoms are primarily enzymatic in activity (e.g., phospholipase A, phosphatases, exopeptidase, hyaluronidase, L-amino acid oxidase, proteases, and endopeptidase). These venoms are hematotoxic, vasculotoxic, and necrogenic. They alter the resistance and integrity of blood vessels, cause hypotension and bleeding, affect cardiac dynamics and nervous system function, and produce respiratory depression and myonecrosis. Bites most commonly occur on the face and legs. Bites correlate with the snakes' nonhibernating periods and times of day when owners are most likely to be walking with the pet. Signs of envenomation

vary and depend on the species of snake, the volume of venom, and the size of the victim. The bite of a pit viper usually produces two puncture marks surrounded by edema. The fang marks may bleed. Erythema, edema, and pain are immediate local effects. Envenomation has not occurred if these signs are not seen within 20 minutes of the bite; envenomation does not occur in approximately 20% to 25% of bites. Progressive swelling and sometimes local hemorrhage occur with moderate to severe envenomation. Tissue discoloration caused by petechiae and ecchymosis occurs, followed by local tissue necrosis. Tissue damage varies with the depth of the bite and the amount of venom injected. Systemic signs of crotalid envenomation are usually lethargy, vomiting, diarrhea, hypotension, and shock. Other signs may include anorexia, salivation, thirst, lymph node pain, weakness, bradycardia or tachycardia, generalized tremors, coma, tachypnea, pulmonary edema, urinary and fecal incontinence, paralysis, convulsions, and hemorrhage. Venom-induced coagulation defects may be severe (activated clotting time >120 seconds). Other common laboratory abnormalities include echinocytosis (burr cells), leukocytosis, and thrombocytopenia. Serious effects of envenomation, such as respiratory paralysis and acute renal failure, may not develop for several hours; therefore animals should be monitored for a minimum of 24 hours after being bitten. A snake bite severity score (SSS; Box 15.13) can be used to help assess how significantly an animal is injured, as well as guide therapy, including need for antivenom administration.[13]

NOTE A canine vaccine (Red Rock Biologics) is available for Western Diamondback Rattlesnake bites. It may also protect against bites from the Western rattlesnake, sidewinder, timber rattlesnake, massasauga, and Copperhead. Partial protection may be obtained against Eastern Diamondback Rattlesnake bites. It does not protect against venom from the water moccasin (cottonmouth), Mohave rattlesnake, or coral snake.

Treatment

Treatment goals include neutralizing the venom, treating systemic effects and wounds, and reconstructing tissue defects (see Box 15.12). The animal should be supported with IV fluids. Glucocorticoids may help treat shock and reduce edema and pain. However, glucocorticoid use is controversial because it may enhance venom toxicity. Antihistamines are often given, and broad-spectrum antibiotics are used to inhibit wound infection. However, recent studies show little to no benefit to the administration of glucocorticoids, diphenhydramine, or prophylactic antibiotics.[14,15] Additional supportive care may include analgesics, sedatives, transfusions, and oxygen supplementation.

The bite wound should be immobilized and excitement or exertion avoided. The wound should be lavaged and cleaned with antiseptics or germicidal soaps. The use of tourniquets or incision, suction, or manipulation of the bitten area is rarely helpful and must be done immediately after the bite to have any beneficial effect. These techniques can also easily cause additional tissue damage. A tourniquet, if applied, should be placed 10 cm proximal to the fang marks, should be lightly constrictive, and should be released for 60 to 90 seconds every 30 minutes. However, tourniquets can prevent dilution of the venom and reduce tissue perfusion, thereby promoting ischemia and tissue necrosis.

The site should be clipped to facilitate examination for fang marks. Hospitalization and observation for systemic signs are indicated. Hemograms, coagulation profiles, urinalysis, and serum biochemical analyses should be monitored every 6 to 12 hours, depending on the severity of the envenomation. Persistent decreased platelet counts and prolonged clotting times suggest progressive venom activity. Myoglobinuria indicates rhabdomyolysis, and hemoglobinuria indicates hemolysis. The electrocardiogram should be monitored. The circumference of the edematous area around the bite should be measured and recorded to monitor progression.

Antivenom (antivenin) (Antivenin Cortalidae Polyvalent [ACP], Crotalidae Polyvalent Immune Fab [Crofab]) should be administered only if a snakebite is known to have occurred, but may not be indicated in every case of envenomation. One study

BOX 15.13 Snakebite Severity Score[13]

Pulmonary System	
Signs within normal limits	0
Minimal: slight tachypnea	1
Moderate: respiratory compromise, tachypnea, use of accessory muscles	2
Severe: cyanosis, dyspnea, extreme tachypnea, respiratory insufficiency, respiratory arrest of any cause	3
Cardiovascular System	
Signs within normal limits	0
Minimal: tachycardia, general weakness, benign dysrhythmia, hypertension	1
Moderate: tachycardia, hypotension (but tarsal pulse still palpable)	2
Severe: marked tachycardia, hypotension (nonpalpable tarsal pulse or systolic blood pressure <80 mm Hg), malignant dysrhythmia, or cardiac arrest	3
Local Wound	
Signs within normal limits	0
Minimal: pain, swelling, ecchymosis, erythema limited to bite site	1
Moderate: pain, swelling, ecchymosis, erythema involves less than half of extremity and may be spreading slowly	2
Severe: pain, swelling, ecchymosis, erythema involves most or all of one extremity and is spreading rapidly	3
Very severe: pain, swelling, ecchymosis, erythema extends beyond affected extremity, or significant tissue slough	4
Gastrointestinal System	
Signs within normal limits	0
Minimal: abdominal pain, tenesmus	1
Moderate: vomiting, diarrhea	2
Severe: repetitive vomiting, diarrhea, or hematemesis	3
Hematologic System	
Within normal limits	0
Minimal: coagulation parameters slightly abnormal, PT <20 s, PTT <50 s, platelets 100,000–150,000/mm^3	1
Moderate: coagulation parameters abnormal, PT 20–50 s, 50–75 s, platelets 50,000–100,000/mm^3	2
Severe: coagulation parameters abnormal, PT 50–100 s, PTT 75–100 s, platelets 20,000–50,000/mm^3	3
Very severe: coagulation parameters markedly abnormal with bleeding present or the threat of spontaneous bleeding, including PT unmeasurable, PTT unmeasurable, platelets <20,000/mm^3	4
Central Nervous System	
Signs within normal limits	0
Minimal: apprehension	1
Moderate: chills, weakness, faintness, ataxia	2
Severe: lethargy, seizures, coma	3
Total score (0–20)	

PT, Prothrombin time; *PTT,* partial thromboplastin time.

found no difference in outcome in dogs receiving supportive care versus those receiving supportive care plus antivenom.[16] However, in an uncontrolled separate study, antivenom given to dogs with worsening envenomation syndrome had marked improvement in clinical signs.[13] When antivenom is given, it should be administered as soon as possible to limit tissue necrosis and prevent systemic reactions. Pretreating with antihistamines before intravenous administration may prevent anaphylactic reactions, although the incidence of adverse effects is low (~6%).[13] Recommended antivenom doses range from one to five vials. The number of vials used is directly related to the clinical signs, the animal's body fluid volume, and the location of the bite. Snakebites on digits or in small animals may require 50% more antivenom than those found elsewhere on the body or in larger animals. Although it is not known how long antivenom can be given after envenomation and still be effective, administration after 8 hours is considered of questionable value. In human beings, antivenom is given until pain associated with the bite is relieved. This end point is difficult to determine in animals; therefore antivenom should be given until serial examinations and coagulation profiles suggest that the animal's condition is stable. Administration of more vials of antivenom in crotalid envenomation is potentially associated with negative outcome in a large number of cases. Necrotic tissue should be treated as an open, infected wound (see p. 183). Bandages that support moist wound healing and debridement (see p. 195) should be applied until healthy granulation tissue has formed. Then nonadherent absorbent bandages (see p. 196) should be used and the wound allowed to heal by secondary intention or reconstructed with flaps or grafts.

PRESSURE SORES

Animals incapable of or unwilling to change positions are prone to pressure sores because pressure is exerted on bony prominences when animals lie down (Table 15.7). Pressure sores form when animals (especially large dogs) are recumbent for long periods because of paralysis, fractures, injuries, or illness. Pressure sores may also develop under improperly fitted or padded casts and bandages. Pressure on the wound pushes wound edges apart, complicating healing. They can be prevented by providing well-padded bedding (i.e., water mattress, air mattress, egg-crate type of foam-rubber mat, artificial sheepskin mat, and fleece), by repositioning the animal frequently, and by keeping the animal clean and dry. Bony prominences should be checked daily for signs of an impending ulcer (i.e., hyperemia, moisture, and easily epilated hair) (Box 15.14). The lateral humeral epicondyle, tuber calcaneus, greater femoral trochanter, tuber coxa, and ischiatic tuberosity are most susceptible to pressure sores (Box 15.15). Less common sites are the acromion of the scapula, lateral tibial condyle, lateral malleolus, olecranon, and sternum. Soft tissues, including skin, loose connective tissue, fat, deep fascia, and periosteum, cover these prominences. All intervening tissues are compressed when pressure is exerted on a bony prominence. Typically, repeated trauma and inflammation are mild, and protective callus develops. Prolonged or severe compression leads to soft tissue ischemia and cell death. Biochemical changes (oxygen free radicals, thromboxane) occur in ischemic tissue and contribute to necrosis. Elevated tissue thromboxane levels cause vasoconstriction, platelet aggregation, and ischemia to exacerbate already compromised tissue circulation. Persistent neutrophilia causes an ongoing inflammation, leading to a chronic wound.

As pressure sores begin developing, blood vessels dilate and inflammatory edema of skin and subcutaneous tissue occurs. If trauma persists, tissues break down, causing a hematoma or an open sore. Untreated hematomas are not absorbed because the surrounding tissues have been damaged. The fluid is mucinous and yellow to red. Tissues thicken around the hematoma, forming a false bursa (hygroma). The wall of the hygroma is thick and tough, composed of granulation tissue and collagen. The lining of this sac is pale and smooth or rough with irregular, villus-like projections extending into the lumen. Open sores may involve the epidermis and dermis or may extend through subcutaneous tissue and fascia to bone. Osteomyelitis or septic arthritis may develop. Diagnostic imaging may be helpful in determining the extent of soft tissue injury (ultrasound or computed tomography [CT]) and the presence of osteomyelitis or skeletal abnormalities (radiographs, CT, magnetic resonance imaging [MRI]).

Treatment

Treatment and prevention are similar (see Box 15.14). Early pressure sores are treated by padded bedding (water mattress, air mattress, egg-crate type of foam-rubber mat, artificial sheepskin mat, and fleece), bandaging the limb or using slings or side bars to eliminate pressure over the bony prominence, and changing the recumbent animal's position every 1 to 5 hours. A well-padded, doughnut-type of bandage or pipe insulation bandage should be applied to prevent trauma (see p. 201). In addition, the skin must be kept clean and dry. Treatment for open or chronic pressure sores is similar, but the response is poorer (see Table 15.7). Open wounds should be treated with topical agents and bandages that promote moist wound healing,

TABLE 15.7 Pressure Sore Classification and Treatment

Classification	Description	Treatment
Grade I	Dark red erythema with superficial to partial-thickness skin loss	Wound cleansing, debridement, bandaging, healing by secondary intention
Grade II	Full-thickness skin loss (ulcer) extending into the subcutis	Wound cleansing, surgical or bandage debridement, bandaging, and healing by secondary intention or wound excision and primary closure, delayed primary closure, or secondary closure
Grade III	Ulcer extends through subcutis to deep fascia overlying bony prominences; edges may be undermined	Treatment as for grade II, but drains may be necessary with undermined edges; muscle flaps or myocutaneous flaps and partial excision of the bony prominence may be necessary
Grade IV	Ulcer extends to bone; osteomyelitis or septic joint (or both) may be present	Treatment as for grade III, but sinus tracts and pockets may need to be excised or opened

BOX 15.14 Prevention and Treatment of Pressure Sores

Prevention

- Keep pressure off vulnerable sites
- Bedding: Vinyl covered, thick egg-crate type of foam rubber with artificial sheepskin mat; water mattress or air mattress with fleece
- Keep clean and dry to prevent urine scalds
- Change animal's position every 1 to 5 hours
  - Rotate from right lateral, to sternal, to left lateral
  - Place in a sling for 2 to 4 hours daily
  - Support pelvic area in wheeled carts
- Apply properly padded and fitted bandages, splints, and casts
  - Do not apply extra padding over pressure points (actually increases pressure)
  - Use doughnut type of pad (see p. 202)
  - Reduce weight bearing: Foam pad, clamshell splint, or extension splints
- Apply skin toughening agents (e.g., Pad Toughening Compound)
- Provide good hygiene
  - Inspect skin daily
  - Reduce local skin moisture
  - Whirlpool baths
  - Clip perineal area if incontinent
- Physical therapy: Passive range of motion, massage, hydrotherapy, local hyperthermia and hypothermia, ultrasonography, neuromuscular stimulation (see Chapter 11)
- Provide good nutrition: High-protein, high-carbohydrate diet with vitamin supplements
- Surgery: Amputation, wedge osteotomy, arthrodesis or phalangeal fillet techniques for nerve or musculoskeletal abnormalities

Treatment

- Follow the prevention guidelines above
- Keep pressure off the wound
- Cleanse wound
- Debride and drain wound as necessary
- Apply appropriate topical medications (see p. 186)
  - Antibiotics
  - Acemannan products: Stimulate macrophages to produce cytokines and growth factors
  - D-glucose polysaccharide: antibacterial, bacteriostatic, and provides glucose for cell metabolism
  - Tripeptide-copper complex: Attracts mast cells and macrophages to stimulate healing
- Apply bandages that promote moist wound healing (see p. 195)
- Allow healing by secondary intention or transpose flaps to cover wound

BOX 15.15 Common Pressure Sore Sites

Most Common	Less Common
Lateral humeral epicondyle	Acromion of scapula
Tuber calcaneus	Lateral tibial condyle
Greater femoral trochanter	Lateral malleolus
Tuber coxae	Olecranon
Ischiatic tuberosity	Sternum

which encourages debridement and granulation. When deep ulcers are present, dead space should be drained and infected tissue and bone should be surgically debrided.

Small superficial wounds may heal by secondary intention. However, healing by secondary intention may not provide a surface durable enough to prevent reinjury. Secondary closure is performed after healthy granulation tissue has formed in large, deep wounds. Skin edges should be undermined and apposed if possible. Skin flaps (e.g., local advancement, transposition, axial pattern, or musculocutaneous [see pp. 217–228]) and grafts (see p. 232) may be necessary for a tension-free closure. Suture lines should not be positioned over bony prominences. A well-padded bandage and a soft padded bed should be used to protect the site during healing. Ulcers may recur if the cause goes uncorrected.

ELBOW HYGROMA

A hygroma is any chronic tissue swelling that contains serous fluid that develops as a result of chronic, repetitive compressive trauma to soft tissues over a bony prominence. An elbow hygroma (elbow seroma, olecranon bursitis) is the most common type of hygroma; it is a fluid-filled cavity surrounded by dense fibrous connective tissue that occurs over the lateral aspect of the olecranon (Fig. 15.59). Elbow hygromas often occur bilaterally as painless swellings. Most occur in young dogs (6–18 months old) of large and giant breeds before a protective callus forms over the bony prominence; however, they may occur in older animals with neuromuscular disease. Some dogs with thin skin and sparse subcutaneous fat are predisposed to hygromas. Others with hip dysplasia or pain from other orthopedic disease may exert excess pressure on the elbows while positioning themselves in sternal recumbency. Elbow hygromas vary in size, becoming larger and thicker with repeated trauma. They are usually sterile initially, but bacteria may be introduced during aspiration. Infected hygromas are painful. Small, painless hygromas are cosmetic problems that persist if not treated. Hygromas may also occur over other bony prominences (e.g., tuber calcaneus, greater trochanter, tuber coxa, tuber ischium, external occipital protuberance, and thoracic vertebral dorsal spinous processes).

Treatment

The primary treatment for elbow hygromas is elimination of repeated elbow trauma. Affected animals should be housed on yielding surfaces with soft, thick padding (see Box 15.14). External coaptation is applied to the elbow with a spica bandage (see p. 1166), elbow splint, or adjustable compressive bandage (e.g., DogLeggs). Most acute lesions regress slowly if repeated trauma is eliminated. The hygroma retains its ability to produce a fluid transudate until all granulation tissue and connective tissue

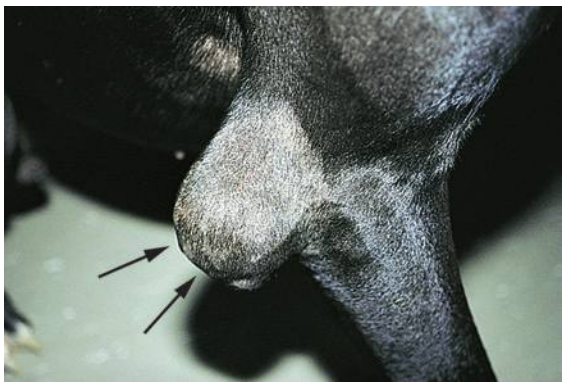

FIG. 15.59 Elbow hygroma in a dog. Note the fluid-filled swelling over the olecranon *(arrows)*.

undergo fibrosis. Aspiration of the hygroma is of little benefit and may introduce bacteria. Although surgery should be avoided if possible as it often results in significant complications, development of infection or a chronic, fibrous capsule may require it. Infection requires drainage and administration of appropriate antibiotics. Prolonged drainage may be obtained by placing closed suction (preferred) or Penrose drains in the hygroma. Nonhealing wounds and infection are potential complications of drains. The advantage of this technique is that the protective callus is preserved; however, drains should not be used on ulcerated hygromas.

For nonulcerated (infected or sterile) hygromas, prepare the limb for aseptic surgery and make several dorsal and ventral stab wounds into the hygroma cavity. Probe the cavity, breaking down fibrous septa, and lavage it. Place one or more fenestrated closed suction drains in the hygroma cavity and secure them. Apply a nonadherent, absorbent bandage with a "doughnut" (see p. 202) to relieve pressure, absorb drainage, and prevent trauma. Change the bandage daily. Remove the drains when drainage becomes minimal and scar tissue adheres (i.e., 2–3 weeks). Continue to bandage the elbow for at least 1 week after removing the drains or until healing is complete.

When all conservative treatment attempts have failed, hygromas are occasionally surgically excised if fibrous tissue, fistulae, or infection develops without a large, fluid-filled cavity. The naturally protective callus is removed during excision, and postoperative management is often complicated. Incisions may dehisce and ulcerate, bandages are difficult to maintain, and recurrence is common. Wounds that dehisce may not heal. Small hygromas can be excised and the defect closed by undermining and advancing local tissue until skin edges can be approximated with interrupted sutures. Complete excision of fibrous tissue is ideal; however, when this is not possible because of the size of the lesion, the cavity lining should be debrided and lavaged, and a closed suction drain should be placed before closure. Incision and suture lines are positioned medial or lateral to the olecranon and other bony prominences if possible. It is difficult to excise large hygromas and close the wound without using skin flaps (i.e., axial pattern [see p. 222], pedicle [see p. 217], or myocutaneous [see p. 228]).

NOTE Surgical treatment of elbow hygromas may result in significant complications; however, surgery may be necessary in recurrent and complicated hygromas.

LICK GRANULOMAS

Lick granulomas (acral lick dermatitis, acral pruritic nodule, acropruritic granuloma, psychogenic dermatoses, and neurodermatitis) are self-induced by continuous licking or chewing. They are usually single and unilateral and may occur anywhere, although the cranial and medial aspects of the carpus-metacarpus and the cranial and lateral aspects of the tarsus-metatarsus are most commonly affected. Less frequent sites include the stifle, tibia, flank, and tail base. They usually occur in older, male, large breed dogs, especially Labrador retrievers, golden retrievers, German shepherds, German shorthair pointers, Great Danes, Saint Bernards, and Staffordshire terriers. Although wounds, foreign bodies, infections, and musculoskeletal pain may be initiating factors, most lick granulomas are believed to be psychogenic (obsessive-compulsive disorder) and associated with boredom, inactivity, or environmental change. A cycle of obsessive licking and secondary pruritus and infection develops that is difficult to interrupt. The lesion is sparsely haired, thickened, firm, ulcerated, erythematous, and surrounded by a hyperpigmented halo (Figs. 15.60 and 15.61). Secondary furunculosis and apocrine hidradenitis contribute to enlargement and inflammation of the lesion. Superficial tissue may erode and expose bone. Lameness sometimes results from the mechanical presence of the mass or from underlying periostitis. Dermatologic examination, skin scraping, fungal culture, biopsy, radiographs, electrodiagnostics, allergy testing, thyroid function testing, and/or hypoallergenic diet trials may be necessary. Diagnostic imaging may reveal periosteal proliferation secondary to soft tissue inflammation or associated arthritis, osteomyelitis, osteosarcoma, or foreign bodies. Biopsy to rule out neoplasia and deep cultures to determine bacterial involvement and antimicrobial sensitivity are recommended. Expected histopathology results include cellulitis, dermal fibroplasias, epidermal hyperplasia with compact hyperkeratosis, furunculosis, and vertical collagen streaking.

FIG. 15.60 Lick granulomas often occur in the carpal-metacarpal or tarsal-metatarsal area. They are sparsely haired, thickened, firm, ulcerated, erythematous, and surrounded by a hyperpigmented halo.

FIG. 15.61 Close-up view of a chronic lick granuloma.

Treatment

Previously recommended treatments have included activity or environmental modification, bandaging, collars, muzzles, topical antichew agents, glucocorticoids, orgotein, radiation therapy, cryosurgery, surgical excision, behavior modifying drugs (phenobarbital, diazepam, hydroxyzine, naltrexone, hydrocodone), cobra venom, acupuncture, and other medications (i.e., fluocinolone acetonide, dimethyl sulfoxide, proteolytic enzymes). The results have been inconsistent, and recurrence is common.

Treatment should be individualized and initiated before the lesion becomes chronic and unresponsive. Initially, administer long-term antibiotic therapy (45–90 days) based on culture and susceptibility results; also use bandages and restraint devices. Periodic CO_2 laser crosshatching of the granuloma surface may help to eliminate hair embedded in the granulation tissue and facilitate control of infection. If an underlying cause is identified, it should be treated or eliminated (especially allergies), and behavior should be modified.

Treatment investigations involving behavior modification have shown beneficial results using serotonin reuptake-blocking drugs: clomipramine (1–3 mg/kg PO every 12–24 hours [dog] or 0.5 mg/kg PO per day [cat]), fluoxetine hydrochloride (1–3 mg/kg PO per day [dog] or 0.5–1 mg/kg PO per day [cat]), sertraline hydrochloride (0.5–1 mg/kg per day; compulsive disorder dose: 1–3 mg/kg per day [dog] or 0.5–1 mg/kg per day [cats]); amitriptyline (1–4 mg/kg PO every 12–24 hours [dog] or 0.5–1 mg/kg PO every 12 to 24 hours [cat]); or imipramine (2.2–4.4 mg/kg [dog] or 0.5–1 mg/kg PO every 12–24 hours [cat]); and electronic stimulation. Acupuncture may also be useful in treating lick granulomas. Although not commonly performed, surgical excision of a lick granuloma followed by reconstruction using direct apposition, flaps, or grafts is possible. The surgical site should be protected with a bandage until suture removal. However, the lesion usually recurs at the same or a different site unless the causative factor or factors are eliminated.

DERMOID SINUS (PILONDIAL SINUS)

A dermoid sinus or cyst is a tubular skin indentation that extends ventrally as a blind sac from the dorsal midline. It is a neural tube defect caused by incomplete separation of skin and the neural tube during embryonic development. Sinus depth varies; some are superficial, whereas others extend to the supraspinous ligament or dura mater (Table 15.8). Multiple or single draining tracts may be identified, especially in the cervical region (Fig. 15.62). Cervical sinuses are generally attached to the dorsal spinous process of the second cervical vertebra. They are most common in Rhodesian ridgebacks, occurring along the dorsal midline cranial and caudal to the midline ridge. Isolated cases have also been reported in many other breeds. Because the lesion is believed to be hereditary (complex dihybrid mode of inheritance) in Rhodesian ridgebacks, affected animals should be neutered.

Lesions can be recognized at a young age as openings on the dorsal midline with protruding hair or a whorl of hair. A tube or cord is palpated in the subcutaneous tissue when a skin fold is elevated in the area of the sinus. The cord is 1 to 5 mm in diameter and courses toward the spine. Cystlike subcutaneous swellings may also be palpated. The lumen of the sinus is filled with inspissated sebum, exfoliated keratin debris, and hair. Periodic plugging of the sinus opening leads to cellulitis, infection, and abscessation. Sinuses are classified as one of six types and one of three subtypes (see Table 15.8). Myelitis, meningomyelitis, or encephalitis can occur if the infected sinus extends to the spine. Cervical radiographs and advanced imaging (CT or MRI) should be performed to determine the extent of involvement (Fig. 15.63).

Congenital dermoid sinuses have also been reported on the dorsal nasal midline of golden retrievers, spaniels, and English bull terriers. Presenting signs are usually a fluctuant, nasal swelling and intermittent discharge. An opening, or "nasal pit," is usually found immediately behind the nasal planum (Fig. 15.64). It courses caudally and extends through an incomplete suture into the nasal septum. Embryogenesis of these sinuses is not completely understood, but it is believed to be a failure of the foramen cecum to close during maturation of the skull. The foramen cecum is a canal in the frontal bone at the base of the skull, which allows an outpouching of the meninges into the prenasal space and into contact with the somatic ectoderm. Dogs are usually presented in early adulthood for treatment of sebaceous discharge or secondary infection from the sinus. The sinus may be difficult to identify, and diagnostic imaging may be helpful in determining its caudal extent.

TABLE 15.8 Classification of Dermoid Sinuses

Type I	Tract extends as far as the supraspinatus ligament or nuchal ligament and attaches there.
Type II	Tract does not extend to the ligament but is attached by a fibrous band.
Type III	Tract does not extend to or attach by fibrous band to the ligament.
Type IV	Tract attaches to the dura mater.
Type V	Sinus has no connection to the skin surface; closed epithelial-line sac
Type VI	Tract extends to supraspinatus ligament and connects to dura mater by a fibrous cord.
Subtype a	Dorsal midline
Subtype b	Head, excluding nose
Subtype c	Nose

FIG. 15.62 Severely infected dermoid sinus in a 2-year-old dog.

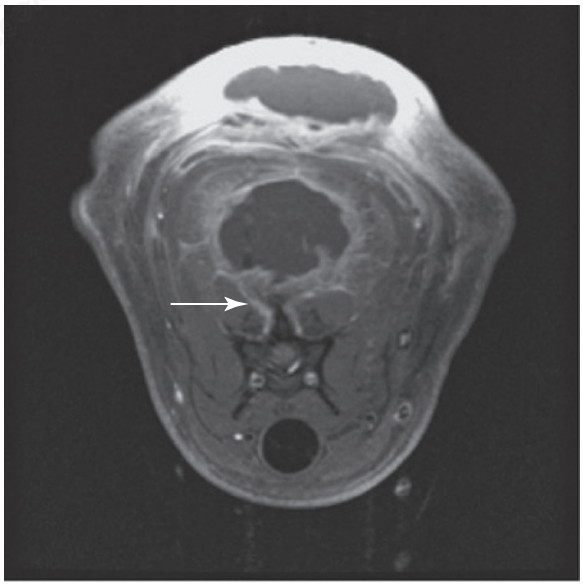

FIG. 15.63 Transverse T1-weighted magnetic resonance image of the cervical spine of the dog in Fig. 15.62. Note communication of the infected sinus with the dorsal spinous process of C4 *(arrow)*.

FIG. 15.64 Nasal dermoid sinus in a dog.

Differential diagnoses include foreign bodies, sebaceous cysts, abscesses, epidermal inclusion cysts, follicular retention cysts, and intracutaneous cornifying epitheliomas. Samples should be collected for cytologic studies and microbial culture and sensitivity testing. Metrizamide fistulography and myelography may reveal spinal communications, especially in conjunction with CT or MRI. Excised tissue should be submitted for histologic examination to rule out other causes of draining tracts. The histology of the dermoid sinuses is consistent with normal skin plus adnexa.

Treatment

Dermoid sinuses may be resected if they are associated with drainage or neurologic signs. Treat with antibiotics before surgery if the sinus is infected. Strict asepsis is essential to prevent postoperative meningitis if the sinus extends to the dura. Incomplete excision may occur if the sinus attaches to the dura and causes a chronic draining lesion. Successful treatment of nasal dermoid sinuses requires complete surgical excision with careful dissection between the nasal bones into the nasal septum. They usually terminate in the septum but may communicate with the dura.

Complications include recurrence if incompletely excised, abscesses, and meningitis. The prognosis is good with complete surgical excision. The prognosis is guarded if neurologic signs occur before surgery.

Clip and aseptically prepare a large area around the sinus. Position the dog in ventral recumbency with the spine or nose deviated dorsally; then make an elliptic incision around the sinus opening. Carefully dissect the sinus to its origin and free its attachment. Divide or split the nuchal ligament if necessary. Perform a laminectomy or hemilaminectomy (see pp. 1372 and 1379) if the sinus tract extends to the dura. Lavage thoroughly before closure. If the nuchal ligament has been transected, reappose it with a locking loop or modified Bunnell suture pattern (see p. 1283). Appose muscles and deep tissue with interrupted absorbable sutures to eliminate dead space (e.g., 3-0 or 4-0 polydioxanone or polyglyconate). If a large amount of dead space is still present, place a closed suction drain at the site. Appose subcutaneous tissue and skin routinely. Submit tissue samples for culture and sensitivity testing and histologic evaluation. Give analgesics and antibiotics, and bandage the site after surgery. Neuter affected animals.

INTERDIGITAL PYODERMA

Interdigital pyoderma (granuloma, acne, furunculosis, folliculitis) is a bacterial pododermatitis that may coexist with other conditions. Sometimes erroneously called an *interdigital cyst*, pododermatitis may be caused by parasites, allergies, mycoses, irritants, neoplasms, and metabolic, neurologic, or autoimmune disease. Bacterial infections usually occur secondary to demodicosis, allergy, hypothyroidism, or hyperglucocorticoidism. Immunosuppression is suspected in some animals. The primary bacterial pathogen is *Staphylococcus pseudintermedius;* secondary opportunistic bacteria include *Proteus* spp., *P. aeruginosa,* and *E. coli.* The condition is seen frequently in West Highland white and Scottish terriers, Pekingese, and English bulldogs.

Varying degrees of pruritus, pain, paronychia, swelling, erythema, and hyperpigmentation are common. Papules, pustules or nodules, draining tracts, and ulcers may be present. Chronic infections may produce interdigital fibrosis and pyogranulomas. Antibiotic and steroid therapy may cause remission, but recurrence is common. The underlying cause should be identified and treated. Diagnostics include hematologic and serum biochemistry profiles, urinalysis, skin scraping, culture and sensitivity testing, cytologic studies, and biopsy. Consider referring animals that do not respond to conservative treatment to a dermatologist.

Treatment

Conservative surgical treatment involves incision, exploration, and debridement of all fistulous tracts. Lesions should be medicated with antibacterial agents (e.g., chlorhexidine, povidone-iodine, and nitrofurazone) and bandaged for 24 to 48 hours. Subsequently, they should be soaked with an antibacterial solution for 15 to 20 minutes twice daily. Oral antibiotics based on sensitivity testing are administered for 6 to 8 weeks. Lesions that fail to respond to this treatment may require fusion podoplasty (see p. 265). Excision of all the interdigital tissue is usually curative in cases that fail to respond to medical therapy.

REDUNDANT SKIN FOLDS

Redundant skin is characteristic of some breeds and is exacerbated by obesity. Chronic skin overlap or apposition creates skin folds of varying depths. Commonly involved areas include the labia, face, vulva, tail head, and leg folds, with severity and frequency varying with breed and conformation. Pyoderma occurs in the skin fold recesses (intertriginous dermatitis) because they provide a poorly ventilated, dark, warm, moist environment that permits the accumulation of surface debris, such as sebum, saliva, tears, urine, or feces. Sebum contains fatty acids that are both bacteriostatic and fungistatic; however, excessive accumulation of sebaceous material allows surface bacteria within the skin fold to proliferate. Coagulase-positive *Staphylococcus* spp. are most commonly involved, but other organisms include streptococci, coliforms (*E. coli,* pseudomonads, *Proteus* spp.), and yeasts, such as *Malassezia* and *Candida* spp. Friction at contact points, retention of secretions, and bacterial proliferation cause skin maceration and superficial ulceration. In addition to impairing the cutaneous barrier, immune function may be impaired. Affected areas become painful and foul smelling causing the animal to further traumatize the area by scooting, rubbing, licking, or scratching. The severity of clinical signs is affected by coexisting skin disease.

Skin fold resection is the most effective treatment for skin fold pyoderma (discussed later). First, medical therapy should reduce infection, inflammation, and secretions or exudates. Medical therapy consists of clipping hair from the folds and surrounding area, applying topical antibacterial solutions and medicated soaps, using antiseborrheic shampoos and astringents, and giving appropriate systemic antimicrobials. Culture and sensitivity testing is necessary to select appropriate antimicrobials. Glucocorticoids are sometimes necessary to reduce pruritus-induced self-trauma. Weight reduction is beneficial for obese animals. Continuous medical therapy is palliative, not curative. The surgical site must be kept clean, dry, and protected from trauma. Continued antimicrobial therapy may be necessary. General complications of skin fold resection and reconstruction are self-trauma, infection, dehiscence, and pyoderma recurrence.

Lip Folds

Breeds with excessive mandibular labial tissue (large pendulous lips) (e.g., spaniels, Saint Bernards, Newfoundlands, Labrador retrievers, golden retrievers, and Irish setters) most commonly have lip fold dermatitis. It may also occur after partial maxillectomy or mandibulectomy. The fold usually occurs behind the mandibular canine tooth, where food and saliva accumulate. Affected dogs rub and paw the face, and the skin becomes inflamed and thickened. Halitosis and pruritus are the most common presenting complaints.

Lip Fold Resection (Cheiloplasty)

Position the anesthetized animal in dorsal recumbency to allow access to both lips. Clip and aseptically prepare the mandibular area (Fig. 15.65A). Make an elliptical incision around the affected area, paralleling the horizontal ramus of the mandible (see Fig. 15.65B). The incision may involve the mucocutaneous junction. *Elevate and remove the outlined skin segment, preserving underlying muscles. Control hemorrhage with ligation, electrocoagulation, and pressure. Assess the adequacy of resection and excise additional skin if necessary. Lavage the site and appose subcutaneous and subcuticular tissue with continuous or interrupted approximating monofilament absorbable sutures (e.g., 3-0 or 4-0 polydioxanone, poliglecaprone 25, glycomer 631, or polyglyconate). Place interrupted appositional sutures in the skin (e.g., 3-0 or 4-0 polypropylene or nylon) (see Fig. 15.65C). Use an Elizabethan collar or bucket to prevent self-inflicted trauma to the surgical site. Keep the area clean and dry, removing food and saliva as necessary.*

Antidrool Cheiloplasty

Dogs whose face and neck are constantly wetted by saliva are candidates for this procedure. Antidrool cheiloplasty (cheilopexy) reduces the loss of food and saliva from the lateral vestibules of the oral cavity when there is excessive eversion or denervation of the lower lip. This is accomplished by suspending the lower lip from the inside of the upper cheek. Oral function is usually normal after surgery, but inflammation and infection occasionally occur at the surgical site. Permanent flap adhesion and cheek scars are expected.

Position the anesthetized patient in lateral recumbency. Clip the lateral face, lavage the oral cavity, and aseptically prepare the skin for surgery. Grasp the lower lip 2 to 3 cm rostral to the commissure, and elevate it dorsally until the lip is taut when the dog's mouth is completely opened (Fig. 15.66A). The site of maximum tautness is usually near the level of the caudal root of the upper fourth premolar. Beginning near an imaginary line between the medial canthus of the eye and the commissure, make a 2.5- to 3-cm, horizontal, full-thickness incision through the maxillary skin at the site of tautness (see Fig. 15.66B). Adjust the length of the incision to match the breed size. Control hemorrhage with ligation or electrocoagulation. The dorsal labial vein lies just dorsal to the proposed incision site. Use scissors to remove a 2-mm strip of mucosa adjacent to the mucocutaneous junction of the lower lip, beginning 2 cm rostral to the commissure and extending 2.5 cm (see Fig. 15.66C). Create 0.5- to 0.75-cm mucosal and skin flaps by undermining on each side of the incision (see Fig. 15.66D). Place stay sutures at the rostral and caudal aspects of the flaps. Evert the flaps through the cheek incision with the stay sutures (see Fig. 15.66E). Secure and bury the flap edges in the cheek skin incision with three to four preplaced vertical mattress sutures (e.g., 2-0 or 3-0 polypropylene or nylon) (see Fig. 15.66F and G). Place additional approximating skin sutures if necessary to achieve good skin apposition. Reposition the patient and repeat the procedure on the other side. Lavage the oral cavity with water after meals. Fit the dog with an Elizabethan collar to prevent self-inflicted trauma if necessary. Remove sutures at 21 days. Delay suture removal because constant lip movement may interfere with healing. Do not permit retrieving or chew toys for 2 months after surgery.

Nasal Folds

Brachycephalic breeds (i.e., English bulldogs, French bulldogs, Pekingese, Boston terriers, pugs, and Persian cats) characteristically have facial or nasal skin folds across the bridge of the nose. Prominent folds cause pyoderma and a foul odor (Fig. 15.67). Hair rubbing on the cornea is associated with keratitis, ulceration, epiphora, pain, and blepharospasm. Facial folds remain moist and become stained secondary to epiphora. Fold resection and ophthalmic medications are necessary. Excision of too much skin may cause ectropion or promote dehiscence.

Nasal Skin Fold Resection

Position the patient in ventral recumbency. Protect the eyes with a petrolatum-based ophthalmic ointment. Clip and aseptically prepare the dorsum of the nose and lips. Estimate the amount of

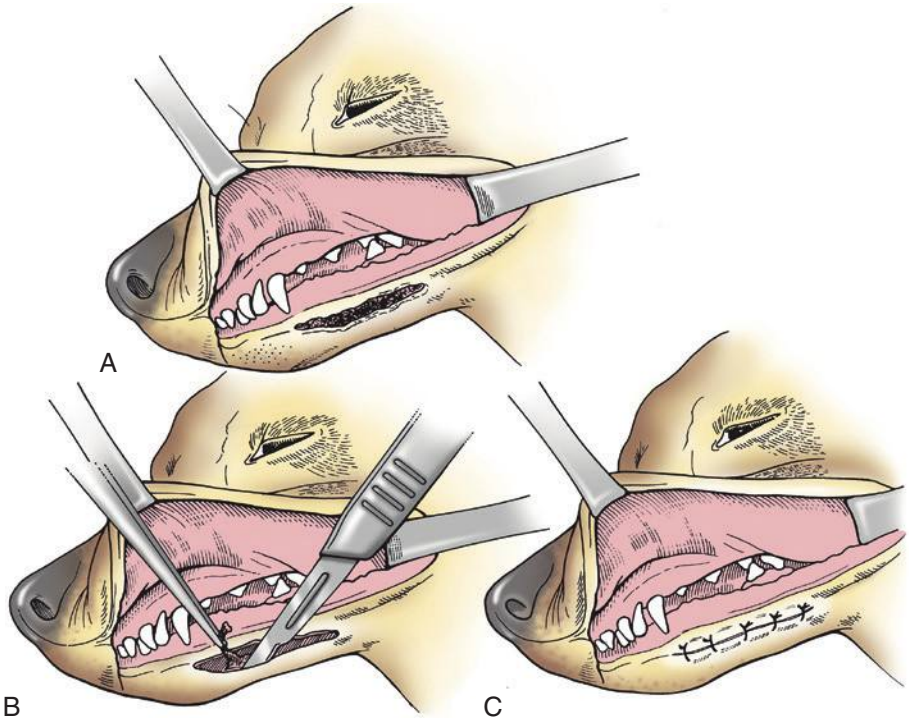

FIG. 15.65 (A) Cheiloplasty for lip fold dermatitis. (B) Make an elliptic incision and excise the infected skin. (C) Appose healthy skin edges with approximating sutures.

skin that must be resected to eliminate the skin folds without causing excess tension or ectropion. Make an elliptical incision around or through the skin folds in unmacerated tissue. Keep the caudal incision approximately 1 cm away from the medial canthus. Undermine and remove the outlined skin segment. Avoid traumatizing the nasolabialis muscle and facial vessels during dissection. Control hemorrhage with ligatures, electrocoagulation, and pressure. Lavage the area with sterile saline. Bury three or four interrupted sutures in the subcutaneous and subcuticular tissues to align and appose the skin edges and assess the adequacy of resection. Resect more skin if skin recesses remain. If necessary, undermine the skin edges to allow apposition without tension. Place additional interrupted, subcuticular sutures (e.g., 4-0 polydioxanone, poliglecaprone 25, glycomer 631, or polyglyconate) with buried knots. Use approximating skin sutures (e.g., 4-0 nylon or polypropylene), and cut the ends short to prevent further corneal irritation. Place an Elizabethan collar to prevent self-trauma. Keep the site free of exudates and ocular discharge. Continue to medicate the eyes.

Vulvar Folds

Vulvar skin folds occur in obese females and those with infantile, recessed vulvas (Fig. 15.68). Urine and vaginal secretions are trapped by the skin fold, resulting in superficial perivulvar dermatitis. Clinical signs include perineal pain, odor, vaginitis, repeated urinary tract infections, urinary incontinence, and pollakiuria. Skin fold pyoderma should be resolved medically before surgery. Episioplasty is a vulvar reconstructive procedure that removes the skin fold (see p. 740 for a description of the technique). Excessive suture line tension may cause dehiscence. Other complications include inflammation, swelling, infection, and recurrent perivulvar dermatitis. Perivulvar dermatitis recurs if the amount of skin excised is inadequate. Urinary incontinence may persist if associated with other abnormalities. Prognosis is good following surgery because most clinical signs are expected to improve.

Tail Folds

Redundant skin often overlaps deformed terminal caudal vertebrae ("screwtails," "corkscrew" tails, ingrown tails) (Fig. 15.69). Tail fold pyoderma occurs most commonly in brachycephalic breeds, but it has also been reported in Schipperke dogs and Manx cats. The skin fold may be quite deep (5–10 cm) with severe pyoderma. The depth of the folds varies with the animal's size, amount of fat, abundance of skin, and degree of vertebral deviation. Fecal contamination, licking, and scooting exacerbate the condition. Signs include perineal pruritus, pain, odor, ulcers, and fistulous tracts. Differential diagnoses should include perianal fistula, anal sacculitis, perianal tumors, trauma, and foreign bodies. Radiographs may be helpful to delineate the degree of caudal vertebral malformation. Draining tracts should be probed or a fistulogram performed to determine their site of origin. To remove all skin recesses at the tail head, complete caudectomy is necessary (see also p. 255).

Tail Fold Resection

Administer perioperative antibiotics based on skin fold culture and sensitivity results, otherwise broad-spectrum empirical antimicrobials should be used. Scrub the skin folds separately from the remainder of the surgical field. Resect the tail and skin folds en bloc, taking care during dissection to avoid penetrating the skin folds or traumatizing the rectum. Manipulate the tail with bone-holding forceps or towel clamps. Ankylosis or severe ventral deviation may make the vertebrae immobile. *Transect the tail cranial to the deviated vertebrae with Gigli wire or a bone cutter if the intervertebral space cannot be located. Smooth sharp bone edges with rongeurs or a bone rasp. Lavage thoroughly and insert closed suction drains (if*

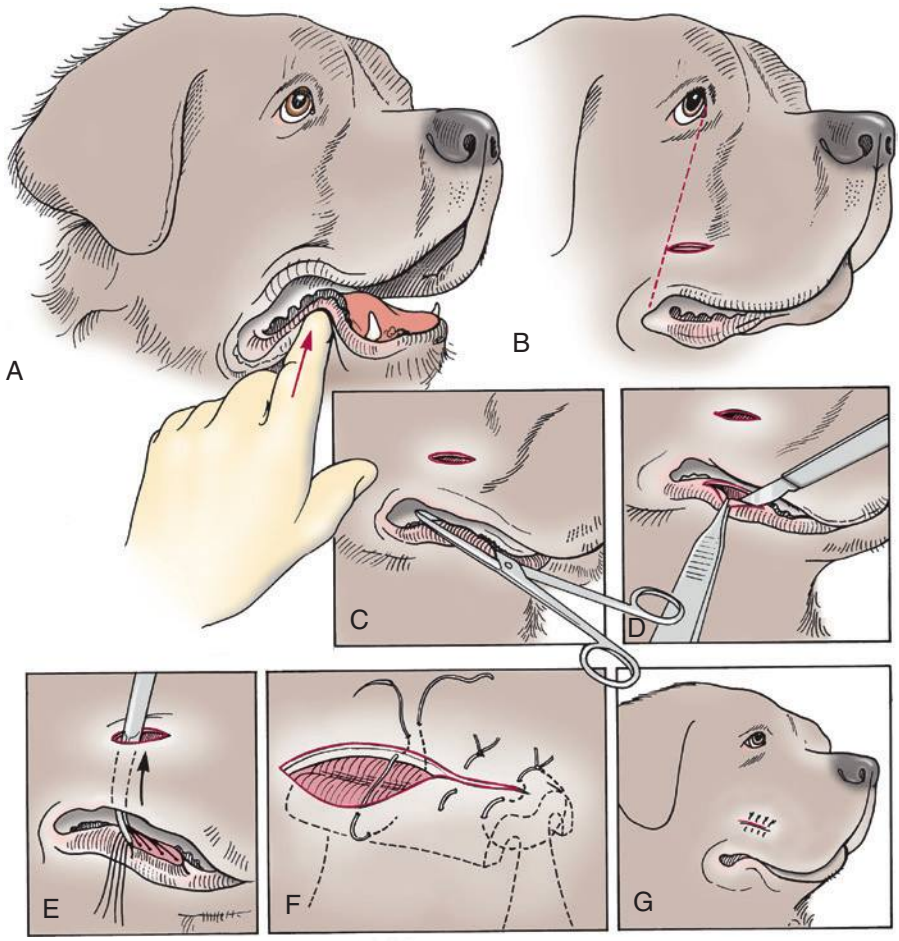

FIG. 15.66 (A) For cheiloplasty in dogs that drool excessively, elevate the everted lip dorsally until it is taut when the dog's mouth is opened maximally. (B) Make a 2.5- to 3-cm horizontal, full-thickness incision through the maxillary skin at the site of tautness near the upper fourth premolar. (C) Remove a 2-mm-wide strip of mucosa 2.5 cm long from the mucocutaneous junction of the lower lip beginning 2 cm rostral to the commissure. (D) Create 0.5- to 0.75-cm flaps. (E) Evert the flaps through the skin incision. (F–G) Secure with vertical mattress sutures.

FIG. 15.67 This English bulldog has a severe facial fold with pyoderma; the nares have been resected.

indicated) before apposing the subcutaneous tissues with absorbable sutures (e.g., 3-0 or 4-0 polydioxanone, poliglecaprone 25, glycomer 631, or polyglyconate). Close the skin with nonabsorbable sutures (e.g., 3-0 or 4-0 nylon, polybutester, or polypropylene). Keep the area clean and free of exudate and fecal contamination by applying warm, moist compresses two or three times daily for 15 to 20 minutes. Remove drains in 3 to 5 days.

SURGERY OF THE TAIL

CAUDECTOMY

Caudectomy, or amputation of a portion of the tail, which is performed to comply with breed standards or tradition, is ethically and morally controversial. *Therapeutic caudectomy* is indicated for traumatic lesions, infection, neoplasia, and possibly perianal fistula. The tail should be amputated with 2 to 3 cm of normal tissue margins when resecting tumors or traumatic lesions. Amputation should be performed near the anus if the end of the tail chronically bleeds because of repeated abrasion or chewing. Amputation near the base is recommended for avulsed tails and

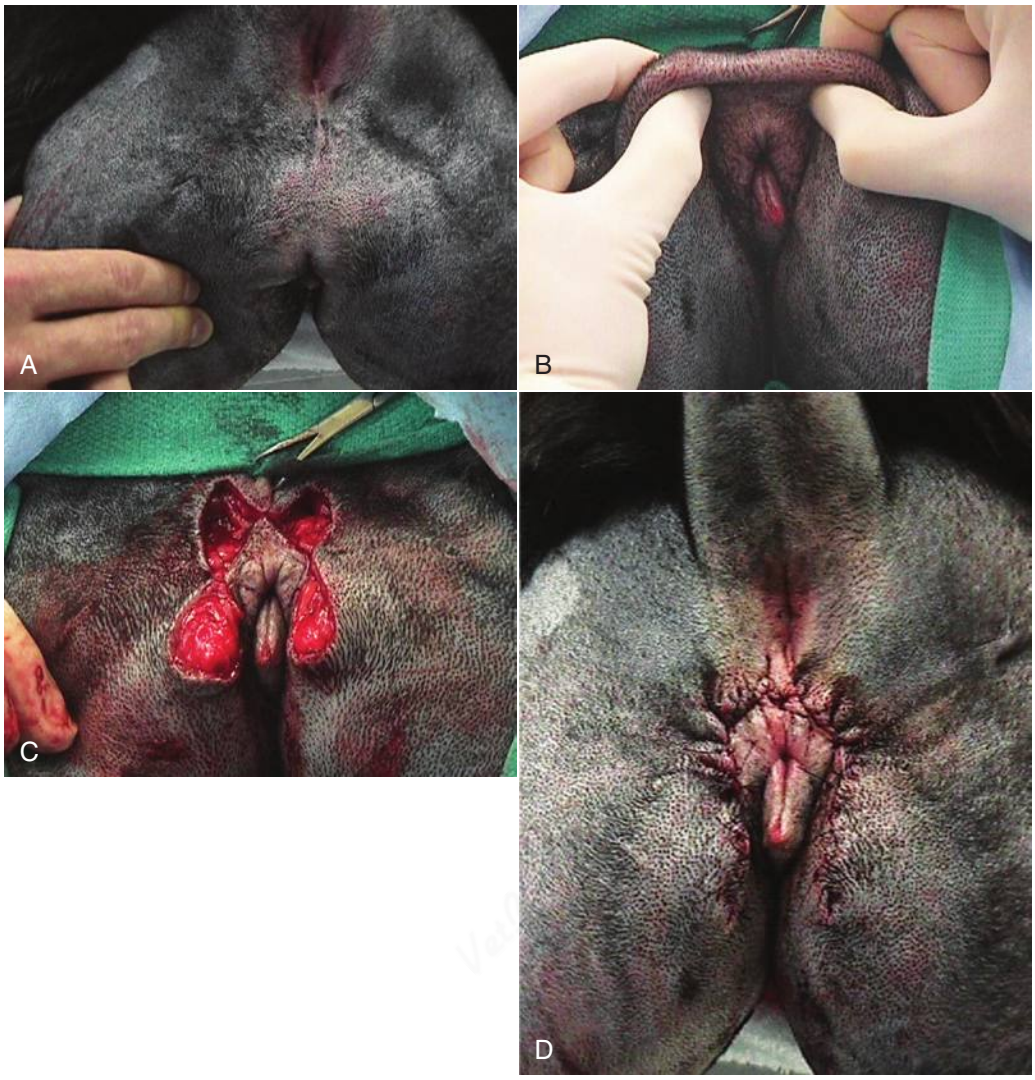

FIG. 15.68 (A) The vulva is completely obscured by the adjacent skin fold. (B) The skin is evaluated to determine the amount to be resected. (C) Skin has been resected and tacked into place to determine if resection was adequate. (D) Appearance of vulva following reconstruction.

FIG. 15.69 Screwtail in an English bulldog.

if necessary for tail fold pyoderma and perianal fistula. *Cosmetic caudectomy* (tail docking) is performed in puppies in order to adhere to breed standards. Many countries and veterinary professional organizations oppose the procedure when performed solely for cosmetic purposes.

Caudectomy in Adults

A caudectomy in dogs and cats older than 1 week requires general or epidural anesthesia. The surgical site should be observed for swelling, draining, inflammation, and pain. Healing after caudectomy is uncomplicated if excess skin tension and self-trauma are prevented. The site should be protected with a bandage or restraining device if necessary. Complications include infection, dehiscence, scarring, fistula recurrence, and anal sphincter or rectal trauma. Incisions that dehisce after partial amputation may heal by secondary intention, which usually leaves a hairless scar. Reamputation may be necessary to relieve irritation and improve cosmesis.

Partial Caudectomy

Wrap the distal tail with gauze or insert it into an examination glove and secure the covering with tape. Clip a generous area near the amputation site and aseptically prepare it for surgery. Place the patient in a perineal position or lateral recumbency. Position a tourniquet proximal to the transection site. Retract the skin toward the tail head. Make a double V incision in the skin distal to the desired intervertebral transection site. Orient the V to create dorsal and ventral skin flaps that are longer than the desired tail length (Fig. 15.70A). Identify and ligate the medial and lateral caudal arteries and veins slightly cranial to the transection site (see Fig. 15.70B). Incise soft tissue slightly distal to the desired intervertebral space and disarticulate the distal tail with a scalpel blade. If bleeding occurs, place a circumferential ligature around the distal end of the remaining tail or religate the caudal vessels (see Fig. 15.70C). Appose subcutaneous tissue and muscle over the exposed vertebrae with interrupted approximating sutures (e.g., 3-0 polydioxanone, poliglecaprone 25, glycomer 631, or polyglyconate). Position the dorsal skin flap over the caudal vertebrae (see Fig. 15.70D). Trim the ventral skin flap as needed to allow skin apposition without tension. Appose skin edges with approximating sutures (e.g., 3-0 or 4-0 nylon or polypropylene with a reverse cutting needle) (see Fig. 15.70D). Protect the surgical site with a bandage or by placing an Elizabethan collar over the animal's head.

Complete Caudectomy

Anesthetize the patient; clip and aseptically prepare the entire perineum and tail head area. Position the animal in ventral recumbency. Make an elliptic incision around the tail base (Fig. 15.71A). Incise subcutaneous tissues to expose the muscles. Separate the attachments of the levator ani, rectococcygeus, and coccygeus muscles to the caudal vertebrae (see Fig. 15.71B). Ligate the medial and lateral caudal arteries and veins before or after transection. Transect the tail by disarticulation with a scalpel blade at the second or third caudal vertebra. Lavage the site after hemostasis is achieved. Appose the levator ani muscles and subcutaneous tissue with simple interrupted or continuous suture patterns (e.g., 3-0 or 4-0 polydioxanone, poliglecaprone 25, glycomer 631, or polyglyconate). Excise redundant skin if necessary, and appose skin edges with approximating, nonabsorbable sutures (e.g., 3-0 or 4-0 nylon, polybutester, or polypropylene). As an alternative, the tail fold may be preserved; however, skin fold pyoderma may persist.

SURGERY OF THE DIGITS AND FOOTPADS

BIOPSY

Diagnosis of dermatologic conditions of the claw may require biopsy if history, physical examination, cytology, and cultures have not yielded an answer. Submission of an avulsed or sloughed claw is usually not helpful because claw matrix is absent. Punch biopsies are often not diagnostic, and owners are often reluctant to allow distal phalanx (P3) amputation to achieve a definitive diagnosis. The described technique yields appropriate samples of the claw epithelium to allow diagnosis without onychectomy; however, claws may not grow back properly following biopsy. Dewclaws should be biopsied when affected and present to prevent postoperative lameness.

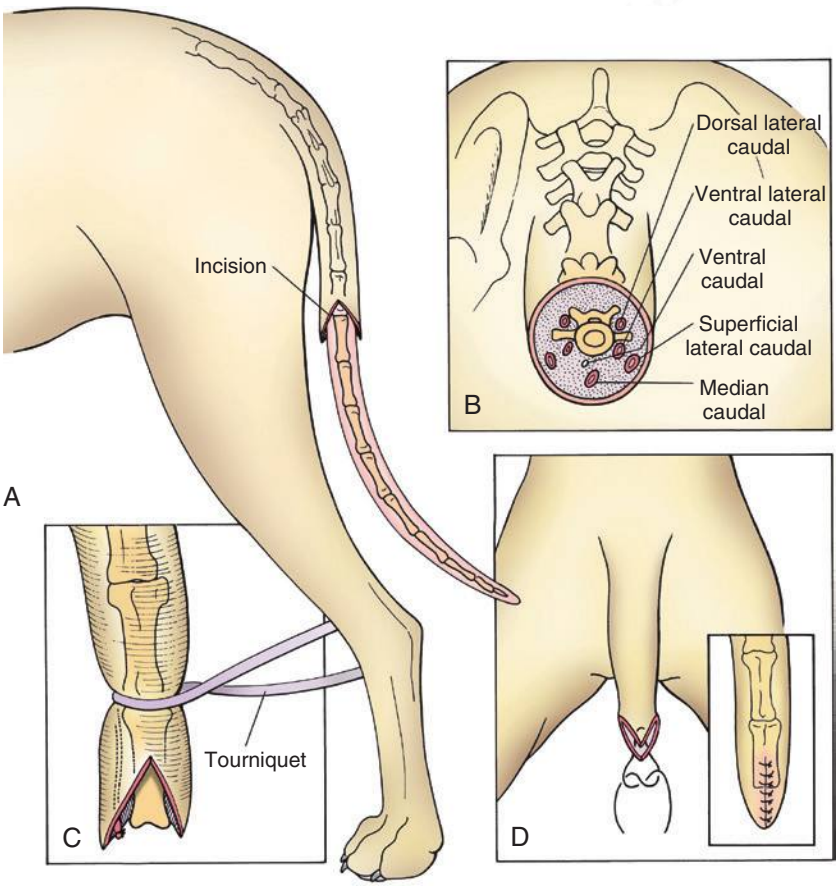

FIG. 15.70 Partial caudectomy in an adult. (A) Retract the tail's skin toward the tail head and make a double V incision in the skin distal to the desired transection site. (B) Ligate the medial and lateral caudal arteries and veins. (C) Transect the soft tissue distal to the desired intervertebral space. Transect the tail through the desired intervertebral space. A proximally placed tourniquet assists hemostasis. (D) Appose soft tissue and skin with approximating sutures.

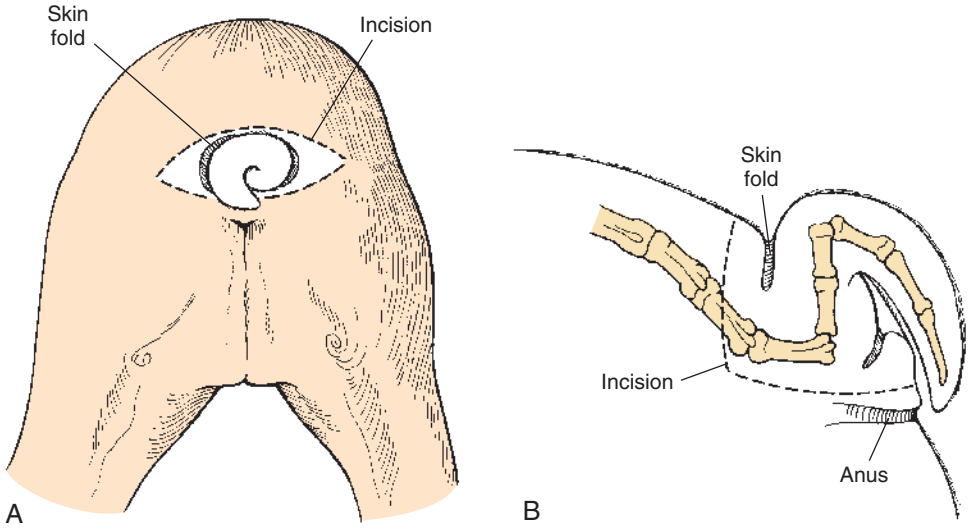

FIG. 15.71 Complete caudectomy with tail fold pyoderma requires (A) an elliptic incision around diseased skin and (B) deep dissection to locate the caudal vertebrae rostral to the vertebral deviation.

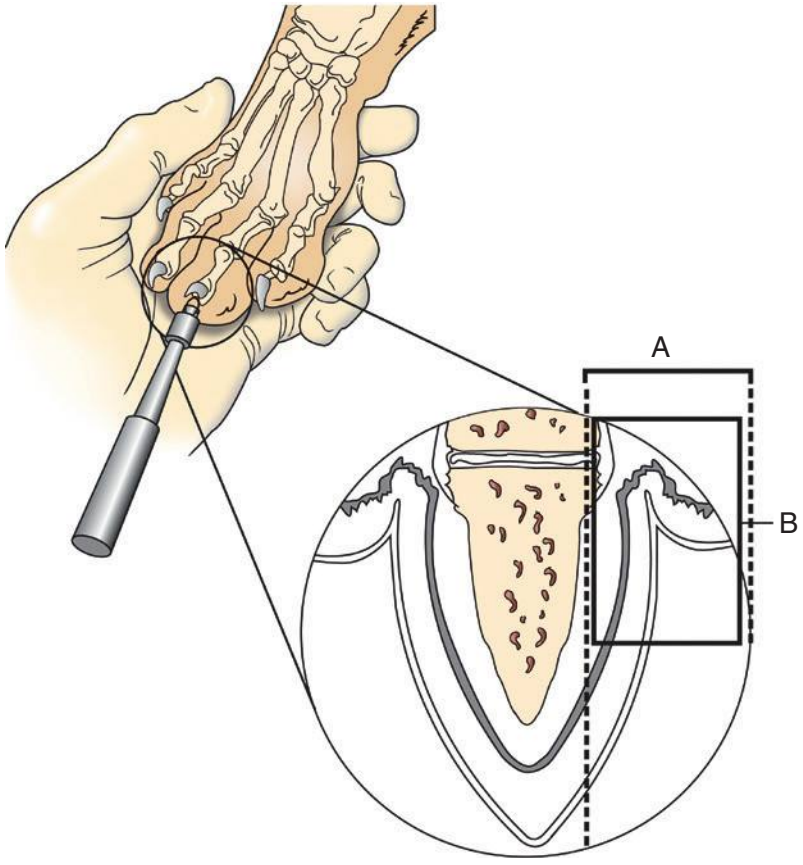

FIG. 15.72 (A) Position an 8-mm-diameter biopsy punch parallel to the long axis of the claw 1 to 2 mm distal to the claw fold. Rotate the punch slowly in one direction deep into the tissue initially through the horn of the claw, then through the bone of the distal phalanx and laterally through normal skin on the lateral aspect of the claw fold. (B) *Inset,* claw segment biopsied.

After the induction of general anesthetic, the paws designated for biopsies are clipped, but not scrubbed to prevent removing important pathologic surface evidence. *Apply a tourniquet to decrease hemorrhage. Position a 6- to 8-mm diameter biopsy punch parallel to the long axis of the claw 1 to 2 mm distal to the claw fold. Rotate the punch slowly in one direction deep into the tissue (Fig. 15.72). Initially, cut through the horn of the claw, then through the bone of the distal phalanx and laterally through normal skin on the lateral aspect of the claw fold. Transect the base of the biopsy with a scalpel blade or iris scissors. Control hemorrhage with pressure.*

Mark the haired surface for identification and place the specimen in formalin. Place interrupted sutures (3-0 to 4-0 monofilament nonabsorbable) to appose the skin and cover the exposed bone. Give analgesics postoperatively, as the animal will experience pain.

ONYCHECTOMY

Onychectomy (i.e., declawing) is removal of the third digital phalanx (P3) (Fig. 15.73A). Elective onychectomy is a controversial procedure; it is usually performed between 3 and 12 months of age to prevent cats from scratching furniture or people. Usually only the forelimb claws are removed. Although it is recommended that declawed cats be kept indoors because the procedure interferes with a cat's ability to protect itself, those with hind-limb claws can climb to escape some dangers. Alternatives to elective onychectomy are to glue a vinyl cap to each claw every 6 to 8 weeks (SoftPaws) or perform deep digital flexor tenectomy (see p. 260). Vinyl caps blunt the claws to render them less damaging.

Onychectomy or more extensive digit amputation may be required to remove infected nail beds and neoplasms. The most common nail bed tumors are squamous cell carcinomas, melanomas, soft tissue sarcomas, osteosarcomas, and mast cell tumors. Complete excision may require that adjacent phalanges be removed with the affected claw. Onychomycosis, usually caused by *Trichophyton mentagrophytes,* produces dry, cracked, brittle, and deformed nails with inflamed alopecic nail beds. Follicular infections with *Demodex* spp. and staphylococci produce similar lesions.

Onychectomy is performed with the patient under general anesthetic with multimodal analgesia (Table 15.9). Perioperative analgesia (buprenorphine, butorphanol, oxymorphone, meloxicam, or transdermal fentanyl) is recommended for a minimum of 24 to 48 hours after surgery. Additional perioperative analgesia may be provided by blocking regional nerves with 0.5% bupivacaine. The dorsal and palmar branches of the radial, median, and ulnar nerves provide sensory innervation to the feline forepaw. These branches are blocked at four sites using 0.1 to 0.2 mL of 0.5% bupivacaine at each site (not to exceed a total dose of 2 to 3 mg/kg), which provides 4 to 6 hours of analgesia.

Perform the nerve blocks after the induction of anesthesia and preparation of the paw for onychectomy. Fully extend the carpus and palpate the superficial digital flexor tendon along the palmar aspect of the paw. Block the median nerve with 0.15 mL of bupivacaine injected just medial to the superficial digital flexor tendon

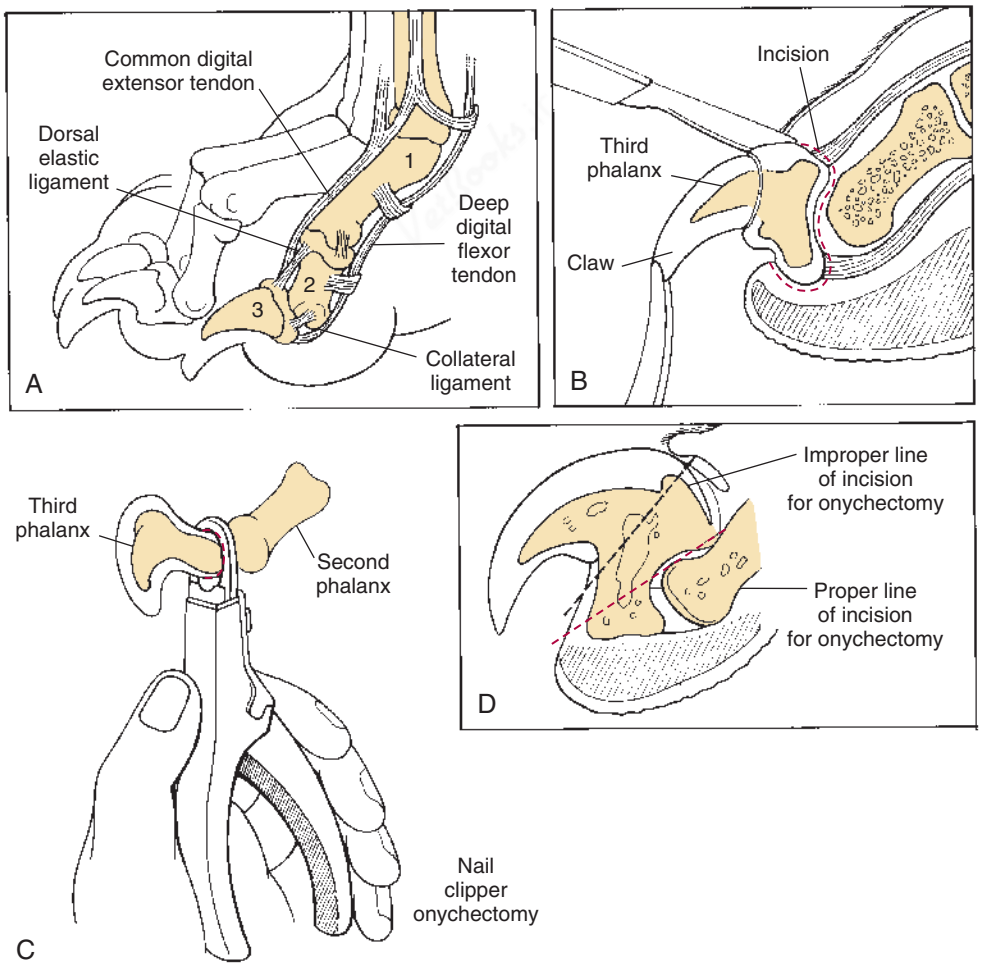

FIG. 15.73 (A) Distal phalangeal anatomy for onychectomy. (B) Dissection onychectomy disarticulates the third phalanx by transecting tendons, ligaments, and other soft tissue attachments. (C) Nail clipper onychectomy should remove the entire ungual crest but often leaves a portion of the ventral flexor process of P3. (D) Proper and improper lines of transection.

TABLE 15.9 Anesthetic Considerations for Onychectomy in Cats

Preoperative Considerations	
Associated conditions	• Minimal; usually healthy
Blood work	• HCT, TP • In patients >5–7 y, consider electrolytes, liver enzymes, BUN, Cr
Physical exam	• Normal
Premedications	• Hydromorphone[a] (0.05–0.1 mg/kg IV, IM), *or* • Morphine[b] (0.1–0.2 mg/kg IV or 0.2–0.4 mg/kg IM), *or* • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM), *or* • Fentanyl patch placed 6–12 h prior to surgery (see Table 12.1)
Intraoperative Considerations	

Induction	• If premedicated, give:
	  • Ketamine (5.5 mg/kg IV) with diazepam (0.28 mg/kg IV), *or*
	  • Propofol (4–8 mg/kg IV), *or*
	  • Thiopental (8–10 mg/kg IV)
	• If no premeds given, then:
	  • Dexmedetomidine[d] (33 µg/kg IM), *plus*
	  • Butorphanol (0.66 mg/kg IM), *plus*
	  • Ketamine (6.6 mg/kg IM); use ½ of all doses if given IV

Maintenance	• Isoflurane or sevoflurane • Atipamezole (333 µg/kg IM) at end of procedure if reversal of dexmedetomidine is needed
Monitoring	• HR, respiratory rate, SpO_2, temperature, blood pressure
Blocks	• Digital block
Postoperative Considerations	
Analgesia	• Morphine[b] (0.1–0.2 mg/kg IV or 0.1–0.5 mg/kg IM q1–4h), *or* • Hydromorphone[a] (0.05–0.1 mg/kg IV, IM q3–4h), *or* • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM q4–8h or 0.01–0.02 OTM q6–12h) • ± Ketamine CRI (2 µg/kg/min IV; if no previous loading dose, then give 0.5 mg/kg IV prior to CRI), *plus* • Meloxicam[e] (0.05–0.1 mg/kg PO, SC once)
Monitoring	• SpO_2, blood pressure, HR, respiratory rate, temperature
Estimated pain score	• Severe

[a]Monitor for hyperthermia in cats.
[b]Give slowly to prevent histamine release.
[c]Buprenorphine is a better analgesic than morphine in cats.
[d]Use only in young animals.
[e]Black box warning added by the Food and Drug Administration in October 2010 identified cases of renal failure and death in cats with repeated uses of meloxicam. Meloxicam is approved for single use only in cats in the United States.
BUN, Blood urea nitrogen; *Cr,* creatinine; *CRI,* constant rate infusion; *HCT,* hematocrit; *HR,* heart rate; *IM,* intramuscular; *IV,* intravenous; *OTM,* oral transmucosal; *PO,* orally; *q,* every; *SC,* subcutaneous; *SpO_2,* oxygen saturation via a pulse oximeter; *TP,* total protein.

at a point approximately one-third the distance between the carpal pad and the first digital pad (Fig. 15.74A). Block the palmar branches of the ulnar nerve at approximately the same level along the lateral aspect of the superficial digital flexor tendon using 0.15 mL bupivacaine (see Fig. 15.74A). Block dorsal digital nerves II through V by inserting the needle from lateral to medial just distal to the carpus. Inject 0.2 mL of bupivacaine as the needle is withdrawn, being careful to block dorsal digital nerve V, which lies lateral to metacarpal V (see Fig. 15.74B). Inject 0.1 mL of bupivacaine to block dorsal digital nerve I. Locate this nerve by inserting the needle from distal to proximal to the point of articulation between metacarpals I and II.

Dissection Onychectomy

In cats, either a scalpel, radiofrequency, or CO_2 laser may be used to remove the third phalanx. Onychectomy performed with CO_2 laser is associated with improved limb function and decreased postoperative pain in the perioperative period. Radiofrequency has been recently shown to be a reasonable alternative to laser for performing onychectomy, as the degree of collateral tissue damage was similar between modalities.

The dissection technique is also the preferred procedure for canine onychectomy. Clipping hair from the paw and around the toes is advised in dogs and long-haired cats. Although most germinal cells are located in the ungual crest, the entire process must be removed to guarantee there will be no claw regrowth.

Aseptically scrub the paw, digits, and nails for surgery. Block the regional nerves to each front paw. Position the animal in lateral recumbency and apply a tourniquet below the elbow to minimize blood loss and improve visualization. In cats, tourniquet application above the elbow may damage the radial, median, or ulnar nerves because feline arm muscles lack protective bulk. *As an alternative, have an assistant compress the brachial artery with a thumb or index finger against the humeral shaft by applying pressure just cranial to the triceps muscle on the medial aspect of the brachium. Drape the feet. Extend the claw by pushing up on the digital pad and by grasping the nail tip with a towel clamp or grasping forceps (e.g., Allis tissue forceps). Circumferentially incise the hairless, cuticle-like skin away from the claw near the articulation between the second and third phalanges (see Fig. 15.73B). Transect the common digital extensor tendon and dorsal ligaments with a No. 11 or No. 12 scalpel blade. Follow the contour of the proximal end*

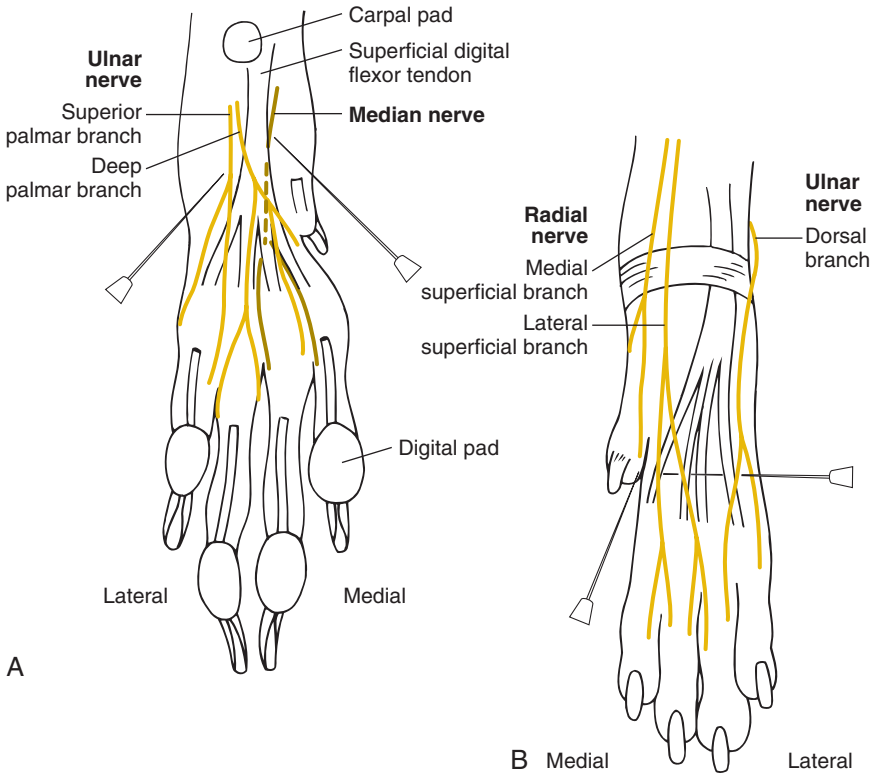

FIG. 15.74 Sites for nerve blocks of sensory innervation to the feline forepaw. (A) Extend the carpus and palpate the superficial digital flexor tendon along the palmar aspect of the paw. Block the median nerve with 0.16 mL of bupivacaine just medial to the superficial digital flexor tendon. Similarly block the palmar branches of the ulnar nerve along the lateral superficial digital flexor tendon. (B) Block dorsal digital nerves II to V by inserting the needle from lateral to medial just distal to the carpus. Inject 0.2 mL of bupivacaine as the needle is withdrawn. Block dorsal digital nerve I at the articulation between metacarpal I and II with 0.1 mL of bupivacaine.

of P3 to transect the deep digital flexor tendon and dissect the phalanx from the digital pad and other soft tissue attachments (i.e., joint capsule, collateral ligaments, and other tendons). Avoid cutting the digital pad. Remove all 10 claws from the front paws for elective onychectomy. Appose skin edges with a bandage, single interrupted cruciate sutures, or cyanoacrylate absorbable tissue adhesive (e.g., Vetbond). Do not place sutures through the digital pads. Apply tissue adhesives over the apposed surface of the skin and not between the cut edges. Apply a bandage from the paw to the distal antebrachium (see p. 203) and remove the tourniquet.

Nail Clipper Onychectomy

Prepare the paws for surgery as described in the section on Dissection Onychectomy. Trim the claws to facilitate positioning the nail trimmer in the interphalangeal space. Position a sharp, guillotine type of nail clipper (Resco nail shears) around the claw (see Fig. 15.73C). Extend the claw by grasping the tip with a towel clamp or grasping forceps (e.g., Allis tissue forceps). Position the blade dorsally at the joint space and transect the extensor tendon or tendons. Rotate the blade ventrally with continuous contact with the skin. Lift the claw dorsally to close the joint space and deviate the flexor process ventrally. After ensuring that the digital pad is proximal to the line of transection and the instrument is in the joint space, close the instrument to amputate the phalanx. Inspect the articular surfaces for complete excision of P3 (see Fig. 15.73D). If a small portion of the palmar aspect of P3 remains, grasp it with a thumb forceps and carefully dissect it from the digital pad with a scalpel blade or sharp-sharp scissors. Some prefer to retain this portion of P3, especially in large cats, to maintain deep digital flexor function. *Remove all 10 claws from the front paws for elective onychectomy. Appose skin edges with a single interrupted suture or absorbable tissue adhesive, if necessary. Apply a bandage from the paw to the distal antebrachium (see p. 203) and remove the tourniquet.*

Postoperative Care and Complications

Mild bleeding should be expected when the bandage is removed after 12 to 24 hours; if bleeding persists, the bandage should be reapplied for 2 to 3 days. Shredded paper, instead of litter, should be used for 2 weeks while the nail beds heal. The cat will usually remove sutures within a week. Convalescence is more rapid in young, growing cats than in older or obese cats. Owner satisfaction with this procedure is high. Complications (i.e., pain, hemorrhage, pad damage, lameness, swelling, infection, claw regrowth, second phalanx protrusion, and palmigrade stance) occur in 50% of patients. Cutting the digital pads prolongs postoperative pain and lameness. Early postoperative pain is more common after blade onychectomy than after the nail clipper procedure. Hemorrhage is most common in older animals and when wounds are not apposed. Late postoperative complications are more common when nail clippers are used. Nonabsorbable tissue adhesives may cause postoperative lameness (frequently non–weight bearing)

FIG. 15.75 This cat was not confined after onychectomy, and its bandages got wet and were left on longer than desired. All four paws were injured, with the right rear leg requiring amputation.

BOX 15.16 Breeds Recommended for Possible Dewclaw Removal

- Alaskan malamute
- Basset hound
- Belgian malinois
- Belgian sheepdog
- Belgian tervuren
- Bernese mountain dog
- Boxer
- Cardigan Welsh corgi
- Chesapeake Bay retriever
- Dalmatian
- Dandie Dinmont terrier
- Kerry blue terrier
- Komondor
- Lakeland terrier
- Norwegian elkhound
- Papillon
- Puli
- Rottweiler
- Shetland sheepdog
- Siberian husky
- Silky terrier
- Saint Bernard
- Vizsla
- Weimaraner

and infections and may be extruded from the wounds as a foreign body. Improper tourniquet use may cause neurapraxia, tissue necrosis, and lameness. The radial nerve is most often affected, but signs usually resolve in 6 to 8 weeks. Tight bandages can result in ischemic necrosis of the paw (Fig. 15.75). Incomplete removal of the germinal cells in the dorsal aspect of the ungual crest allows claw regrowth. If only a small remnant of the flexor process remains, claw regrowth is not anticipated. Claw regrowth should be suspected if draining tracts develop. The regrown claw is usually deformed. Chronic pain evidenced by behavioral changes (e.g., decreased activity, decreased appetite, or increased aggression) is sometimes observed and may be caused by the windup pain phenomenon associated with unsatisfactory perioperative analgesia (see Chapter 13).

DEEP DIGITAL FLEXOR TENECTOMY

The deep digital flexor tendon inserts on the flexor process of the third phalanx and is needed to flex the phalanx. Claws remain retracted after the deep digital flexor tendons have been severed, which limits the cat's ability to scratch; however, the nails become thick and blunt and must be trimmed regularly. Hemorrhage, infection, and lameness may occur postoperatively. Tenectomy of the superficial digital flexor (which inserts on the proximal aspect of P2) instead of the deep digital flexor results in an abnormal flat-footed stance. Problems may include persistent lameness and ability to scratch, interphalangeal joint immobility, fibrosis, pain, and claw ingrowth into the digital pads. Owners are frequently dissatisfied because of the cat's continued ability to scratch, the unaesthetic appearance of the thickened claws, the long-term lameness, and the necessity for nail clipping, which is difficult to accomplish. Cats may require an onychectomy to relieve clinical signs. For these reasons, this technique is not routinely recommended.

Anesthetize the cat and position it in dorsal or lateral recumbency. Clip and aseptically prepare the paws. Apply a tourniquet below the elbow to minimize hemorrhage. Make a 3- to 5-mm skin incision over the palmar surface of the second phalanx (P2), near the P2-P3 interphalangeal joint and digital pad (Fig. 15.76A). The glistening white tendon of the deep digital flexor lies directly beneath the skin. *Dissect under the tendon with mosquito hemostats or small scissors (see Fig. 15.76B). Excise a 5-mm segment of tendon with a scalpel blade, electrosurgery blade, or laser (see Fig. 15.76C and D). Appose the skin edges with an interrupted suture or absorbable tissue adhesive as for onychectomy. Repeat the procedure on each digit, and trim each claw.*

Use torn paper rather than litter for 2 weeks. Limit activity and discourage jumping for 1 week.

DEWCLAW REMOVAL

The dewclaw is the first digit of the canine rear paws. The first and second phalanges of the digit are inconsistent. Dewclaws are absent in some dogs and double in others. Great Pyrenees and Briards must have double rear dewclaws to meet breed standards. In other breeds, loosely attached dewclaws are removed to prevent inadvertent or self-trauma during hunting or grooming (Box 15.16). Often only the rear dewclaws are removed. Dewclaws can be removed at 3 to 5 days of age with local analgesia. Hemorrhage is more excessive after 5 days of age, and anesthetics are necessary. Complications include hemorrhage, pain, infection, and dehiscence. Premature suture removal may cause scarring. Bandages applied too tightly may cause swelling or ischemic necrosis.

Dewclaw Removal in Puppies

Aseptically prepare the medial aspect of the paw. Have an assistant cup the puppy in his or her hands and immobilize the paw. Facilitate restraint and analgesia by giving a sedative, a local anesthetic, or both (see p. 144). Abduct the digit and transect the web of skin, attaching the dewclaw to the paw with Mayo scissors, electrosurgery, or laser (Fig. 15.77A). Disarticulate the metatarsal/metacarpal-phalangeal joint or transect the bone near the metatarsal or metacarpal bone with a scalpel blade or Mayo scissors, electrosurgery, or laser. Control hemorrhage with pressure or electrocautery. Appose skin margins with a single approximating suture or absorbable tissue adhesive or allow healing by secondary intention.

Dewclaw Removal in Adults

If dewclaw removal is not performed within the first week of life, it should be delayed until after 3 months of age and performed using a general anesthetic. It is convenient to remove dewclaws at the time of neutering.

Position the patient in lateral recumbency. Clip and aseptically prepare the paws for surgery. Make an elliptic incision around the base of the digit where it articulates with the metatarsal or metacarpal bone (see Fig. 15.77B). Abduct the digit and dissect subcutaneous tissue to the metacarpophalangeal or metatarsophalangeal joint.

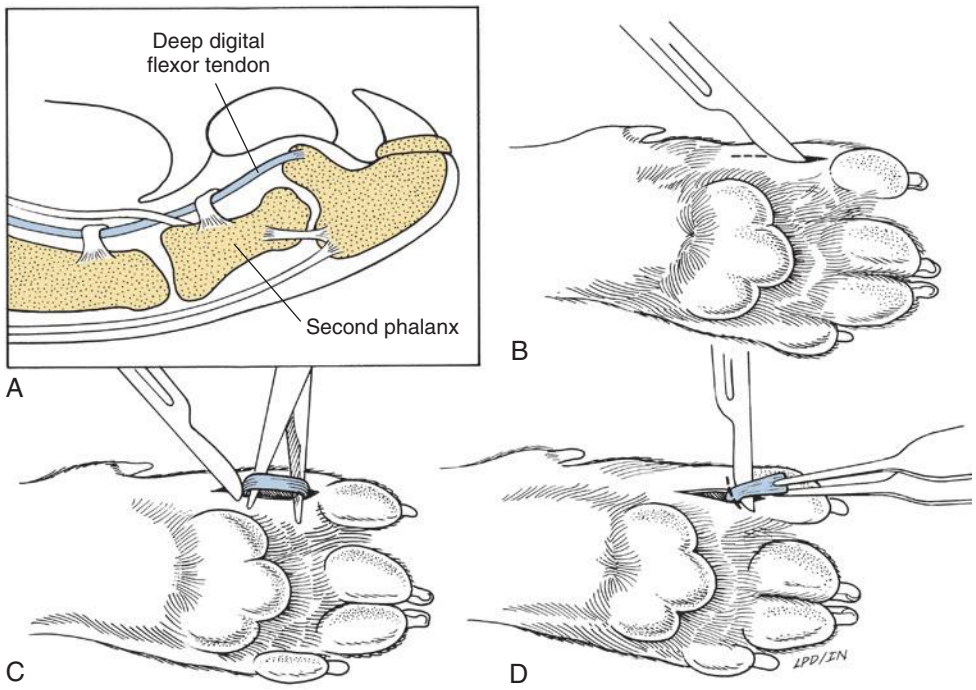

FIG. 15.76 Deep digital tenectomy. (A) Make a 3- to 5-mm incision over the palmar surface of the second phalanx. (B) and (C) Elevate and excise a 5-mm segment of deep digital flexor tendon. (D) shows the relationship of the deep digital flexor tendon to P1, P2, and P3.

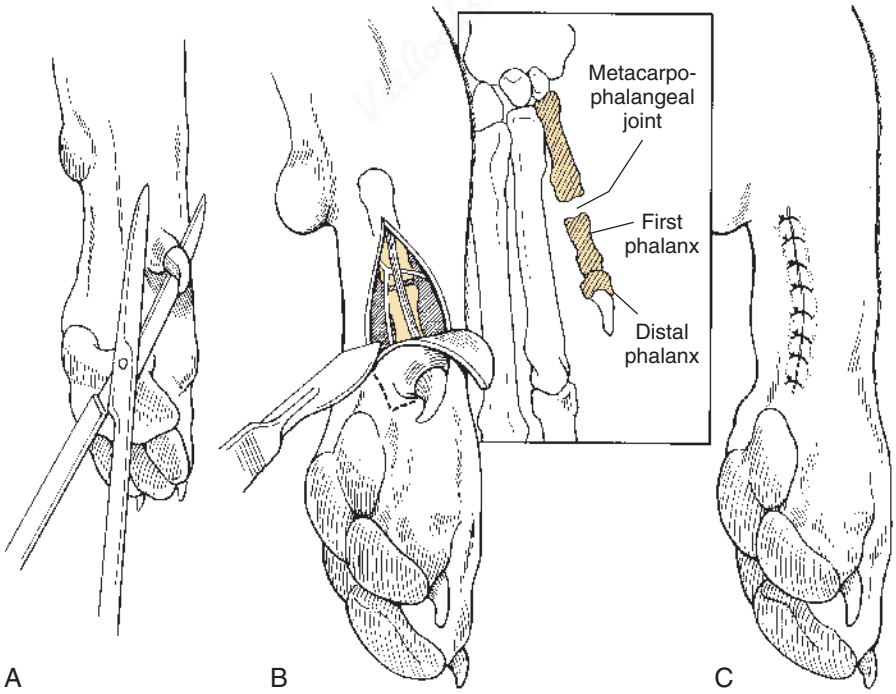

FIG. 15.77 Dewclaw removal. (A) In puppies, abduct and transect the dewclaw with scissors, disarticulating at the metatarsal (carpal)-phalangeal joint. (B) In adults, make an elliptic incision around the base of the dewclaw, dissect subcutaneous tissue, and ligate the dorsal common and axial palmar arteries. Then disarticulate the joint or transect P1 with bone cutters *(inset)*. (C) Appose subcutaneous tissue and skin with approximating sutures.

If the first and second phalanges are firmly attached, free them with a No. 11 blade. Ligate the dorsal common and axial palmar digital arteries. Disarticulate the metacarpophalangeal or metatarsophalangeal joint with a scalpel blade. The results are less cosmetic when bone cutters are used to transect the first phalanx near the metacarpophalangeal or metatarsophalangeal joint. *Appose subcutaneous tissue with 3-0 or 4-0 simple continuous or interrupted approximating sutures using absorbable suture material (i.e., polydioxanone, polyglyconate, poliglecaprone 25, glycomer 631 or polyglactin 910). Appose the skin with interrupted approximating sutures (i.e., 3-0 or 4-0 nylon or polypropylene) (see Fig. 15.77C). Apply a soft, padded bandage to protect the surgical site for 3 to 5 days. Remove sutures at 7 to 10 days.*

DIGIT AMPUTATION

Digit amputation is performed because of neoplasia, chronic bacterial or fungal infections, osteomyelitis, or severe trauma (Fig. 15.78). Affected digits are swollen and painful with thickened, dystrophic, or absent claws. Squamous cell carcinoma is the most common tumor identified in canine and feline digits; however, numerous neoplastic processes can occur in this location. Occasionally a digit is amputated to facilitate salvage of a weight-bearing pad or portion of the paw.

The level of amputation is determined by the site of the lesion and the disease process. General anesthesia is required. Complications include hemorrhage, infection, dehiscence, and recurrence. Tight bandages may cause swelling or ischemic necrosis. The primary weight-bearing digits are the third and fourth digits. In dogs undergoing removal of one or both central weight-bearing digits, postoperative transient lameness is expected.

Digital tumors occur in older dogs (mean age, 10 years) and more rarely in cats (mean age 12.7 years) and are often initially misdiagnosed as infections. They occur most often in male large- to medium-breed dogs (10 to >30 kg). Bone invasion is common. Clinical signs include lameness, digit swelling and ulceration, and a fixed protruding, deviated, or lost nail. Tumors must be differentiated from paronychia. Squamous cell carcinomas, malignant melanomas, soft tissue sarcomas, osteosarcomas, and mast cell tumors are common digital tumors. Squamous cell carcinomas, mast cell tumors, and melanomas arising in the subungual epithelium are aggressive and sometimes metastatic. Black dogs are predisposed to subungual squamous cell carcinomas. The 1-year survival rate after digital amputation varies from 45% to 100%, depending on the tumor type; digital melanomas have a median survival of 1 year.

Aside from squamous cell carcinoma and fibrosarcoma, digital tumors in cats can also be metastatic, most commonly from pulmonary adenocarcinoma. These tumors typically involve weight-bearing digits and can involve more than one toe. Cats with digital tumors should be carefully evaluated for primary disease. Prognosis for digital tumors in cats is guarded. Median survival in cats with digital squamous cell carcinoma is 73 days, whereas cats with metastatic lesions have similarly poor survival.

Clip and aseptically prepare the paw for surgery. Position the dog or cat in ventral or lateral recumbency with the leg suspended. Place a tourniquet and drape the area. Release the aseptically prepared paw into the sterile field. Begin a dorsal skin incision at the distal end of the appropriate metacarpal (metatarsal) or the proximal end of the first phalanx. Make a transverse encircling incision at the appropriate interphalangeal joint (inverse Y incision) (Fig. 15.79A and B). Preserve the digital pad if only the third phalanx is removed. Transect the flexor and extensor tendons, ligaments, and joint capsule. Ligate the digital arteries and veins with 3-0 or 4-0 absorbable suture. Disarticulate with a scalpel blade or transect the phalanx with bone cutters. Include the sesamoid bones with the excision. Suture the extensor tendon to the dorsal surface of the pad when it is preserved. Appose subcutaneous tissues over the end of the bone with interrupted absorbable sutures (e.g., 3-0 or 4-0 polydioxanone, poliglecaprone 25, glycomer 631, or polyglyconate). Appose skin with approximating sutures (e.g., 3-0 or 4-0 nylon or polypropylene) (see Fig. 15.79C). Apply a padded bandage and, if necessary, an Elizabethan collar. Keep the bandage clean and dry. Change the bandage in 2 to 3 days or as needed to evaluate the wound. Remove the bandage and sutures after 7 to 10 days.

FIG. 15.78 (A) A melanoma caused this digit to enlarge, and the nail was lost. (B) The digit was amputated, and the adjacent toes were fused.

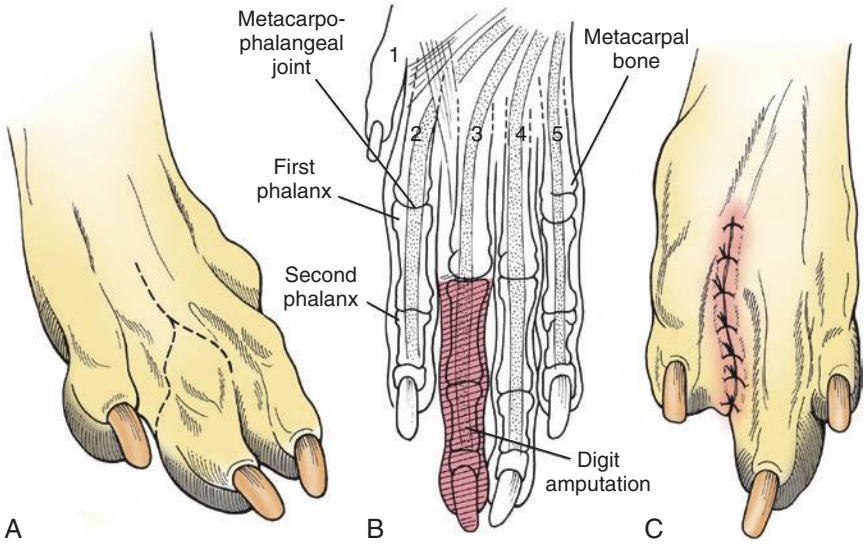

FIG. 15.79 Digit amputation. (A) Begin the skin incision dorsally and extend it laterally on each side of the involved digit. (B) Ligate the digital vessels and transect the tendons, ligaments, and joint capsule to disarticulate the digit between P3–P2, P2–P1, or P1–metacarpal (tarsal). (C) Appose subcutaneous tissue over the end of the bone and approximate skin edges.

FOOTPAD INJURIES

The footpad is the toughest area of the canine skin and is designed to absorb shock, standing, and abrasive forces. The stratum corneum is usually pigmented, thick, and keratinized, with a rough surface of conical papillae. Footpad injuries include laceration, degloving, abrasion, avulsion, burns, and tumors. Injuries may not heal well as a result of the weight-bearing forces and pad loss. Weight-bearing areas without pads may ulcerate.

Superficial Pad Loss

Wounds with superficial pad loss are allowed to heal by secondary intention and treated with nonadherent, absorbent, or semiabsorbent bandages and a spoon splint. A functional pad is maintained if epithelial tissue remains at the periphery and the wound is able to heal by contraction and epithelialization. Splinting the paw promotes healing because wound contractile forces are antagonized by weight bearing, which pushes the wound edges apart. Aloe vera extract gel has a positive effect on early stages of paw pad healing. Acemannan-containing hydrogel wound dressing also stimulates wound healing. Bandaging and splinting the paw should be continued until reepithelialization and some keratinization occur. Exercise should be restricted while the limb is bandaged. After the bandage has been removed, exercise may be gradually allowed on nonabrasive surfaces.

Lacerations

Improperly managed simple lacerations can become chronic nonhealing wounds because forces applied on the pads during standing or walking flatten and spread the pad, separating the lacerated edges. Proper management of lacerated pads includes lavage, suturing, and bandaging. Acute lacerations should be thoroughly lavaged and minimally debrided. Old, severely contaminated or infected lacerations need hydrophilic bandages for several days.

Debride the edges of chronic lacerations to remove necrotic tissue and provide a bleeding edge for apposition. Appose deep layers of the pad with buried simple interrupted absorbable sutures (e.g., 3-0 and 4-0 polydioxanone, poliglecaprone 25, glycomer 631, polyglyconate). Appose epithelial edges with interrupted approximating sutures (simple, vertical mattress, far-near-near-far) (e.g., 2-0 or 3-0 polypropylene or nylon), taking bites several millimeters from the cut edge. After closure, protect the pad with a nonadherent, thick, absorbent bandage with a foam sponge, with or without a splint (see p. 203). Change the bandage every 1 to 3 days, depending on the amount of drainage. Remove the sutures after 10 to 14 days and reapply the splint and bandage for 3 to 4 days. Remove the splint but rebandage the paw for an additional 3 to 6 days to allow the wound to strengthen. As an alternative, protect the pad with a commercial dog boot after suture removal. Restrict exercise while the limb is bandaged. Gradually institute exercise on a nonabrasive surface after bandage removal.

Paw Salvage

Degloving or crushing injuries to the paw may result in a nonfunctional paw. Amputation or multiple surgical procedures may be required to maintain paw function when injury is severe. Free grafts, axial pattern flaps, or thoracic wall pouch flaps, pedicled muscle flaps, and microvascular free tissue transfer have been used to reconstruct distal limb injury. Partial amputation may be performed with carpal pad transfer for weight-bearing or in preparation for a prosthetic device (Fig. 15.80). Indoor cats and small dogs that walk primarily on carpets may function well on grafted skin that does not have pads; however, most dogs require salvage or replacement of the metacarpal-metatarsal pad. Replacement of metatarsal, metacarpal, or weight-bearing digital pads may be achieved by transposing adjacent pads, segmental digital pad grafts, or microneurovascular free digital or carpal pad transfer (Fig. 15.81). Tissue should not be transposed over a pad injury caused by tendon malfunction, bone malalignment, or nerve damage until the cause is corrected. A digital pad is transposed to replace a portion of the metatarsal or metacarpal pad. The phalanges of digit two or five are removed through a palmar incision. The digital pad is maintained on a pedicle of

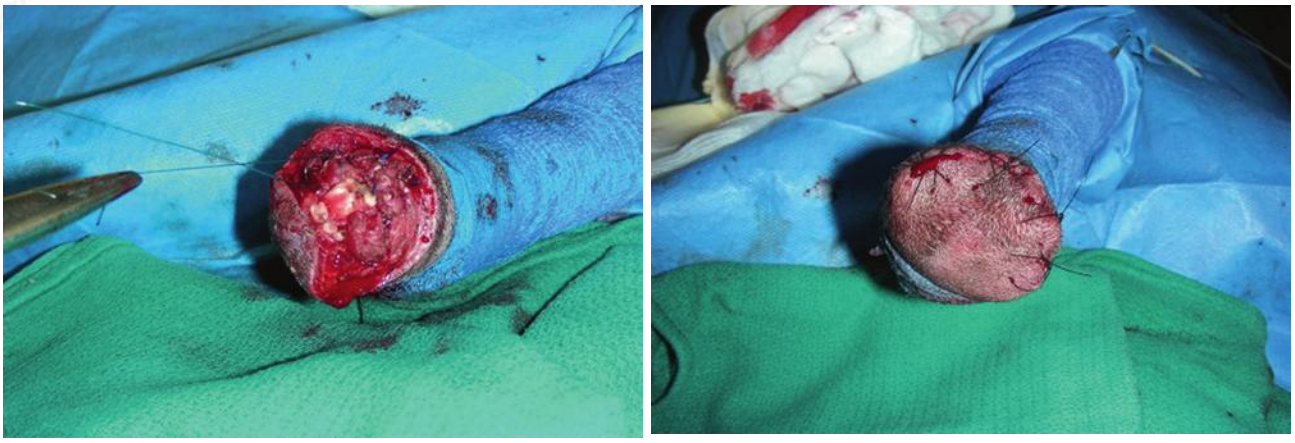

FIG. 15.80 Partial amputation of the distal rear limb in a dog due to severe frostbite of the digits.

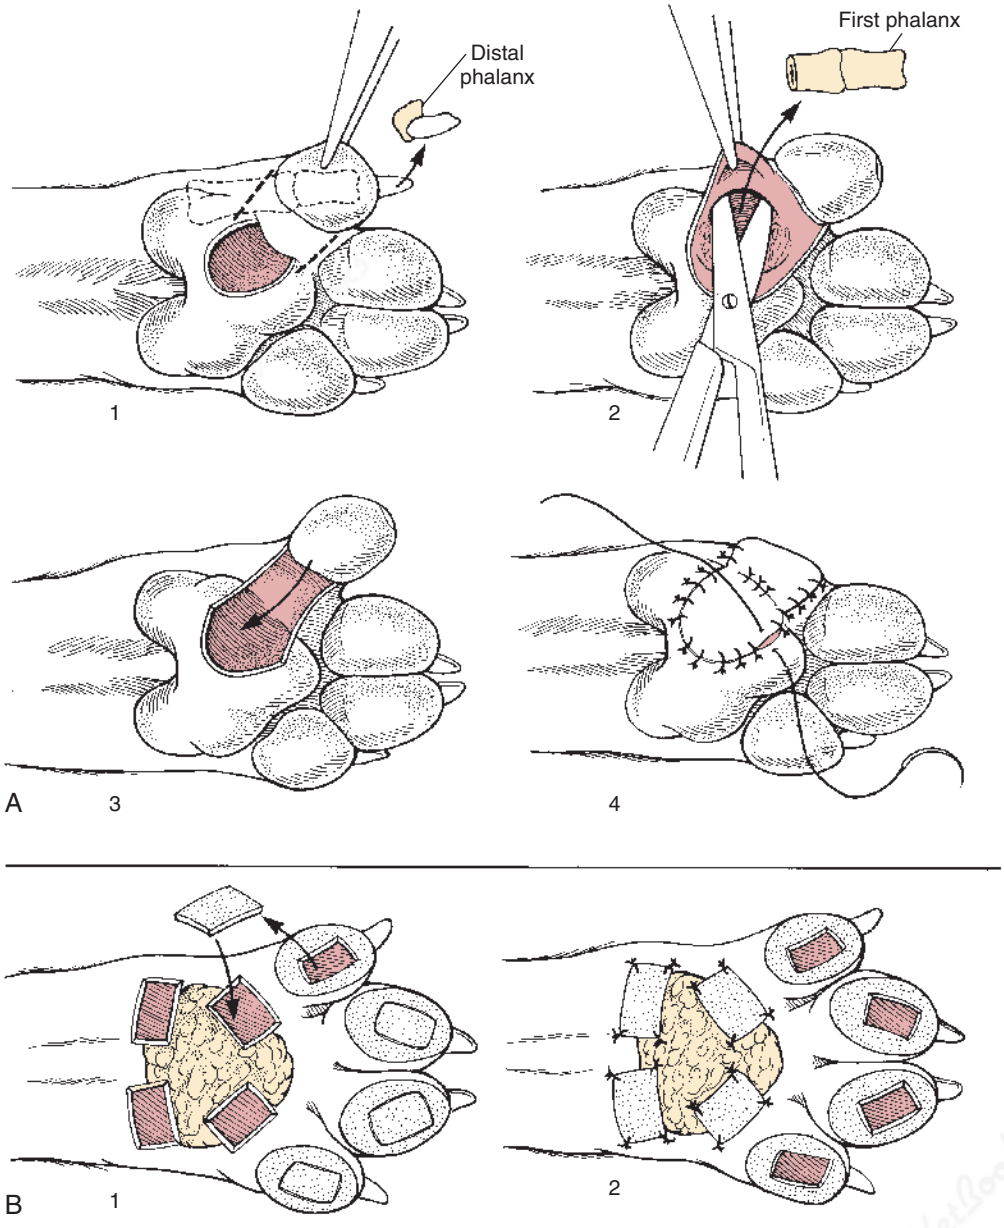

FIG. 15.81 Replacement or salvage of weight-bearing pads. (A) Partly or completely replace a pad by removing P3 and P2 from digit 2 or 5 and transposing the pad and skin to the injured area (phalangeal fillet technique). (B) The metacarpal or metatarsal pad may be salvaged by grafting from digital pads. Place the free segmental graft on a healthy granulation bed and across the skin pad junction. Donor sites are apposed with approximating sutures if tissue is pliable or allowed to heal by secondary intention under a protective bandage.

skin and is transposed to the metatarsal-metacarpal pad. As an alternative, severe trauma to all digits may necessitate digital amputation and transposition of the metatarsal or metacarpal pad over the bone ends to provide a weight-bearing surface. Free segmental digital pad grafts (6 × 8 mm) sutured into recessed recipient beds in granulation tissue allow pad reepithelialization with a tough, keratinized, and effective weight-bearing surface. Microneurovascular pad transfer requires specialized instrumentation and training. The paw should be bandaged after surgery as described previously for lacerations.

Fusion Podoplasty

Fusion podoplasty is a salvage procedure used to treat chronic interdigital pyoderma that is refractory to medical therapy. The procedure can also be used to palliate animals with chronic flexor tendon injury or to reconstruct the paw after digit amputations. Fusion podoplasty is not recommended on all four paws during a single surgery because of the prolonged operative time and postoperative discomfort.

Clip and aseptically prepare the paw. Position the anesthetized patient in dorsal or lateral recumbency. Consider placing a tourniquet around the distal limb to minimize hemorrhage, but be mindful of the length of the surgical procedure. Use a sterile marking pen to outline interdigital skin to be removed. Excise the interdigital web and skin between the digital and metacarpal-metatarsal pads. Preserve 2 to 3 mm of skin adjacent to the nail. Prevent damage to the digital vessels and nerves during dissection. Control hemorrhage with electrocoagulation or digital pressure; alternatively the dissection can be performed with radiofrequency or laser. Thoroughly lavage the wound. Suture the digital pads in apposition with simple interrupted sutures (e.g., 3-0 polypropylene or nylon). Approximate the digital and metacarpal-metatarsal pads with simple interrupted sutures; direct apposition of epithelial edges may not be possible. Approximate adjacent skin edges dorsally with simple interrupted sutures (e.g., 3-0 polypropylene or nylon). Repeat the procedure on the opposite paw if indicated. Remove the tourniquet.

Following amputation of the third or fourth digit, or both (see p. 262), the weight-bearing portion of the foot can be reconstructed with the second and fourth or fifth digits. The digits and tumor are removed en bloc with the digital pads while the metacarpal or metatarsal pads are preserved.

Close the defect in three layers. First appose the interosseous muscles of the adjacent digits with 3-0 or 4-0 monofilament absorbable interrupted sutures; next appose the subcutaneous tissue on both the palmar (plantar) and dorsal surfaces with absorbable sutures. Finally, appose the dorsal skin remaining on the second digit with the dorsal skin of the fourth or fifth digit and then the plantar or palmar skin between the digits with 3-0 or 4-0 monofilament nonabsorbable appositional sutures.

Apply a nonadherent, absorbent bandage and spoon splint or clamshell type of splint extending from the paw to the elbow or hock. For patients with interdigital pyoderma, change the bandage and splint daily until drainage diminishes, usually within 10 to 14 days. Remove sutures between 10 and 21 days after surgery, but continue bandaging until granulation is complete.

When healing nears completion, a lighter bandage or a paw boot allows transition between a heavy-splinted bandage and full weight bearing. Lameness is expected after digit amputation with fusion podoplasty for 4 or more weeks. Infection may persist in animals with interdigital pyoderma.

16

Surgery of the Eye

Surgery of the Eyelid

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Meibomian glands line the eyelid margins and produce the oil layer of the tear film that reduces tear evaporation. **Trichiasis** is the condition in which hairs arising from normal haired skin contact the cornea. **Distichia** are hairs growing out of the meibomian gland openings. **Ectopic cilia** are hairs that grow from palpebral conjunctiva to contact the cornea. **Entropion** is eyelid margin inversion, and **ectropion** is eyelid margin eversion. **Lagophthalmos** is an incomplete blink. **Exotropia** refers to eyes that are turned outward (laterally).

PREOPERATIVE CONCERNS

Eyelid function is essential to corneal health, comfort, and vision because the eyelids distribute tears over the cornea surface and protect the eye. Eyelid surgeries should be planned to preserve eyelid function for the health of the cornea. Eyelid margins that are improperly aligned in surgery or become misaligned postoperatively can result in corneal disease. If eyelid function is lost from trauma or neurologic disease, eyelid surgery may be urgently needed to prevent corneal ulcers and disease. Ideally, skin infections should be treated before surgery, and drugs that may interfere with healing should be given at a reduced dose or stopped entirely at the time of surgery.

Correct instrumentation and suture should be acquired before any planned surgery, and the prospective surgeon should have adequate knowledge of the condition, anatomy, procedure, and other requirements before attempting surgery. Complex or unfamiliar procedures should be referred to a veterinary ophthalmologist for the best outcome, particularly those requiring microsurgical equipment and skills to line skin flaps with conjunctiva.

PREPARATION OF THE SURGICAL SITE

Liberally apply sterile eye ointment or antibiotic ophthalmic ointment to both eyes for lubrication. Clip an approximately 2-inch wide (5 cm) area around the eyelids with a No. 40 clipper blade. Gently brush away the clipped hair; avoid using a vacuum cleaner around the eye. Alternatively, tape (as on a lint roller) may be used to remove the clipped hairs from skin. *Prep the skin with 5% povidone-iodine solution (not scrub) on quarter-folded gauze squares or swab sticks. Irrigate the conjunctival sac with eye wash or artificial tear drops to remove excess hair and relubricate. Avoid using chlorhexidine, any surgical scrubs, soaps, or alcohol because these will damage the cornea. After moving into the operating room, reprep the eye with 5% povidone-iodine (e.g., Betadine Swabstick) and drape the eye with sterile quarter drapes and a top surgical drape.*

ANESTHETIC CONSIDERATIONS

General anesthesia is usually indicated when an eyelid surgery requires eyelid margin incisions, when placing sutures, or when using sharp objects such as scalpel blades or suture needles near the cornea. More precise suture placement can be performed when the small animal patient is still, rather than mobile. Although topical anesthetics and minimal sedation are commonly used for some ophthalmic procedures in human patients, the likelihood of unnecessary trauma to the eye is greater in veterinary patients when only these are used.

Preoperative sedatives such as a benzodiazepine with an opioid can be helpful in achieving quiet, struggle-free induction (Table 16.1). If possible, induce the animal in an area where monitors are immediately available after intubation. With ophthalmic patients, in addition to monitoring pulse oximetry, heart rate, respiratory rate, and electrocardiogram (ECG), it is also important to monitor blood pressure and end-tidal carbon dioxide ($EtCO_2$). Common monitoring techniques, such as evaluating palpebral reflex, ocular movements, or jaw tone, are more difficult because the head is draped and is often turned away from the person administering anesthesia. A pulse oximeter with an ear tip sensor that can be secured to the vulva, prepuce, or toes is helpful because repositioning a sensor on the tongue may be difficult once surgery has begun.

Eye and head movement during surgery can lead to iatrogenic eye injuries; therefore depth of anesthesia must be carefully monitored to reduce movement while preventing hypotension and hypoventilation. In addition, positive pressure ventilation may be needed throughout the procedure.

Monitoring heart rate and ECG is important during ophthalmic surgery because of the potential for initiation of the oculocardiac reflex.[1] This reflex consists of a trigeminal (V) afferent and a vagal (X) efferent pathway. Traction on extraocular muscles or pressure applied to the globe can cause asystole or a variety of cardiac arrhythmias, including severe bradycardia, ventricular fibrillation, premature ventricular contractions, and ventricular tachycardia. If this reflex occurs, manipulation of the eye must stop and pharmacologic treatment initiated. For asystole or bradycardia, atropine (0.02–0.04 mg/kg IV) or glycopyrrolate (0.01–0.02 mg/kg IV) should be given. Because atropine has a faster onset and an increased cardiac effect, it is the drug of choice in cases of severe bradycardia or sinus arrest

ABSTRACT

Ophthalmic surgery requires precision and a detailed knowledge of the anatomy of the eye and adjacent structures. Care should be taken to ensure that appropriate surgical instrumentation and suture material are available before any eye surgery is undertaken.

TABLE 16.1 Anesthetic Considerations in the Ophthalmic Patient

Preoperative Considerations

Associated conditions	• May be geriatric with comorbidities
Bloodwork	• Minimum PCV, TP, Cr, ALT but ideally CBC, chemistry panel • If patient >5 years old, CBC, chemistry panel ± UA • Consider cardiac workup if heart murmur is present
Physical examination	• May be painful at presentation depending on the cause • If trauma, stabilize and systemically evaluate

Premedications	• Anticholinergics (caution with cardiac disease, geriatric cats):
	  • Atropine (0.02–0.04 mg/kg IM, SC) *or*
	  • Glycopyrrolate (0.01 mg/kg IM, SC)
	• Anxiolytics:
	  • Diazepam (0.1–0.2 mg/kg IV), *or*
	  • Midazolam (0.1–0.2 mg/kg IM, IV)
	• Analgesics:
	  • Hydromorphone[a] (0.1–0.2 mg/kg IM in dogs; 0.05–0.1 mg/kg IM in cats), *or*
	  • Morphine (0.1–0.5 mg/kg IM, SC in dogs; 0.1 mg/kg IM, SC in cats), *or*
	  • Butorphanol (0.1–0.4 mg/kg IM, SC), *or*
	  • Oxymorphone (0.02–0.1 mg/kg IM) *or*
	  • Buprenorphine[b] (0.01–0.02 mg/kg IM in dogs, 0.005 mg/kg SC in cats or Simbadol 0.24 mg/kg SC qd for up to 3 d in cats)

Intraoperative Considerations

Induction	• Propofol (2–6 mg/kg IV), *or* • Alfaxalone (2–3 mg/kg IV in dogs; 2–5 mg/kg IV in cats) • Use caution with a face mask if the animal has a fragile eye
Maintenance	• Isoflurane or sevoflurane, *plus* • If needed for analgesia: fentanyl (loading dose 10–20 µg/kg plus infusion 0.6–10 µg/kg/min) IV CRI • If severe bradycardia or other dysrhythmias, give atropine (0.02–0.04 mg/kg IV) *or* glycopyrrolate (0.005–0.01 mg/kg IV)
Fluid needs	Crystalloids, 5–10 mL/kg per h
Monitoring	• Blood pressure • HR • Respiratory rate • ECG • $EtCO_2$ • SpO_2 • Temperature • Neuromuscular transmission via a peripheral nerve stimulator (also known as a *train-of-four monitor*) if an NMB agent was used Note: most likely there will be limited or no access to enable assessment of palpebral reflex or jaw tone
Blocks	• Orbital block after closing orbital septum: 0.5% bupivacaine (0.5–2 mg/kg in dogs; 0.2–0.5 mg/kg in cats) (max 2 mg/kg) (see p 152) • Topical analgesia such as proparacaine, tetracaine

Postoperative Considerations

Analgesia	• Oxymorphone (0.02–0.04 mg/kg IV, IM), *or* • Methadone (0.1–0.5 mg/kg IM, SQ q3–4h) *or* • Morphine (0.1–0.5 mg/kg IV or 0.1–2 mg/kg IM q1–4h in dogs[d]; 0.05–0.2 mg/kg IV or 0.1–0.5 mg/kg IM q1–4h in cats), *or* • Hydromorphone[a] (0.1–0.5 mg/kg IV or 0.1–1 mg/kg IM, SC q2-4h in dogs; 0.05–0.1 mg/kg IV or 0.1–0.2 mg/kg IM, SC q2-4h in cats), *or* • Buprenorphine[b] (0.01–0.02 mg/kg IV, IM, SC q4–6h), *plus* • Carprofen (2.2 mg/kg PO, IM q12h in dogs), *or* • Robenacoxib (2 mg/kg PO, SC q24h for 3 doses [extralabel] in dogs; 1–2 mg/kg SC q24h for 3 doses in cats), *or* • Meloxicam[c] (0.1–0.2 mg/kg once SC or PO, then 0.1 mg/kg PO q24h in dogs; 0.3 mg/kg SC once in cats)
Monitoring	• SpO_2 • Blood pressure • HR • Respiratory rate and effort, particularly if NMBs were used • Temperature
Bloodwork	• Usually not needed unless the patient has diabetes mellitus
Estimated pain score	• Can be mild to severe depending on cause and/or procedure

ALT, Alanine aminotransferase; *BUN,* blood urea nitrogen; CBC, complete blood count; *Cr,* creatinine; *ECG,* electrocardiogram; *EBL,* estimated blood loss; *$EtCO_2$,* end-tidal CO_2; *HCT,* hematocrit; *HR,* heart rate; *IM,* intramuscular; *IOP,* intraocular pressure; *IV,* intravenous; *NMB,* neuromuscular blocker; *OTM,* oral transmucosal; *PCV,* packed cell volume; *PO,* orally; *PRN,* as needed; *SC,* subcutaneous; *SpO_2,* oxygen saturation via a pulse oximeter; *TP,* total protein; *UA,* urinalysis.

[a]Monitor for hyperthermia in cats.

[b]Buprenorphine is a better analgesic than morphine in cats.

[c]Black box warning added by the Food and Drug Administration in October 2010 identified cases of renal failure and death in cats with repeated uses of meloxicam. Meloxicam is approved for single use only in cats in the United States.

[d]Give slowly to prevent histamine release.

(see Chapter 12). Premedication with glycopyrrolate or atropine (see Table 16.1) can reduce or prevent this reflex but they should be used with caution in animals with cardiac disease or geriatric feline patients who may not tolerate tachycardia. In these cases, having glycopyrrolate or atropine available in the operating room with the appropriate dose already calculated, so that it may be given rapidly IV if necessary, is recommended.

For eyelid surgeries, induction, intubation, and anesthetic maintenance can be done as for other soft tissue surgeries. Because tear production decreases substantially during general anesthesia, the eyes should be lubricated at least every 2 hours. Reduced tear production may persist for 24 hours postoperatively; therefore continued application of a topical lubricant such as ophthalmic ointment for 1 to 2 days postoperatively should be considered.[2] In addition, ensure that there is no pressure on the opposite eye if the patient is in lateral recumbency.

Whenever possible, extubation and anesthetic recovery need to be done in a quiet environment to avoid head banging that can cause eyelid bleeding and swelling. Because of their sedating and analgesic effects, opioids are helpful in the postoperative period. Low-dose acepromazine (0.005–0.01 mg/kg IV) will enhance the sedative effects of the opioid and may be useful if the patient is dysphoric during recovery (see Chapter 12 and Table 12.1).

ANTIBIOTICS

Perioperative antibiotics are indicated for eyelid surgery because the normal flora of ocular surfaces and eyelids include potential pathogens. Systemic antibiotics should be administered before surgery so that therapeutic blood levels will be achieved by the time of surgery (see Chapter 9). Broad-spectrum topical antibiotics are most commonly chosen for perioperative prophylaxis (Box 16.1), and systemic antibiotics (e.g., IV cefazolin) are typically given preoperatively. If eyelid surgery is extensive, skin infection is present, or tissue is already damaged, systemic antibiotics may be indicated postoperatively for 10 to 14 days.

The most commonly used prophylactic topical antibiotic for dogs is neomycin/polymyxin/bacitracin and for cats is erythromycin or oxytetracycline (see Box 16.1). Cats very rarely have an anaphylactic reaction on their first exposure to neomycin or polymyxin; ideally those medications should therefore not be given for the first time to an anesthetized cat.

BOX 16.1 Examples of Prophylactic and Therapeutic Antibiotics for Eye Surgery

Oral

Amoxicillin, 22 mg/kg PO BID
Cephalexin, 30 mg/kg PO BID to TID
Cefpodoxime, 5–10 mg/kg PO SID

Topical Broad-Spectrum Antibiotics

Neomycin-polymyxin-bacitracin, 0.25 inch (0.6 cm) QID
Neomycin-polymyxin-gramicidin, 1 drop QID
Erythromycin, 0.25 inch (0.6 cm) QID
Oxytetracycline, 0.25 inch (0.6 cm) QID

Topical Gram-Positive Spectrum Antibiotics for Infected Corneal Ulcers

- Cefazolin 5% eye drops made from a 1 g vial of IV injectable cefazolin to be used 1 drop q1–2h initially. Note: the solution must be **refrigerated**; with the injectable it is made from, it expires in 10 days. Use sterile syringes, needles, and containers. To formulate in artificial tears and LRS: remove 3 mL from a 15 mL bottle of artificial tears solution (e.g., Tears Again drops) and add to 1 g injectable cefazolin bottle. Then add 2 mL of LRS to the cefazolin bottle. Reconstitute the cefazolin and mix well. Remove 4 mL of the cefazolin solution and add it back to the 15 mL bottle of artificial tears and mix well. Note: do not use artificial tears with glycerin or viscous tears; use only liquid artificial tears.
- *LRS:* Reconstitute 1 g vial of cefazolin in 10 mL of LRS to make a 100 mg/mL solution. Dilute the solution 1:1 in a sterile container (e.g., red top tube with no additive) with LRS; e.g., for a 3 mL red top tube, draw up 1.5 mL of 100 mg/mL cefazolin solution and add to the red top then add 1.5 mL of LRS to the red top and mix well. Use a needle and syringe to draw up the medication; remove the needle to place a drop of the solution on the eye.
- Moxifloxacin (Vigamox), 1 drop q1–2h initially
- Gatifloxacin, 1 drop q1–2h initially

Topical Gram-Negative Spectrum Antibiotics for Infected Corneal Ulcers

Ciprofloxacin, 1 drop q1–2h initially
Ofloxacin, 1 drop q1–2h initially
Gentamicin 0.9%, 1 drop q1–2h initially
- Can fortify by adding 0.33 mL of 100 mg/mL gentamicin to every 5 mL of 0.3% gentamicin ophthalmic solution

Tobramycin, 1 drop q1–2h initially

BID, Twice daily; *IV,* intravenous; *LRS,* lactated Ringer's solution; *PO,* orally; *QID,* four times daily; *SID,* once daily; *TID,* three times daily.

SURGICAL ANATOMY

The eyelids and orbit house and protect the eye (Fig. 16.1). Eyelids are mobile folds of skin that block light and protect the cornea. The upper lid is slightly larger and more mobile than the lower lid. Upper and lower lids join at the *medial and lateral canthi* (see Fig. 16.1) and are stabilized by the medial and lateral palpebral ligaments. The width of the opening between the lids is controlled by opposing groups of muscles; the orbicularis oculi muscle closes the palpebral fissure, whereas the fissure is widened by the levator palpebrae superioris, levator anguli oculi medialis, and smooth muscles of the periorbita. The upper and lower *nasolacrimal puncta* (see Fig. 16.1), which drain excess tears from the ocular surface to the nose and pharynx via the nasolacrimal duct, are located just posterior to the eyelid margin, approximately 2 to 5 mm from the medial canthus. The eyelids close like a zipper from lateral to medial to move tears toward the nasolacrimal puncta. The medial canthus (inner corner of the eyelids) has the *lacrimal caruncle* that projects small fine hairs, has sebaceous glands, and may be pigmented.

The eyelid margins of dogs and cats are typically devoid of hairs. The upper eyelid skin has long *cilia* projecting from the upper lateral eyelid skin just above the eyelid margin; the lower lid is devoid of cilia (see Fig. 16.1). Long tactile hairs arise from a caruncle dorsomedial to each eye and correspond to human eyebrows. The eyelid margin is a mucocutaneous junction where the conjunctiva meets skin.

The eyelid margins are lined with a row of *meibomian glands* that secrete the oil component of the tear film that helps prevent tear film evaporation (see Fig. 16.1). The meibomian glands are visible through the palpebral conjunctiva at the eyelid margin and contain white infiltrate when diseased. The meibomian gland openings look like a row of small gray dots along the eyelid margin.

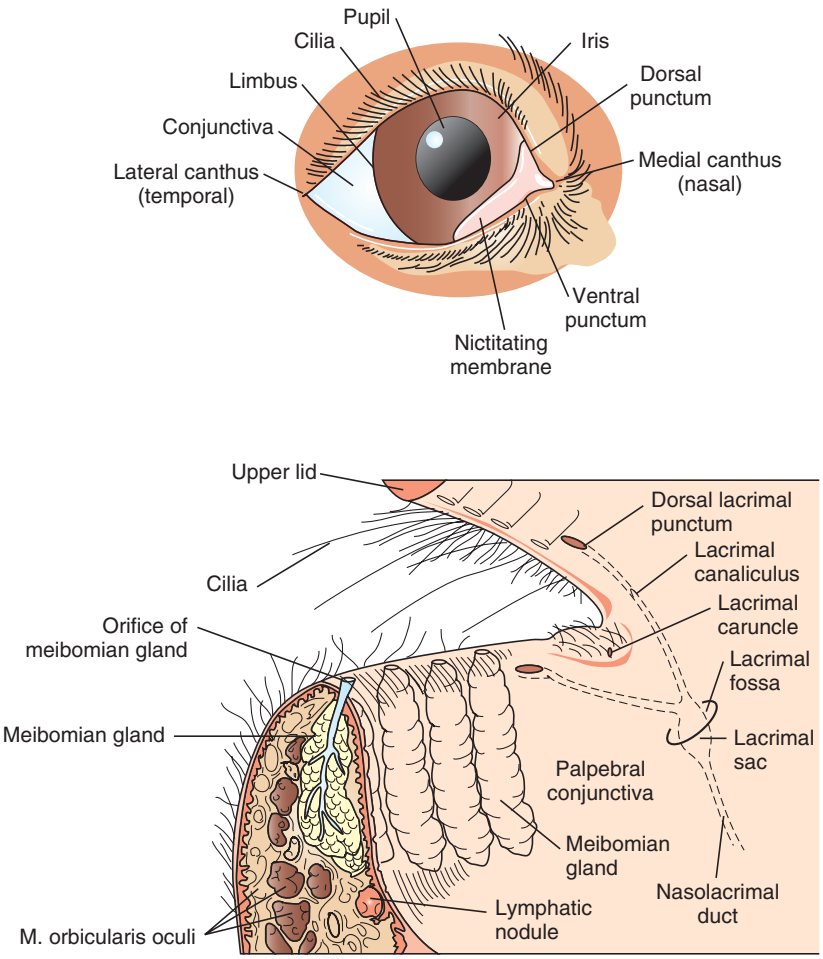

FIG. 16.1 Periocular and eyelid (as viewed from the inside) anatomy.

SURGICAL TECHNIQUES

Eyelid surgery involves handling small amounts of tissue; precision and delicacy are required. Sutures should always be placed partial thickness in the skin, and sutures and knots should always be placed such that they do not contact the cornea.

Temporary Tarsorrhaphy

A temporary tarsorrhaphy is indicated for patients who cannot blink or have traumatic proptosis. This procedure is also used after some eyelid surgeries to reduce tension on the surgery site and to help reduce wound contracture during healing or for temporary treatment of exophthalmos with excessive corneal exposure. A temporary tarsorrhaphy should be avoided for deep corneal ulcers, corneal lacerations, corneal perforations, or any ocular disease not involving excessive corneal exposure because this procedure will not assist healing and it prevents visualization of the diseased area.

Place horizontal mattress sutures at the eyelid margins with 4-0 silk to appose the eyelids, using partial-thickness bites oriented perpendicular to the lid margin (Fig. 16.2). Tie the suture knots snugly because loose sutures could contact the cornea. Stents may be used if needed to reduce pressure of the suture on the lids.

The owner should monitor the animal for a dramatic increase in eye discharge or pain after a tarsorrhaphy has been placed. If this is seen, the sutures should be removed immediately and the eye reevaluated. Uncomplicated tarsorrhaphy sutures should be removed in 14 days, or sooner if they loosen. If the tarsorrhaphy sutures become loose and are not immediately removed they can traumatize the cornea, leading to corneal ulcers.

HEALING OF THE EYELID

The eyelid heals similar to any other skin. Because the eyelids are exposed to more moisture than other skin, moist dermatitis may occur more commonly than at other sites.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

For eyelid surgery, a "soft" suture such as polyglactin 910 (absorbable) or silk (nonabsorbable) should be used. Polyglactin 910 can be left to dissolve, or the sutures can be removed. Being nonabsorbable, silk should be removed after the incision is healed because reaction to silk suture material will eventually develop. For the eyelid margin, suture size should be 5-0; for eyelid skin away from the margin, it should be 3-0 to 5-0. Suture should have a curved, swaged on fine, reverse cutting needle (Box 16.2). Stiffer sutures (polydioxanone, nylon) should be avoided because they can cause tissue distortion and become a hazard to the cornea if they loosen or shift in position.

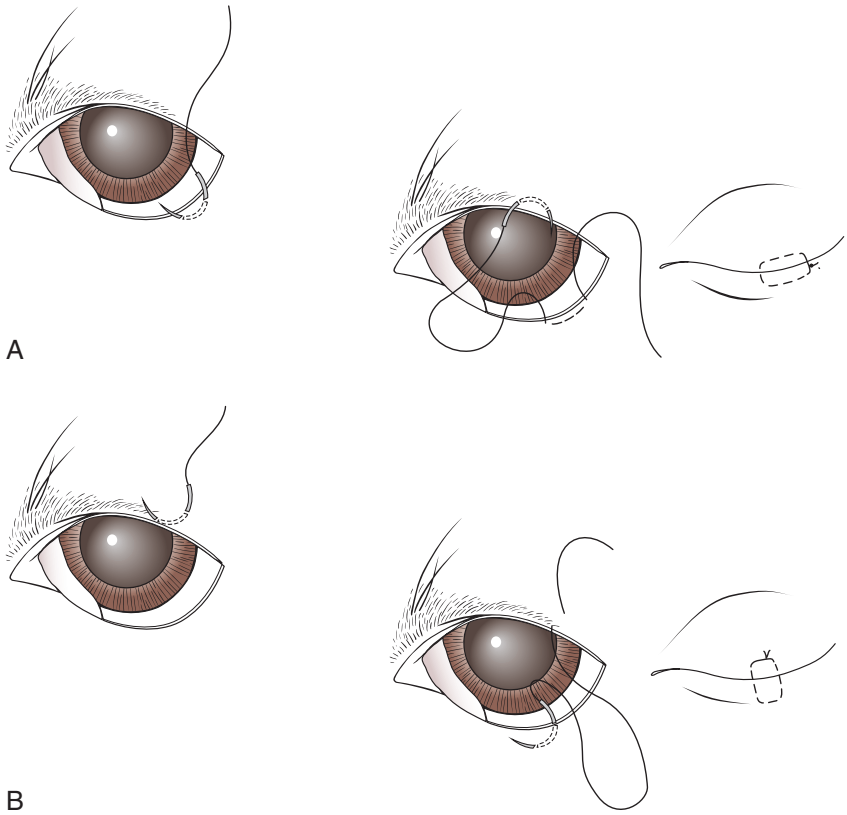

FIG. 16.2 Temporary tarsorrhaphy achieved by orienting horizontal mattress suture (A) parallel or (B) perpendicular to the eyelid margin. Sutures do not penetrate the full thickness of the eyelid.

BOX 16.2 Examples of Specialized Instruments and Materials Needed for Eye Surgeries

Eyelid Surgery

4-0 to 5-0 polyglactin 910 suture, 4-0 silk, or staples, depending on procedure; tissue glue for eyelid tacking
Baby Jones or other towel clamps (4)
Jaeger lid plate
Derf or Pars needle holders
0.8 mm Bishop-Harmon or Brown-Adson forceps
Iris or ocular scissors
Optional: chalazion clamp, Bard-Parker blade handle, and No. 15 blade for eyelid mass resection, mosquito hemostats
Optional: Allis tissue forceps for single lid Hotz-Celsus procedure
Optional: stent material such as sterile IV tubing or holed button

Cherry Eye

5-0 or 6-0 polyglactin 910 suture
Baby Jones or other towel clamps (4 or 6)
Castroviejo or Barraquer curved tip needle holders
Microsurgical forceps such as Colibri 0.3 mm with a tying platform
Bishop-Harmon forceps 0.8 mm
Iris or ocular scissors

Conjunctival Graft

6-0 polyglactin 910 suture
Baby Jones or other towel clamps (4)
Barraquer or Castroviejo eyelid speculum
Stevens tenotomy scissors
Colibri forceps 0.3 mm with a tying platform (2)
Barraquer or Castroviejo needle holders
Iris scissors
Bishop-Harmon forceps 0.8 mm
Magnification

Proptosis

4-0 nylon or silk suture
4-0 or 5-0 polyglactin 910 suture
Mayo scissors
Derf needle holder
Brown-Adson or Bishop-Harmon 0.8 mm forceps
Mosquito hemostats
Jaeger lid plate, smooth blade handle, or other material to help push globe back atraumatically
Iris or other scissors for suture cutting
Optional: stent material

Enucleation

2-0, 3-0, or 4-0 PDS for the orbital septum
2-0, 3-0, or 4-0 polyglactin 910 for the subcutaneous tissue and skin
Towel clamps (4)
Optional Allis tissue forceps
Brown-Adson forceps
Bard-Parker blade and No. 15 scalpel blade
Short curved Metzenbaum scissors
Mayo scissors
Sharp curved enucleation scissors
Curved mosquito or Crile forceps
Large hemoclips
Derf or other small needle holder
Optional: cautery and suction
Optional: silicone orbital implant

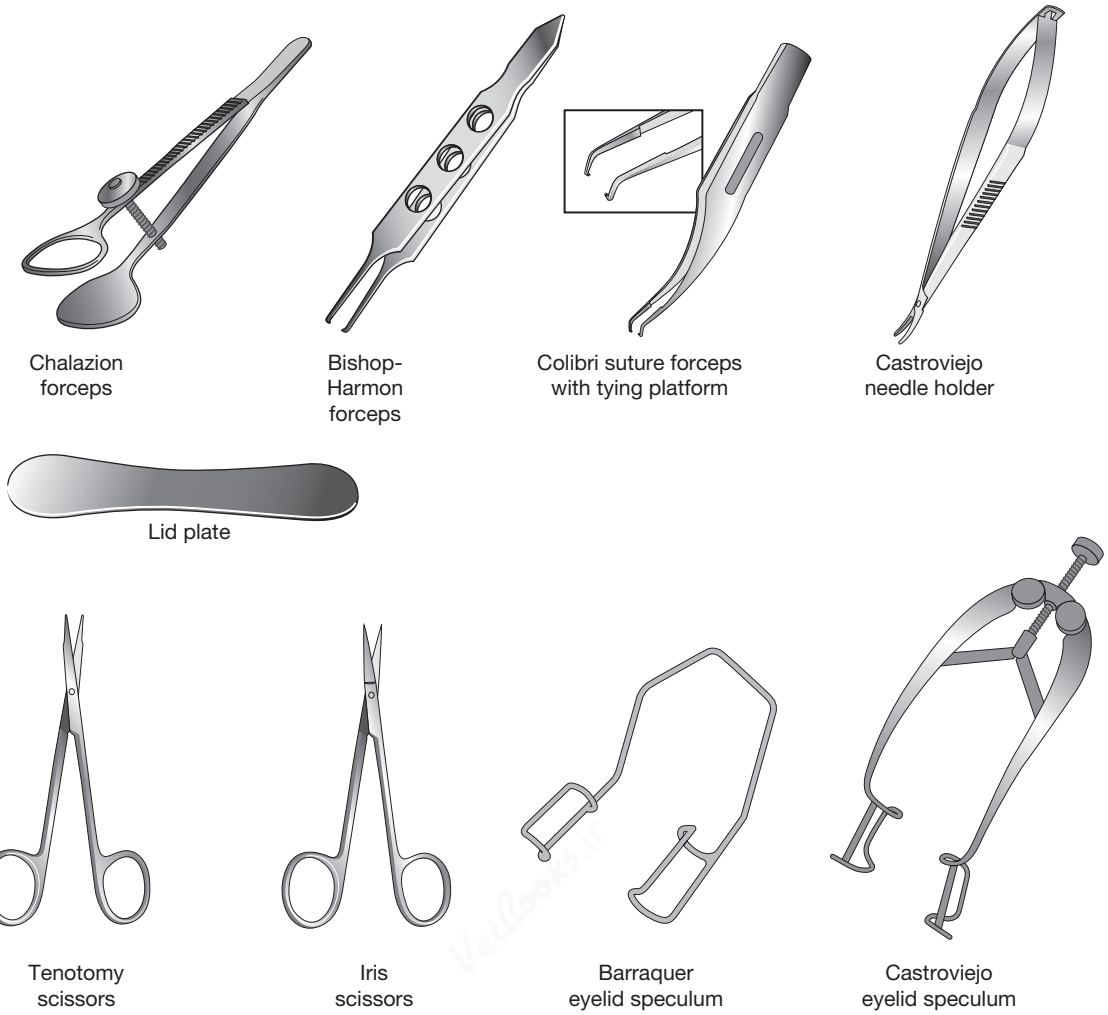

FIG. 16.3 Ophthalmic surgical instruments (not to scale).

Ophthalmic surgery instruments (see Box 16.2) should include 0.8 mm Bishop-Harmon forceps for handling eyelid tissue. Use Derf or Pars needle holders and small ocular or iris scissors to handle and cut 5-0 suture. An autoclavable Jaeger lid plate or chalazion clamp will also provide tissue support and protection to the cornea during eyelid surgery. Chalazion clamps have a solid rounded plate and an open ring that clamp together when compressed (Fig. 16.3). When the chalazion forceps is closed, pressure is applied to tissues under the ring edges, causing a temporary blockage of bleeding to the surgery site. Bleeding should be treated with direct pressure; sterile cotton swabs allow for precise but gentle wiping to allow visualization of the surgery site. A handheld battery-operated Medline or Bovie Medical cautery pen can also be used for surface hemorrhage.

POSTOPERATIVE CARE AND ASSESSMENT

After surgery, the eyelid and facial skin incisions should be protected with a rigid plastic Elizabethan collar (E-collar) that extends just beyond the animal's nose when the head is fully extended. Patients can compromise the surgery site if they traumatize their surgical incisions, which sometimes necessitates additional surgery. Patients usually rub their eyes on objects or the floor, so a properly sized rigid E-collar is more effective than eye patches, inflatable neck collars, or soft E-collars.

NOTE Soft E-collars, rigid neck restraints (e.g., Bite Not collar), and inflatable neck restraints allow the patient to rub the eyes against objects, so they are not effective protection.

Medical therapy after surgery consists of topical prophylactic antibiotics (see Box 16.1) four times daily, oral antibiotics for extensive surgeries, antiinflammatories, and analgesics. Administering medications four times daily can be difficult, but a typical regimen is for the owner to medicate the animal when they wake up, leave the house, get home, and before they go to bed. Mucoid discharge from the eyes can be normal in the initial period after surgery and is typically caused by postoperative conjunctivitis.

Owners should monitor for increased swelling, redness, or discharge from the incision in addition to pruritus, blepharospasm, epiphora, or pain. At the postoperative exam, the cornea should be checked for ulceration, vascularization, or signs of topical irritation. If an incision infection occurs, consider culture, sensitivity, and systemic antibiotics.

COMPLICATIONS

Eyelid margin imperfections and notches can adversely affect the even distribution of the tear film over the cornea. The incision can dehisce from infection or be disrupted by the patient. Poor eyelid alignment and inappropriate tissue tension may cause entropion, ectropion, or a distorted eyelid, and hair contact from these areas can lead to corneal ulceration, vascularization, granulation, or pigmentation. Sutures rubbing against the cornea can cause ulceration, necessitating suture replacement or removal.

Epiphora may occur if the nasolacrimal puncta or duct is injured. Hypersensitivity to topical neomycin or polymyxin can cause severe eyelid swelling, pruritus, and chemosis (conjunctival edema) or, very rarely, anaphylaxis in cats.

SPECIAL AGE CONSIDERATIONS

Younger animals are more prone to trauma or problems from conformation such as entropion, but they heal faster than older animals.

SPECIFIC DISEASES

EYELID LACERATION

DEFINITIONS

Eyelid laceration is a partial or full-thickness cut on the eyelid.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Eyelid lacerations are caused by trauma such as bite wounds or contact with a sharp object. They should be repaired as soon as possible to protect the cornea and maintain an effective blink response. Healing of lid lacerations by secondary intention can cause eyelid fibrosis and distortion that can secondarily cause corneal scarring, pain, and corneal exposure. Direct reapposition of wound ends is possible if one-third or less of the lid margin is missing. More extensive injuries require advancement flaps or grafts for repair. Preservation of the maximum amount of eyelid margin is essential for normal eyelid function. Even very narrow flaps of eyelid should be replaced rather than excised if they appear to be viable (Fig. 16.4). If the distal tissue does not survive, the eyelid margin may need to be reconstructed if greater than one-third of the eyelid margin is lost.

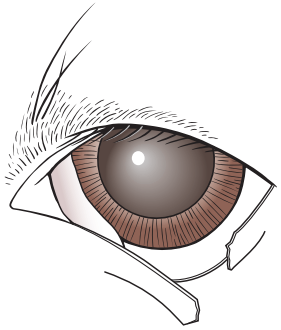

FIG. 16.4 Eyelid laceration involving the lid margin. Preserve even thin strips of tissue to avoid lid margin reconstruction.

DIAGNOSIS

Clinical Presentation

Signalment

Eyelid lacerations can occur at any age and in any breed but are more common in young, active animals.

History

Bleeding, swelling, or a distorted eyelid may be observed. Copious bleeding may be seen at the time of initial injury, but often stops quickly.

Physical Examination Findings

The eyelid margin will look irregular with a full-thickness laceration. Eyelid swelling can be considerable and thus distorting. A strip of tissue at the margin may have been torn away from the rest of the eyelid. Check the cornea, the third eyelid, inside the globe, on the head, and body for other signs of injury.

DIFFERENTIAL DIAGNOSIS

Eyelid distortion from skin disease, scarring, or ulcerative neoplasms could look similar.

MEDICAL MANAGEMENT

Topical and oral antibiotics should be initiated as for other skin injuries after an eyelid laceration. If the cornea is not being covered completely by the eyelids during blinking, lubrication of the cornea is indicated.

SURGICAL TREATMENT

Surgery is indicated when the eyelid margin is affected, incomplete corneal coverage by the eyelids is seen during blinking, or the eyelid defect is large. For eyelid lacerations involving the nasolacrimal duct, or potentially complicated eyelid repairs, referral to a veterinary ophthalmologist is recommended.

Preoperative Management

Initiate treatment for skin contamination or infection before surgery. If the laceration is less than one-third of the eyelid margin length and is still bleeding, fresh, and recent (few hours), then primary closure may be possible. If the laceration is older, the edges of the lacerated tissue will need to be debrided. Keep the cornea lubricated if compromised lid function causes corneal exposure.

Anesthesia

General anesthesia is required due to the precise eyelid margin alignment needed (see pp. 266–268).

Surgical Anatomy

See Fig. 16.1.

Positioning

Position the animal in ventral recumbency with a towel roll under the chin to hold the head up.

SURGICAL TECHNIQUES

After clipping the hair, thoroughly irrigate and gently cleanse the wound with a 5% povidone-iodine solution. Identify the eyelid

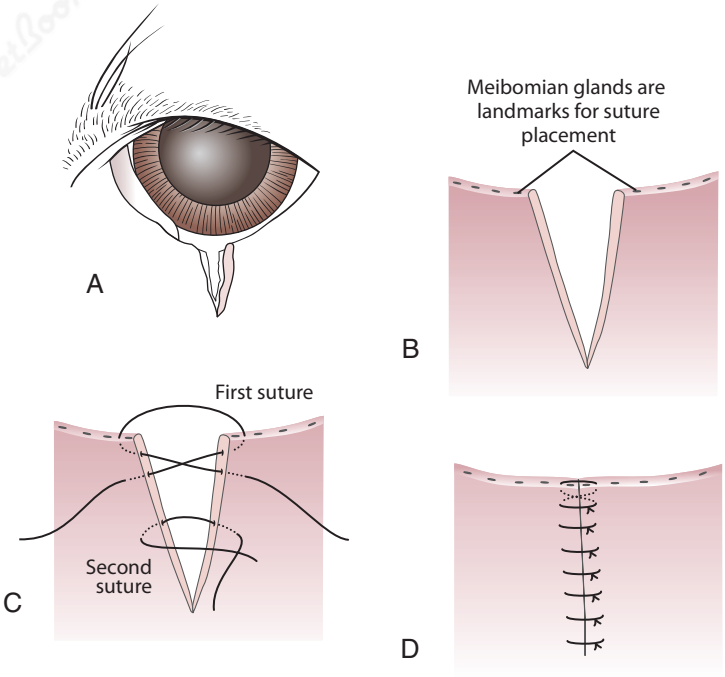

FIG. 16.5 Eyelid laceration. (A) Take care to preserve as much eyelid margin as possible. (B) Align and close the eyelid margin first. Use the meibomian gland openings to guide eyelid margin alignment. (C) Use a partial-thickness modified figure-eight cruciate to align the eyelid margin. Place the second suture in the middle of the laceration site to align the skin. (D) Taking care to place skin sutures at partial thickness, close the skin and align it using a simple interrupted pattern. Place sutures approximately 3 to 5 mm apart.

margin, the meibomian glands openings along the edge of the eyelid margin (see Figs. 16.1 and 16.5B), and the palpebral conjunctiva. For older lacerations, debride the edges in a narrow strip no more than 1-mm wide with iris scissors to freshen the skin edges before closure. Take care to preserve as much eyelid margin as possible (Fig. 16.5A). Align and close the eyelid margin first, ensuring that the lid margin has perfect alignment. Correctly placed sutures on the eyelid margin will be placed along the line of meibomian gland openings (Fig. 16.5B). *Use a partial-thickness modified figure-eight cruciate or simple interrupted suture pattern with 5-0 or 4-0 polyglactin 910 to align the eyelid margin (Fig. 16.5C). Taking care to place skin sutures partial thickness, close the skin and aligne it with a simple interrupted pattern. Place sutures approximately 3 to 5 mm apart, and direct the suture and knot ends away from the cornea (Fig. 16.5D).* When the surgery is complete, the inside of the eyelid should have no visible suture, leaving the conjunctival tissue to heal on its own, and no suture should be touching the cornea.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Surgical instruments and suture should be used as described in the General Principles on pp. 269–271.

POSTOPERATIVE CARE AND ASSESSMENT

A complete temporary tarsorrhaphy may be indicated to protect the cornea after repair of extensive eyelid injuries because of impaired eyelid function and blink reflex. Suture placement should be reevaluated after the patient is awake and periodically after surgery to ensure no corneal contact with sutures.

COMPLICATIONS

Complications of surgery, in addition to the general principles listed previously, include necrosis of eyelid tissue. Corneal disease will occur if there is poor lid conformation and function. Sutures can be removed after 14 days.

PROGNOSIS

If eyelid laceration repairs are done shortly after the trauma, lid margin restoration is good, and the tissue destruction was minimal, the prognosis can be excellent for long-term eyelid function. If the laceration was chronic or extensive tissue damage was present, the prognosis can be guarded to good.

NEOPLASTIC EYELID MASS

DEFINITIONS

Meibomian glands are the oil glands that line the eyelid margins.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Eyelid masses, even if benign, can create ongoing trauma to the cornea, necessitating surgical mass removal. Eyelid masses can cause corneal trauma and discomfort, interfere with eyelid function, and cause keratitis. Chronic eyelid masses are usually less urgent if they are slowly progressive or are small. Eyelid neoplasms in dogs are most often associated with the meibomian glands (see Figs. 16.1 and 16.5B), and 70% to 80% are benign. Sebaceous adenomas and epitheliomas are the most common eyelid tumor in dogs; they sometimes grow rapidly. Malignant eyelid tumors are less common and include squamous cell carcinoma, sebaceous adenocarcinoma, basal cell carcinoma, and fibrosarcoma. Of the eyelid melanomas, approximately 60% are benign and 40% are malignant.

In cats, eyelid neoplasms tend to be malignant, and squamous cell carcinomas (~60% of cases) are the most common. Others include fibrosarcoma, adenocarcinoma, basal cell carcinoma, melanoma, and hemangiosarcoma.

DIAGNOSIS

Clinical Presentation

Signalment

The average age of dogs presenting with eyelid neoplasia is 8 years, whereas cats are on average 10 years old. Beagles, Siberian huskies, English setters, toy and miniature poodles, and Labrador and golden retrievers have an increased prevalence for eyelid tumors.

History

Eyelid masses are grossly visible and can develop slowly or rapidly. Clinical symptoms include ocular discharge, blepharospasm, hemorrhage, and topical irritation. Some animals rub at the eye but many are not bothered by the mass.

Physical Examination Findings

In affected animals a mass can be visualized or palpated on the eyelid, eyelid margin, or conjunctiva. Evert the eyelid and inspect the underside of the lid to see if the mass extends into the meibomian glands along the eyelid margin (Fig. 16.6). Multiple eyelid masses may be of the same or different types. Approximately 10% of malignant canine lid tumors are locally invasive. Ophthalmic examination may show secondary corneal ulcers, keratitis (corneal blood vessels), or corneal melanosis (pigmentation). In severe cases, periocular excoriations, skin ulceration, or bleeding from the skin may be present.

Laboratory Findings

If large enough, an eyelid mass may be aspirated for cytology; an eyelid plate, scalpel handle, or sterile tongue depressor should be placed between the needle and the eye. Aspiration of enlarged local lymph nodes may also be considered. Eyelid tumors can be associated with secondary infections; therefore culture and sensitivity and treatment with appropriate antibiotics may be considered before surgery to shrink the diseased area if infection is suspected. Histopathologic examination of all excised masses should be performed for a definitive diagnosis and to check surgical margins.

DIFFERENTIAL DIAGNOSIS

Differentials include inflammatory lesions such as chalazion or meibomian gland disease, fungal granulomas from histoplasmosis, eyelid cysts, and cicatricial distortion.

MEDICAL MANAGEMENT

Chemotherapy, radiation therapy, cryotherapy, or photodynamic therapy may be used in combination with or as an adjunct to surgical treatment. In particular, squamous cell carcinoma may be treated with beta-irradiation using a strontium-90 probe.

SURGICAL TREATMENT

Eyelid tumors that are progressively enlarging, contacting the cornea, or causing clinical symptoms should be excised. If less than one-third of the eyelid margin is involved, primary closure may be used after mass excision. Mast cell tumors requiring wide 0.5 cm margins or masses involving more than one-third of the eyelid margin length should be referred to a veterinary ophthalmologist for reconstructive surgery. More eyelid length may be able to be resected in some breeds, such as cocker spaniels, that have excessive eyelid length. Breeds with short, tight-fitting eyelid fissures such as miniature poodles or cats may have less than the expected amounts of resectable lid, making dehiscence, visible lid shortening, reduced palpebral fissure size, facial asymmetry/disfigurement, and epiphora more likely.

Preoperative Management

Treat eyelid infections or conjunctivitis if needed before surgery. Estimate the amount of tissue to be removed before anesthetizing the animal.

Anesthesia

If the patient has metastatic neoplasia involving the lungs or liver, special precautions are necessary when anesthetizing them; however, general anesthesia is usually necessary due to the precision required to perform this surgery.

Surgical Anatomy

Many meibomian adenomas extend proximally and may be more visible from the underside of the eyelid, so this area should always be inspected before starting surgery (Figs. 16.1 and 16.6; also see p. 268).

Positioning

Ventral or lateral recumbency provides the best access for eyelid surgery. In ventral recumbency, elevate the chin on a towel roll to improve the airway and head positioning.

FIG. 16.6 (A) Eyelid mass not visible from the outside of the eyelid. (B) Eyelid mass visible from the underside of the eyelid.

SURGICAL TECHNIQUES

Primary Mass Removal and Closure

Full-thickness eyelid excisions are usually needed to remove the eyelid mass completely.

Stabilize the lid and provide support with a lid plate or chalazion clamp (Fig. 16.7A). If a lid plate or chalazion clamp is not available, use a sterile tongue depressor to support and stabilize the lid. Ensure that the planned excision area involves less than one-third of the eyelid margin length. Using a No. 15 Bard-Parker blade, make a V or house-shaped incision around the mass with a 1 to 2 mm grossly visible margin. Cut any conjunctiva with iris or tenotomy scissors to fully loosen and remove the mass (Fig. 16.7B). Control hemorrhage with direct pressure or a battery operated handheld cautery pen. Align and close the eyelid margin and skin first, ensuring that the lid margin has perfect alignment (Fig. 16.7C, inset). The line of punctate meibomian gland openings along the eyelid margin can be used as a landmark to place the eyelid margin sutures in the correct position. *Use a partial-thickness modified figure-eight cruciate (Fig. 16.7C) or simple interrupted suture pattern with 5-0 polyglactin 910 to align the eyelid margin. While taking care to place skin sutures at partial thickness, close and align the skin using a single-layer simple interrupted pattern.[3] Put the second suture in the middle of the incision to bring the cut skin edges margins together and space remaining skin sutures approximately 2 to 4 mm apart. Direct suture knot ends away from the cornea.* When the surgery is complete, the inside of the eyelid should have no visible suture (Fig. 16.7D) and no suture should be touching the cornea anywhere along the incision.

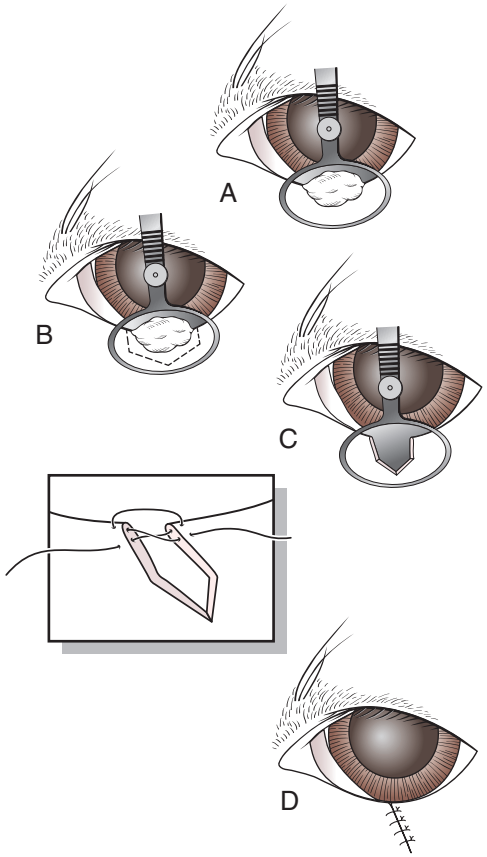

FIG. 16.7 Eyelid mass resection. (A) Stabilize the lid and provide hemostasis with a lid plate or chalazion clamp. (B) Make a V or a house-shaped incision around tumors involving less than one-third of the eyelid margin. (C) Align the eyelid margin first with a figure-eight modified cruciate suture. (D) Close the remaining skin partial thickness in a simple interrupted pattern with skin sutures 2 to 4 mm apart.

NOTE The suture at the eyelid margin is the most critical for eyelid alignment and to reduce the likelihood that a notch will develop.

Small (<3 mm) pedunculated conjunctival masses that do not involve deeper tissues may be removable with only a topical anesthetic in a still patient. Deeply attached or extensive conjunctival mass removals require general anesthesia.

Expose masses arising from the conjunctiva by everting the lid with a chalazion clamp. Excise the mass with the conjunctiva surrounding the mass using tenotomy scissors, then allow the palpebral conjunctival defect to heal by secondary intention.

Masses involving more than one-third of the eyelid margin length require advancement flaps for reconstruction, and referral to a veterinary ophthalmologist is recommended. If referral is not possible, an H-plasty skin advancement or semicircular graft may be considered to reconstruct the eyelid when more than one-third of the eyelid margin was removed.

H-plasty Pedicle Advancement Flap

AP An H-plasty advancement flap should only be performed on the lower eyelid, should not be performed on the upper eyelid, and is more appropriate for masses away from the canthi.

After resecting the mass with parallel incisions perpendicular to the lid margin, create a single-pedicle advancement flap by extending these incisions away from the eyelid margin (Fig. 16.8A). Make the length of the advancement flap 1 to 2 mm longer than the defect left from the mass removal. Excise small triangular sections of skin on either end of the distal incision (Fig. 16.8B). Advance the flap to the lid margin, align it carefully with the remaining lid, and suture it with 5-0 polyglactin 910 into place with a figure-eight suture pattern (Fig. 16.8C) at the eyelid margin. Suture the rest of the graft skin to the adjacent skin using 4-0 to 5-0 absorbable polyglactin 910 (Fig. 16.8D). Remove the external haired dermis from distal edge of the graft to create a hairless area in the area closest to the cornea.

Semicircular Flap

AP A semicircular incision at the lateral canthus may be used to advance the lateral skin into a defect on the upper or lower lateral eyelid; it is therefore most appropriate for large, laterally located eyelid lesions.

Excise and remove the eyelid mass (Fig. 16.9A). Following the curvature of the lateral eyelid, make a lateral semicircular skin incision where the length of the curve is approximately twice the length of the excised portion of the eyelid, with the peak/trough of the curve in the center of the incision (Fig. 16.9A). Excise a triangular area of skin at the lateral incision to remove the dog ear formed when the graft is slid into the defect (Fig. 16.9B). Slide the skin graft medially into the eyelid defect and align the eyelid margin with the skin graft with a figure-eight modified cruciate suture (Figs. 16.9B–D). Next, align the peak/trough of the semicircular skin graft to the lateral canthus with another figure-eight modified cruciate suture (see Fig. 16.7D). Close the skin with simple interrupted

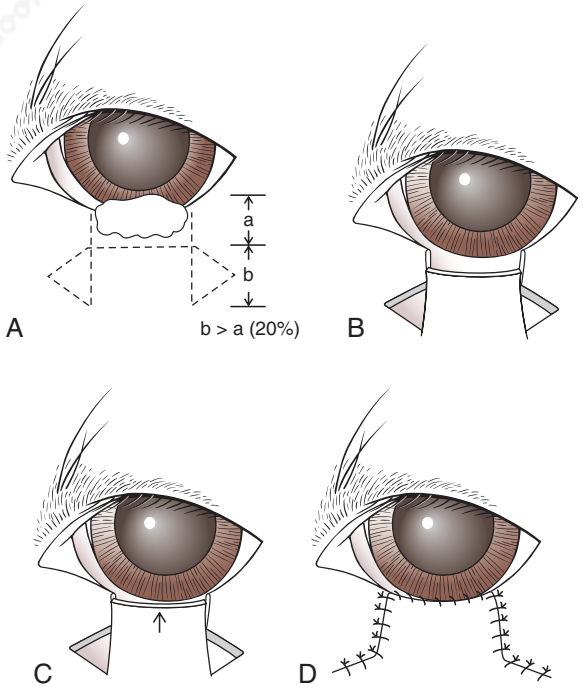

FIG. 16.8 H-plasty to reconstruct the lower eyelid margin after more than one-third of the eyelid margin length was removed. (A) Resect the mass with a rectangular incision, including 2-mm margins of normal skin. Create an advancement flap by extending proximally the medial and lateral incisions. (B) Remove triangles of tissue on each side of the flap to prevent dog ears. Undermine and mobilize the conjunctiva. (C) Advance the flap to the lid margin, aligning it carefully. (D) Suture conjunctiva and skin at the new lid margin with a simple continuous pattern, and try to align so no growing hairs will touch the eye. Place interrupted sutures to appose the remaining incision.

sutures (4-0 to 5-0 absorbable polyglactin 910; Fig. 16.9E). Along the lateral free skin graft margin, remove a narrow 2- to 3-mm margin of superficial haired dermis, taking care to preserve the deeper skin graft tissue. The goal is to create a hairless skin margin to try to reduce trichiasis.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Surgical instruments and suture should be used as described previously in the General Principles, pp. 269–272. Sliding eyelid grafts should be ideally lined by conjunctiva; microsurgical techniques are needed for conjunctival tissue handling, so these surgeries are best referred to a veterinary ophthalmologist.

POSTOPERATIVE CARE AND ASSESSMENT

In addition to the eyelid General Principles on p. 271, expect postoperative eyelid swelling that should resolve in 2 to 4 weeks. Apply first cold and then later warm compresses to reduce eyelid swelling and promote circulation if major reconstruction or grafts were used. Reserve assessment of the repair for 2 to 4 weeks, when swelling subsides. Remove the sutures after 14 days when the skin is healed. Maintain the E-collar for 2 to 3 days after suture removal if the animal wants to scratch at the site.

COMPLICATIONS

In addition to the eyelid General Principles on p. 272, dehiscence following repair can occur if there has been excessive tension on the site or incision infection. Tumor recurrence can occur if the surgical margins still contain neoplastic cells.

Trichiasis causing chronic irritation is common after surgeries in which the eyelid margin is not maintained or recreated (H-plasty, semicircular, and other flaps) and can be a significant complication that can lead to discomfort, corneal ulceration and scarring, epiphora, self-trauma, and so forth and may require additional procedures.

PROGNOSIS

Prognosis depends on the type of tumor identified and its biologic behavior as well as the margins achieved.

ENTROPION AND ECTROPION

DEFINITIONS

Entropion is the inward rolling of the eyelid margin; **ectropion** is an outward rolling of the eyelid margin.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Entropion and ectropion are often an inherited breed characteristic or can occur if an eyelid laceration did not heal properly. Primary entropion is most common in young adult dogs of predisposed breeds. Entropion may worsen over time, so clinical disease may show up later in life. Enophthalmos (globe sunken inwards) or a smaller than normal globe (microphthalmos, phthisis bulbi) can also cause entropion. In certain breeds (e.g., English bulldogs, cocker spaniels, and giant breed dogs) excessive eyelid length can lead to both entropion and ectropion in the same eyelid. In cats, entropion can develop with chronic conjunctivitis,[4] weight loss, corneal ulceration, and age; feline conjunctivitis is usually caused by infection from feline herpesvirus-1, chlamydia, and mycoplasma. Chronic entropion in cats can commonly lead to the formation of a corneal sequestrum. Severe ectropion can lead to excessive corneal exposure and disease.

DIAGNOSIS

Clinical Presentation

Signalment

Entropion and ectropion in dogs most often occur due to breed conformation. The most common dog breeds that are severely affected include shar-peis, chow chows, English bulldogs, Rottweilers, English and springer spaniels, bloodhounds, basset hounds, Bouvier des Flandres, and giant breed dogs. Breeds that may have lower eyelid entropion include Labrador retrievers, golden retrievers, Chesapeake Bay retrievers, and Irish setters. Medial lower eyelid entropion is commonly seen in brachycephalic breeds, including Boston terriers, pugs, and shih tzus. Brachycephalic cats (e.g., Persians, Himalayans) may have conformational lower medial entropion or enophthalmos.[5] Feline entropion may occur from trauma or from ongoing blepharospasm related to irritation of the globe associated with infectious conjunctivitis or corneal ulceration.

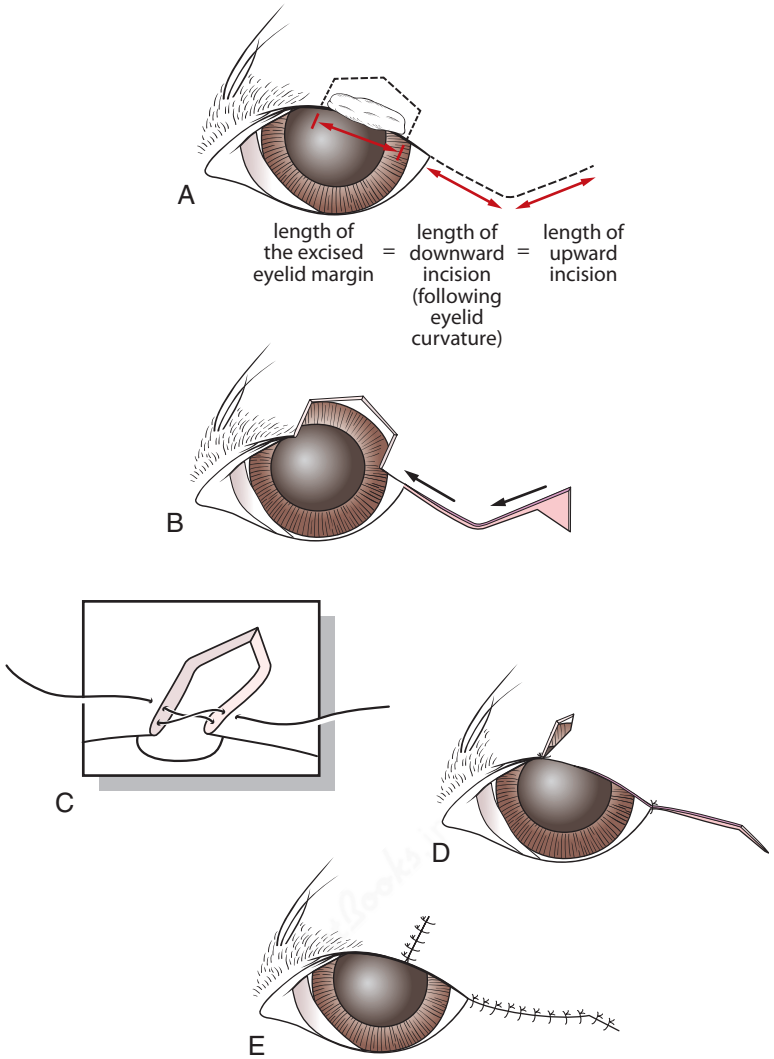

FIG. 16.9 Semicircular graft to reconstruct the eyelid after more than one-third of the eyelid margin length has been removed. (A) Remove the eyelid mass. (B) Following the curvature of the lateral eyelid, make a lateral semicircular skin incision where the length of the curve is approximately twice the length of the excised portion of the eyelid with the peak/trough of the curve in the center of the incision; at the lateral end of the incision, excise a triangular area of skin. (C) Advance the skin flap into the defect and close the eyelid margin with a figure-eight suture. (D) Appose the skin of the new lateral canthus with the peak/trough of the skin graft using a figure-eight suture. (E) Close the skin in a simple interrupted pattern.

History

Animals with entropion typically have a history of blepharospasm, ocular discharge, and rubbing at their eyes. Symptoms can be intermittent early in the disease but worsen over time. Vision may be impaired in chronic cases in which secondary corneal scarring (vascularization, pigmentation) develops.

Physical Examination Findings

Entropion causes epiphora, blepharospasm, and conjunctivitis. Excessive tearing and moisture can lead to eyelid discoloration, moist dermatitis, alopecia, and skin excoriations. Apply a topical anesthetic (e.g., proparacaine) to the eye before evaluating for entropion because spastic entropion should resolve with the topical anesthetic. Be aware that restraining the animal to examine the face may itself stimulate squinting that can cause the appearance of entropion. Restraint of the head may also push skin toward the eyes, causing the appearance of entropion. Examine the cornea for hair contact that sometimes may look like a disrupted or raised area in the tear film meniscus. Roll the eyelid margins out and see if the eyelid retains that position or rolls back in. Eyelids with entropion may have alopecia or a color change from the constant moisture. Corneal ulceration, vascularization, granulation, and pigmentation (pigmentary keratitis) will develop over time in the area of hair contact as the cornea strengthens itself to withstand the ongoing trauma from entropion. Pull the lateral canthus laterally and examine the palpebral fissure size compared to the corneal diameter to evaluate for macropalpebral fissure and ectropion.

DIFFERENTIAL DIAGNOSIS

Spastic entropion should resolve after a topical anesthetic has been applied and does not require surgery. Distichiasis, trichiasis, ectopic cilia, imperforate lacrimal puncta, dacryocystitis, foreign bodies, KCS, and corneal ulcers are other causes of excessive eye discharge, blepharospasm, secondary dermatitis, and pigmentary keratitis.

MEDICAL MANAGEMENT

A topical eye ointment will lubricate the surface and may reduce irritation from trichiasis until surgery can be performed. Topical anesthetics such as proparacaine should not be used because they mask symptoms of corneal ulceration, and chronic use is toxic to the cornea.[6] In cats, treat conjunctivitis with topical antivirals (e.g., 0.1% idoxuridine or trifluridine, 1 drop five times daily) and antibiotics (e.g., erythromycin or Terramycin [oxytetracycline/polymyxin 0.25 inch (0.6 cm), four times daily]). Avoid topical corticosteroids because feline conjunctivitis occurs from infection (e.g., feline herpesvirus-1, chlamydia, mycoplasma).[4]

SURGICAL TREATMENT

Surgery is indicated when the entropion or ectropion is causing secondary corneal disease or discomfort. After application of a topical anesthetic, estimate the amount of correction needed on an awake animal. Surgery is not always required in cases of ectropion.

Preoperative Management

Initiate treatment for corneal ulcers before performing surgery if necessary. Treat feline conjunctivitis with topical antivirals and antibiotics if needed.

Anesthesia

See pp. 266–268. General anesthesia is required to achieve exact alignment.

Surgical Anatomy

See p. 268. Examine the lateral canthus for laxity and entropion before surgery.

Positioning

Position the animal in ventral recumbency with a towel roll under the chin to hold the head up. Make sure the skin and ears are placed in a natural position, and that draping and towel clamps are not distorting the eyelid position.

SURGICAL TECHNIQUES

Keep tissue handling minimal, tissue resection precise, and hemostasis well controlled.

Eyelid Tacking

Entropion in the neonate or young animal (≤20 weeks of age), especially shar-pei puppies, may be treated by temporarily rolling out the eyelid margin and may eventually resolve with growth. Temporary eyelid tacking may also be used for spastic entropion to provide relief from corneal irritation until the primary cause is corrected.

Use a sterile eyelid plate or tongue depressor between the eyelid and globe to protect the eye. Use the wooden end of a long sterile cotton swab parallel to the eyelid margin and compress the skin approximately 5 to 7 mm away from the eyelid margin to evert it. Place skin staples perpendicular to the eyelid margin over the swab stick and approximately 0.5 to 1 cm apart to hold the eversion (Fig. 16.10). The staples should not go over the eyelid margin, touch the cornea, or be visible inside the eyelid.

Alternatively, use skin sutures to evert the eyelid skin. Using 3-0 or 4-0 polyglactin 910, place a partial-thickness vertical mattress pattern perpendicular to the eyelid margin, with one bite 3 to 5 mm from the eyelid margin that is approximately 5 mm wide, and place another bite into the skin over the rim of the orbit (see Fig. 16.10). Do not penetrate the eyelid margin or conjunctiva. Tie the suture to create a furrow in the skin. Place additional sutures as necessary to correct both upper and lower lid entropion. Place a few drops of surgical glue within the created furrow to reduce tension on the suture line. Glue keeps the sutures in place longer and helps keep them from being rubbed out.

If necessary, the tacking procedure may be repeated in young dogs until they have outgrown their entropion. Depending on the breed, permanent correction by excision of tissue may be needed in dogs approximately 5 months or older. Severely affected dogs such as shar-peis, chow chows, and English bulldogs should be referred to a veterinary ophthalmologist.

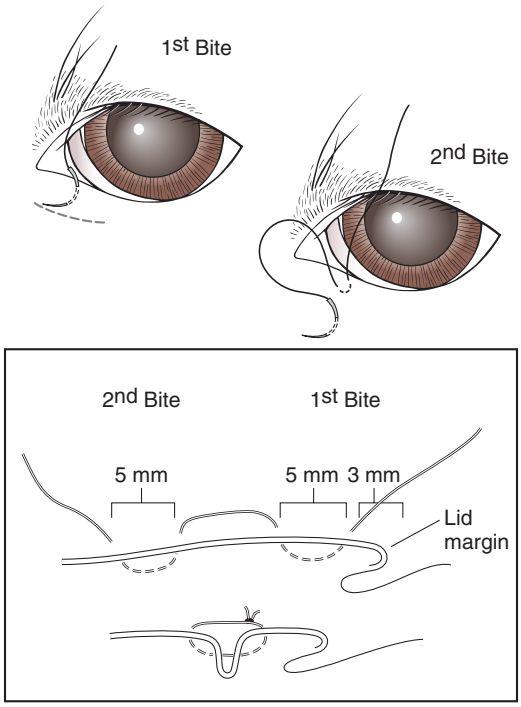

FIG. 16.10 Entropion eyelid tacking. Use vertical mattress sutures in the neonate to temporarily evert the eyelid margin. The first bite is 5-mm wide and begins 3 mm from the eyelid margin *(inset)*. Position the second 5-mm-wide bite over the rim of the orbit, biting into the orbital fascia. Tie the suture, inverting a furrow of skin. A few drops of surgical glue placed within the created furrow minimizes tension on the sutures and helps maintain their position if the patient rubs at the eyes.

Modified Hotz-Celsus

Various adaptations of the Hotz-Celsus procedure provide a definitive surgical correction for entropion. Skin excision surgery may need to be combined with palpebral fissure reduction in some breeds. Animals with severe entropion, macropalpebral fissure, or distichia should be referred to a veterinary ophthalmologist for correction because specialized equipment is needed to treat distichia with cryosurgery, and severe cases may also need concurrent eyelid or head skin lifts.

Starting 3 to 5 mm from the eyelid margin, estimate the size of the crescent-shaped skin to be removed by crimping the skin to be excised with a curved mosquito, Kelly, or Crile forceps. (Fig. 16.11A). In severe cases for which a large correction will be needed, Allis tissue forceps can also be used to crimp the skin. The lower and upper eyelid margins should be aligned with no entropion after the forceps have been removed and the crimped skin approximates the amount of skin to be removed.

Stabilize the eyelid by placing a Jaeger lid plate or tongue depressor under the affected eyelid (Fig. 16.11B). Using a No. 15 blade, incise the skin partial thickness and parallel to the eyelid margin along the length of the crimped skin. Place the incision 3 to 5 mm from the lid margin (Fig. 16.11B). Make a second, crescent-shaped skin incision on the other side of the crimped skin and remove the strip of skin. The orbicularis muscle may or may not be removed, but removal of muscle will make the entropion correction more secure, although more bleeding will occur. *Control hemorrhage with direct pressure. Do not incise the palpebral conjunctiva. Align and suture one bite at the lateral canthus and then close at the center of the defect with simple interrupted 4-0 to 5-0 polyglactin 910 skin sutures (Fig. 16.11C). Place each suture precisely to appose the skin (Fig. 16.11C, inset). Split the distances of the remaining defects when placing additional sutures, so that ultimately the sutures are spaced 2 to 4 mm apart (Fig. 16.11D–F). To prevent corneal irritation, cut the suture ends short enough and orient them so they will not contact the cornea.*

Whenever lateral canthus entropion is present or both the upper and lower lateral eyelids are operated, the skin excisions should be extended around the lateral canthus in combination with the lower and upper eyelid skin excisions.

Make a horizontally oriented U-shaped resection at the lateral canthus, carrying the elliptical incision around the lateral canthus, staying 3 to 5 mm from the eyelid margin (Fig. 16.12A). The lateral canthus incision should be an extension of the upper and lower eyelid incisions. *Place the first suture at the most lateral part of the lateral canthus (Fig. 16.12B). Split the distances of the remaining defects when placing additional sutures (Fig. 16.12C), so that ultimately the sutures are spaced 2 to 4 mm apart (Fig. 16.12D).*

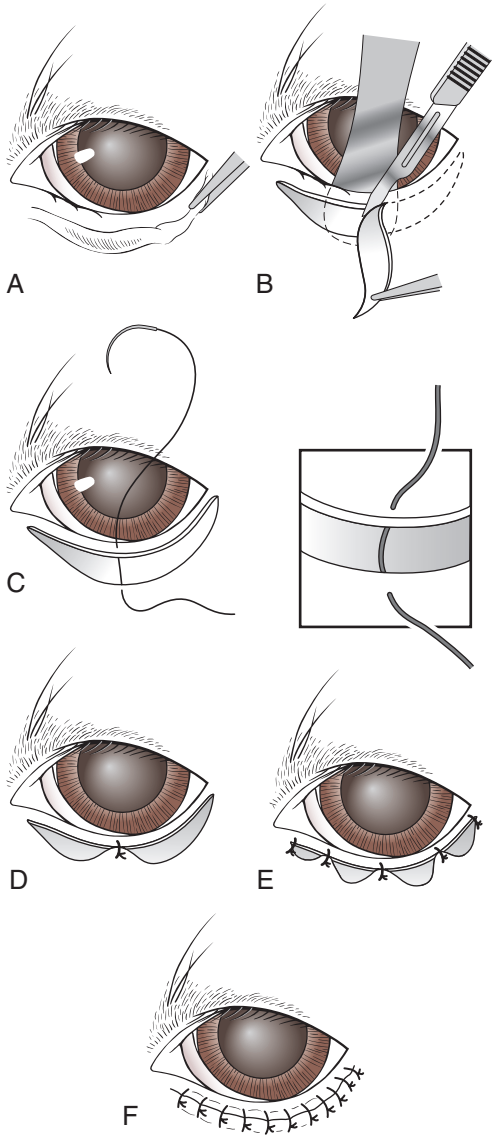

FIG. 16.11 Hotz-Celsus procedure for entropion repair. (A) Starting 3 to 5 mm from the eyelid margin, crimp the skin to be excised with a curved mosquito, Kelly, Crile, or Allis tissue forceps to estimate the size of the skin to be removed. (B) Stabilize the lid by placing a Jaeger eyelid plate under the affected eyelid. Using a No. 15 blade, incise the skin partial thickness and parallel to the eyelid margin along either side of the crimped skin and remove the strip of skin. (C–D) Begin closing the defect at the center of the wound with a simple interrupted split-thickness skin suture *(inset)*. (E) Split the distance of the remaining defects when passing additional sutures. (F) The final sutures are spaced 2 to 4 mm apart.

Permanent Lateral Tarsorrhaphy

Permanent lateral tarsorrhaphy reduces the palpebral fissure size in animals with macropalpebral fissure (large eyelid openings) that have ectropion, entropion, excessive corneal exposure, or risk for traumatic proptosis.[4] A medial canthoplasty is generally preferred in brachycephalic breeds with exotropia to reduce lagophthalmos by correcting the ventromedial entropion, as well as reducing the palpebral fissure size. Due to the nasolacrimal ducts and vasculature at the medial canthus, referral to an ophthalmologist is recommended for medial canthoplasty.

For permanent lateral tarsorrhaphy surgery, determine the amount of eyelid margin to be removed laterally by examining the eyelid opening size relative to the horizontal corneal diameter. After the tarsorrhaphy, the palpebral fissure opening should cover most of the exposed bulbar conjunctiva but should not cover the cornea.

Rather than making the initial part of the incision through the eyelid margin perpendicular to the eyelid margin (as would be done to remove an eyelid mass), angle the incision so that it's more parallel to a line that bisects the canthus; the angled incisions will make the new lateral canthus more natural looking (Fig. 16.13A).

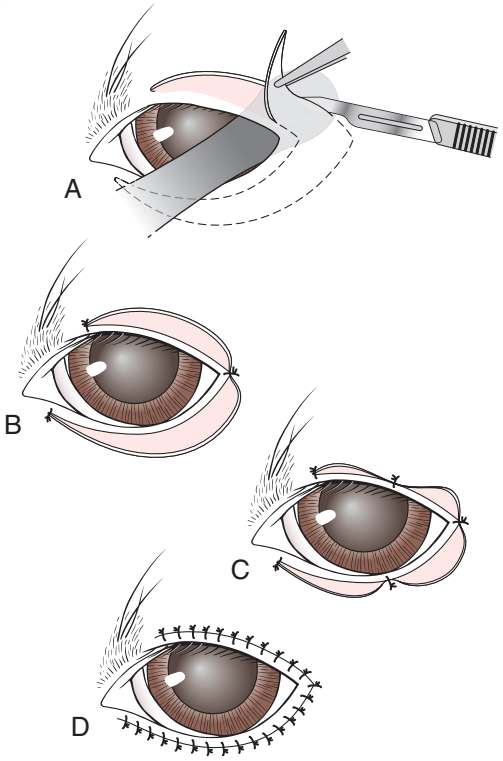

FIG. 16.12 Modification of the Hotz-Celsus procedure is performed when there is lateral canthal entropion (i.e., affecting both the upper and lower lateral lids). (A) Make a U-shaped resection around the lateral canthus staying 3 to 5 mm from the eyelid margin. (B) Place the first suture at the most lateral aspect of the excised area. (C) Split the distances of the remaining defects when placing additional sutures. (D) Skin sutures are placed 2 to 4 mm apart.

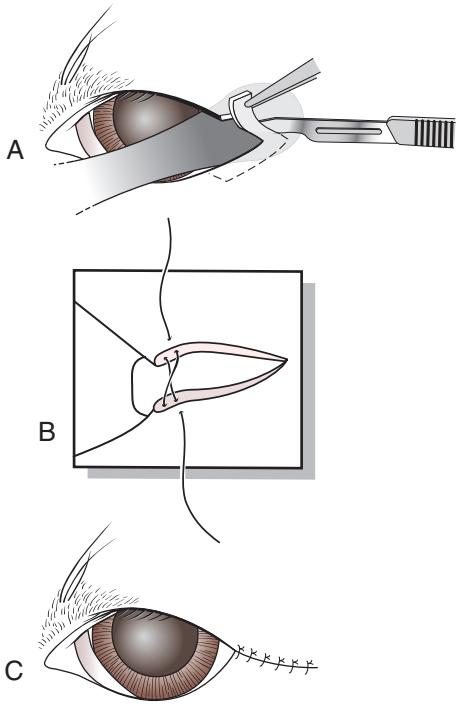

FIG. 16.13 Permanent lateral tarsorrhaphy. (A) Excise upper and lower lid margins at the lateral canthus, removing a V-shaped segment of skin. (B) Align the lateral eyelid margins with a figure-eight suture at the new lateral canthus. (C) Place skin sutures to precisely align the eyelid margins and appose the skin.

Using either a Jaeger lid plate and No. 15 scalpel blade or iris scissors, make a full-thickness eyelid incision into the upper and lower eyelid margins so the incisions on the upper and lower eyelids are equidistant from the lateral canthus (Fig. 16.13B). Remove a 3 to 4 mm wide section of lateral eyelid margin, including the meibomian glands from the upper and lower eyelids. The amount of eyelid margin removed will directly correlate to the size of the palpebral fissure reduction. *Align the eyelid margins in a figure-eight suture (Fig. 16.7C) and close the skin in a simple interrupted pattern with 5-0 or 4-0 polyglactin 910 taking care to place sutures partial thickness (Fig. 16.13C) so that no suture contacts the cornea.*

Ectropion causing folds and lid drooping can be corrected by wedge resection, as with an eyelid mass removal. The wedge is often placed laterally but ultimately depends on the eyelid shape of the individual.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Use 4-0 to 5-0 absorbable polyglactin 910 or silk suture and instruments as listed on pp. 269–271.

POSTOPERATIVE CARE AND ASSESSMENT

See p. 271. Use a rigid plastic E-collar, topical and oral antibiotics (see Box 16.1), antiinflammatories (such as nonsteroidal antiinflammatory drugs [NSAIDs]), and analgesics if not otherwise contraindicated. Prophylactic antibiotic treatment should be continued until the incisions are healed. The increased moisture at eyelid sites make these areas more prone to infection. With aggressive animals, suture such as polyglactin 910 can be left to dissolve, but silk sutures must be removed because they will not dissolve, and leaving them will predispose to infection. Maintain the E-collar for 2 to 3 days after suture removal if the animal wants to rub or scratch the eyelids.

After eyelid surgeries, tissue swelling will typically peak on the day after surgery and will take 2 to 4 weeks to resolve. Because of inflammation, ectropion may be present postoperatively; therefore delay assessment of the adequacy of correction until swelling subsides (4 weeks to several months). If undercorrection has occurred or if entropion recurs, the procedure may need to be repeated.

NOTE Warn owners of young animals that more that one surgery may be needed to fully correct the entropion or ectropion.

Corneal lesions should rapidly resolve after surgical correction. Urgent additional surgery will be needed if corneal ulceration is worsened by the eyelid changes.

COMPLICATIONS

Complications include undercorrection and overcorrection of the entropion or ectropion. Incisions made too far from the

eyelid margin may not effectively correct the entropion, and those made too closely may overcorrect it. If the eyelid margins are not aligned at the end of surgery, the upper eyelid entropion may worsen after the lower entropion is corrected in severely affected breeds. If suture ends are left too long or sutures are placed full thickness through the eyelid, the sutures could contact the cornea and cause a corneal ulcer. Correction of severely affected animals, especially shar-peis, should be performed by an experienced ophthalmologist.

Incision infection and dehiscence from self-trauma are complications that can be conservatively managed but may also lead to additional surgery. Facial appearance may be altered by eyelid surgery.

PROGNOSIS

The prognosis is good for comfort and vision if surgical correction has adequately resolved the problem.

Surgery of the Conjunctiva and Third Eyelid

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Bulbar conjunctiva is the conjunctiva on the globe, and **palpebral conjunctiva** is the conjunctiva on the inside of the eyelids. The **bulbar** surface of the third eyelid refers to the conjunctival surface of the third eyelid facing the globe (posterior side of the third eyelid). The **palpebral** surface of the third eyelid refers to the conjunctival surface of the third eyelid facing the external eyelid (rostral or anterior side of the third eyelid). **Cherry eye** is a prolapse of the third eyelid gland.

The limbus is the junction of the cornea and sclera. **Hypopyon** is white blood cells in the anterior chamber, and **hyphema** is red blood cells inside the anterior chamber. **Keratoconjunctivitis sicca** (KCS) is ocular surface inflammation caused by a lack of aqueous tears that is usually immune mediated in the dog and caused by feline herpesvirus in the cat. **Anterior uveitis** is inflammation of the anterior uvea causing a breakdown of the blood-eye barrier. **Glaucoma** is the disease of high pressure inside the eye causing vision loss. **Leukoma** is a white corneal scar.

PREOPERATIVE CONCERNS

Procedures involving the conjunctiva, third eyelid, and third eyelid gland should be performed by an individual who is trained and comfortable with the diagnosis, surgical procedure, follow-up, and possible complications. Surgeries requiring microsurgery, corneal suturing, or surgery inside the eye should be referred to a veterinary ophthalmologist.

Each animal should be thoroughly evaluated for concurrent and contributing abnormalities (e.g., corneal ulcers caused by a foreign body inside the eyelid, concurrent dry eye, neurologic disease). A complete ocular exam should include examination of the cornea, anterior chamber, and fundus (optic nerve head and retina). Systemic diseases such as hyperadrenocorticism or treatments with systemic corticosteroids can also adversely affect healing and should be taken into consideration with the treatment plan.

Successful ophthalmic surgery requires a correct diagnosis, appropriate choice of surgical procedure and materials, attention to detail, proper instrumentation and equipment, and suitable follow-up. With surgical treatment, appropriate postoperative medical therapy is essential to success. Infected corneal ulcers, for example, require continued monitoring and medical management after surgery.

The conjunctiva rapidly swells and becomes inflamed with any tissue handling. Conjunctiva is highly vascular, whereas the cornea is avascular. Antiinflammatory drugs (NSAIDs or steroids) given topically or systemically can minimize swelling but will slow corneal vascularization and healing; they should be used conservatively, if at all, in cases for which ocular surface healing is needed.

NOTE Intraocular, corneal, and microsurgical procedures are best referred to a veterinary ophthalmologist or an individual trained and experienced in these procedures.

PREPARATION OF THE SURGICAL SITE

For conjunctival and third eyelid procedures, treat with a prophylactic sterile broad-spectrum antibiotic ophthalmic ointment (e.g., neomycin, polymyxin, bacitracin) to keep the corneal surfaces lubricated and reduce surface bacteria (see Box 16.1). Prep and drape as previously described (p. 266).

NOTE Identification of tissue layers and accurate placement of sutures with conjunctiva are facilitated by use of magnifying loupes. Surgical loupes and appropriately high magnification are necessary for any procedures near the cornea.

ANESTHETIC CONSIDERATIONS

Conjunctival surgery and surgery near the cornea require precision and delicacy; therefore general anesthesia is necessary (see pp. 266–268). In addition, animals with conjunctival or corneal disease can have fragile eyes, thus minimizing head movements and thrashing is necessary to avoid additional eye trauma.

Many brachycephalic breeds have shallow orbits, and prominent eyes and are particularly susceptible to ocular disease. These animals also tend to have elongated soft palates, small tracheas, and they may have chronic airway disease; thus diligent monitoring and support are necessary before, during, and after anesthesia. Premedications may be administered both to calm and relax them and to avoid the oculocardiac reflex that can cause severe bradycardia or cardiac sinus arrest (e.g., glycopyrrolate or atropine; see p. 266 and Table 16.1).

Propofol is an excellent option for induction because of its rapid, titratable effect and rapid elimination. Alfaxalone may cause less respiratory and cardiac depression than propofol, allowing for a rapid and smooth induction, particularly in brachycephalic dogs, heart patients, and cats (see Table 12.1 and p. 134). Both alfaxalone and propofol may increase intraocular pressure (IOP) in healthy dogs,[7] though this may not be clinically significant. Induction with a face mask may place pressure on

or near the eyes and should be avoided when possible. Ketamine should also be avoided because it causes undesirable eye movements. Anesthesia should be maintained with inhalants (see Table 16.1); injectable anesthetics alone (unless given as a constant-rate infusion) will not typically last sufficiently long or provide sufficient immobilization for delicate, precise eye surgery (see Chapter 12). Use a cuffed, wire-reinforced, guarded endotracheal tube to prevent airway collapse if the neck is bent to position an eye for surgery. For other anesthetic considerations (fluid therapy, monitoring depth of anesthesia) see Chapter 12.

With eye surgery, neuromuscular blockers (NMBs) and a ventilator may be used to prevent any eye movement. These drugs require specialized equipment and training to use safely. NMBs cause muscle paralysis, including the respiratory muscles, and even low doses are dangerous without ventilation respiratory support. In these cases, measuring $EtCO_2$ is imperative to evaluate anesthesia. Staff need to be educated and experienced with supporting ventilation manually or mechanically in all patients given NMBs, and they should also be skilled in interpreting anesthetic monitors and parameters. Analgesics (see Chapter 13) must be administered to these patients because, although NMBs prevent movement, they do not provide analgesia. The animal must continue to be ventilated until the NMB agents have worn off as determined with a nerve stimulator.

Whenever possible, a smooth recovery that minimizes excessive head motion is ideal, especially if the eye is fragile from a deep corneal ulcer. Extubation should be performed after the animal can maintain its own oxygenation. Brachycephalic animals should be extubated as late as possible and monitored carefully for a few hours after anesthesia. Postoperative analgesics (e.g., opioids; see Chapter 13) will also help smooth the recovery.

ANTIBIOTICS

Perioperative and postoperative antibiotics are indicated prophylactically with conjunctival and cornea surgery. Topical medications that can penetrate through the cornea will reach the anterior chamber of the eye, whereas systemic antibiotics are needed to reach the posterior segment.

NOTE Avoid using topical ointments on deep corneal ulcers or perforations because ointments inside the eye cause uveitis.

SURGICAL ANATOMY

The special mucous membrane on the inner aspect of the lids is called the *palpebral conjunctiva* (see Figs. 16.1 and 16.15). At the level of the orbital rim, the palpebral conjunctiva reflects at the conjunctival *fornix* onto the eye to become the *bulbar conjunctiva.* The palpebral conjunctiva has goblet cells, whereas the bulbar conjunctiva is thinner and is without goblet cells. Conjunctival goblet cells secrete mucin that makes up the innermost layer of the tear film and adheres the tear film to the ocular surfaces. Lymphatic nodules are found throughout the conjunctiva but are especially prominent on the bulbar surface of the third eyelid. Lymphatic drainage from the conjunctiva empties into the parotid lymph nodes. The *third eyelid* is located ventromedially, is covered with conjunctiva, and is mobile enough to cover the entire anterior face of the cornea. A T-shaped piece of hyaline cartilage stiffens the third eyelid (Fig. 16.14). The *third eyelid gland*, a mixed seromucous gland that contributes the middle aqueous layer of tear film, surrounds the base of the cartilage and is normally tucked in the orbit out of view. The third eyelid is important in protecting the cornea and spreading the tear film. The wall of the globe is comprised of the transparent, multilayered cornea anteriorly and the yellow-white, opaque *sclera* posteriorly (Fig. 16.15). The two meet at the corneoscleral junction or limbus. The *cornea* is usually less than 1 mm thick and is composed of four layers: (1) epithelium with its basement membrane, (2) stroma, (3) Descemet's membrane (basement membrane of endothelium), and (4) endothelium.

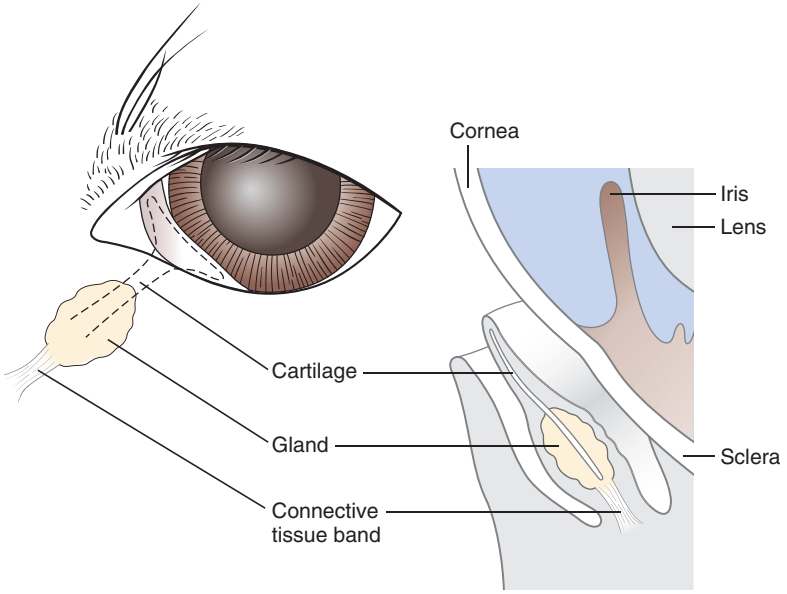

FIG. 16.14 Anatomy of the conjunctiva, third eyelid, and third eyelid gland. (Modified from Severin GA. *Severin's Veterinary Ophthalmology Notes.* 3rd ed. Lakewood, CO: American Animal Hospital Association; 1995.)

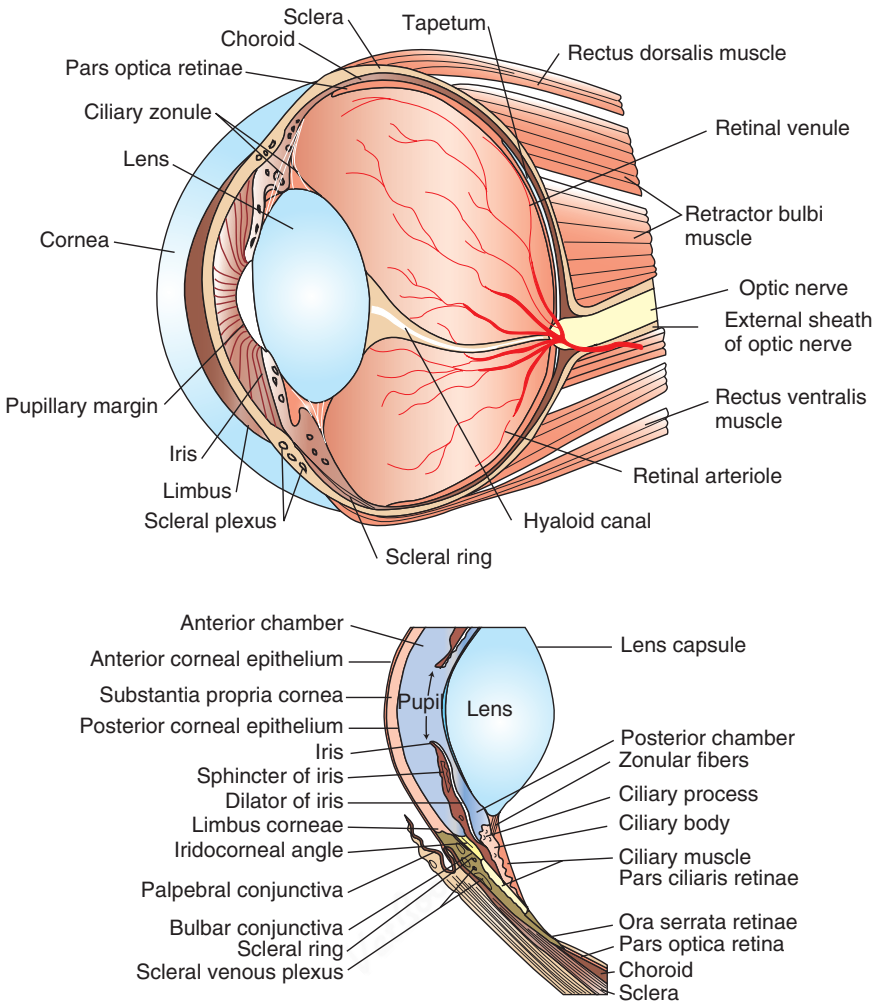

FIG. 16.15 Intraocular anatomy.

SURGICAL TECHNIQUES

Third Eyelid Flap

Third eyelid flaps can serve as bandages (similar to an opaque contact lens) to mechanically protect the cornea after trauma. It is important to note that they do not function like conjunctival grafts because conjunctival grafts provide vascularization, as well as metabolic and tectonic support, to the cornea by integrating into the cornea. Third eyelid flaps should *not* be used on deep corneal ulcers, descemetoceles, or corneal perforations. The raised third eyelid can place pressure on the delicate cornea, increasing the risk of rupture. Third eyelid elevation also prevents any direct monitoring of the cornea during treatment. Indications for a third eyelid flap include bullous keratopathy and indolent corneal ulceration where the corneal epithelium is not adhering well to the underlying corneal stroma.

Exteriorize and extend the third eyelid by grasping it with forceps and elevating it. Pass a cutting needle with swaged-on 3-0 or 4-0 suture monofilament absorbable, such as PDS, through the upper eyelid into the dorsolateral conjunctival fornix (Fig. 16.16A). Direct the needle through the external surface of the third eyelid under the crossbar of the T-shaped cartilage, and exit through the external surface of the third eyelid on the opposite side of the cartilage. Alternatively, direct the suture around the cartilage but do not penetrate the conjunctiva on the bulbar surface of the third eyelid. Direct the suture back through the dorsolateral conjunctival fornix and out the upper eyelid (see Fig. 16.16B). Apply tension on the suture, pulling the third eyelid over the cornea. Tie the suture and use a stent (sterile button or sterile piece of tubing), if needed, to distribute suture knot pressure on the skin (see Fig. 16.16C).

Remove the third eyelid flap sutures 14 days after placement, or sooner if the suture loosens. Complications of third eyelid flaps include eyelid or skin necrosis, corneal irritation from suture contact, cartilage deformation, and persistent third eyelid protrusion following release. Eyelid swelling is expected. Because the cornea is covered by the third eyelid flap, the corneal disease could worsen without being evident, so the patient should be monitored closely for increased ocular pain.

HEALING OF THE CONJUNCTIVA, THIRD EYELID, AND GLAND

Conjunctiva heals rapidly due to its extensive vascularization.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Magnification of ×2 to ×3 using a lighted MagniVisor, Optivisor, or surgical loupe is recommended when operating on the

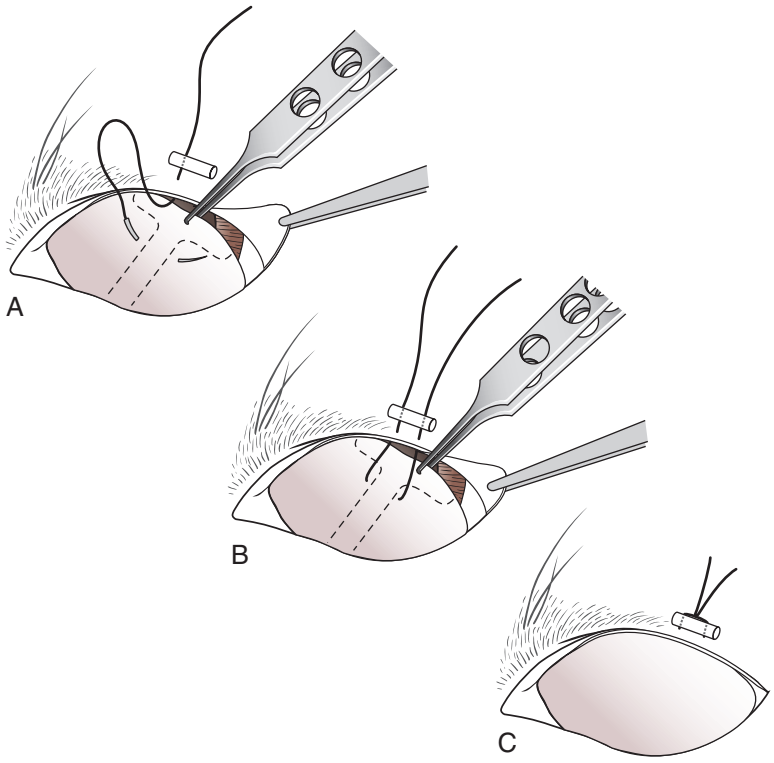

FIG. 16.16 Third eyelid flap. (A) Pass a cutting needle through the upper eyelid in the dorsolateral conjunctival fornix. Exteriorize and extend the third eyelid with forceps and direct the needle through the external surface of the third eyelid, around the cartilage cross-bar but keeping the suture buried so it does not penetrate the posterior surface of the third eyelid. (B) Direct the suture through the dorsolateral conjunctival fornix and out the upper eyelid. (C) Tie the suture in a simple interrupted tightly. Use a stent if needed to distribute pressure.

conjunctiva or near the cornea. Consider using a focal light source with loupes because lighting assists magnification. For suturing conjunctiva, an absorbable small-gauge soft suture such as 6-0 polyglactin 910 with a reverse cutting ¼ curvature swaged-on needle (see Box 16.2) is recommended. To handle such small sutures, microsurgical forceps, needle holders, and scissors should be used because these instruments are specially designed to be delicate with fine tips and unique curves for specific purposes (see Fig. 16.3). Microsurgical techniques should be applied with 6-0 sutures or smaller to avoid damaging both sutures and fragile instruments (i.e., grasp the needle with only needle holders because grasping the needle with tying forceps will damage the forceps; handle suture with only microsurgical instruments and not hands to avoid damaging the suture). An eyelid speculum to hold the eyelids open for surgery on the conjunctiva or third eyelid is recommended (see Fig. 16.3).

POSTOPERATIVE CARE AND ASSESSMENT

The small, delicate sutures placed in the conjunctiva or third eyelid are easily torn or disrupted by the patient. Use a rigid E-collar as discussed on p. 271 that extends just beyond the nose when the head is extended. Soft E-collars and neck-only restraints (e.g., Bite Not collar) will not prevent the animal from rubbing the eye against objects. Topical antibiotics (see Box 16.1) should be administered until the eye is healed.

COMPLICATIONS

Complications of conjunctival and third eyelid surgeries are primarily hemorrhage and dehiscence. Conjunctiva is extremely vascular so infection is rare, but the delicate tissue can tear easily.

SPECIAL AGE CONSIDERATIONS

Cherry eye usually starts at a young age but may not be noticed until later in life. Corneal ulcers can occur at any age.

SPECIFIC DISEASES

THIRD EYELID GLAND PROLAPSE (CHERRY EYE)

DEFINITIONS

Cherry eye is defined as a prolapsed third eyelid gland. **Chemosis** is conjunctival edema resulting in visible swelling.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Prolapse and protrusion of the third eyelid gland are most likely caused by laxity in the attachments between the third eyelid gland and periorbita. Prolapsed third eyelid glands usually occur

in the first few years of life as a primary condition with genetic risk factors. Trauma can also cause a third eyelid gland prolapse. Uncommon contributing factors may be primary or secondary adenitis, breed-related fascial attachment abnormalities, or specific pathogens affecting the glands. The condition is not usually caused by primary inflammation, neoplasia, or hyperplasia. KCS occurring after protrusion (sometimes years later) suggests involvement of both the lacrimal and third eyelid glands. The hypertrophied, protruding gland, which extends beyond the leading edge of the third eyelid, can become abraded and dry, resulting in secondary inflammation and swelling. Protrusion may be unilateral but is more frequently bilateral. Adenitis is found on histologic examination.

DIAGNOSIS

Clinical Presentation

Signalment

Breeds most often affected are cocker spaniels, English bulldogs, beagles, Pekingese, Boston terriers, basset hounds, shih tzus, and Lhasa Apsos. Most are first affected at a young age (usually <1 year). The condition is more common in dogs than in cats; the Burmese is the most commonly affected cat breed.

History

Owners may notice a sudden third eyelid mass, ocular discharge (serous or mucoid), and/or conjunctivitis. The condition usually begins unilaterally but eventually may become bilateral. Prolapse may be intermittent.

Physical Examination Findings

If protruding, the prolapsed third eyelid gland will look like an obvious round to oval, pink, fleshy mass behind the third eyelid margin near the medial canthus. Lymphoid follicles on the anterior surface of the protruded gland may be seen. If not visible, elevating the third eyelid by gently retropulsing the globe will show a distinct oval pink mass on the palpebral surface of the third eyelid. Ophthalmic exam may show conjunctivitis and mucoid discharge. If KCS is also present, the cornea may have vascularization and/or pigmentation (pigmentary keratitis). Sometimes the third eyelid gland is abraded or has cysts.

Laboratory Findings

Culture of the mucopurulent discharge is not indicated. Cytology of the protruding gland will reveal normal conjunctival epithelial cells and possibly inflammation and glandular cells and is also generally not indicated.

DIFFERENTIAL DIAGNOSIS

Differentials include third eyelid neoplasia, adenitis, hyperplastic lymphoid follicles, elevated third eyelid (Horner syndrome, Haws syndrome, enophthalmos), cyst, everted third eyelid cartilage, and malformation of the third eyelid.

MEDICAL MANAGEMENT

If the cornea is fluorescein negative and the gland is swollen, topical antibiotics with corticosteroids can be used to reduce the swelling and size of the prolapsed third eyelid gland so that it becomes smaller, although this will generally not resolve the prolapse.

SURGICAL TREATMENT

Preoperative Management

Clipping the periocular hair is not required. Remove exudates from the corneal and conjunctival surfaces with sterile gauze and cotton swabs moistened by eye wash or lactated Ringer's solution (LRS). Keep the cornea lubricated.

Anesthesia

See pp. 266 and 281 for anesthetic considerations in young animals.

Surgical Anatomy

The third eyelid is a roughly triangular fold of mucosa located at the medial canthus and covered by conjunctiva (see Figs. 16.1 and 16.14). The base of the triangle is the free or leading margin. A T-shaped piece of cartilage lies within the third eyelid providing internal structure to it, and the "arms" of the T extend along the leading margin. The third eyelid gland is typically within the bulbar conjunctiva at the base of the third eyelid. Lymphoid follicles found primarily on the bulbar surface of the third eyelid appear as small raised translucent bumps. Blood supply to the third eyelid comes from branches of the internal maxillary artery. Lacrimal excretory ductules leave the gland and emerge in the middle section of the bulbar mucosal surface.

Positioning

Position the animal in ventral recumbency with a rolled towel placed under the chin to hold the head level.

SURGICAL TECHNIQUES

Replacement, not removal, of the prolapsed gland is the standard of care and is recommended to reduce the incidence of KCS later in life. Goals of surgical treatment include replacing the protruding gland back into its normal anatomic position on the bulbar third eyelid, maintaining third eyelid mobility, and preserving glandular tissue and excretory ducts. Described techniques include creating an envelope or pocket in adjacent conjunctiva and covering it, with or without scarification of the gland surface. In addition to pocket procedures, anchoring the third eyelid to the base of the third eyelid cartilage,[8] extraocular muscles,[9] sclera, periorbital fascia, or periorbital bony rim[10] have been described. Anchoring procedures interfere with third eyelid mobility, whereas pocket procedures may damage excretory ducts. Combined pocket and tacking procedures may be more successful for larger and more chronic protrusions than pocket procedures alone. Pocket procedures without tacking may be more effective in young animals and those with mild protrusions.

Pocket procedure: *Place an eyelid speculum to maximize exposure. Grasp and extend the third eyelid with two small towel clamps or mosquito forceps placed on either side of the third eyelid gland. Make a linear conjunctival incision between the protruded gland and cornea (i.e., proximal to the gland), taking care to retain at least 5 to 7 mm of conjunctiva at the limbus (Fig. 16.17A). Deepen the incision until prominent conjunctival blood vessels are visible. Make a second parallel incision into the conjunctiva between the third eyelid margin and gland (i.e., distal to the gland), taking care to retain at least 4 to 5 mm of conjunctiva along the third eyelid margin (see Fig. 16.17A). At one end of the incision, place a suture knot of 6-0 polyglactin 910 on the external palpebral surface of the third eyelid with tying forceps (e.g., Colibri) and nonlocking Castroviejo needle holders or the equivalent (see Box 16.2). Pass the needle through the third eyelid*

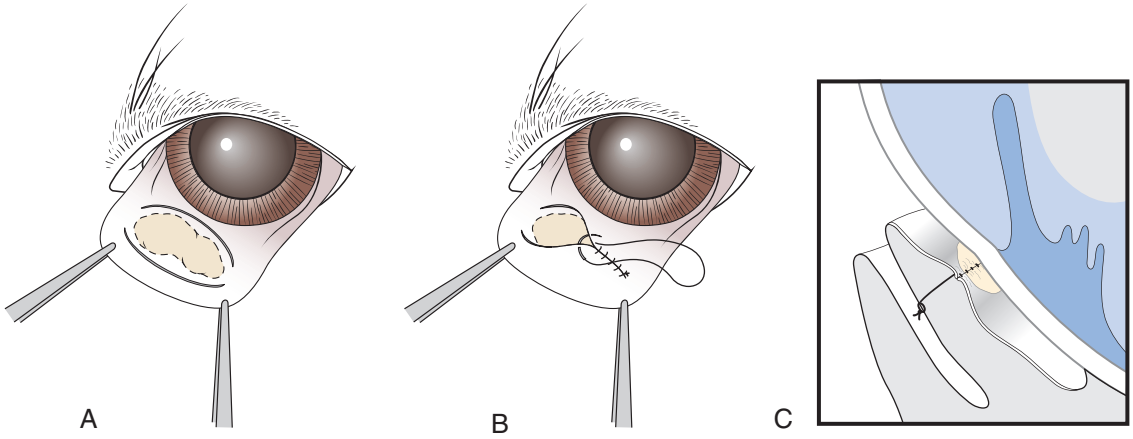

FIG. 16.17 Pocket procedure for cherry eye. (A) Make a linear conjunctival incision on either side of the protruded gland, taking care to retain a least 4 to 5 mm of conjunctival tissue on either side for suturing. (B) Anchor the first knot of 6-0 polyglactin 910 partial thickness on the anterior surface of the third eyelid, and then pass the suture through the third eyelid into the incision. Close the incision in a simple interrupted pattern taking bites on either side of the gland, while pushing the gland into the resulting pocket, keeping the suture snug and unexposed. (C) Pass the suture back through the third eyelid and anchor the knot on the anterior third eyelid surface.

from the palpebral to the bulbar surface of the third eyelid so the needle exits inside one end of one of the conjunctival incisions. Tuck the gland into its normal position by suturing (imbricating) the two incisions together over the gland in a simple continuous pattern with 6-0 polyglactin 910 (see Fig. 16.17B). Apply downward pressure to the gland with a cotton-tipped applicator as the suture is tied, tucking or "pocketing" it into the bulbar conjunctiva. Pass this suture back through the third eyelid and place the final bite and knot on the external palpebral surface of the third eyelid (Fig. 16.17C). Take care to avoid corneal contact or tearing the conjunctiva, and avoid grasping the needle with the microsurgical tying forceps because the needle can damage the forceps.

NOTE Removal of the gland of the third eyelid increases the risk of dry eye (KCS) and is contraindicated.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

For smaller dogs and cats, use 6-0 polyglactin 910 and microsurgical forceps, needle holders, and scissors (see Box 16.2). For very large dogs, either 5-0 or 6-0 polyglactin 910 can be used to suture conjunctiva.

POSTOPERATIVE CARE AND ASSESSMENT

Use a rigid E-collar that extends just beyond the nose when the head and neck are extended as discussed previously (see p. 271). Administer a topical antibiotic (e.g., neomycin, polymyxin, bacitracin) four times daily until the conjunctiva is healed in 10 to 14 days (see Box 16.1). Avoid topical corticosteroids for several weeks after surgery because they adversely affect healing. Swollen glands may take several weeks to return to a normal size.

COMPLICATIONS

Complications include suture exposure to the corneal surface causing ulceration, and dehiscence of the incision or holes torn in the conjunctival pocket allowing for repeat prolapse of the third eyelid gland.

PROGNOSIS

The prognosis for gland replacement can be good with the pocket procedure. Warping of the third eyelid margin and visible thickened tissue at the base of the gland may be present after surgery, especially if the gland was very large. KCS is much more likely if the gland is partially or completely removed. Recurrence may require additional surgery to try to replace the gland.

DEEP OR INFECTED CORNEAL ULCERS

DEFINITIONS

A **superficial corneal ulcer** is an injury where only the corneal epithelium has been removed. A **stromal corneal ulcer** involves loss of the corneal stroma in addition to the epithelium. A **descemetocele** is a very deep corneal ulcer in which most or all of the corneal stroma is absent, causing a defect that extends down to Descemet's membrane (the basement membrane of the corneal endothelium). Melting corneal ulcers involve liquefaction of the corneal stroma by protease and collagenase proteolytic enzymes; the enzymes are produced by inflammatory and corneal cells. **Infectious endophthalmitis** is infection inside the eye. **Phthisis bulbi** is an acquired shrunken, atrophied eye resulting from chronic diseases such as corneal perforation or chronic uveitis. **Epithelial downgrowth** occurs when corneal epithelium grows down through a corneal perforation and into the eye.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Corneal ulcers often occur from an injury that removes some corneal epithelium with or without stroma. The trauma can be endogenous from dry eye, poor blinking and exposure, ectopic cilia, distichia, entropion, eyelid masses, facial folds, or excoriations. Exogenous causes of corneal ulcers are physical contact of the cornea against an object. With cats, active feline herpesvirus infection also causes corneal ulceration.

Uncomplicated superficial injuries to the cornea undergo avascular healing. An uncomplicated cornea ulcer is quickly covered by sliding epithelium. When the epithelium is absent from the cornea, hydration of the corneal stromal can occur, causing focal corneal edema in the ulcer bed. With healing, epithelial cells lose cilia, flatten, and begin migration over a corneal wound defect within 1 hour. The entire cornea can be reepithelialized in 7 to 10 days. Once the cells have covered the defect, mitosis occurs and the multilayered epithelial surface is reconstituted. Attachment of the epithelium to the underlying tissues may be fragile for 6 to 8 weeks. Indolent ulcers occur when the epithelium does not adhere to the underlying stroma and typically appear as a superficial corneal ulcer with loose epithelium. Superficial indolent ulcers (and no other kinds of ulcer) should be treated with corneal epithelial debridement and a grid, punctate, or diamond burr keratotomy.

Bacterial and fungal organisms can make up the normal flora of the conjunctival and corneal surfaces. Opportunistic organisms may infect an open corneal wound and cause progressive corneal stromal loss. In infected or destructive stromal corneal ulcers, vascular healing is necessary. Because the cornea is naturally avascular, the immune system has limited access to a corneal injury until neovascularization develops. In response to the infected corneal ulcer, corneal neovascularization will start growing from the limbus after 3 to 5 days and typically grows at a rate of approximately 1 mm per day. The length of corneal vascularization can sometimes provide an estimate of how long the infected corneal ulcer has been present. Corneal vascularization usually takes approximately 4 weeks to reach the center of the cornea. Once corneal vascularization reaches an infected ulcer site, the immune system will eliminate the infection and the corneal tissue can rebuild through granulation. Collagen fibers in the regenerating stroma are irregular and thus decrease corneal transparency. Scar density decreases over time, but a focal white corneal scar (leukoma) typically remains. If a deep corneal ulcer does not vascularize, the ulcer bed will remain as a thin area of cornea that looks "indented" or flat when viewed from the anterior surface and may be more susceptible to future injury or infection.

The cornea contains extensive innervation, and a corneal ulcer will cause reflex anterior uveitis. Uveitis is a breakdown of the blood-eye barrier inside the eye that causes aqueous flare (protein leakage into the aqueous humor), as well as miosis, diffuse corneal edema, and reduced IOP (in the early phase). The severity of the uveitis is proportional to the severity of the corneal infection. As the corneal infection responds to therapy, the reflex uveitis will improve. Monitoring the uveitis allows evaluation of how the corneal ulcer is responding to treatment. If the uveitis worsens despite treatment, the corneal infection may be antibiotic resistant, so therapy should be escalated. Release of various enzymes (collagenases, proteases) from corneal cells and leukocytes can cause corneal stromal melting and liquefaction.

If a corneal perforation occurs, the corneal endothelium will be damaged as well. Infected corneal ulcer pathogens have access into the eye, and intraocular anatomy will be distorted. The body will often place a fragile plug of fibrin, iris, and/or blood in the perforation site. *Anterior synechiae* (adhesion of iris to the cornea) usually develop, and eventually epithelial downgrowth and adhesion formation inside the eye can lead to glaucoma, pain, and blindness. Blood at the ulcer bed when corneal vascularization has not yet reached the site is usually from a corneal perforation.

DIAGNOSIS

Clinical Presentation

Signalment

Any animal can acquire an infected or deep corneal ulcer. Animals with poor ocular surface health (e.g., KCS, lagophthalmos) may be predisposed to ulceration. Brachycephalic animals are predisposed to ulceration due to corneal exposure. Animals with a compromised immune system (i.e., cats with feline leukemia virus [FeLV] or feline immunodeficiency virus [FIV]; dogs with hyperadrenocorticism) or those treated with immunosuppressive drugs are more likely to develop an infected corneal ulcer.

History

Symptoms observed are usually eye discharge, squinting, holding the eye closed, and/or rubbing the eye. Animals usually present within days of the eye problem first being noted, although some owners will try various topical eye drops before presentation; it is therefore important to obtain a careful history. Previous medical therapy, such as the use of corticosteroids on a corneal ulcer, can also be essential to the history and medical management.

Physical Examination Findings

Symptoms of an infected corneal ulcer are listed in Box 16.3.

Descemetoceles usually look like a dent or crater on the cornea that is clear at the bottom although surrounded by cloudy corneal edema. In contrast, corneal perforations have a raised, opaque, white to brown focal bulge in an area that was previously ulcerated. The central bulge represents protruding fibrin and/or iris. The pupil may be distorted or not visible and the anterior chamber may be shallow.

Laboratory Findings

No change in white cell count is expected unless the infection from a ruptured eye is beginning to ascend or spread systemically. Any contributing health problems that may lower immunity should be evaluated because these diseases adversely affect corneal healing.

DIFFERENTIAL DIAGNOSIS

Other causes of ocular pain include ectopic cilia, severe distichia, dry eye, entropion, and an eyelid mass. Other ocular diseases, such as anterior uveitis and glaucoma, can also cause diffuse

! BOX 16.3 Symptoms of an Infected Corneal Ulcer

- Inappropriately severe anterior uveitis as noted by:
  - Diffuse corneal edema
  - White blood cells *(hypopyon),* red blood cells *(hyphema),* or fibrin in the anterior chamber
  - An extremely miotic pupil
  - Aqueous flare ("flashlight in fog") caused by protein in the aqueous humor
  - Significantly reduced intraocular pressure especially when compared to the normal eye
- Ulcer edges with an opaque white or yellow color (presence of white blood cells)
- Visible "denting" or progressive deepening of the corneal ulcer bed
- Melting or liquefaction of the corneal ulcer tissue
- Significant, diffuse corneal edema associated with the ulcer

corneal edema. If a corneal dent/defect is visible with a comfortable eye and negative fluorescein stain, a previous stromal ulcer may have occurred in the past, leaving an epithelialized thin area of cornea (a corneal facet).

MEDICAL MANAGEMENT

Simple uninfected corneal ulcers are typically treated prophylactically with topical antibiotics, and most heal rapidly without complications. Corneal ulcers should not be treated with systemic or topical corticosteroids because they suppress the local immune system and potentiate corneal ulcer infection. Topical NSAIDs are also not generally advisable. Infected corneal ulcers, descemetoceles, and corneal perforations should ideally be referred to a veterinary ophthalmologist. Apply a rigid E-collar as described on p. 271.

Deepening of infected corneal ulcers can occur rapidly (i.e., over a period of several hours). Medical therapy can be pursued until the animal can be seen by an ophthalmologist or if the owner declines referral. Some corneal ulcers can be managed medically, but severe corneal ulcers may require surgery to save the eye.

Before starting antibiotic therapy, a culture and sensitivity of the ulcer bed, while possibly risky, may help direct medical therapy. Antibiotic resistance has increased, making sensitivity results nearly essential to successful treatment of a corneal ulcer. *After adequate topical anesthesia and immobilization, carefully swab the ulcer edges for culture and sensitivity with a sterile cotton-tipped applicator that is then placed in blood culture broth or a culturette. Because the sample size will be small, ask the microbiology laboratory to start the culture in enrichment broth to amplify the organisms before plating.*

Use topical antibiotics for corneal ulcers because the cornea has no inherent blood supply, which prevents systemically administrated antibiotics from reaching adequate concentrations. Bacterial numbers can double as rapidly as every 30 minutes, so frequent treatment is essential to try to control an active infection. Diligent treatment with antibiotic drops every 1 to 2 hours around the clock for at least 24 to 48 hours can interrupt the bacterial growth cycle. While awaiting culture results, broad-spectrum antibiotics should be administered or selected based on a Gram stain (see Box 16.1). For gram-negative bacteria, use topical antibiotics such as fortified 0.9% gentamicin (add 0.33 mL of 100 mg/mL IV gentamicin to every 5 mL of 0.3% gentamicin) or a second-generation fluoroquinolone (e.g., ofloxacin; see Box 16.1). For gram-positive organisms, use topical antibiotics such as fourth-generation fluoroquinolones (e.g., moxifloxacin or 50 mg/mL cefazolin [add LRS to the IV vial to make 100 mg/mL then dilute 1:1 by removing 5 mL of cefazolin solution and adding 5 mL of LRS to make 5% or 50 mg/mL]; dilution can also be made in a sterile dropper bottle using artificial tears solution). Cefazolin needs to be refrigerated in the same way as the IV solution to maintain its efficacy, and it expires similarly to the IV solution. After the first 24 to 48 hours, reduce the topical antibiotic frequency to every 4 to 6 hours depending on the response to treatment. If a corneal ulcer is treated too frequently in the long-term, corneal neovascularization will slow or stop such that blood vessels may not reach the ulcer site. A reduced frequency of treatments encourages the corneal ulcer to vascularize. As the treatment frequency is decreased, corneal infection may worsen; thus topical treatments should be balanced in frequency to encourage neovascularization while also trying to prevent progression of the corneal infection. If the corneal infection progresses, the ulcer will deepen and the anterior uveitis will worsen. Topical NSAIDs should be avoided with corneal ulcers because they can slow corneal ulcer healing and some (i.e., diclofenac) may even cause sterile corneal melting.[11] Continue medical treatment until the corneal ulcer has either filled completely with vascularization or the vascularization stops progressing. Systemic antibiotics are indicated if the corneal ulcer has ruptured because this is associated with a risk of internal eye infection.

Symptomatic treatment of secondary anterior uveitis is also essential to ulcer management because uveitis can lead to internal iris adhesions that can cause glaucoma. Glaucoma is progressive over time and causes pain and blindness. Atropine administered topically reduces painful ciliary muscle spasm and minimizes adhesions of iris to lens *(posterior synechiae)* by causing pupil dilation, although atropine usage may increase the risk of glaucoma in an eye that is anatomically predisposed to this condition.

Positive indicators of control of corneal infection are reduced pain, reduced corneal edema, reduced aqueous flare and anterior uveitis, and more effective or longer lasting pupil dilation from atropine as the uveitis decreases. Negative indicators are increased pain, increased corneal edema, increased anterior uveitis, and deepening of the corneal ulcer. If the ulcer is worsening, additional antibiotics or surgery may be needed.

Melting corneal ulcers are very unstable because the liquefied tissue is physically very soft and can slough from the eye. In addition, melting corneas are not strong tissue for suture placement. Collagenase inhibitors such as 10% acetylcysteine, serum that contains macroglobulins, or ethylenediaminetetraacetic acid will help stabilize melting as the ulcer is treated. These cases are best referred to an ophthalmologist and may need to have a conjunctival graft placed to try to save the eye.[12]

If a corneal ulcer ruptures, the anterior chamber depth (spacing between the cornea and iris) may become narrow, and anterior synechiae, pupil distortion, hyphema, and other anatomic abnormalities may be seen. These patients should be referred to an ophthalmologist to best evaluate the prognosis and determine appropriate therapy to save the eye, or determine if enucleation is indicated. If the owners decline referral, medical therapy may be considered for nonleaking corneal perforations less than 5 mm in size (see Seidel test on p. 289). Medical therapy is the same as for an infected corneal ulcer. Deep but small nonleaking corneal ruptures might vascularize and heal, but the prognosis is generally very guarded to poor for saving the eye or vision. Rerupture and further intraocular anatomic derangement, as well as glaucoma, blindness, and ongoing pain, are risks in such cases. Enucleation may be indicated for large, leaking corneal ruptures with extensive intraocular anatomic derangement, extensive hyphema, and/or active infection. If corneal infection progresses to internal eye infection *(endophthalmitis),* the eye will become very painful and require enucleation. If the infection spreads into the orbit and the infection is not contained to the orbit by enucleation, the infection could ascend into the cranium through the optic canal and become life-threatening.

SURGICAL TREATMENT

Surgery for infected corneal ulcers is indicated when the ulcer is very deep and/or large, the ulcer and uveitis are worsening despite aggressive medical therapy, and/or when corneal blood vessel growth is inadequate. Such ulcers are generally best treated by referral to an ophthalmologist.

Preoperative Management

Use a wire-reinforced, guarded endotracheal tube to prevent airway collapse when the neck is bent to position the eye for surgery.

*Perform a **Seidel test** to determine if a corneal ulcer has reached full-thickness and ruptured. Fill a 3-mL syringe with sterile eye wash or LRS after removing the plunger. Dip the stained tip of the fluorescein strip into the solution repeatedly until the solution is a dark, dense yellow. Have an assistant drip the fluorescein solution onto the cornea ulcer site while you watch the area with magnification and a cobalt light. Alternatively, moisten the tip of a fresh sterile fluorescein strip with a full drop of sterile eye wash, and allow this drop to fall onto the top of the globe; monitor the site in question under magnification with a cobalt light. Observe to see whether a clear rivulet of aqueous humor is seen running through the fluorescein stain.* A positive Seidel test indicates aqueous humor leakage and that the corneal ulcer has ruptured. If a corneal perforation is leaking, referral to an ophthalmologist is indicated because accurate evaluation and repair requires use of specialized skills and an operating microscope.

NOTE Corneal perforations and conjunctival grafts needing corneal sutures require an operating microscope with specialized microsurgical techniques and are best referred to a veterinary ophthalmologist.

Anesthesia

See pp. 266 and 281.

Surgical Anatomy

The white part of the eye has three layers: the *conjunctiva*, *episclera,* and *sclera* proper (collagen fibers and fibroblasts), which make up the structural wall of the eye (Fig. 16.18). The episclera and sclera are covered anteriorly by the conjunctiva; posteriorly, muscles insert around vessels and nerves that penetrate the globe surface. The conjunctiva is a thin, vascularized tissue that has epithelium on the external surface. The underside of the conjunctiva is nonepithelialized and thus used in graft surgery.

Positioning

Position the animal in dorsal recumbency with the eye directed straight up (iris parallel to the floor). Sand bags with vacuum (e.g., Olympic Vac-Pac) will assist with head positioning. Be sure the endotracheal tube is guarded with wire reinforcement. The surgeon may prefer to be seated for surgery.

SURGICAL TECHNIQUES

Conjunctival Flap

AP Conjunctival flaps are typically harvested from the perilimbal bulbar conjunctiva and are placed over corneal ulcers. A conjunctival graft provides blood supply to the ulcer and bypasses the slower healing that occurs with endogenous corneal vascularization. Although a graft may block vision in the healed eye and surgery generally leaves more scarring than medical therapy, grafts are much more likely to save an eye with a severe ulcer than is medical treatment. The conjunctiva is a thin, elastic tissue with extensive blood supply that also delivers systemic antibiotics to an ulcer. The conjunctival tissue provides strength to the ulcer bed and replaces the tissue lost to corneal infection when it integrates into the corneal tissue.

Smaller (pedicle or rotational) grafts are preferable in almost all cases where a conjunctival graft is indicated. However, these require an operating microscope and are generally best done by an ophthalmologist or a surgeon well versed on microsurgical techniques. Examples of larger grafts that block more of the cornea, but do not require corneal suture placement, are detailed here. Of the two grafts described below, the hood graft is more appropriate for a small and/or peripheral lesion. The 360-degree graft is more appropriate for a large and/or central corneal lesion, although it will cause complete corneal opacity. In addition to potentially causing blindness, the 360-degree graft also prevents any visualization of intraocular structures and cannot be evaluated for healing or complications. These grafts may be able to be trimmed of nonadherent attachments at a later date, to try to expose the cornea, though blindness may still result.

Plan the conjunctival graft or flap so it will be several millimeters larger than the defect it must cover; conjunctiva will contract after it is cut so the graft will become smaller after harvesting. Prepare a thin, sliding conjunctival flap by grasping the conjunctiva with ophthalmic tying forceps such as 0.3 mm Colibri forceps (see Box 16.2 and Fig. 16.3) approximately 2 mm from the limbus. Apply traction to tent the conjunctiva, and incise a few millimeters from the limbus with a pair of Stevens or Wescott tenotomy scissors (Fig. 16.19A). Elevate the cut edge, bluntly dissecting under the

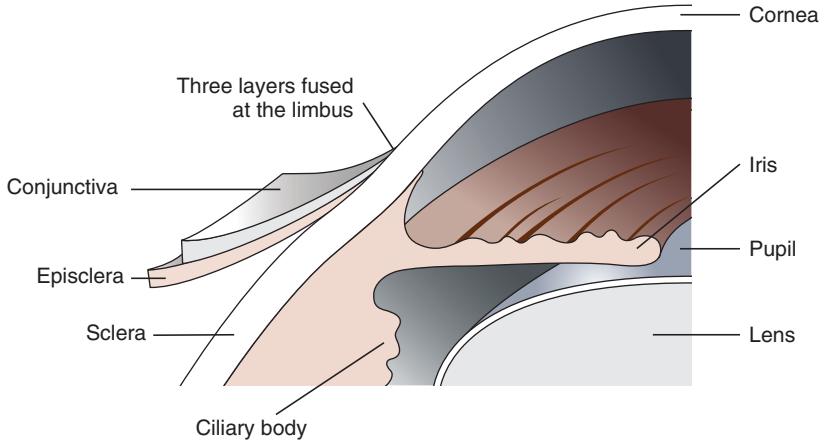

FIG. 16.18 Anatomy of conjunctiva, episclera, and sclera.

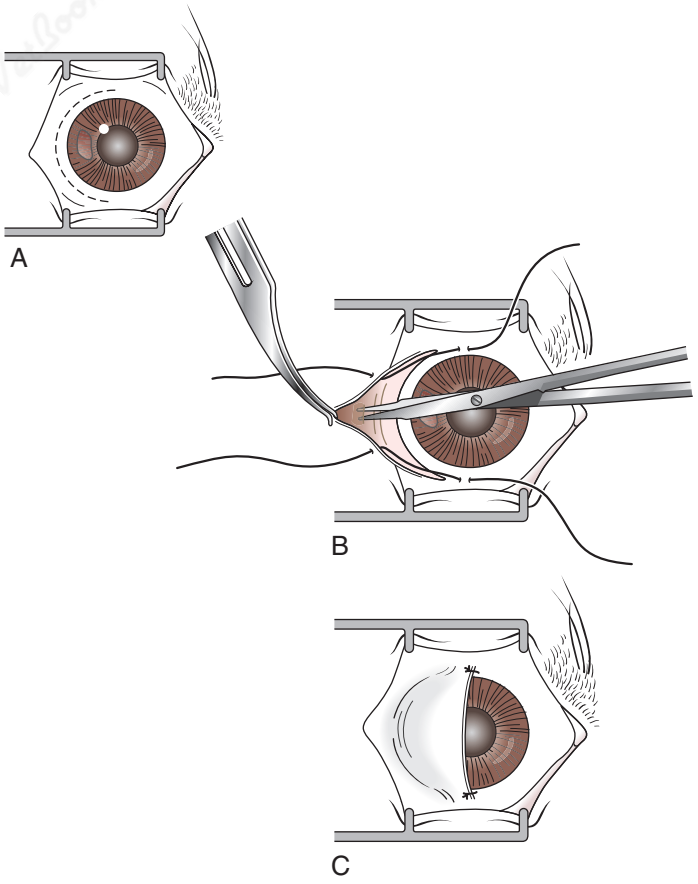

FIG. 16.19 Hood flap. (A) Incise the bulbar conjunctiva adjacent to the lesion parallel to the limbus, and undermine it. (B) Carefully, bluntly dissect the conjunctiva from the fibrous episcleral tissue using tenotomy scissors. The final graft should have no tension. (C) Advance the graft to cover the lesion and suture it in place, usually with two to four simple interrupted sutures into the sclera at the limbus.

conjunctiva and parallel with the limbus, using tenotomy scissors to separate the conjunctiva from the underlying sclera. Starting at the free edge of the tissue flap, use the tenotomy scissor tips directed at a 90-degree angle to the flap and make small cuts with the tips to sharply and bluntly dissect the fibrous episclera from the more superficial thin conjunctiva, taking great care not to make any holes in the conjunctiva (such holes only enlarge with further manipulation and may ruin the elevated graft), yet keeping the graft tissue as thin as possible (Fig. 16.19B). After dissection, the conjunctival flap becomes much more mobile. Position the conjunctival graft over the defect; it should lay over and beyond the ulcer bed on its own with no tension. Carefully debride the corneal epithelium from the corneal ulcer bed and edges with cellulose spears, taking great care not to rupture the ulcer, before placing the conjunctival graft on top so the corneal stroma (and not epithelium) will be in contact with the bleeding underside of the conjunctiva (Fig. 16.19C). Secure the conjunctiva into position so that it can heal and integrate with the corneal stroma. Note that suture should never penetrate the cornea full thickness.

NOTE Stevens or Wescott tenotomy scissors and microsurgical forceps, such as Colibri forceps, are required for this procedure (see Fig. 16.3).

Hood Conjunctival Flap

AP *Dissect a hood flap from the bulbar conjunctiva dorsal to the lesion or from the bulbar conjunctiva as close to the corneal ulcer as possible (see Fig. 16.19A). Dissect a semicircular area of conjunctiva as described previously and place it over the ulcer and at least several mm beyond. Ensure that the conjunctiva lies flat on the cornea with no traction; this will occur if the episclera has been well dissected from the conjunctiva with tenotomy scissors. Place two absorbable sutures (6-0 polyglactin 910; see Box 16.2) in a simple interrupted pattern at the limbus 180 degrees apart to position the flap over the cornea. Provide tension across the free edge of the flap to keep it in place over the corneal ulcer; corneal sutures are not required. Place partial-thickness sutures into the episclera in a simple interrupted pattern with 6-0 polyglactin 910, taking care not to place the sutures full-thickness through the eye wall. If needed, place additional limbal sutures to further anchor the flap (see Fig. 16.19C).*

360-Degree Conjunctival Flap

AP *Starting 2 to 3 mm from the limbus, make an incision in the conjunctiva and use tenotomy scissors under the perilimbal tissue to bluntly dissect the conjunctiva from the globe 360 degrees (Fig. 16.20A). Separate the conjunctiva from the episclera (see Fig. 16.20B) as described earlier. Use caution near the area of the third eyelid when harvesting the donor conjunctiva and make every effort to minimize involvement of the third eyelid into the graft; keep the natural mobility of the third eyelid in mind.*

After the episclera has been adequately dissected from the conjunctiva, the conjunctiva should stretch easily over the corneal ulcer bed with minimal traction.

If the graft has a great deal of tension, continue to dissect the episclera off the conjunctiva, starting at the free edge of the conjunctiva and moving the tenotomy scissors down to the globe, taking care not to cause button-holes in the conjunctiva. After the conjunctival graft has been harvested 360 degrees, suture the free edges of the conjunctival graft together in a line with a horizontal mattress pattern (see Fig. 16.20C–D) using absorbable suture (6-0 polyglactin 910 or smaller). Ensure that the sutures are tight, so that no corneal contact is made by sutures. The conjunctival graft will be sutured to itself and not to the cornea.

It is important to get the undersides of the conjunctival edges apposed with the sutures. The tissues cannot heal together if the conjunctival underside of one side is sutured to the epithelial surface of the other side.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Conjunctiva is a thin, delicate tissue; therefore small sutures such as 6-0 polyglactin 910 should be used (see Box 16.2). Larger sutures and associated suture needles can tear conjunctiva; a large suture can also cause iatrogenic problems if it contacts the cornea. Piercing of the conjunctiva and cornea with the suture needle will create holes that will not seal, so precise needle placement is required (and repeated needle piercings are to be avoided). Forceps not designed for handling conjunctiva can also damage any harvested graft material, and proper instrumentation is critical. Be sure use have Stevens or Wescott tenotomy scissors and microsurgical forceps (see Fig. 16.3).

POSTOPERATIVE CARE AND ASSESSMENT

Eyes with deep corneal ulcers are extremely fragile and susceptible to injury upon recovery from anesthesia; therefore recovery

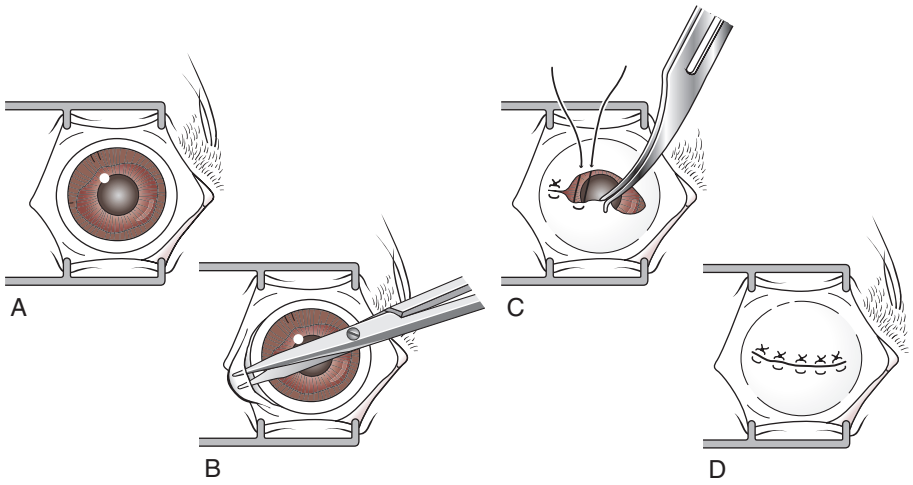

FIG. 16.20 Total or 360-degree conjunctival graft/flap. (A) Start the flap by making a 360-degree conjunctival incision adjacent to the limbus. (B) Undermine the conjunctiva then dissect the episcleral tissues from the conjunctiva using tenotomy scissors and advance it to the center of the cornea. (C–D) Close the conjunctiva by suturing it to itself and not to the cornea in a horizontal mattress pattern.

should be slow, calm, and smooth to prevent head thrashing or self-trauma. Use a rigid E-collar as discussed previously (see p. 271) sized to just beyond the nose when the head is extended (soft E-collars and inflatable neck-only collars will not prevent the animal from rubbing the eye against objects).

Topical antibiotics (see Box 16.1) should be administered until the eye is healed. Analgesics (e.g., opioids) are essential to prevent pain (see Chapter 13). Postoperative sedatives (e.g., acepromazine; see Chapter 12) may be needed to calm the patient. Systemic NSAIDs can be used briefly after surgery because they will help reduce postoperative uveitis, pain, and conjunctival swelling, but they also will slow corneal vascularization and healing. Topical NSAIDs should be avoided with corneal ulceration because some (e.g., diclofenac) can cause corneal melting.[11] The cornea has denser nerve receptors than anywhere else on the body; therefore analgesics like opioids may be prescribed for corneal pain.[13] Use 1% atropine drops once to twice daily to treat secondary uveitis.

Perform an eye exam in a few days and then every 1 to 2 weeks following conjunctival graft surgery. Continue topical antibiotic drops as guided by culture and sensitivity (see Box 16.2) until the conjunctival graft has integrated into the cornea ulcer or the corneal ulcer has completely vascularized. Tissue over the ulcer site should not be removed; it should be left integrated into the cornea. Scar remodeling occurs over several months, and final results vary from an insignificant opacity to a dense leukoma causing significant corneal opacity and vision loss.

COMPLICATIONS

If a corneal ulcer ruptures under the conjunctival graft and intermittent or continuous leaking occurs, the eye should be enucleated. Ruptured corneal ulcers that heal will leave synechiae (adhesions) inside the eye that can later lead to secondary glaucoma. Blindness with phthisis bulbi may also result if there is extensive leaking and/or intraocular damage.

If the conjunctival graft pulls off the corneal or uncovers the ulcer bed, the ulcer still may heal by vascularization. If the conjunctival graft detaches from the cornea and the ulcer ruptures, enucleation will likely be needed. Infectious endophthalmitis can develop even weeks after intraocular contamination and will present with hypopyon and severe pain. These eyes should be enucleated. Conjunctival grafts may fail if the corneal epithelium was not adequately debrided from the ulcer site, if surgical technique was poor, or if local bacterial infection develops. Too much tension on the conjunctival graft may cause premature graft retraction or dehiscence.

PROGNOSIS

With surgical management for infected or deep corneal ulcers, the prognosis for saving the eye is guarded.

Surgeries of the Face and Orbit

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Proptosis is an outward displacement of the eye from its normal position in the orbit. **Exophthalmos** is forward displacement of the globe. **Buphthalmos** is enlargement of the globe from chronic glaucoma. **Enucleation** is removal of the globe, nictitating membrane, orbital glands, and eyelid margins. **Evisceration** is removal of the internal contents of the globe including the iris, uveal tract, lens, and retina. **Intrascleral prosthetic** (ISP) is an eye that has been eviscerated and the internal contents have been replaced with a black round silicone prosthetic (implant).

PREOPERATIVE CONCERNS

If head trauma has occurred, ensure the patient is stable before focusing on the eye problem. Treat any shock or life-threatening problems first.

PREPARATION OF THE SURGICAL SITE

All members of the surgery staff need to confirm that the correct eye is being prepped and operated on. Antibiotic ophthalmic ointment is applied to both eyes for lubrication and prophylaxis (see Box 16.1). If the eyelid margins are visible, hair around the surgery site should be clipped in a 2-inch (5 cm) wide area with a No. 40 clipper blade. Prep and drape as previously described (see p. 266).

NOTE Procedures requiring surgery inside the eye are best referred to a veterinary ophthalmologist.

ANESTHETIC CONSIDERATIONS

General anesthesia should be performed for globe and orbital surgeries. Globe surgeries are often painful, and perioperative opioids should be considered for analgesia (see Chapter 13). As with other ophthalmic surgeries, consider premedicating patients with glycopyrrolate or atropine to reduce the risk of the oculocardiac reflex that can cause bradycardia (see p. 266); these drugs may need to be repeated intraoperatively.

For enucleation, local adjunctive anesthesia may be considered intraoperatively to improve analgesia (see pp. 152 and 298).[14] Retrobulbar injections of local anesthetics before surgery may increase bleeding during surgery or cause globe perforation if inadvertently injected into the globe. Preoperative retrobulbar injections also risk an intraarterial or intrathecal injection that can cause direct damage to the optic nerve, apnea, or seizures.[15] Systemic toxicosis is unlikely, but maximum doses should be determined and not exceeded in very small animals. Local anesthetics can also be given after the globe is removed and the orbital septum has been closed.

ANTIBIOTICS

Orbital infections can be dangerous due to the proximity of the brain and optic nerve; thus perioperative prophylactic IV antibiotics and postoperative oral antibiotics are indicated (see Chapter 9).

SURGICAL ANATOMY

The orbit contains several secretory tissues that produce tear film fluids. The conjunctival fornix at the intersection of the bulbar and palpebral conjunctiva contains cells that produce mucin, the inner layer of the tear film. The aqueous layer of tears is produced by the lacrimal gland in the dorsolateral orbit and the third eyelid gland on the bulbar side of the base of the third eyelid. The meibomian glands that line the eyelid margins produce an oil that prevents tear film evaporation.

The orbit is the cavity in the skull containing the eye, fat, and the ocular adnexa (Fig. 16.21). The bony orbital margin (frontal, lacrimal, and zygomatic bones) encompasses approximately four-fifths of the orbit circumference; the remainder is completed by the orbital ligament. The orbital ligament is a thick, fibrous band connecting the zygomatic process of the frontal bone with the frontal process of the zygomatic bone. Both the orbicularis oculi muscle and the lateral palpebral ligament attach to the orbital ligament. The medial wall and part of the roof of the orbit are bony (frontal, lacrimal, presphenoid, and palatine bones). Five foramina are present in the medial wall: the optic canal, orbital fissure, lacrimal canal, and two small ethmoidal foramina. The optic canal is rostral to the other foramina in the orbit and is traversed by the optic nerve and the internal ophthalmic artery. The orbital fissure between the basisphenoid and presphenoid bones gives passage to the oculomotor, trochlear, ophthalmic, and abducens nerves; the anastomotic branch of the external ophthalmic artery; and the orbital venous plexus. The retractor bulbi muscle originates in the orbital fissure. The rostromedial orbit houses the lacrimal canal, through which the nasolacrimal duct travels. The *nasolacrimal duct* connects to the two canaliculi, whose two puncta are found at the medial canthus. A fossa for the lacrimal gland is present in the ventral surface of the zygomatic process of the frontal bone, where the orbital ligament originates. The lateral orbital wall and floor are formed by soft tissues: the

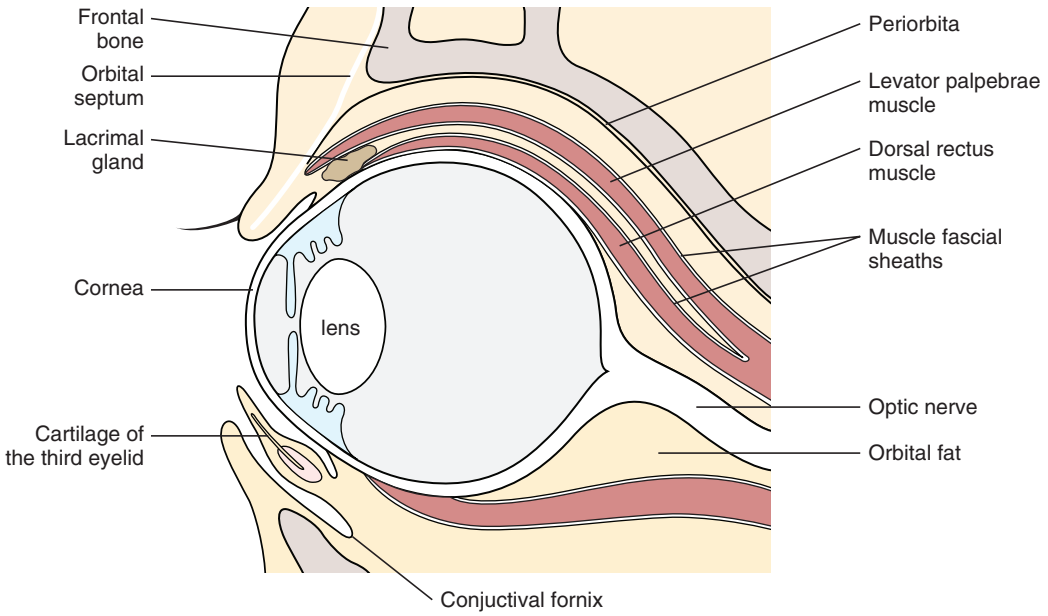

FIG. 16.21 Globe and orbital anatomy.

medial pterygoid muscle, the temporalis muscle, and the zygomatic gland. The maxillary artery and nerve cross the floor of the orbit near its apex. Orbital fat is present at the caudal pole of the eye, surrounding the optic nerve with spaces between extraocular muscles. This fat serves as a cushion and permits rotation and retraction of the eye. Extraocular muscles insert on the sclera and function to rotate and retract the eye. These muscles include the rectus muscles (dorsal, ventral, medial, and lateral), the oblique muscles (dorsal and ventral), and the retractor bulbi muscle. The orbit, extraocular muscles, and other orbital structures are covered with fascia (periorbital, muscular, and bulbar).

SURGICAL TECHNIQUES

Facial Fold Removal

Facial folds are breed-related skin folds rostral to the eyes on the bridge of the nose that may be large enough to touch the corneal surface. Affected breeds include the pug, Pekingese, and bulldog. Facial fold removal surgery is indicated when they touch the cornea, as they increase the risk for corneal trauma and ulceration. Facial skin infection should ideally be treated and controlled before surgery.

NOTE Warn the owner that removing the facial fold will change the shape and appearance of the face.

Consider the breed in determining how much to reduce or remove the facial fold. Using a No. 15 scalpel blade or Mayo scissors, make parallel incisions along the base of each skin fold or approximately 0.5 to 1 inch (1.3–2.5 cm) above the base of the skin fold to remove the excessive skin (Fig. 16.22A). Align the skin with buried interrupted 3-0 absorbable sutures. Use a simple continuous subcuticular pattern to close the skin incision with 3-0 to 4-0 absorbable intradermal sutures. Close the skin routinely with simple interrupted 3-0 to 2-0 sutures (see Fig. 16.22B). Due to the moisture at the site of the facial folds, continue the oral antibiotics while the skin heals, or for at least 4 weeks if skin infection is present.

HEALING OF THE FACE AND ORBIT

The face and orbital skin heal like other skin. Skin sutures should be tied tightly.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

A typical soft tissue surgery set is used for most of the procedures described.

POSTOPERATIVE CARE AND ASSESSMENT

After surgery, use a rigid E-collar as discussed previously (see p. 271). Antibiotics (see Box 16.1) should be administered until the surgery site is healed.

COMPLICATIONS

Hemorrhage, infection, and incision dehiscence are the major complications of orbital surgeries.

SPECIAL AGE CONSIDERATIONS

Younger animals are more prone to trauma and conformation issues such as facial folds. Glaucoma can be congenital or can affect animals of any age.

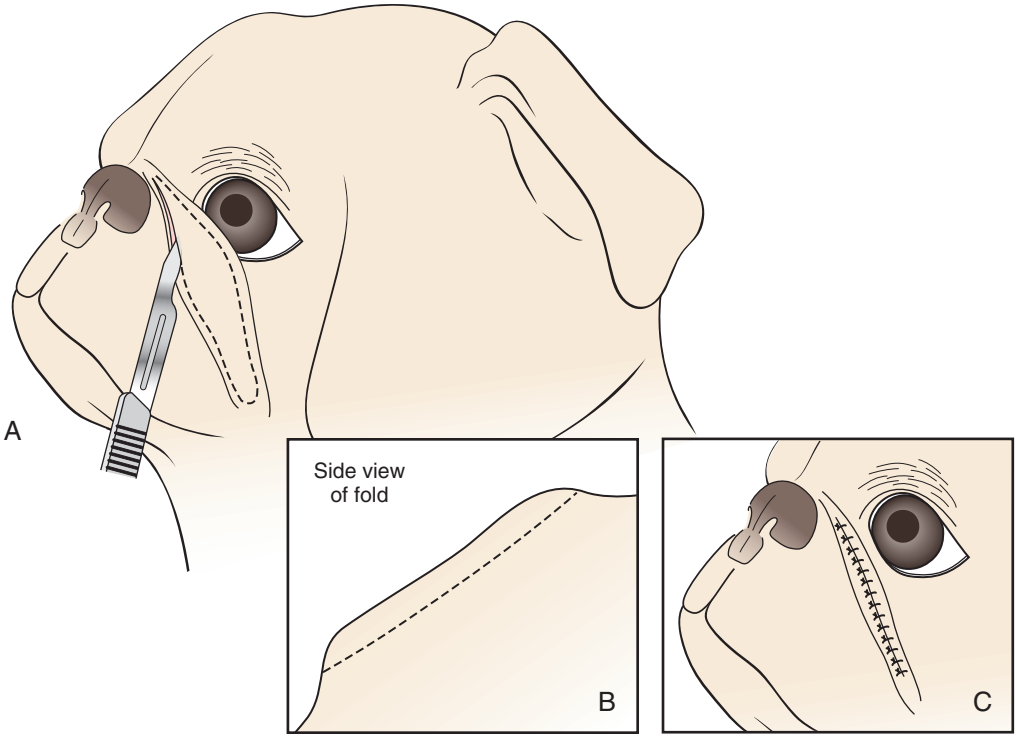

FIG. 16.22 Facial fold removal. (A–B) Start by making parallel skin incisions just above the base of each facial fold to reduce the height of the fold and eliminate corneal contact with the hair and skin. (C) Align and close the subcutaneous layer and then the skin.

SPECIFIC DISEASES

TRAUMATIC PROPTOSIS

DEFINITIONS

Traumatic proptosis is a forward displacement of the globe from the orbit by a traumatic episode resulting in entrapment of the eyelids behind the eye. **Tarsorrhaphy** is closure of the eyelids.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Blunt head trauma, combined with retrobulbar hemorrhage and/or swelling and orbital fractures, can cause acute forward displacement of the globe beyond the bony orbit and eyelids. Excessive restraint of animals with large palpebral fissures and shallow orbits can also cause globe proptosis. Once displaced, contraction and inward rolling of the eyelids and spasms of the orbicularis oculi muscle prevent return of the prolapsed globe to its normal position. Ocular muscle damage, hemostasis, conjunctival swelling, and corneal exposure leading to corneal ulcers may occur. **Traumatic proptosis is an emergency.**

In brachycephalic dog breeds, proptosis occurs easily because they have shallow orbits and large palpebral fissures that allow their globes to move forward more easily. With these dogs, less severe trauma (e.g., restraint) can cause proptosis and usually results in less tissue damage than nonbrachycephalic dogs.

In dolichocephalic dog breeds and in cats, the naturally deeper orbits mean that severe trauma (e.g., vehicular accident or animal fight) is needed to cause a traumatic proptosis, and the orbital tissue damage is usually more severe. Head trauma can also cause skull, mandibular, and brain injuries. Longer eye exposure times result in more extensive corneal damage and more severe retrobulbar hemorrhage and edema. Pressure and stretching may damage the optic nerve, extraocular muscles, and orbital tissues (e.g., the lacrimal gland).

DIAGNOSIS

The globe will be severely protruded, and the eyelid margins will not be visible because they are entrapped behind the eye. Subconjunctival hemorrhage, chemosis, corneal exposure, periocular bruising, and other signs of trauma are usually present.

Clinical Presentation

Signalment

Any animal may suffer proptosis with trauma; however, this is seen most commonly in brachycephalic breeds (e.g., Pekingese, Lhasa Apso, shih tzu, Boston terrier, pug). Sexually intact males are most often affected.

History

The event causing the proptosis may or may not be witnessed by the owner; events that are not witnessed may lead to a delay in treatment.

Physical Examination Findings

A thorough physical examination should be conducted to evaluate other injuries, and the most life-threatening problems or shock should be treated first. Triage the patient and check for evidence of shock, head trauma, pneumothorax, or hemothorax, and palpate the skull for fractures. Puncture wounds, orbital rim fractures, and other injuries should be identified. If cranial trauma has occurred, ensure the patient is stable before focusing on the eye problem.

The eye should be evaluated and lubricated as soon as possible. Check the pupillary light reflexes and, if possible, examine the intraocular structures for hyphema, retinal detachments, or uveitis. The globe should be rapidly evaluated to determine whether it can be replaced. If the optic nerve is torn, the posterior pole of the globe is clearly visible, or a large perforation of the eye wall is present (may be indicated by a deflated globe or ocular hypotony), enucleation should be performed because the prognosis for globe salvage is grave. If three or more extraocular muscles are torn (typically leading to marked dorsolateral strabismus), the orbit is fractured, or the pupil is not visible owing to diffuse hyphema, the prognosis for saving vision is poor, although the globe itself may be salvageable. Pupil size itself is not always a good predictor of vision prognosis because this is determined by multiple factors. Positive prognostic indicators include a brachycephalic dog signalment, intact direct and consensual pupillary light reflexes, intact vision (indicated by tracking of a thrown cotton ball or head retraction when the eye is menaced), a normal fundus appearance, and short duration of proptosis before treatment.[16]

Diagnostic Imaging

Imaging the thorax may reveal concurrent pneumothorax, pleural fluid, or pulmonary contusions. Imaging of the skull may reveal fractures of the orbit and mandible.

Laboratory Findings

The animal may be anemic if significant hemorrhage has occurred.

DIFFERENTIAL DIAGNOSIS

Other possible causes of exophthalmos (forward displaced globe) include retrobulbar abscess, orbital neoplasia, orbital cellulitis, salivary mucocele, or other space occupying orbital disease. Buphthalmos (enlarged globe) is caused by chronic glaucoma (see later).

MEDICAL MANAGEMENT

While stabilizing the patient, immediately and frequently apply topical ointments or gels to the exposed cornea to keep it moist and minimize damage. In many cases, the animal will not allow topical treatments to be applied, but an attempt should be made. The animal should be kept without food and water, and self-trauma should be prevented with a rigid E-collar sized as previously discussed (p. 271).

SURGICAL TREATMENT

Once the patient is stable, replacement of the globe should be done as rapidly as possible because prolonged or progressive retrobulbar swelling may eventually prevent replacement.

Preoperative Management

Keep the eye moist with topical lubricants such as ointments, gels, or an irrigating solution (eye wash or LRS) until the animal is anesthetized. Lubricate the eye with a sterile ophthalmic viscous lubricant or antibiotic ointment. Administer antiinflammatory

drugs (corticosteroids or NSAIDs) for optic neuritis and orbital edema if not systemically contraindicated. Administer a perioperative IV antibiotic with a gram-positive spectrum (e.g., cefazolin or ampicillin). Significant systemic conditions (pneumothorax, shock, bleeding, head trauma, etc.) need to be addressed first; the animal must be stable enough to tolerate surgery.

Anesthesia

Anesthetic drug selection should consider any cranial or thoracic injuries, and drugs with a short duration of action should be used (see Chapter 12).

Surgical Anatomy

See p. 292.

Positioning

Position the animal in lateral or ventral recumbency. In ventral recumbency, elevate the chin on a towel roll to improve the airway and head positioning.

SURGICAL TECHNIQUES

If possible, make a lateral canthus incision using a Mayo or iris scissor to enlarge the palpebral fissure enough to move the eyelids in front of the globe (Fig. 16.23A). Lubricate the cornea with sterile ophthalmic antibiotic ointment. Reduce entrapment of the lid margins using atraumatic forceps. Place two to four partial-thickness temporary tarsorrhaphy sutures of 4-0 nylon or silk, but do not tie them, leaving the area of the medial canthus open (see Fig. 16.23B). Take care to allow the sutures to exit the lid margins so that sutures will not touch the cornea when tightened. Grasp the ends of the preplaced sutures with a hemostat and pull them anteriorly while applying gentle posterior pressure to the well-lubricated globe with a Jaeger lid place, smooth Bard-Parker scalpel blade handle, or the cut finger of a surgical glove (see Fig. 16.23C). Tie the sutures with the ends left long; place stents if the sutures are excessively tight (see Fig. 16.23D). Close the canthotomy incision with a figure-eight suture at the lateral canthus (see Fig. 16.7C) and simple interrupted sutures of 4-0 to 5-0 absorbable polyglactin 910 (see Fig. 16.23E). Place the sutures partial thickness in the eyelid to prevent corneal contact.

Some have advocated tying the tarsorrhaphy sutures in a bow for ease of opening and retying, but this may not be necessary. The cornea may not be visible after the sutures are placed.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

A lid plate, Derf needle holders, and Bishop-Harmon forceps facilitate the procedure. Suture with excellent knot security (e.g., 4-0 silk or nylon) is needed for a temporary tarsorrhaphy. The tarsorrhaphy should remain in place without loosening for at least 14 days.

POSTOPERATIVE CARE AND ASSESSMENT

Monitor for pain, increased mucopurulent exudate, malaise, and/or pyrexia. The temporary eyelid sutures may need to be removed for reevaluation of the eye if it becomes increasingly painful. Topical medications should be applied at the medial opening in the palpebral fissure. Administer a broad-spectrum topical ointment (see Box 16.1) four times daily, 1% atropine ointment every 12 to 24 hours, and an oral antibiotic with gram-positive coverage (e.g., amoxicillin or cephalexin). For optic nerve and retrobulbar swelling, consider administering systemic corticosteroids (e.g., prednisolone) or NSAIDs at an antiinflammatory dose for 2 weeks and then tapering weekly. Decreasing optic nerve swelling is a critical component of treatment to try to restore vision. A rigid E-collar (see p. 271) should be placed on the

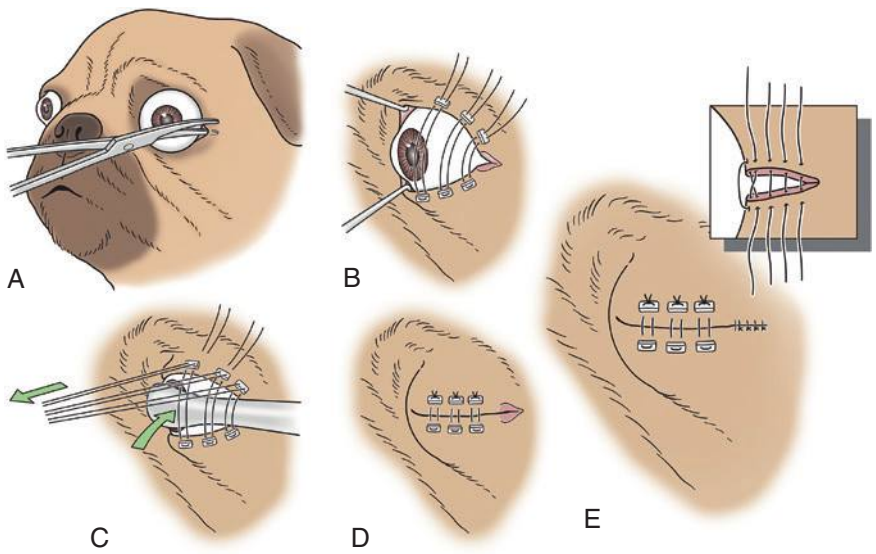

FIG. 16.23 Replacement of a proptosed globe. (A) A lateral canthotomy is often helpful to increase lid laxity, making lid reduction easier. (B) After the lid margins are pulled from their entrapped position, preplace several partial-thickness tarsorrhaphy sutures, but do not tie them. Do not place sutures in the medial aspect of the palpebral fissure. (C) Grasp the sutures simultaneously and pull them anteriorly, while pushing the globe posteriorly with a lid plate or a similar broad object while protecting the corneal surface. (D) Tie the sutures. Do not allow sutures to have contact with the cornea. (E) Close the canthotomy routinely. Use a figure-eight suture at the canthus.

animal to prevent self-trauma. To reduce swelling, if the animal will allow it, cold compresses should be used postoperatively for the first day, and then warm compresses applied three to four times a day for several more days. The sutures may need to be replaced or tightened if the eyelids open as swelling decreases. Loose sutures should be immediately removed or replaced to prevent corneal contact and ulceration. The tarsorrhaphy sutures are removed from medial to lateral after 14 days; this may be done in a stepwise fashion over a few weeks. If the eye is still exophthalmic, retain the more lateral sutures for a longer time or until they loosen.

COMPLICATIONS

Short-term complications requiring treatment include progressive corneal ulceration secondary to suture irritation, exposure, or infection. Long-term complications after proptosis include blindness and strabismus (very common), corneal scarring, KCS, lagophthalmos, corneal hypoesthesia, and phthisis bulbi. Post-proptosis strabismus improves over 6 to 9 months in many cases and often does not require repair.

PROGNOSIS

The prognosis for vision in proptosed globes is guarded to poor. The prognosis for retaining the globe is good although the degree of eventual ocular cosmesis and comfort is variable. The prognosis for vision and a cosmetically acceptable eye depends on the duration and severity of the proptosis. The prognosis is better with a visual eye, mild proptosis, short duration, absent hyphema, minimal extraocular muscle damage, normal fundic exam, and in brachycephalic breeds. Blindness occurs in approximately 60% to 70% of dogs and in 100% of cats. Postproptosis strabismus occurs in approximately 36% of dogs, most frequently resulting from medial rectus muscle avulsion. Deviation of the globe may improve over 6 to 9 months if the muscle damage was not a complete avulsion. Blindness, lagophthalmos (incomplete blink), deviation of the globe, corneal ulcers, corneal perforations, keratitis, hyphema, phthisis bulbi, chronic uveitis, and glaucoma are possible sequelae to traumatic proptosis.

END-STAGE GLAUCOMA

DEFINITIONS

IOP is intraocular pressure. **Glaucoma** is high IOP. **Buphthalmos** is enlargement of the globe from chronic glaucoma.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Normal IOP in dogs is 10 to 20 mm Hg and in cats is 10 to 25 mm Hg. Glaucoma or high pressure inside the eye occurs when IOP is over 25 mm Hg in dogs and 30 mm Hg in cats. Glaucoma can be primary or inherited where the drainage area of the eye is abnormal, leading to aqueous humor outflow obstruction. Glaucoma can also be secondary to chronic uveitis, intraocular neoplasm, or anterior lens luxation, causing the blockage of aqueous outflow from the eye. Chronic uveitis leads to synechiae (adhesions) inside the eye and the accumulation of inflammatory debris (fibrin, red blood cells, white blood cells) over the irido-corneal drainage angle.

DIAGNOSIS

Clinical Presentation

Signalment

Primary glaucoma in dogs is more frequently seen at middle age in certain breeds (cocker spaniel, basset hound, shar-pei, chow, Bouvier des Flandres, shiba inu). Glaucoma in cats is typically secondary to chronic uveitis or other intraocular disease. Feline primary glaucoma is rare but may be seen in Siamese and Persian breeds. Dogs and cats can also be born with congenital glaucoma.

History

Many owners notice diffuse corneal edema, episcleral redness, or the development of buphthalmos, but they may not notice that the animal is blind in one eye. Blindness is easiest to observe when animals lose vision in both eyes and are in unfamiliar surroundings. Eye problems have usually been long-standing before buphthalmos is noted; onset of blindness due to glaucoma is usually reported to have occurred suddenly.

Physical Examination Findings

Mature dogs with chronic glaucoma will present with a blind, buphthalmic eye that has diffuse corneal edema, an episcleral bloodshot appearance, and possibly an aphakic crescent from a lens subluxation. The cornea may have 360 degrees of corneal vascularization and linear tracks that are splits in the corneal endothelial layer from globe stretching *(striate keratopathy)*. The pupil may be fixed and dilated if primary (inherited) glaucoma is present or may be small or irregular from posterior synechiae if the glaucoma occurred secondary to chronic uveitis. The exception to buphthalmic eyes being blind is in some puppies, shar-peis, and cats, who may sometimes develop buphthalmos yet retain some degree of vision. If the eye is already blind and buphthalmic, vision will not improve even if the IOP can be reduced. Less commonly, a chronically enlarged eye may have an IOP in the normal range because the globe stretching has accommodated for the elevated pressure, and/or ciliary atrophy has occurred.

Diagnostic Imaging

In opaque eyes with glaucoma, ocular ultrasound with 7.5, 10, or 20 MHz probes may reveal as little as a lens subluxation or as much as intraocular masses and/or retinal detachments. If the glaucoma is caused by uveitis due to a systemic disease such as metastatic neoplasia or systemic fungal infection, thoracic radiographs and abdominal ultrasound may reveal the underlying problem.

Laboratory Findings

If glaucoma is secondary to uveitis due to systemic infectious, inflammatory, or neoplastic disease, laboratory testing may reflect the underlying cause. Chronic uveitis in dogs can be caused by systemic infection (fungal disease, rickettsial disease, leptospirosis, *Neospora canis*, *Brucella canis*, Chagas disease, canine distemper, etc.) intraocular or metastatic neoplasia, and immune-mediated disease. In cats, chronic uveitis can be caused by infection (FeLV, FIV, feline infectious peritonitis, toxoplasmosis, *Bartonella felis*, systemic fungal disease), neoplasia, and immune-mediated disease. Immune-mediated disease is diagnosed by excluding other causes of uveitis or by histopathology. Other primary ocular conditions may also cause uveitis severe enough to result in glaucoma, including lens-induced uveitis, immune-mediated ocular disease,

migrating ocular parasites, or foreign bodies. In these cases, results of hematologic and biochemical analyses may be normal. Surgically removed ocular tissues should always be evaluated histologically to help determine the cause of the glaucoma.

DIFFERENTIAL DIAGNOSIS

Exophthalmos, where the globe is pushed outwards from the orbit, is typically caused by retrobulbar disease. With exophthalmos, the corneal diameter is symmetric with the normal eye, whereas with buphthalmos, the corneal diameter is larger in the diseased eye than the normal eye.

MEDICAL MANAGEMENT

For acute glaucoma with a normal-sized eye, aggressive medical treatment with IV mannitol and topical antiglaucoma medications should be initiated to try to restore and preserve vision. Medical treatment with topical carbonic anhydrase inhibitors (e.g., dorzolamide, brinzolamide), β-blockers (timolol), or prostaglandin analogues (i.e., latanoprost, travoprost) should be considered with any glaucoma while diagnostics are pursued (Box 16.4). Miotics (i.e., demecarium bromide, pilocarpine) and prostaglandin analogues can potentiate uveitis and cause iris muscle spasm pain. The alpha-2 agonists (i.e., brimonidine, apraclonidine) can cause severe bradycardia or death in some small animals with heart disease and should therefore be avoided.

Glaucoma is ultimately a painful, incurable, progressive disease. If the animal lives long enough, glaucoma will generally progress until medical therapy no longer controls IOP and pain.

Referral for chemical cycloablation (to try to reduce the aqueous humor production) with a vitreal aspirate and injection of gentamicin and dexamethasone may be considered in dogs with uncomplicated primary glaucoma. This procedure should be avoided in cats due to the risk of posttraumatic sarcoma. Chemical cycloablation may be an option when owners have financial constraints or when patients have significant risks with general anesthesia. Chemical cycloablation succeeds approximately 50% of the time at controlling glaucoma and chronic medical treatment is frequently needed for uveitis. Additional risks include recurrence or persistence of glaucoma, lens luxation, cataract formation, uveitis with chronic discomfort, recurrent intraocular bleeding, and phthsis bulbi. These patients should be treated surgically.

BOX 16.4 Examples of Chronic Glaucoma Medication Dosages

Carbonic Anhydrase Inhibitors
Dorzolamide, 1 drop BID to TID
Brinzolamide, 1 drop BID to TID

β-Blockers
Timolol, 1 drop BID to TID

Prostaglandin Analogs
Latanoprost, 1 drop SID to BID
Travoprost, 1 drop SID to BID

Miotics
Demecarium bromide, 1 drop BID to TID

BID, Twice daily; *SID,* once daily; *TID,* three times daily.

SURGICAL TREATMENT

Surgical treatment for end-stage glaucoma causing permanent blindness is intended to be palliative and eliminate the need for chronic medical therapy. When medical therapy can no longer control glaucoma, surgery (enucleation or evisceration and implant) should be performed to alleviate the pain.

Preoperative Management

Initiate medical treatment for glaucoma and corneal ulcers until surgery is performed.

Anesthesia

The animal should be evaluated for underlying systemic diseases when the glaucoma occurs secondary to chronic uveitis. See also p. 292.

Surgical Anatomy

Orbital anatomy is discussed on p. 292, and the wall of the eye is composed of the sclera and cornea as discussed on p. 282. The interior of the eye is divided into chambers (Fig. 16.15). The *anterior chamber* is the space between the cornea and the iris. The *posterior chamber* is the narrow space between the iris and the lens. Both chambers are filled with aqueous humor. The *posterior segment,* located behind the lens, is filled with the semisolid gel-like vitreous that is connected to the posterior lens capsule and the retina. The *uvea* (see Fig. 16.15) is the vascularized tissue inside the eye made up by the *iris*, *ciliary body,* and *choroid*. The iris is the colored part of the eye visible through the cornea and controls pupil size to regulate how much light reaches the retina. The ciliary body is a ring of tissue folds that produce aqueous humor and contains the muscles that regulate the lens shape. The lens is a transparent structure suspended just behind the pupil by 360 degrees of *zonules* or modified cilia arising from the ciliary body. The *retina* is the nerve layer lining the back of the inside of the eye and contains the rod and cone photoreceptors that convert light into the nerve impulses that travel through the optic nerve to the brain. The choroid lies between the retina and sclera, and this vascular layer provides nutrient supply to the retina.

Positioning

Position the animal in ventral recumbency with a rolled towel placed under the chin to hold the head level.

SURGICAL TECHNIQUES

Enucleation

Enucleation involves removing the eye along with the tear-producing tissues around the eye (lacrimal glands and third eyelid, conjunctival fornix, and eyelid margins with the meibomian glands). Besides end-stage glaucoma, enucleation may also be performed for irreparable corneal or intraocular injury, neoplasia, severe proptosis, and chronic uveitis causing blindness. Owners may resist having this surgery performed even though it may improve the animal's quality of life.

Transconjunctival, transpalpebral, and lateral enucleation techniques are described here.[17] With all techniques, excessive traction on the globe and optic nerve should be avoided (particularly in cats) because traction on the optic nerve and chiasm can blind the remaining eye. The globe should not be incised or drained because that can spread disease locally and may also

cause artifacts in tissues submitted for histopathology. Histopathologic evaluation of the globe and any other removed tissue of concern should always be performed.

Transconjunctival Enucleation

The transconjunctival enucleation technique is commonly used. Advantages of this approach include reduced orbital tissue loss (reduced postoperative orbital sinking) and reduced intraoperative bleeding. However, this technique is not preferred for eyes with infected corneal ulcers or perforations. The sterile surgical site will be exposed to a contaminated ocular surface, allowing for possible spread of infectious agents into the orbit. This situation is worsened by rupture of the cornea because intraoperative pressure on the globe may expel infected material from the eye. In these cases, transpalpebral enucleation would be a better choice, especially in dogs.

Using Mayo scissors, make a wide lateral canthotomy to improve exposure (Fig. 16.24A). The area to be cut may be clamped with a straight hemostat before incising to reduce hemorrhage. Placing an eyelid speculum will improve visibility. Make a 360-degree bulbar conjunctival incision a few mm from the limbus using small blunt scissors, such as Stevens tenotomy or small Metzenbaum scissors (see Fig. 16.24B). Palpate the bony dorsal orbital rim so it can be used as a landmark. At the level of the dorsal orbital rim, deepen the incision by dissecting bluntly and sharply with the tip of the scissors until the yellowish sclera and extraocular muscle tendons are exposed (Video 16.1). Incise the tendons with scissors close to the globe (see Fig. 16.24C). Optionally use small hemostats to clamp these areas before cutting to reduce hemorrhage. While grasping the remaining conjunctival tissue at the limbus to prevent pulling on the eye, carry the incision 360 degrees around the globe. The globe should be able to freely rotate once the tissues around the globe are cut; but do not rotate the globe more than 90 degrees; rotate just enough to determine where further dissection is needed.

Do not pull on the eye because this could apply traction to the optic chiasm and blind the remaining eye. While grasping the globe to prevent pulling the eye, clamp the orbital stalk containing the orbital blood vessels, optic nerve, and retractor bulbi muscle with curved hemostats to crush the tissues before cutting (see Fig. 16.24D). While clamping, feel for the back of the globe and the back of the orbit. Incise the orbital stalk with enucleation scissors (strong curved ideally) or curved Metzenbaum scissors approximately halfway between the posterior globe and back of the orbit. Take care to avoid cutting the posterior sclera and rupturing the eye; this could spread disease or adversely affect histopathology. Control hemorrhage from the orbit with clamping the vessels extending from the medial orbit, direct pressure, hemoclips, and/or calcium alginate.

Remove the lid speculum and broadly incise the base of the nictitans, clamping before cutting again to reduce hemorrhage. Remove the entire nictitans, including cartilage and gland at the base. Ensure that all the orbital lacrimal gland, third eyelid with gland, and all the conjunctiva have been removed because these can be fluid producing tissues (see Fig. 16.24E). Remove the eyelid margins with heavy straight scissors, starting at the lateral canthotomy (see Fig. 16.24F). Fully excise the smooth hairless lid margin so that the skin edges will close without excessive dead space or tension. Ensure that the meibomian oil glands along the eyelid margins have been completely removed. If any fluid producing tissue is left behind, the orbit can ultimately develop orbital cysts, infection, or chronic drainage, which may require another surgery. The medial canthal area must be removed. The medial canthus is closely adherent to its deeper attachments, so sharp dissection is sometimes required. Large vessels are occasionally encountered at the medial canthus.

Copiously flush the orbit with sterile saline. Grasp and pull the tissues inside the eyelid to feel for the orbital septum (dense fascia within the eyelid); when the orbital septum is pulled, the whole head will move (Video 16.2). When only subcutaneous tissue without the orbital septum is pulled, much less traction is applied to the head. *Close the orbital septum tightly with 3-0 or 4-0 PDS in a horizontal mattress pattern. Use the tips of your needle holders to feel for openings in the orbital septum. Close any openings so there is no area that will sink in.*

Inject 1 to 3 mL of 0.5% bupivacaine (0.2–0.5 mg/kg cat, 0.5–2 mg/kg dog) into the orbit through the orbital septum using a 23-gauge needle; local anesthesia will improve analgesia for

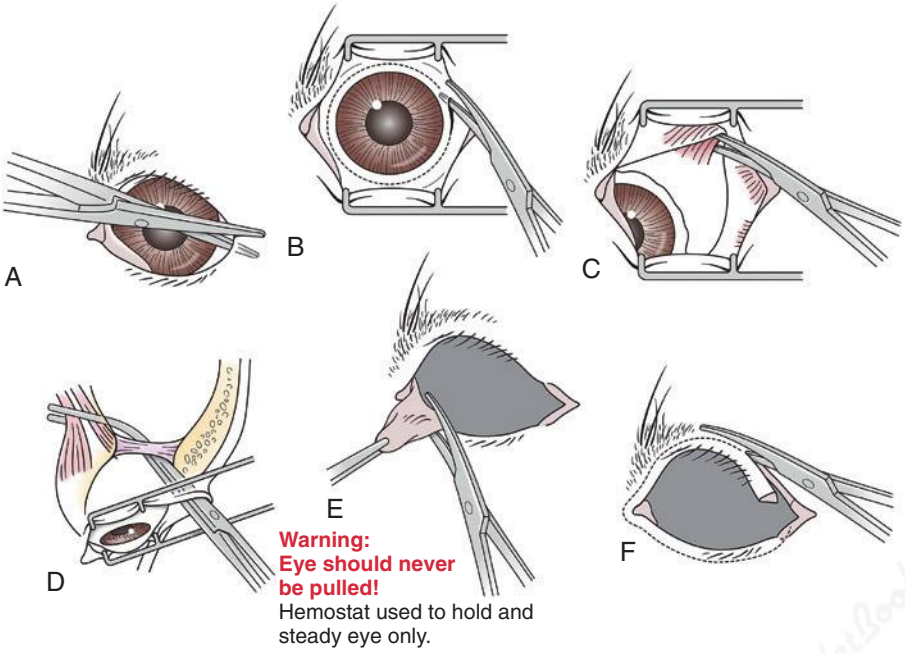

FIG. 16.24 Transconjunctival enucleation. (A) Perform a lateral canthotomy with heavy scissors. (B) Make a 360-degree peritomy (conjunctival incision) with tenotomy scissors. (C) Identify the extraocular muscle attachments and incise them close to the sclera. Optionally, clamp the muscles before incision to reduce bleeding. (D) Clamp the optic nerve and retractor bulbi muscles with a curved hemostat and then incise them. (E) Sharply excise the nictitans and all associated conjunctiva. (F) Sharply excise the lid margins before closing the orbit.

recovery and the postoperative period (Video 16.3). Close subcutaneous tissues and skin routinely.

To create more space around the globe and improve access to the posterior pole of the globe before it has been removed, remove the eyelid margins and third eyelid after the lateral canthotomy and before subconjunctival enucleation.

Other techniques used to improve cosmesis and reduce skin sinking over the orbit after enucleation include orbital mesh placement, sphere implantation (see later), a combination of the two, or tissue reconstruction (e.g., transposing the temporalis muscle to the orbit). Placing an orbital meshwork is simple. A taut continuous pattern of 3-0 to 5-0 monofilament nonabsorbable suture (nylon or polypropylene) is placed with bites 2 to 4 mm apart in the periosteum of the anterior orbital rim. Meshwork may be placed both horizontally and vertically. All gauze that has been placed in the orbit should be removed before the final bites are placed.

Solid implants of methylmethacrylate or, more commonly, silicone have been placed in the orbit to fill its volume. Spherical implant sizes of 16 to 22 mm diameter are typically used for dogs and cats, with brachycephalic breeds generally tending to require smaller implants and dolichocephalic breeds requiring larger ones. Implants should be gas sterilized and rinsed just before use. Removal of the anterior 25% of a solid silicone sphere (such as those used for ISP surgery, discussed later) has been advocated before the implant is placed into the orbit with the flat side facing forward. The implant may then be retained in position with closure of the orbital septum layer or an overlying mesh on the orbital rim, as described. Alternatively, scarifying the sphere has been used to improve retention.

Lateral Enucleation

Advantages of the lateral approach include better visualization of retrobulbar tissues before the globe has been removed, especially in those with deep orbits; improved confinement of the ocular surface from the sterile surgical site; and retention of more orbital tissue than occurs with the transpalpebral technique. Disadvantages compared with the transconjunctival technique include greater loss of orbital tissue and potentially increased bleeding (because much of the dissection occurs more superficially than the sub-Tenon's space).

Perform a wide lateral canthotomy using straight Mayo scissors (Fig. 16.25A). Bluntly dissect the cut surface of each lid into an anterior skin-orbicularis oculi layer and a posterior tarsoconjunctival layer using a curved Metzenbaum scissor (see Fig. 16.25B). Continue blunt dissection medially until the medial canthus is reached. Remove the scissors, replace one blade of the scissor in the subcutaneous pocket just created, and cut the anterior layer parallel to the lid margin as close to the medial canthus as possible (see Fig. 16.25C). Close the lids with Allis tissue forceps or with a 3-0 or 4-0 simple continuous suture, leaving the ends long (see Fig. 16.25D). Working from the lateral aspect of the globe, use blunt and sharp dissection

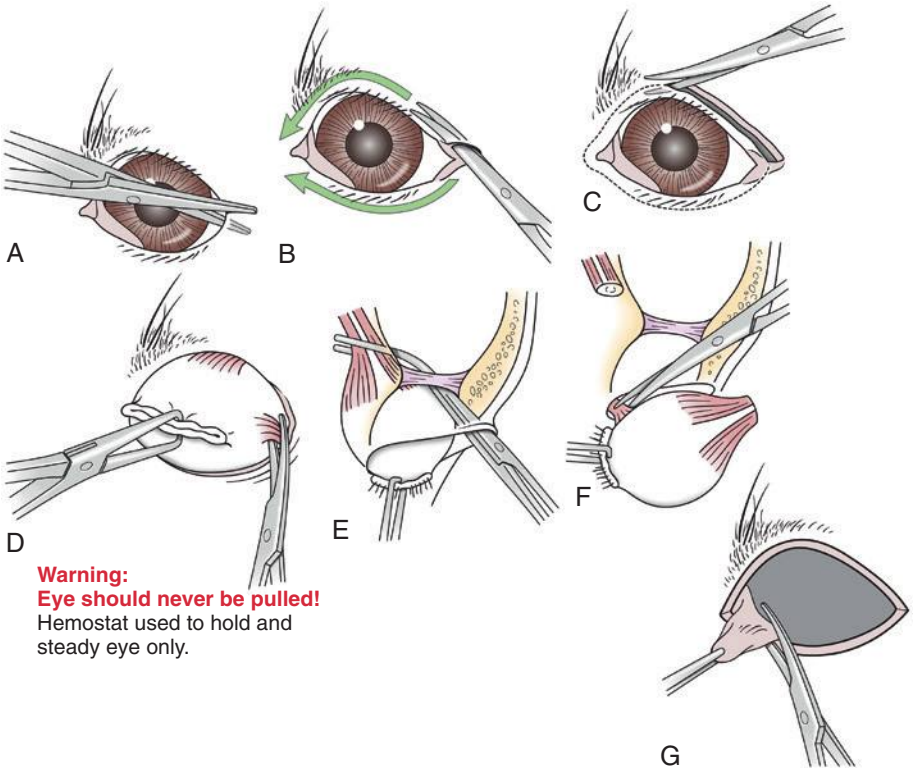

FIG. 16.25 Lateral enucleation (left eye). (A) Perform a lateral canthotomy with heavy scissors. (B) Separate the lid tissues with a curved Metzenbaum scissor to the medial canthus into an anterior skin-orbicularis layer and a posterior tarsoconjunctival layer. (C) Incise the skin-orbicularis layer. (D) Close the palpebral fissure and identify the extraocular muscle attachments; incise them close to the sclera starting with the lateral aspect and continuing posteriorly. The muscles may be clamped before incision. (E) Clamp the optic nerve and retractor bulbi muscles and then incise. (F) Similarly incise the medially located extraocular muscles. (G) Sharply excise the nictitans and all associated conjunctiva.

of tissues around the lateral globe outside the conjunctival sac while clamping before incising the extraocular muscles close to their attachments on the globe (see Fig. 16.25E). Gently retract and rotate the dissected orbital tissues medially as the dissection is performed. Do not pull on the eye because this could apply traction to the optic chiasm and blind the remaining eye. Clamp the tissues of the posterior pole of the globe with a curved hemostat; then cut the orbital stalk between the back of the globe and the posterior orbit. Roll the globe out of the orbit from lateral to medial, and transect the remaining extraocular muscles, the medial canthal tendon, and the attachments of the medial canthus to the orbit from posterior to anterior (see Fig. 16.25F). Remove the third eyelid with gland, and excise any remaining conjunctiva (see Fig. 16.25G). Close the orbital septum, subcutaneous tissue, and skin, and place local anesthetics as previously described for transconjunctival enucleation (p. 298). Procedures to improve cosmesis (orbital sutures and/or implant) may be considered as for transconjunctival enucleation (p. 299).

Transpalpebral Enucleation

The transpalpebral enucleation technique takes the level of dissection slightly further external to the globe. The main advantage of this technique compared with the other methods of enucleation is the superior confinement of the ocular surface from the surgery site; this is particularly important when infection or neoplasia is present on the surface of the eye. Disadvantages include increased bleeding and increased traction on the optic nerve, a particular concern in all cats and in dogs with deep orbits.

Start with closure of the eyelids. Clamp the eyelids closed with Allis tissue forceps or suture the lids closed with a simple continuous suture, leaving the ends left long; these may be used to position the globe (Fig. 16.26A). Circumferentially incise the anterior skin-orbicularis layer of the eyelids parallel to and 4 to 5 mm from the lid margins with a No. 15 Bard-Parker scalpel (see Fig. 16.26B) or electrocautery. From the initial skin incisions, bluntly dissect the subcutaneous tissues with a small curved Metzenbaum scissor around the globe, while keeping the plane of dissection outside the conjunctival sac (i.e., posterior to the conjunctival fornix) (see Fig. 16.26C–D). Use Allis tissue forceps on the subcutaneous tissue inside the incision to keep the eyelids open dorsally and ventrally. Cut the medial and lateral canthal tendons with Mayo scissors to free up the canthal areas (Video 16.4). Palpate the bony dorsal orbital rim so it can be used as a landmark. At the level of the dorsal orbital rim, deepen the incision by bluntly and sharply dissecting with the tip of the scissors into the tissue until the yellowish sclera and extraocular muscle tendons are exposed (see Video 16.1). Bluntly and sharply dissect 360 degrees around the globe, making the incision parallel to the limbus. Free rotation of the dissected sac indicates that most of the attachments of the globe have been freed.

Do not pull the eye because it could place traction on the optic nerve and cause trauma to the optic chiasm, resulting in blindness of remaining eye. Clamp the tissues at the posterior pole of the globe then remove the hemostat. With enucleation scissors (strong curved, ideally) or curved Metzenbaum scissor, cut the optic stalk halfway between the back of the eye and posterior orbit (see Fig. 16.26E). Remove the block of tissue containing the globe, lid margins, orbital lacrimal gland, conjunctiva, and third eyelid with gland (see Fig. 16.26F). Flush the orbit.

Close the orbital septum (see Video 16.2), subcutaneous tissue, skin, and place local anesthetic (see Video 16.3) as previously described for transconjunctival enucleation (p. 298). Procedures to improve cosmesis (orbital sutures and/or implant) may be considered as for transconjunctival enucleation (p. 299); however,

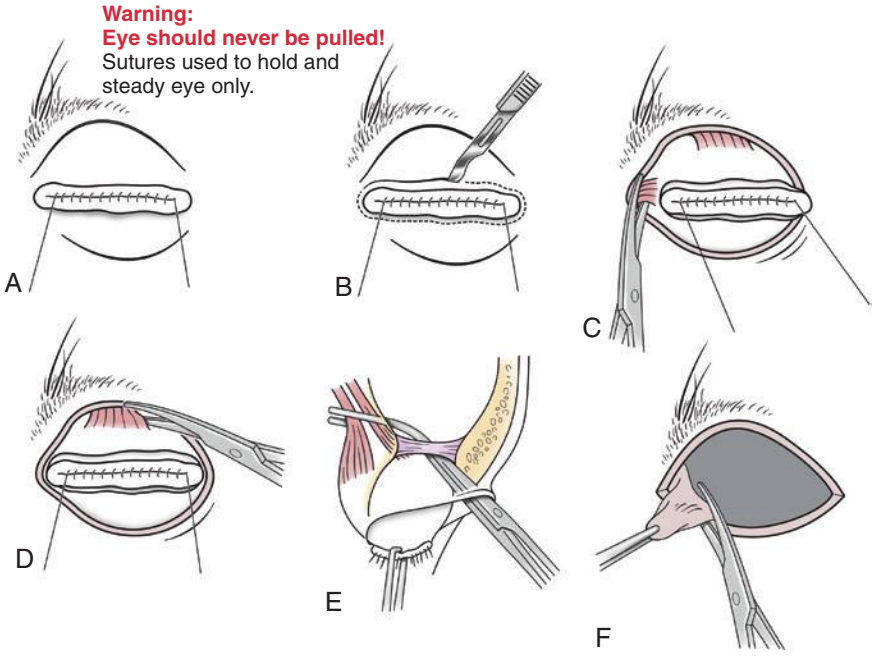

FIG. 16.26 Transpalpebral enucleation (left eye). (A) Suture together the lid margins and leave the ends long to allow for traction. (B) Make a sharp incision around the palpebral fissure through the skin. (C–D) Dissect the subcutaneous tissues to identify the extraocular muscle attachments and isolate and incise them close to the sclera. To reduce bleeding, try to clamp the muscles before incising them. (E) Clamp the optic nerve and retractor bulbi muscles with a curved hemostat and then incise. (F) Sharply excise the nictitans and all associated conjunctiva if any remain.

if contamination of the surgery site may have occurred, the cosmetic benefits of orbital prosthetic placement should be weighed against the possibility of introducing foreign material into a potentially infected space.

Evisceration and Implant

AP Evisceration and implant surgery (ISP) involves removing the internal contents of the globe while preserving the sclera, cornea, and attachments to the globe, including the extraocular muscles. Due to the retention of the ocular wall, cosmesis can be much greater than with enucleation because after surgery, the globe still remains, and the lids can blink and globe motility remains. Because ISP involves intraocular surgery and requires having a variety of implant sizes on hand, these patients should be referred to a veterinary ophthalmologist.

The primary indication for evisceration and ISP placement is chronic uncontrollable primary glaucoma that is painful. The goal of surgery is to provide long-term comfort with minimal long-term medications. Other indications include certain types of chronic secondary glaucoma, chronic uveitis, progressive phthisis bulbi, and blinding corneal trauma, but only when there is no evidence of infection or neoplasia. Globes suspicious for intraocular infection or neoplasia are generally poor candidates for ISP surgery because of the potential for recurrence. Globes undergoing progressive phthisis may benefit from ISP surgery because current globe size is maintained although the globe size cannot be enlarged. Eviscerated ocular contents should always be submitted for histopathologic evaluation to determine the cause of the intraocular disease.

Contraindications for ISP surgery include corneal ulceration, uncontrolled KCS, severe corneal edema, and intraocular neoplasia. Corneal disease is a concern with ISP surgery because the patient retains the ocular surface, along with any preexisting problems it may have. Ideally before ISP surgery, the corneal disease or dry eye should be well controlled and the cornea should be free of ulceration. Buphthalmic enlarged eyes from glaucoma will shrink over 2 to 3 months after surgery to fit the implant size.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

With enucleation surgeries, strong curved enucleation scissors can greatly assist in incising the optic nerve stalk and removing the eye.

POSTOPERATIVE CARE AND ASSESSMENT

Skin incision care and monitoring are the same as for other soft tissue surgeries. The skin incision should be monitored for increased swelling, redness, or discharge.

COMPLICATIONS

Like any soft tissue surgery, enucleations can have complications with infection and incision dehiscence. A more significant complication is chronic discharge, fluctuance, or swelling of the orbit after surgery. If air or fluid intermittently increases in the orbit, some pathway into the orbit exists and could be a route for the entry of infection. In any fluid-producing tissues (lacrimal gland, third eyelid gland, conjunctival fornix tissue, or meibomian glands) remain, fluid will be produced in the orbit and could lead to orbital infection. If the enucleation site has chronic drainage, orbital cyst formation or the intermittent accumulation of air or fluid, the site should be reoperated to remove any fluid-producing tissues, cysts, the medial/lateral canthal tissues, and/or to ablate the nasolacrimal duct openings.

PROGNOSIS

Long-term prognosis for comfort after enucleation is typically excellent.

Surgery of the Ear

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Otitis externa is inflammation of the vertical or horizontal ear canal or both; **otitis media** is inflammation of the tympanic cavity and membrane. **Otitis interna** is inflammation of the inner ear that typically causes vestibular disease in dogs. It is nearly always caused by extension of infection into the petrosal bone from otitis media. **Presbycusis** is a term used to describe age-related hearing loss.

PREOPERATIVE CONCERNS

To anticipate surgical complications in animals undergoing ear surgery, it is imperative to determine the extent and severity of disease. Thickening and calcification of the ear canal indicate irreversible inflammatory disease. A sharp pain response on deep palpation of the ear may indicate middle ear infection, whereas a head tilt may indicate severe pain in the ear on the lower side or otitis media or interna (see p. 317). The latter conditions should be suspected if the head tilt is associated with circling, nystagmus, and/or vestibular dysfunction (loss of balance). Periorbital and retrobulbar abscesses may be associated with chronic otitis externa, media, and interna. Facial nerve deficits in patients with chronic otitis externa (e.g., poor palpebral reflex, lip droop, and facial spasms) suggest that the facial nerve is embedded in the horizontal canal, or that serious concurrent middle ear disease is present. Such abnormalities should be noted before surgery to avoid confusion with problems caused by intraoperative trauma during total ear canal ablation (TECA). Soft palate hypoplasia/malformation has been associated with middle ear disease in dogs.

Otoscopic examination should determine whether the tympanic membrane is intact and should define the severity of change in the horizontal and vertical canals. Digital video otoscopy under anesthesia is commonly used for diagnostic examination and treatment of the external ear canal. Always inspect both ear canals, even if the animal has unilateral clinical signs. Skull radiography or computed tomography (CT) should be performed to determine whether concurrent middle ear disease or neoplasia exists (see p. 317). Proliferation of cartilage or bone around the horizontal ear canal should be noted. After imaging, the ear should be cleaned; however, do not use chlorhexidine in a solution stronger than 0.2%, nondilute iodine or iodophors, ethanol, benzalkonium chloride, or some aminoglycosides if the tympanic membrane has ruptured. Drugs and solutions that may be used in animals with a ruptured tympanic membrane are listed in Box 17.1.

Owners' expectations must be considered before surgery is planned in animals with ear disease. Always question owners as to their perception of the ability of their dog to hear before surgery is planned, as TECA may diminish hearing and may be considered unacceptable. Most owners of dogs with severe, chronic otitis externa or media do not report substantial changes in their animal's hearing after this procedure, probably because notable hearing loss occurred before surgery. Similarly, brain stem auditory–evoked response reveals that auditory function declines minimally after TECA in dogs with chronic otitis externa.

> **NOTE** Be sure that the owner is aware of his or her dog's hearing deficits before surgery. This reduces owner dissatisfaction associated with any perceived hearing loss after surgery.

ANESTHETIC CONSIDERATIONS

Ear surgery, particularly TECA, vertical canal resection, and lateral canal resection, is painful. Although butorphanol and buprenorphine are common premedicants in dogs, hydromorphone and morphine are better analgesics for dogs and cats undergoing ear surgery (Table 17.1). Saturating the open surgical site with bupivacaine hydrochloride may provide some analgesia for 4 to 6 hours. A volume of bupivacaine sufficient to cover the area but not exceeding 2 mg/kg should be used. Contact time must be adequate (approximately 15–20 minutes) to allow the local anesthetic to work. The area needs to be relatively free of blood and should not be flushed during the 15 to 20 minutes that bupivacaine is in contact with the tissues. This technique should never be used as the sole method of pain control.

An alternative technique that provides prolonged postoperative analgesia is the constant-rate delivery catheter such as the ON-Q PainBuster (I-Flow Corporation) or the Surefuser (ReCathCo) local anesthetic systems (Box 17.2; Fig. 17.1). The fenestrated catheter is placed in the open wound just before closure by extending the fenestrated end from one end of the wound to the opposite end. This catheter is then attached to an extension set, which consists of an air filter, a flow controller, extra tubing, and a clamp. The extension set is attached to the disposable bulb (the drug reservoir), which has a fill port. These bulbs and their corresponding flow controllers are designed to deliver a specific volume of local anesthetic per hour. Volume and flow rate are determined by identifying which bulb and flow controller are used. Bulbs come in a variety of sizes from 65 to 550 mL, and flow controllers can deliver rates of 0.5 to 10 mL/h (see Box 17.2).

Although high doses of ketamine should not be given to patients with neurologic or renal dysfunction, a small ketamine

ABSTRACT

Diseases of the ear include those involving the pinna, the canal, and/or the tympanic bulla. Many infectious or inflammatory causes of ear disease are amenable to medical management. When surgery is indicated, knowledge of the regional anatomy, particularly the courses of the facial and vestibular nerves, and the location of the postganglionic sympathetic trunk are essential to minimize complications. Surgical goals include enhancing drainage of the ear canal, improving access for administration of topical medications, and removing diseased or neoplastic tissue.

BOX 17.1 Partial List of Drugs and Solutions That May Be Used to Flush the Ear in Animals With a Ruptured Tympanic Membrane

Aqueous penicillin
Carbenicillin
Ceftazidime
Ciprofloxacin
Clotrimazole
Enrofloxacin
Fluocinolone (aqueous form)
Miconazole
Nystatin
Ofloxacin
Silver sulfadiazine solution (0.1%)
Squalene (Cerumene)
Ticarcillin
Tolnaftate
Tris-ethylenediaminetetraacetic acid (EDTA)

BOX 17.2 Anesthetic Protocol for Pain Buster/ON-Q or Surefuser Constant-Rate Delivery System in Dogs

- Determine lidocaine dose at 6–18 mg/kg/h.
- If using 2% lidocaine, divide above number by 20 mg/mL to get lidocaine flow rate in mL/h. Use extension set with appropriate flow rate. Range is 0.5–10 mL/h.
- Take above number of mL/h and multiply by number of hours needed to determine total dose of lidocaine needed (in mL). In addition, use this volume to determine the size of the bulb required. Bulbs range in size from 65–550 mL.
- Carefully prime the system before use.
- Overfilling the bulb will cause a decreased rate of delivery of medication. Underfilling the bulb will cause increased rate of delivery of medication.
- When securing the system to the patient, make sure the bulb is close to the wound/incision site. (Attaching to the harness at shoulder height should be sufficient.)
- Discontinue if signs of toxicity occur, such as nystagmus, ataxia, drowsiness, depression, muscle tremors, nausea, or vomiting.
- Leave system in place for 24–48 h.

FIG. 17.1 A constant-rate delivery catheter such as the ON-Q Painbuster (I-Flow Corporation) local anesthetic system allows for prolonged postoperative analgesia after ear surgery.

bolus followed by a ketamine constant-rate infusion (CRI) may facilitate intraoperative management and decrease postoperative pain in dogs or cats that have chronically painful ears (see Table 17.1). Alternatively, a single low-dose bolus of ketamine may be used to augment the pain protocol (see Table 17.1). In dogs, fentanyl, lidocaine, ketamine (FLK) or morphine, lidocaine, ketamine (MLK) CRI may be used intraoperatively or postoperatively for analgesia (see p. 144). Other useful CRIs in dogs include fentanyl and lidocaine; a fentanyl CRI without lidocaine may be used in cats.

Postoperative analgesics should be given after ear surgery. If hydromorphone or morphine was used as a premedicant, it can be readministered 3 to 4 hours after the initial dose (see Table 17.1). However, CRIs are preferred over intermittent administration of opioids postoperatively. If the animal appears dysphoric or anxious, tranquilization or benzodiazepines may be necessary; however, these medications should be used only in animals that have been given sufficient analgesics (see Table 17.1). If a question arises as to whether the animal is in pain, repeating analgesic therapy is nearly always warranted.

ANTIBIOTICS

Preoperative antibiotics are recommended in animals undergoing aural surgery. Severe infection should be treated with systemic and/or topical antibiotics for several weeks before surgery is performed, depending on the site of infection. Otitis externa is best treated with topical therapy because systemic antimicrobials are unlikely to achieve therapeutic concentrations within the fluid and exudates of the external ear canal. Commercially produced topical products typically contain one or more active ingredients (antibacterial, antifungal, or antiinflammatory) in various combinations plus a vehicle and various solubilizers, stabilizers, and surfactants. In contrast, systemic antibiotics are indicated in otitis media because the highly vascularized mucous membrane lining the tympanic cavity of the inflamed middle ear promotes diffusion of drugs from the blood to the bulla. If systemic antibiotics alone do not resolve the infection, the bulla may be instilled with an antimicrobial solution in conjunction with systemic antimicrobials. Selection of systemic antibiotics for treating the middle ear compartment is preferably based on culture and susceptibility testing. Cultures of deep tissues taken during surgery often are more useful than preoperative cultures.

Initial treatment of otitis externa can be empirically based on historical information on the most common isolates and their susceptibility patterns, in conjunction with examination of stained otic swab samples. When treatment failures occur, repeat examination and modification of treatment may be aided by repeat cytology of otic exudate and by submission of cultures. *Malassezia* spp. and *Staphylococcus pseudintermedius* are typically the most common microbial isolates identified in dogs with otitis externa. Most *S. pseudintermedius* organisms are susceptible to cephalothin and oxacillin. Most other bacterial isolates are

TABLE 17.1 Anesthetic Considerations in the Patient With Ear Disease

Preoperative Considerations

Associated conditions	• Minimal; usually healthy
Blood work	• HCT • TP • In patients older than 5–7 y, consider electrolytes, BUN, and Cr
Physical examination	• Pain may be noted at presentation

Premedications	• If patient is anxious, give the following:
	  • Diazepam (0.2 mg/kg IV), *or*
	  • Midazolam (0.2 mg/kg IV, IM), *plus*
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM in dogs; 0.05–0.1 mg/kg IV, IM in cats), *or*
	  • Oxymorphone[e] (0.05–0.2 mg/kg IV, IM), *or*
	  • Morphine[b] (0.1–0.2 mg/kg IV or 0.2–0.4 mg/kg IM in cats, 0.5–1 mg/kg IM in dogs), *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM)

Intraoperative Considerations

Induction	• If premedicated, give:
	  • Propofol (2–4 mg/kg IV), *or*
	  • Ketamine (5 mg/kg IV with diazepam or midazolam as above), *or*
	  • Alfaxalone (2–3 mg/kg IV)
	• If no premeds given, give:
	  • Propofol (4–8 mg/kg) IV), *or*
	  • Alfaxalone (2–5 mg/kg IV)

Maintenance	• Isoflurane or sevoflurane, *plus*
	  • Fentanyl (2–10 µg/kg IV prn in dogs; 1–4 µg/kg IV prn in cats) for short-term pain relief, *plus*
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV prn in dogs; 0.05–0.1 mg/kg IV prn in cats), *or*
	  • Oxymorphone[e] (0.05–0.2 mg/kg IV, IM), *or*
	  • Morphine[b] (0.1–1 mg/kg IV prn in dogs; 0.05–0.2 mg/kg IV prn in cats), give slowly IV to avoid histamine release *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV prn), *plus* prn
	  • Ketamine (low dose) (0.5–1 mg/kg IV), *or*
	  • Ketamine CRI (0.5 mg/kg IV loading dose, then 10 µg/kg/min IV)

Fluid needs	• Crystalloids, 5–10 mL/kg/h plus 3 × EBL • Colloids, (see p. 32 and Table 4.5) 2–10 mL/kg/h IV; when treating hypotension crystalloids are given first, then a bolus of 2–5 mL/kg of colloids over 10–15 min. If continuing colloids as a CRI, the crystalloid rate should be decreased by 40%–50% to avoid volume overload, particularly in cats
Monitoring	• Blood pressure • HR • ECG • Respiratory rate • SpO_2 • Temperature • End-tidal CO_2
Blocks	• Splash block—bupivacaine (max 2 mg/kg) or lidocaine (max dose 5 mg/kg) placed in the surgical field for 15–20 min, *or* • Constant-rate delivery catheter: lidocaine (see Box 17.2)

Postoperative Considerations

Analgesia	• Morphine[b] (0.1–1 mg/kg IV or 0.1–2 mg/kg IM q1–4h in dogs; 0.05–0.2 mg/kg IV or 0.1–0.5 IM q1–4h in cats), *or* • Fentanyl CRI (1–10 µg/kg IV loading dose, then 2–20 µg/kg/h IV), *or* • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM q3–4h in dogs; 0.05–0.1 mg/kg IV, IM q3–4h in cats), *or* • Oxymorphone[e] (0.05–0.2 mg/kg IV, IM), *or* • Lidocaine CRI (1–2 mg/kg IV loading dose, then 1–3 mg/kg/h IV in dogs) • ± Ketamine CRI (2 µg/kg/min IV, if no previous loading dose, give 0.5 mg/kg IV prior to CRI), *plus* • Carprofen (2.2 mg/kg q12h PO in dogs), *or* • Deracoxib (3–4 mg/kg q24h PO for <7 days in dogs), *or* • Meloxicam[d] (0.1–0.2 mg/kg once SC or PO, then 0.1 mg/kg PO q24h in dogs; 0.05–0.1 mg/kg SC, PO once in cats), *or* • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM q4–8h or 0.01–0.02 OTM q6–12h in cats)
Monitoring	• SpO_2 • Blood pressure • HR • Respiratory rate • Temperature • End-tidal CO_2
Blood work	HCT and TP if large blood loss
Estimated pain score	Can be severe depending on source of pain and/or procedure; many of these patients have been in chronic pain

[a]Monitor for hyperthermia in cats.
[b]Give slowly to prevent histamine release.
[c]Buprenorphine is a better analgesic than morphine in cats.
[d]Black box warning added by the Food and Drug Administration in October 2010 identified cases of renal failure and death in cats with repeated uses of meloxicam. Meloxicam is approved for single use only in cats in the United States.
[e]At the time of publication, oxymorphone was not readily available; however, a dose has been provided throughout in the event it can be compounded or becomes available.
BUN, Blood urea nitrogen; *Cr,* creatinine; *CRI,* constant-rate infusion; *EBL,* estimated blood loss; *ECG,* electrocardiogram; *HCT,* hematocrit; *HR,* heart rate; *IM,* intramuscular; *IV,* intravenous; *OTM,* oral transmucosal; PO, orally; *prn,* as needed; *SC,* subcutaneous; *SpO_2,* hemoglobin saturation with oxygen; *TP,* total protein.

susceptible to a number of antimicrobials; however, *Pseudomonas aeruginosa* and *Enterococcus* spp. are often fairly resistant. Ototoxic antimicrobials (e.g., gentamicin, kanamycin, neomycin, streptomycin, tobramycin, amikacin, polymyxin B) should be avoided in animals with otitis. Tris-ethylenediaminetetraacetic acid (EDTA) solution or a combination of tromethamine, EDTA, and benzyl alcohol (see p. 315) may be beneficial in some animals with resistant infection.

SURGICAL ANATOMY

The ear is composed of four parts: (1) the inner ear, which consists of a membranous and bony labyrinth and functions for hearing and balance; (2) the middle ear, which is formed by the tympanic cavity and connects to the pharynx via the auditory tube (eustachian tube); (3) the external ear, which is formed by the auditory meatus and a short canal; and (4) the pinna (Fig. 17.2). The inner ear is located within the osseous labyrinth of the petrous part of the temporal bone. The middle and external ears are separated by the tympanic membrane, and the opening of the horizontal canal into the middle ear is known as the *external acoustic meatus*. Three auditory ossicles (malleus, incus, and stapes) connect the tympanic membrane to the inner ear from the external acoustic meatus to the oval window. Vibrations of the tympanic membrane are transmitted through the chain of these auditory ossicles to perilymph fluid within the vestibule. The tympanic cavity is air filled and, in dogs, is composed of the small dorsal epitympanic recess, the tympanic cavity proper, and the large ventral tympanic bulla. The middle ear connects to the nasopharynx via the auditory tube. Nasopharyngeal polyps (see p. 327) may extend from the nasopharynx into the tympanic cavity and can extrude into the external ear canal.

The tympanic membrane is normally thin and semitransparent but may thicken or rupture when diseased. It is divided into the small, upper pars flaccida and the larger, lower pars tensa. The facial nerve exits the stylomastoid foramen caudal to the ear and courses ventral to the horizontal canal close to the middle ear.

The feline tympanic cavity is divided into two compartments by a thin, bony septum that arises along the cranial aspect of the bulla and curves to attach to the midpoint of the lateral wall (Fig. 17.3). For complete drainage of the middle ear of cats, this bony septum often needs to be perforated. The larger ventromedial compartment is an air-filled tympanic bulla. Most of the lateral wall of the smaller dorsolateral compartment is formed by the tympanic membrane. These compartments communicate through a narrow fissure located dorsally near the cochlear window. Near this fissure, the postganglionic sympathetic nerves form a plexus on a structure known as the *promontory*. Because of their vulnerable location, these nerves can be traumatized during surgical curettage of the feline middle ear, resulting in Horner syndrome (see p. 329).

The canine pinna varies greatly in size and shape among dog breeds. The tip of the pinna is the *apex*, and the *scapha* is the thin, flat pendulous portion. The lateral and medial scaphal margins make up the helix of the ear funneling into the opening of the external ear canal, the *external auditory meatus*. At the base of the ear are several ridges that are important landmarks for surgery (Fig. 17.4): the tragus, the lateral crus of the helix, the pretragic incisure, and the intertragic incisure.

The external ear canal consists of an initial vertical canal and a shorter horizontal canal composed of auricular and annular cartilage. The deepest part of the ear canal (near the tympanic membrane) is osseous. Numerous muscles attach to the cartilage of the ear, allowing it to move to localize sound.

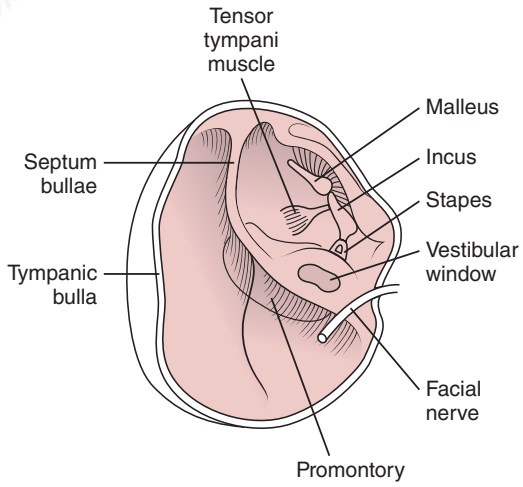

FIG. 17.3 Feline tympanic cavity.

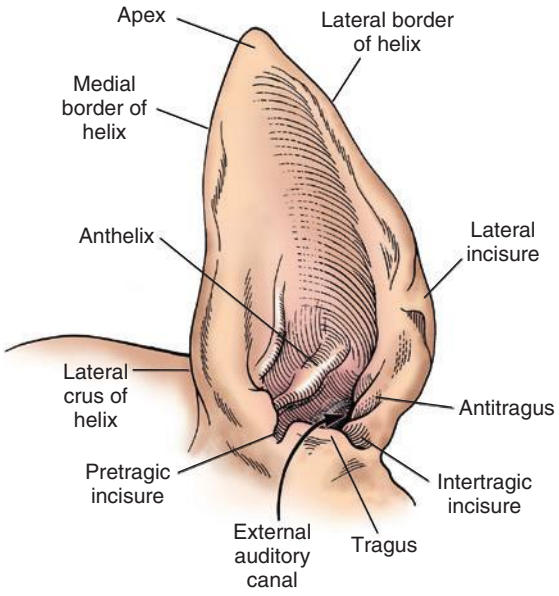

FIG. 17.4 Landmarks of the external ear in dogs.

SURGICAL TECHNIQUES

Numerous surgical techniques have been described for the treatment of ear disease in dogs and cats. When performing a lateral canal resection or a vertical canal ablation, one should be prepared to perform a TECA if the opening of the horizontal canal is stenotic or too narrow to allow adequate drainage.

Lateral Ear Canal Resection

Lateral ear canal resection increases drainage and improves ventilation of the ear canal. It also facilitates placement of topical agents into the horizontal canal. Lateral ear canal resection is indicated in patients with minimal hyperplasia of the ear canal epithelium or with small neoplastic lesions of the lateral aspect of the vertical canal. It should not be performed in animals with obstruction or stenosis of the horizontal ear canal or concurrent otitis media (unless performed in conjunction with ventral bulla osteotomy; see p. 310) or in patients with severe epithelial

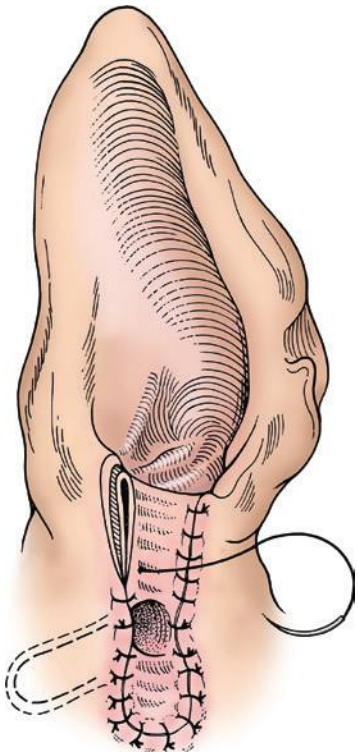

FIG. 17.5 Lateral ear canal resection (Zepp procedure).

hyperplasia. Dogs with underlying disease (e.g., hypothyroidism, primary idiopathic seborrhea) often respond poorly to this surgery. Owner counseling is extremely important before a lateral ear canal resection is performed as most studies have shown that owner satisfaction is low when this procedure is performed for chronic otitis externa in dogs. A modification of the original technique for lateral ear resection establishes a "drainboard" and is known as the *Zepp procedure* (Fig. 17.5). The drainboard restricts hair growth at the horizontal canal opening.

NOTE Make sure the owner understands that lateral ear canal resection is not a cure and that medical management of the ear will likely be necessary for the remainder of the animal's life.

Clip the entire side of the face and both sides of the pinna. Gently flush the ear and remove as much debris as possible. Position the animal in lateral recumbency with the head elevated on a towel and prepare the pinna and surrounding skin for aseptic surgery. Place quarter drapes around the ear with the entire pinna draped into the surgical site. Stand at the ventral aspect of the dog's head and position a forceps into the vertical ear canal to determine its ventral extent. Mark a site below the horizontal ear canal that is half the length of the vertical ear canal (Fig. 17.6A). Make two parallel incisions in the skin lateral to the vertical ear canal that extend from the tragus ventrally to the marked site (see Fig. 17.6B). These incisions should be 1.5 times the length of the vertical ear canal. Connect the skin incisions ventrally and, using a combination of sharp and blunt dissection, reflect the skin flap dorsally, exposing the lateral cartilaginous wall of the vertical ear canal. During dissection, stay as close as possible to the cartilage of the ear canal to avoid inadvertently damaging the facial nerve. Note the parotid

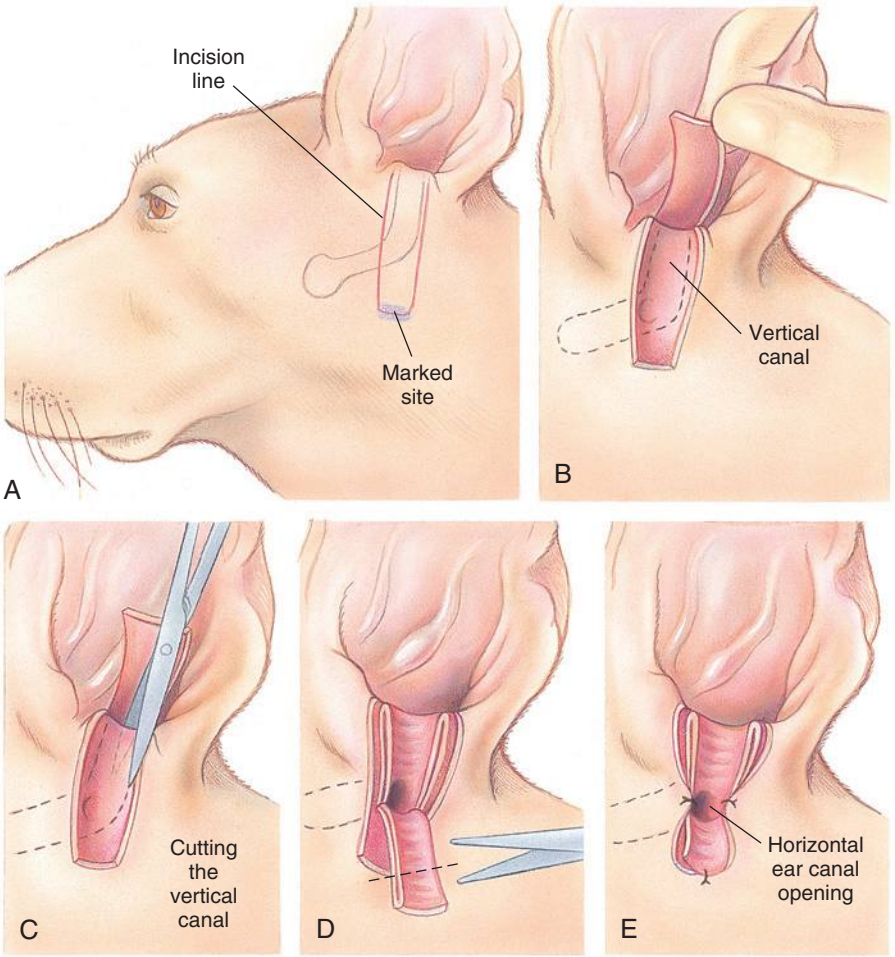

FIG. 17.6 Lateral ear canal resection. (A) Mark a site one-half the length of the vertical ear canal below the horizontal ear canal. (B) Lateral to the vertical ear canal, make two parallel incisions that extend from the tragus ventrally to the marked site. (C) Connect the skin incisions ventrally and reflect the skin flap dorsally, exposing the lateral cartilaginous wall of the vertical ear canal. Use Mayo scissors to cut the vertical canal. (D) Reflect the cartilage flap distally and inspect the opening of the horizontal canal. Resect the distal half of the cartilage flap to make the drainboard, and remove the skin flap. (E) Place sutures from the epithelial tissue to the skin. Begin suturing at the opening of the horizontal canal, then suture the drainboard.

gland at the ventral extent of the incision and avoid damaging it. Standing at the dorsal aspect of the animal's head, use Mayo scissors to cut the vertical canal (see Fig. 17.6C). Place one blade of the scissors in the canal at the pretragic or tragohelicine incisure at the cranial (or medial) aspect of the external auditory meatus and, with the scissors at a 30-degree angle, incise the canal ventrally to the level of the horizontal canal. Repeat the process beginning at the intertragic incisure (caudal or lateral aspect of the external auditory meatus). Do not allow the incisions to converge toward the lateral aspect of the canal, or the drainboard will be too narrow. Be sure to extend the incisions as far distally as the beginning of the horizontal canal, or the drainboard will not lie flat against the skin. Reflect the cartilage flap distally, and inspect the opening of the horizontal canal; if indicated, obtain cultures (see Fig. 17.6D). Occasionally, the opening can be widened by making two small cuts at the cranial and caudal aspects. *Resect the distal half of the cartilage flap to make the drainboard and remove the skin flap.* The ligament between the horizontal and vertical flaps usually acts as a hinge to allow the drainboard to lie flat, but in some cases scoring the cartilage on the ventral aspect of the drainboard facilitates this. *Place absorbable or nonabsorbable monofilament sutures (3-0 or 4-0) from the epithelial tissue to the skin (see Fig. 17.6E). Begin suturing at the opening of the horizontal canal, then suture the drainboard. Last, suture the cranial and caudal aspects of the medial wall of the vertical ear canal to the skin (see Fig. 17.6E).*

Vertical Ear Canal Ablation

Vertical canal ablation can be performed when the entire vertical canal is diseased but the horizontal canal is normal. It may be the technique of choice when neoplasia is confined to the vertical canal or in some animals with chronic otitis externa. Total removal of the vertical canal may result in less postoperative exudation and pain. This technique may provide a better cosmetic appearance of the ear than is provided by lateral ear canal resection when an abundance of hyperplastic tissue is present in and around the vertical canal (Fig. 17.7).

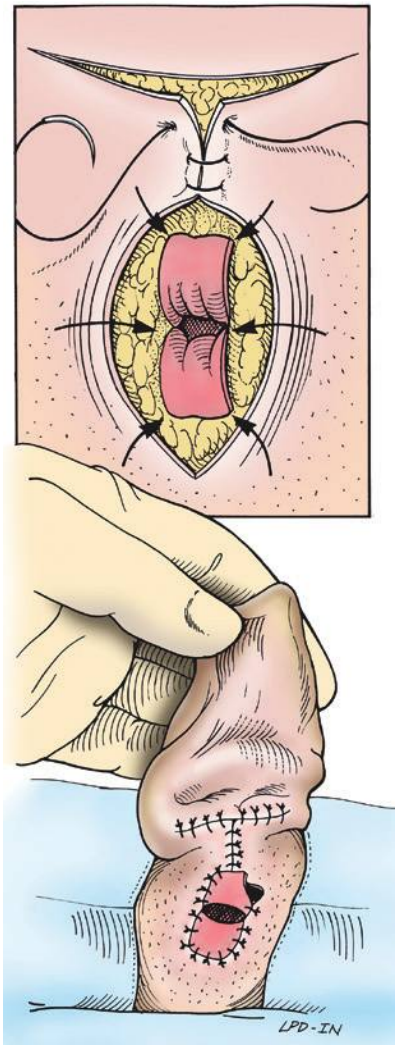

FIG. 17.7 Vertical ear canal resection may be performed when the entire vertical canal is diseased but the horizontal canal is normal.

Position and prepare the animal as for a lateral ear canal resection. Make a T-shaped incision with the horizontal component parallel and just below the upper edge of the tragus (Fig. 17.8A). From the midpoint of the horizontal incision, make a vertical incision that extends to the level of the horizontal canal. Retract the skin flaps, reflect loose connective tissue, and expose the lateral aspect of the vertical canal (see Fig. 17.8B). Continue the horizontal incision through the cartilage around the external auditory meatus with a scalpel blade. Remove as much of the diseased tissue on the medial surface of the pinna as possible, but avoid damaging the major branches of the great auricular artery. Use curved Mayo scissors to dissect around the proximal and medial aspects of the vertical canal. During dissection, stay as close as possible to the cartilage of the ear canal to avoid inadvertently damaging the facial nerve. Free the entire vertical canal from all muscular and fascial attachments (see Fig. 17.8C). Transect the vertical canal ventrally 1 to 2 cm dorsal to the horizontal canal and submit it for histologic examination (see Fig. 17.8D). Incise the remnant of the vertical canal cranially and caudally to create dorsal and ventral flaps (see Fig. 17.8E). Reflect the ventral flap downward, and suture it to the skin for a drainboard using absorbable or nonabsorbable monofilament sutures (2-0 to 4-0). Suture the dorsal flap to the skin and close the subcutaneous tissue with an absorbable suture material (2-0 or 3-0). Close the skin in a T-shaped configuration (see Fig. 17.8F).

Total Ear Canal Ablation

AP TECA is indicated in animals with chronic otitis externa that have failed to respond to appropriate medical management, in cases of severe calcification and ossification of the ear cartilage, or when severe epithelial hyperplasia extends beyond the pinna or vertical ear canal (Fig. 17.9). The procedure is commonly performed on animals in which lateral ear resections have failed, and it may benefit those animals with severely stenotic ear canals (Fig. 17.10). Neoplasia of the ear canal (e.g., ceruminous gland adenocarcinoma) is also treated by TECA.

Because of the potential for serious complications, this surgery should not be performed on animals with mild disease or by surgeons unfamiliar with the anatomy of the ear. Otherwise healthy dogs requiring bilateral procedures can have single-stage or staggered surgery based on surgeon preference, as there are no significant differences in anesthetic or perioperative complications between unilateral or single-stage bilateral procedures.[1] A high percentage of dogs that undergo TECA have associated skin disease such as seborrhea, atopy, or food or contact allergy dermatitis. The skin disease should be treated before surgery is planned because effective dermatologic therapy usually benefits the ears also. If the skin condition is unresponsive, TECA is preferred over lateral ear resection (see p. 308) and should be performed in conjunction with a lateral bulla osteotomy (LBO) (see p. 309).

NOTE Most animals with severe, chronic otitis externa have concurrent otitis media. Removing the avenue for drainage of exudative material by performing a TECA without treating the otitis media is disastrous. Therefore always perform a bulla osteotomy in conjunction with a TECA for otitis externa and media.

Position the animal in lateral recumbency with the head elevated with a towel. Prepare the pinna and surrounding skin for aseptic surgery. Make a T-shaped incision with the horizontal component parallel and just below the upper edge of the tragus (Fig. 17.11A). From the midpoint of the horizontal incision, make a vertical incision that extends to just past the level of the horizontal canal (see Fig. 17.11A). Retract the skin flaps, reflect loose connective tissue, and expose the lateral aspect of the vertical canal. Continue the horizontal incision around the opening of the vertical ear canal with a scalpel blade (see Fig. 17.11B). Dissect around the proximal and medial aspects of the vertical canal using curved Mayo or Metzenbaum scissors or electrosurgery (see Fig. 17.11C). During dissection, stay as close as possible to the cartilage of the ear canal to avoid inadvertent damage to the facial nerve. Avoid damaging the major branches of the great auricular artery at the medial aspect of the vertical canal. Identify the facial nerve as it courses caudoventrally to the horizontal canal (gently retract it if necessary). If the facial nerve is trapped within thickened, calcified horizontal canal tissue, carefully dissect the nerve from the horizontal canal. Continue the dissection to the level of the external acoustic meatus

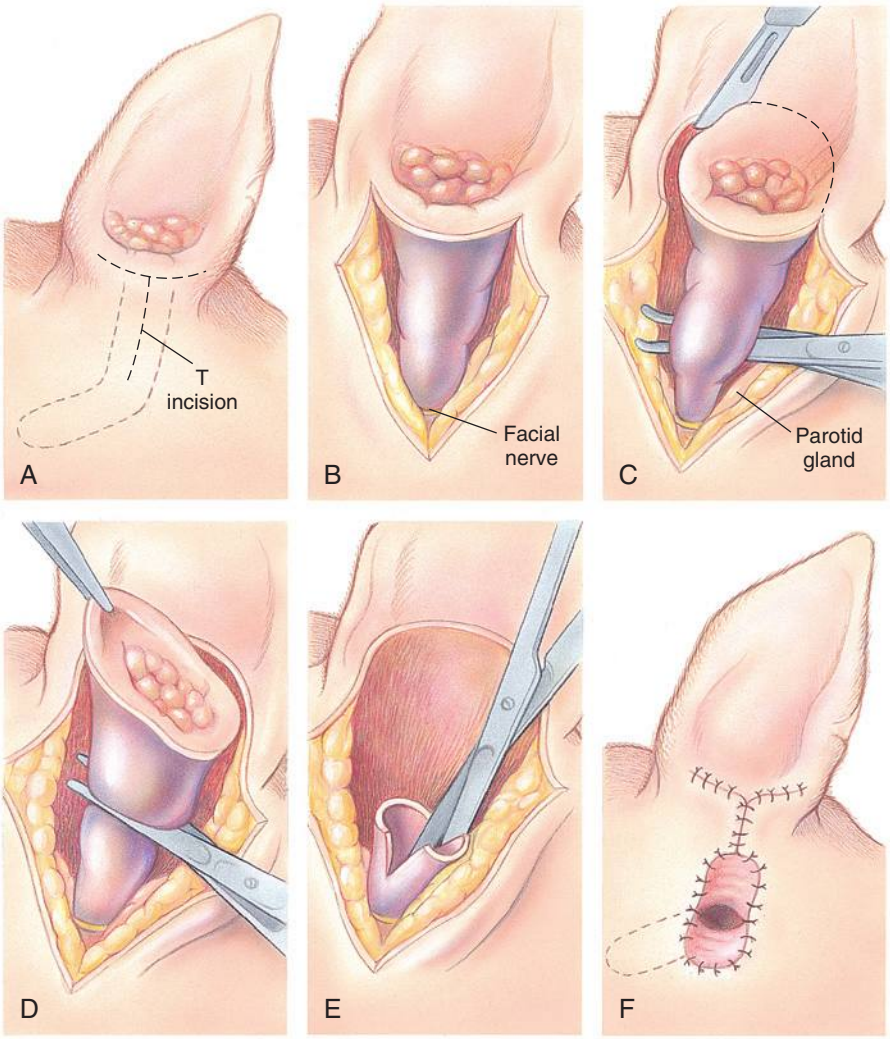

FIG. 17.8 Vertical ear canal ablation. (A) Make a T-shaped incision with the horizontal component parallel and just below the upper edge of the tragus. From the midpoint of the horizontal incision, make a vertical incision that extends to the level of the horizontal canal. (B) Retract the skin flaps, reflect loose connective tissue, and expose the lateral aspect of the vertical canal. (C) Continue the horizontal incision through the cartilage around the external auditory meatus with a scalpel blade. Use curved Mayo scissors to dissect around the proximal and medial aspects of the vertical canal. Free the entire vertical canal from all muscular and fascial attachments. (D) Transect the canal ventrally 1 to 2 cm dorsal to the horizontal canal and submit the canal for histologic examination. (E) Incise the remnant of the vertical canal cranially and caudally to create dorsal and ventral flaps. (F) Reflect the ventral flap downward and suture it to the skin for a drainboard. Suture the dorsal flap to the skin and close the subcutaneous tissue. Then close the skin in a T-shape.

(see Fig. 17.11D). Excise the horizontal canal attachment to the external acoustic meatus with a scalpel blade, rongeurs, or Mayo scissors, but again be mindful of the location of the facial nerve. Remove the entire ear canal, and obtain deep cultures around or just inside the external acoustic meatus. Submit the ear for histologic examination. Use a curette to carefully remove secretory tissue that is adherent to the rim of the external acoustic meatus (see Fig. 17.11E). Be sure to remove all epithelial tissue in this region or chronic fistulation will occur. Perform an LBO (see later discussion). Flush the area with sterile saline solution before closure. Close the subcutaneous tissue with absorbable suture (e.g., 3-0 poliglecaprone 25 or glycomer 631), and close the skin in a T-shaped configuration (see Fig. 17.11F).

Pinna deformity after TECA in cats or in erect-eared dogs can be a source of dissatisfaction for some owners. A technique using a single-pedicle advancement flap at the base of the pinna during a modified TECA may facilitate upright feline ear carriage and improve the cosmetic result and thus enhance owner satisfaction (Fig. 17.12).

Lateral Bulla Osteotomy

LBO exposes the tympanic cavity so that exudate and secretory epithelium can be removed. This procedure should be performed in conjunction with TECA in animals with chronic otitis externa and middle ear disease. Although an LBO affords less exposure to the tympanic cavity than a ventral bulla osteotomy, it does

FIG. 17.9 A 7-year-old Pyrenees with severe epithelial hyperplasia and infection of the left external ear canal, an indication for total ear canal ablation.

FIG. 17.10 Ear canal excised from a dog with severe epithelial hyperplasia. The medial aspect of the canal has been incised, revealing the luminal surface. The horizontal ear canal is to the left of the image, and the vertical canal is held open by the hemostats and is largely unaffected.

not require that the animal be repositioned and is preferred when performed in conjunction with TECA.

Bluntly dissect the tissue from the lateral aspect of the bulla using a small periosteal elevator. Avoid damaging the external carotid artery and the maxillary vein, which travel just ventral to the bulla. Rongeur the lateral and ventral aspects of the bulla until the caudal aspect of the middle ear canal is exposed (Fig. 17.13). Extend the bony excision as needed to fully visualize the contents of the tympanic cavity, but avoid sharp dissection and curettage of the rostral aspect of the osseous ear canal to reduce the risk of retroauricular vein damage. Use a curette to remove infected material, but avoid curetting in the rostral (dorsal) or rostromedial area of the tympanic cavity so as not to damage the auditory ossicles or inner ear structures. A 1.9-mm rigid endoscope can be used to aid visualization of the inside of the tympanic cavity. *Gently irrigate the cavity with saline to remove all remaining debris.*

Ventral Bulla Osteotomy

Ventral bulla osteotomy allows increased exposure of the tympanic cavity and can be performed alone or in conjunction with lateral ear resection. It is the technique of choice for access to the epithelial lining of the bulla in cats with inflammatory polyps (see p. 327). This technique provides better access to the bulla than an LBO and allows for bilateral procedures to be performed without the need to reposition the animal.

Place the patient in dorsal recumbency and prepare a generous area surrounding the angle of the mandible for aseptic surgery. Palpate the bulla immediately caudal and medial to the vertical ramus of the mandible. Draw an imaginary line connecting the mandibular rami and a second imaginary line along the long axis of the ventral aspect of the head (Fig. 17.14A). In dogs, make a 7- to 10-cm incision (3–5 cm in cats) parallel to the midline of the animal and centered 2 cm toward the affected side from where these imaginary lines intersect (see Fig. 17.14A). Incise the platysma muscle, retract the linguofacial vein if necessary, and deepen the incision by bluntly dissecting the digastricus muscle (lateral) from the hyoglossus and styloglossus muscles (medial). Avoid damaging the hypoglossal nerve, located on the lateral aspect of the hyoglossus muscle. Confirm the location of the bulla and use self-retaining retractors (e.g., Gelpi, Weitlaner) to spread the digastric and glossal muscles and retract them from the bulla (see Fig. 17.14B). Palpate the bulla craniomedial to the cornu process of the hyoid bone and caudomedial to the angle of the mandible. Bluntly dissect tissues from the ventral surface of the bulla and use a Steinmann pin to make a hole in its ventral aspect. Enlarge the opening with a small rongeur (e.g., Lempert). Examine the interior of the bulla for inflammatory debris, neoplastic tissue, or foreign bodies, and obtain samples for culture, sensitivity, and histopathologic examination. In cats, be sure to examine both compartments of the bulla (see p. 305 and Fig. 17.3). Gently flush the cavity with warm saline and close the incision routinely.

HEALING AND THE EAR

Hyperkeratinization of the epidermis and hyperplasia of the dermis and epidermis of the ear canals occur secondary to chronic infection or inflammation. Sebaceous glands become less numerous and active, and apocrine tubular glands distend and increase secretion. Healing after the surgical techniques previously described is routine unless incisional infection develops.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Electrosurgery is useful for ear surgery because numerous small vessels are encountered. Small curettes simplify removal of epithelial tissue on the bony rim at the external acoustic meatus. An assortment of rongeurs of various sizes (e.g., Cleveland, Lempert, Kerrison, Ruskin) or an air-driven burr is needed to remove the lateral and caudal aspects of the bulla when a TECA is performed. A Freer elevator is useful for reflecting soft tissue attached around the ventrolateral wall of the bulla. Retractors, such as Senn or Army-Navy, are helpful in visualization of deep structures. A Steinmann pin, a hand chuck, rongeurs, or a

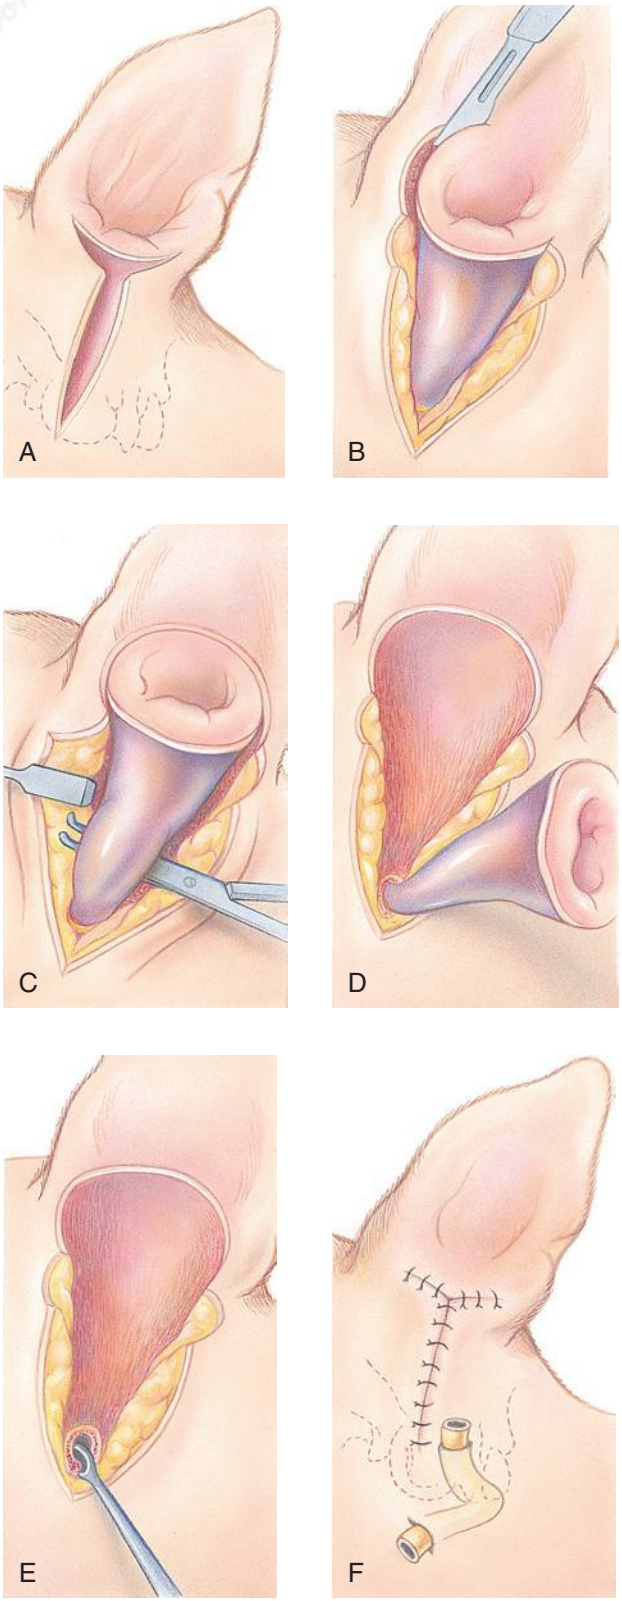

FIG. 17.11 Total ear canal ablation. (A) Make a T-shaped incision with the horizontal component parallel and just below the upper edge of the tragus. From the midpoint of the horizontal incision, make a vertical incision that extends to just past the level of the horizontal canal. (B) Retract the skin flaps, reflect loose connective tissue, and expose the lateral aspect of the vertical canal. Continue the horizontal incision around the opening of the vertical ear canal with a scalpel blade. (C) Dissect around the proximal and medial aspects of the vertical canal. (D) Continue the dissection to the level of the external acoustic meatus. (E) Excise the horizontal canal attachment to the external acoustic meatus with a scalpel blade, rongeur, or Mayo scissors, and use a curette to carefully remove secretory tissue that is adherent to the rim of the external acoustic meatus. (F) If desired, place a Penrose drain. Close the subcutaneous tissue and skin.

high-speed drill with burrs is necessary for access to the tympanic cavity during ventral bulla osteotomy (unless the bone has been eroded by infection or neoplasia). Self-retaining retractors are useful when a ventral bulla osteotomy is performed to allow retraction of the muscles superficial to the bulla. Culture swabs (both aerobic and anaerobic) should be available whenever ear surgery is performed.

POSTOPERATIVE CARE AND ASSESSMENT

Postoperative analgesics should be given after ear canal resection or ablation (see the discussion on anesthetics on p. 302); tranquilizers may be administered if the animal appears dysphoric or anxious (see p. 303). An Elizabethan collar should be used to prevent the animal from scratching at the incision site. If swelling is excessive, a cold pack can be applied to the side of the face several times a day for the first 24 to 36 hours after surgery. Antibiotics should be based on culture results and continued for 3 to 4 weeks. Sutures can be removed in 10 to 14 days.

NOTE Use caution when deciding to perform bilateral procedures, particularly ventral bulla osteotomies in cats. Significant postoperative swelling can lead to upper airway obstruction and respiratory distress. Avoid using head bandages as pharyngeal constriction may result.

COMPLICATIONS

Complications other than inadequate drainage and continued otitis externa are uncommon after lateral ear resection or vertical ear canal ablation. Clinical signs associated with otitis externa may not be relieved in dogs with underlying dermatologic disease that cannot be effectively managed. If the opening of the horizontal canal is insufficient for drainage, or if these techniques are performed in animals with concurrent middle ear disease without treating the middle ear infection, the result is persistent or recurrent signs of otitis externa. Facial nerve palsy is a rare complication of vertical ear canal ablation.

Potential complications of TECA are numerous and occasionally serious. These complications include superficial wound infection, facial nerve paralysis, vestibular dysfunction, Horner syndrome, deafness, chronic fistulation or abscessation, and avascular necrosis of the skin of the pinna (Fig. 17.15). Facial nerve paralysis is caused by stretching or retraction of the nerve; it usually resolves within a few weeks of surgery. Permanent damage may occur if the nerve is transected or is severely stretched. Temporary facial paralysis has been reported to occur

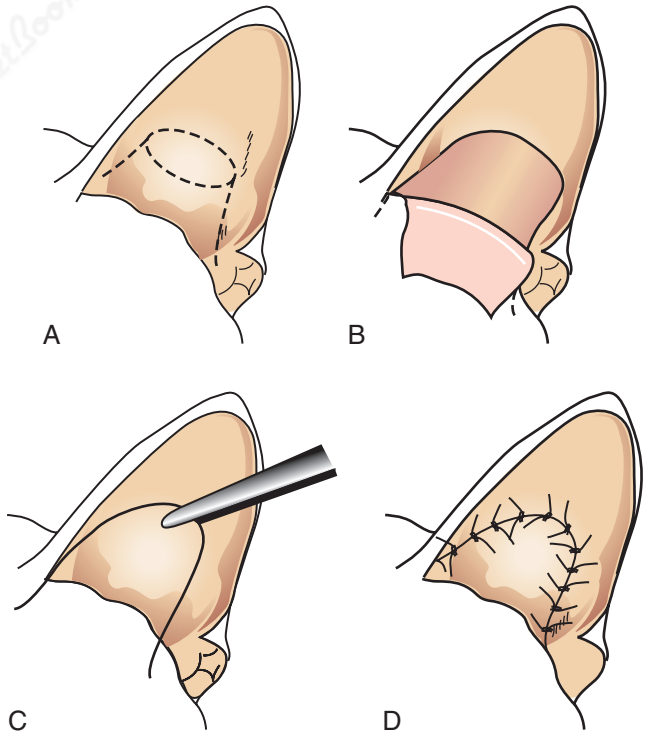

FIG. 17.12 To perform a modified total ear canal ablation in a cat, (A) make a vertical incision at the cranial and caudal ends of an elliptic incision centered around the external auditory meatus. (B) Dissect the single-pedicle advancement flap ventrally, allowing exposure of the subcutaneous tissue over the vertical ear canal. (C) After lateral bulla osteotomy and excision of the ear canal, pull the top of the advancement flap to the base of the pinna to determine whether further release of the flap is necessary to reduce tension on the pinna. (D) Suture the flap to the base of the pinna.

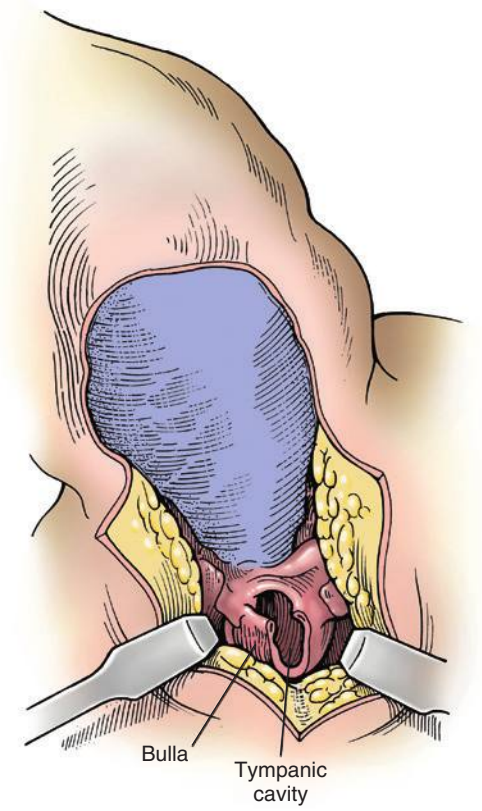

FIG. 17.13 Lateral bulla osteotomy.

in 3% to 27% of dogs undergoing TECA with concurrent LBO.[1] In contrast, facial paralysis in cats undergoing the same procedure can occur in up to 74%, with up to 47% having permanent damage. Horner syndrome following TECA and LBO is uncommon in dogs but frequent in cats. A 2013 study found Horner syndrome occurred in 3.3% of dogs and 58.3% of cats following TECA with LBO.[2]

Facial nerve damage may result in loss of the blink response and parasympathetic innervation to the lacrimal glands. The eye should be kept moistened with artificial tears or an ophthalmic lubricant to prevent corneal ulceration. If normal lid function does not return within 4 to 6 weeks, or if ulceration of the eye occurs as the result of chronic drying, enucleation may be indicated; however, this is seldom necessary, especially if normal tear flow is present.

Postoperative ipsilateral head tilt has been reported to occur in 3% to 11% of dogs, but it is rare in cats. Vestibular signs and a significant head tilt indicate inner ear damage that likely occurred due to curettage of the epitympanic recess and promontory of the tympanic cavity. These signs are transient in most cases, lasting 2 to 3 weeks.

Facial nerve paralysis, vestibular dysfunction, and Horner syndrome may all be caused by otitis media or interna or by surgery. The presence of these abnormalities before surgery must be noted to avoid having them considered as surgical complications.

Following ventral bulla osteotomy, transient Horner syndrome, facial nerve paralysis, and vestibular signs are common, particularly in cats.

SPECIAL AGE CONSIDERATIONS

Young cats with middle or inner ear signs or a previous history of respiratory disease should be examined for nasopharyngeal polyps (see p. 327).

SPECIFIC DISEASES

OTITIS EXTERNA

DEFINITIONS

Otitis externa is an inflammation of the epithelium of the horizontal and vertical ear canals and surrounding structures (i.e., external auditory meatus and pinna).

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Otitis externa is common in dogs (up to 20% of hospital admissions; up to 7% in cats), and between 50% and 89% of affected dogs have concurrent otitis media. It may be associated with other dermatologic conditions, particularly allergic or immune-mediated skin disease (e.g., food allergy dermatitis, atopy, and

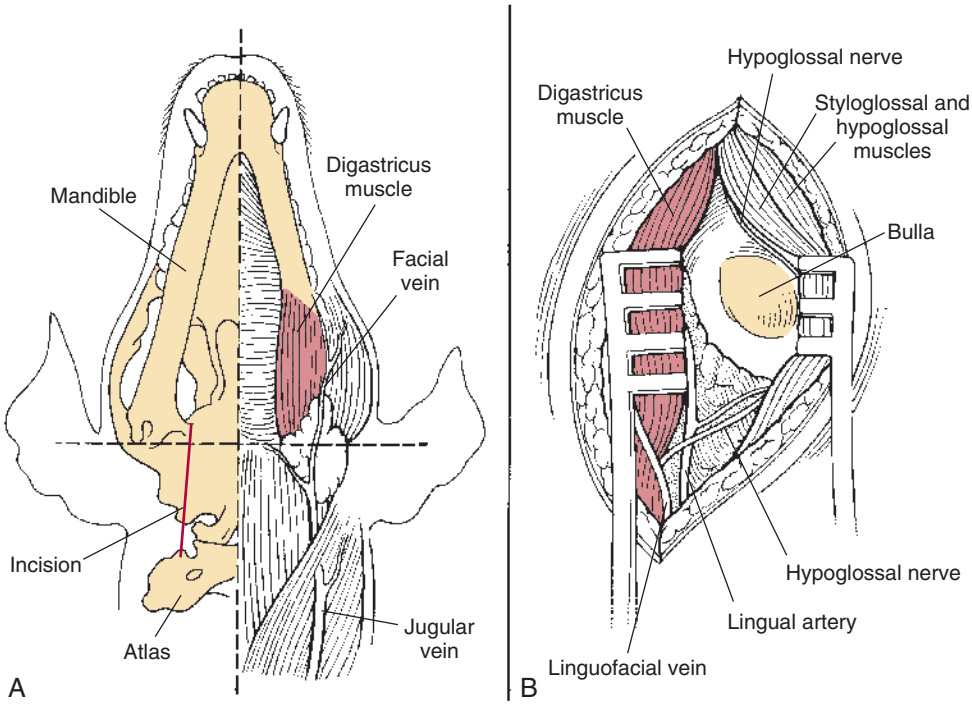

FIG. 17.14 Ventral bulla osteotomy. (A) For ventral bulla osteotomy, draw an imaginary line connecting the mandibular rami and a second imaginary line along the long axis of the ventral aspect of the head. Make a 4- to 10-cm incision (depending on the size of the animal) parallel with the midline of the neck and centered 2 cm toward the affected side from where these imaginary lines intersect. (B) Incise the platysma muscle, retract the linguofacial vein if necessary, and deepen the incision by bluntly dissecting the digastricus muscle (lateral) from the hyoglossal and styloglossal muscles (medial). Confirm the location of the bulla; use self-retaining retractors to spread the digastricus and glossal muscles and retract them from the bulla.

FIG. 17.15 Marginal necrosis of the pinna 2 weeks after total ear canal ablation/lateral bulla osteotomy in a dog. Arrows delineate the line of necrosis, and the suture line is visible on the right side of the image.

contact dermatitis) or systemic disease (e.g., endocrinopathies such as hypothyroidism). Bacterial infection, foreign bodies (e.g., foxtails), parasites (e.g., *Otodectes cynotis, Demodex canis, Sarcoptes scabiei, Notoedres cati,* ticks), fungi, yeasts (e.g., *Malassezia pachydermatis*), or neoplasia may also be the cause. *O. cynotis* is responsible for more than 50% of cases of otitis externa in cats.

Predisposing conditions for otitis externa include excessive moisture or increased humidity in the ear canal, a narrow canal conformation, and obstruction of the canal. The normal ear canal is inhabited by bacteria (e.g., *Staphylococcus* and β-*Streptococcus* spp.). High humidity and temperature promote moisture retention in the ear; this allows maceration of the epithelial lining and fosters secondary bacterial colonization. It has been proposed that in chronic otitis externa the apocrine glands increase in size, number, and secretory activity, whereas the sebaceous glands decrease in number and become less active. However, the dog may not have a common physiologic pathway for progressive changes, as was previously thought. Although the density and distribution of sebaceous and ceruminous gland tissue vary markedly among individuals, in general sebaceous tissue increases gradually from proximal to distal parts of the ear canal, whereas ceruminous gland tissue decreases. In dogs with otitis externa, the distribution of sebaceous and ceruminous glandular tissue is similar to that of normal ears, but the glands become larger and hyperplastic. Hair follicles also become hyperplastic in dogs with otitis externa. Cocker spaniels with otitis externa have been shown to have distinct differences in pathologic characteristics of the horizontal ear canal compared with other breeds. They more commonly have ceruminous tissue responses, whereas other breeds have predominantly fibrosis.

The bacteria most often isolated from the ears of dogs with chronic otitis externa are *Corynebacterium* spp., *Escherichia coli,*

Proteus mirabilis, P. aeruginosa, and *S. pseudintermedius. Pasteurella multocida* and *S. pseudintermedius* are commonly isolated from the ears of cats. In some animals, chronic otitis externa may cause secondary changes in the ear canal (i.e., epithelial hyperplasia and ossification of chronically inflamed tissue) that perpetuate the infection and make medical management difficult because of constriction of the external ear canal lumen. In addition, ulceration and secondary infection with pyogenic bacteria, yeast, and/or fungi commonly occur.

DIAGNOSIS

Clinical Presentation

Signalment

Dogs and cats of any breed or age may develop otitis externa, but some groups are at higher risk. Dogs with long, pendulous ears (e.g., spaniels, basset hounds) and those with abundant hair in the ear canal (e.g., poodles) are commonly affected. Among erect-eared dogs, German shepherd dogs are most frequently affected. Spaniel breeds, particularly cocker spaniels, may have abnormal keratinization and increased sebaceous gland secretion of the pinna or ear canal or both. Chronic bacterial infection and hyperplastic changes in the sebaceous glands and the epithelial lining of the ear often lead to scarring and ear canal obstruction.

History

Animals with otitis externa may be presented for evaluation of acute or chronic signs. If a foreign body is lodged in the ear, head shaking and scratching at or near the ear are typical. Head shaking and ear scratching are also common among animals with parasitic infection and acute bacterial infection. A purulent, odoriferous discharge may be noted with chronic infection. The animal may constantly rub its head on objects and may seem to be in pain when the head or ear is touched.

Physical Examination Findings

Palpation of the ear may suggest thickening or calcification of the ear canal. A thorough otoscopic examination should be performed even if it requires tranquilization. Examination of the ear canal is often difficult if hyperplasia or exudation are present; general anesthesia may be necessary to allow meticulous inspection. The extent of involvement of the vertical and horizontal ear canals and the status of the tympanic membrane should be determined. Purulent yellow or cream-colored exudates may be associated with gram-negative infection, particularly *Pseudomonas* and *Proteus* spp. Dark brown or black exudates are more commonly associated with yeast infection or infection caused by *Staphylococcus* or *Streptococcus* spp. A bloody exudate may be suggestive of neoplasia. Definitive diagnosis requires examination of exudate collected during the procedure by placing sterile swabs into the canal through the otoscope cone. The exudate should be examined for parasites, bacteria, fungi, and yeast; bacterial and fungal cultures should be performed if indicated. The ear should be flushed with a bulb syringe or a soft catheter, and alligator forceps should be available to remove foreign bodies and debris. Biopsy of the external ear canal may allow diagnosis of neoplasia and some allergic conditions.

NOTE Perform a complete dermatologic examination in all animals with otitis externa unless an obvious cause is found, such as a foreign body.

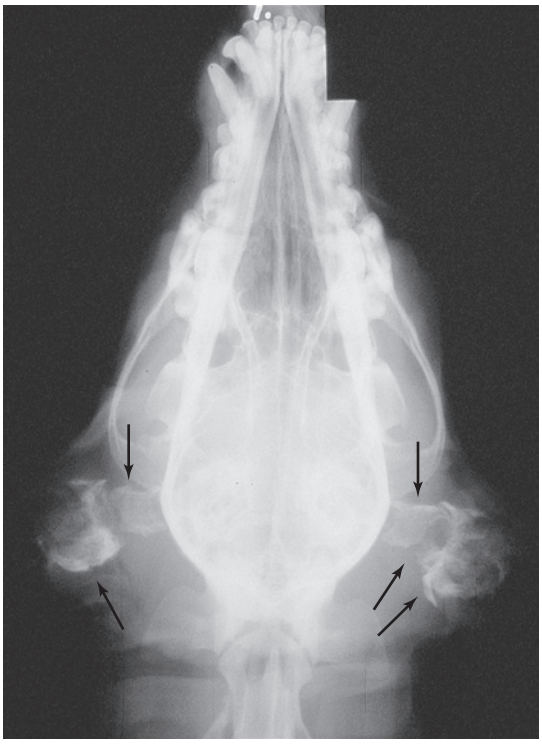

FIG. 17.16 Calcification of the external ear canals *(arrows)* in a dog with chronic otitis externa. (Courtesy L. Homco, Ithaca, NY.)

Diagnostic Imaging

Skull radiography or CT imaging should be performed to determine whether concurrent otitis media is present; CT imaging is preferred because of its lack of superimposition and increased sensitivity in detecting abnormalities (see p. 318). Because improper obliquity or angulation of the skull for radiographs or malpositioning of the tongue can result in an inadequate study, false-negatives or underestimation of the extent of middle ear disease is common with radiographs. Calcification of the external auditory canal is commonly noted with chronic otitis externa (Fig. 17.16); this finding may influence the choice of surgical techniques. Occasionally, imaging signs suggestive of neoplasia are found, such as bony lysis of the petrous temporal bone. CT findings with otitis externa include mineralization of the ear canal, narrowing of the lumen of the external ear canal, and soft tissue attenuating material within the lumen of the ear canal. CT may also be useful for evaluation of abscess formation following a TECA. Uptake of contrast may be noted in areas of infection (abscessation, fistulous tracts). Canalographic evaluation of the external ear canal, although uncommonly performed, may help delineate the status of the tympanic membrane before medical or surgical therapy in dogs. Preferably, video otoscopy can be used.

Laboratory Findings

Specific laboratory abnormalities are not found. Thyroid function tests should be performed if hypothyroidism is possible.

DIFFERENTIAL DIAGNOSIS

The diagnosis of otitis externa is usually simple; however, differentiation of the various causes may be difficult. It is important

to identify treatable underlying causes of otitis externa before considering surgical intervention; optimal results require appropriate treatment of underlying diseases. In some cases, surgery is unnecessary if the underlying cause is treated. Concurrent otitis media should be identified in animals that are to undergo surgery for otitis externa.

NOTE Lateral ear canal resection and vertical canal ablation often fail if concurrent dermatologic or middle ear disease is not resolved.

MEDICAL MANAGEMENT

Treatment of otitis externa involves identifying the underlying or perpetuating causes, cleaning and drying the ear, and using appropriate topical medications (see p. 304). Because ceruminous material impairs the ability of topical medications to reach the infection and may inactivate some drugs, the ears must be thoroughly cleaned before treatment. The status of the tympanic membrane (intact vs. ruptured) should be ascertained. Many topical agents are available for treatment of otitis externa; most contain various combinations of antibiotics and parasiticidal, antiinflammatory, and/or antifungal agents. The reader is referred to a dermatology or medicine text for an in-depth discussion of the use of these various agents. Medications that can be used in animals with a ruptured tympanic membrane are listed in Box 17.1. The combination of tris-EDTA and an antimicrobial has a synergistic effect against some bacteria implicated in otitis externa (Box 17.3). An ear rinse containing tromethamine, EDTA, and benzyl alcohol was found to significantly decrease bacterial growth in vitro of *P. aeruginosa* and β-hemolytic streptococcal organisms within 15 minutes, *Proteus* spp. within 30 minutes, and *Staphylococcus* spp. within 60 minutes. Addition of benzyl alcohol enhanced antiseptic activity against β-hemolytic streptococci and *Proteus* spp., compared with a solution of tromethamine and EDTA alone. Ototoxicity of the various agents should be taken into account before they are used, particularly if the tympanic membrane has been ruptured. Silver sulfadiazine solution (0.1%; see Box 17.3) can be used without an intact tympanic membrane. Persistence of clinical signs after treatment of otitis externa may suggest concurrent otitis media. Targeted systemic antibiotics, administered for 6 to 8 weeks, are indicated for treatment of otitis media (see p. 319).

BOX 17.3 Otic Preparations

Tris-EDTA Solution[a] (0.05 mol/L Tris, 0.003 mol/L EDTA)

24.2 g Tris (base)
4.8 g EDTA (disodium salt)
3900 mL distilled water
100 mL white vinegar (5% acetic acid)
Adjust pH to 8 with additional vinegar (30–50 mL)
Autoclave and store sterile

Silver Sulfadiazine Solution (0.1%)

0.1 g silver sulfadiazine powder
100 mL distilled water
Mix to dissolve

[a]Commercially available (e.g., TrizEDTA [DermaPet], T8 solution [DVM Pharmaceuticals]).
EDTA, Ethylenediaminetetraacetic acid.

Surgical Treatment

Surgical therapy of otitis externa should be considered when medical management fails or in cases involving proliferative growth or stenotic canals. Surgical alternatives in animals with otitis externa that do not have middle ear involvement include lateral ear canal resection (see p. 306), vertical ear canal ablation (see p. 307), and TECA (see p. 308). If concurrent otitis media exists, a lateral ear canal resection in conjunction with a ventral bulla osteotomy (see p. 310) or a TECA with LBO (see p. 309) can be performed.

Preoperative Management

Preoperative antibiotic therapy is recommended. Bacterial cultures should be performed if purulent discharge is present, and appropriate antibiotics should be initiated before surgery is performed. If no discharge is present, perioperative antibiotics (see p. 86) may be given intravenously immediately before the surgical procedure or may be administered during surgery but after intraoperative cultures have been obtained. Based on published culture and susceptibility testing, cefazolin may be a poor choice for perioperative prophylaxis in dogs undergoing TECA and bulla osteotomy. Cefazolin, tetracycline, and trimethoprim-sulfamethoxazole have susceptibilities of less than 50%. Amoxicillin-clavulanic acid or cephalothin may be a reasonable choice for prophylaxis as most *S. pseudintermedius* organisms are susceptible to these (see Chapter 9), and *S. pseudintermedius* is a common isolate of ear samples. Culture and susceptibility testing is strongly advised in cases of chronic otitis externa or those warranting surgical treatment.

Anesthesia

See p. 302 for anesthetic recommendations for animals with ear disease.

Surgical Anatomy

See p. 305 for a description of the surgical anatomy of the ear canal.

Positioning

See pp. 306 to 310 for details on positioning for the various surgical procedures.

SURGICAL TECHNIQUE

The choice of surgical techniques depends on the severity and extent of the disease. See pp. 306 to 310 for a description of the surgical techniques used in animals with ear disease. A discussion is provided of the indications and contraindications for each procedure.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

See p. 310 for a discussion of appropriate suture materials and instruments for surgery of the ear.

POSTOPERATIVE CARE AND ASSESSMENT

Postoperative pain is common in animals that have undergone ear surgery. See p. 302 for a discussion of analgesic therapy in these patients. After administration of adequate analgesics, tranquilizers may be given if the animal appears dysphoric or

anxious (see p. 303). Animals often shake their heads excessively after ear surgery and may try to paw or scratch at the bandage. Close supervision in the early postoperative period and use of an Elizabethan collar or sidebar are recommended.

PROGNOSIS

Chronic otitis externa is a difficult disease to treat with medical therapy or surgery. A poor surgical outcome may be the result of technical failure (e.g., not making the horizontal canal opening large enough with lateral ear canal resection or vertical ear canal ablation), lack of owner compliance in continuing to treat the ear (with lateral ear canal resection or vertical ear canal ablation), unrealistic expectations on the part of the owner, unrecognized middle ear disease, faulty diagnoses (e.g., not recognizing neoplasia as the underlying cause), or failure to treat the underlying disease or perpetuating cause. Surgical procedures designed to increase drainage (i.e., lateral ear canal resection and vertical ear canal ablation) often fail in animals with untreated dermatologic disease or unrecognized middle ear disease. A Zepp procedure results in a satisfactory outcome in less than half of patients; however, this may be related to the fact that the procedure is often done in dogs with chronic otitis externa, in which TECA would have been the preferred technique. A properly performed TECA combined with an LBO resolves clinical signs in most animals.

COMPLICATIONS

Partial or complete facial nerve paralysis occurs in many dogs after TECA with LBO. Other complications include persistent infection (dissecting cellulitis, prolonged wound drainage, incisional dehiscence, periauricular abscess formation), nystagmus, head tilt, postural abnormalities, and loss of hearing (see p. 311).

OTITIS MEDIA AND INTERNA

DEFINITIONS

Otitis media is inflammation of the middle ear; **otitis interna** is inflammation of the inner ear. **Myringotomy** is a surgical puncture of the tympanic membrane to relieve pressure or obtain samples for analysis. **Otoliths** are mineral opacities within the tympanic bullae. **Aural cholesteatomas** are an abnormal accumulation of keratin-producing squamous epithelium in the middle ear. **Primary secretory otitis media** (PSOM), also known as *glue-ear*, is a unique condition seen in Cavalier King Charles spaniels.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Otitis media may occur secondary to infection (i.e., bacterial, yeast, fungal), neoplasia, trauma, or foreign body. Otoliths have also been reported within the tympanic cavity of dogs and may or may not be associated with clinical signs. In cats, inflammatory and nasopharyngeal polyps (see p. 327) are additional causes of otitis media. Congenital palatine defects may also be associated with middle ear disease in dogs and cats. The most common cause in both dogs and cats is bacterial infection; more than half of animals with chronic end-stage otitis externa have documented evidence of otitis media at surgery. Consequently, pathogens cultured from the middle ear are similar to those cultured from the ears of animals with otitis externa (i.e., *Staphylococcus* spp., *Streptococcus* spp., *Pseudomonas* spp., *E. coli*, and *P. mirabilis*). In addition to spreading across the tympanic membrane to the middle ear, infections may ascend from the pharynx via the auditory tube or may reach the inner ear via the bloodstream. Bilateral otitis media is usually indicative of bacterial infection. Otitis media may lead to otitis interna (Box 17.4).

! BOX 17.4 Clinical Signs Associated With Otitis Interna (Vestibular Dysfunction)

- Head tilt to affected side
- Circling to affected side
- Falling to affected side
- Rolling to affected side
- Nystagmus (horizontal or rotary) with fast component away from affected side
- Asymmetric ataxia with strength preserved
- Positional or vestibular strabismus with the eyeball ipsilateral to the lesion deviated ventrally
- Postural reactions (except for the righting reflex)

Inflammatory or nasopharyngeal polyps are benign masses that may be located in the nasopharynx, auditory tube, or tympanic cavity, or all three. In rare cases they may rupture the tympanic membrane and protrude into the external ear canal. When located in the tympanic cavity, they often cause signs of unilateral otitis media. These polyps may occur as a result of ascending infection from the pharynx or may arise from chronic otitis media. Polyps thought to be congenital in origin have also been reported in kittens. Aural cholesteatomas are abnormal accumulations of keratin-producing squamous epithelium in the middle ear or tympanic recesses that may be congenital or acquired. Congenital cholesteatomas, although rare, are thought to arise from embryonal inclusions or nests of epithelial cells and are found behind an intact tympanic membrane and in the absence of causative factors such as a history of ear infections. PSOM in Cavalier King Charles spaniels is recognized by a bulging opaque tympanic membrane with an accumulation of mucus filling the entire middle ear. These dogs commonly present with signs of head and neck pain.[3]

Neoplasia originating in the middle ear is uncommon in both dogs and cats. In dogs, tumors that originate in the external ear canal and then extend into the tympanic cavity are more common than primary middle ear tumors. Benign tumors of the middle ear cavity of dogs (e.g., papillary adenomas and fibromas) have been more commonly reported than malignant tumors. Epidermoid cysts (cholesteatomas) occur in the canine middle ear. These cysts are often associated with chronic otitis media and must be differentiated from neoplastic lesions. Lesions associated with the trigeminal nerve can result in ipsilateral middle ear effusion.[4] In cats, squamous cell carcinoma is the most common tumor of the middle and inner ear. Other tumors found in the feline middle ear have included fibrosarcoma, anaplastic carcinoma, lymphoblastic lymphosarcoma, and ceruminous gland adenocarcinoma.

DIAGNOSIS

Clinical Presentation

Signalment

Most animals that develop otitis media secondary to otitis externa are middle-aged. Older animals more commonly develop neoplasia of the middle ear, and young cats are more apt to have nasopharyngeal polyps. There is no known breed or gender predisposition in cats to nasopharyngeal polyps, or in either dogs or cats to neoplastic middle ear disease, aside from the previously mentioned Cavalier King Charles spaniels with PSOM. Canine breeds predisposed to otitis externa (see p. 314) also have a higher incidence of otitis media.

History

Many cats with nonneoplastic middle ear disease do not have associated clinical signs. The history and clinical signs of symptomatic animals with otitis media do not differ substantially from those of animals with otitis externa alone (see p. 314). Affected animals commonly scratch or paw at their ears, and they may shake their heads excessively. The ear may have an odor, and animals often appear to be in pain on manipulation or palpation of the ears or adjacent skull. A history of chronic, poorly responsive otitis externa is common. Some animals come for evaluation of vestibular signs caused by otitis interna (see Box 17.4). Pain during eating or when the mouth is opened may be noted, especially in cats with neoplastic middle ear disease. Ipsilateral facial nerve paralysis is also common in animals with middle ear neoplasia. In rare cases, neoplastic lesions of the middle ear may extend into the nasopharynx, causing gagging, retching, or dyspnea, or all three. Cats with nasopharyngeal polyps often have nasal discharge, sneezing, or stridor (see p. 327). If a nasopharyngeal polyp is present concurrently, dysphagia and/or dyspnea may be noted. Some nasopharyngeal polyps become so large that they protrude to the edge of the soft palate and cause gagging. Cats that have sinonasal disease with nasal exudate often have concurrent otitis media (which may be clinically silent). Evaluation of the external and middle ear in such cats is warranted. Deafness may be reported with bilateral disease, but loss of hearing is seldom evident with unilateral lesions.

Physical Examination Findings

Discharge from the external auditory canal, hyperplasia, and ulceration of the aural epithelial tissue are often obvious on physical examination in animals with otitis media and externa. Neurologic abnormalities referable to the inner ear and facial nerve paralysis (Box 17.5) are not found in most animals with otitis media. Horner syndrome may occur as a result of damage to the sympathetic trunk as it courses through the middle ear. Clinical signs associated with the syndrome are ptosis, miosis, enophthalmos, and protrusion of the third eyelid.

Otoscopic examination of these patients often requires general anesthesia, but it can be helpful in diagnosing otitis media, particularly as an alternative to advanced imaging. In one study, video otoscopy was 91% sensitive, 98% specific, and 97% accurate in diagnosing otitis media in dogs.[5] The tympanic membrane may be ruptured, or it may bulge outward because of purulent material, blood, mucus, or serum. However, an intact tympanic membrane does not rule out middle ear disease. Abundant mucus in the middle ear cavity has been associated with adenomatous lesions. The normal tympanic membrane appears shiny and is gray or white; it becomes opaque with infection. If the tympanic membrane has ruptured, samples for cytologic studies and culture can be taken directly from the middle ear. Otherwise, samples can be obtained using a 20-gauge, 3.5-inch (9 cm) spinal needle inserted through the ventral half of the tympanum (myringotomy). If the opening is too small, it may be enlarged with a small cannula.

Inflammatory polyps (see p. 327) usually appear as pedunculated, smooth, shiny, light-pink masses. The oral cavity of animals with inflammatory polyps or neoplastic masses should be carefully examined because extension into the nasopharynx may occur. Neoplastic lesions may be friable, but they are often difficult to differentiate grossly from chronically infected tissue.

! BOX 17.5 Clinical Signs Associated With Facial Nerve Paralysis

- Diminished palpebral reflex
- Widened palpebral fissure
- Drooping of the ear and lip
- Excessive drooling
- Blepharospasm
- Elevation and wrinkling of the lip
- Caudal displacement of the labial commissure
- Elevation of the ear on the affected side

Diagnostic Imaging

Radiography is not a sensitive indicator of middle ear disease, as nearly one-fourth of animals with middle ear disease will have normal appearing bullae on radiographs. If performed, the most valuable radiographic view in animals suspected of having otitis media is the frontal open-mouth projection (also known as the *rostrocaudal open-mouth view*) in which the animal is placed in ventrodorsal recumbency with the head flexed 80 to 90 degrees to the table (Fig. 17.17). The mouth is held open with gauze strips hooked on the upper and lower canine teeth, and the x-ray beam is centered on the temporomandibular joints. The tongue and endotracheal tube must be retracted from the field of view with gauze secured to the lower mandible. The tympanic bullae and their contents are demonstrated with this view. The most common findings with middle ear disease are opacification of the air-filled tympanic cavities and thickening and sclerosis of the walls of the bullae (Fig. 17.18). Lateral oblique

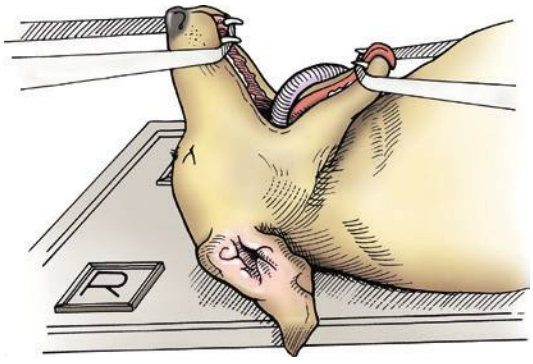

FIG. 17.17 Positioning for a frontal open-mouth projection.

FIG. 17.18 Frontal open-mouth projection showing opacification, thickening, and sclerosis of the bullae *(arrowheads)*. (Courtesy L. Homco, Ithaca, NY.)

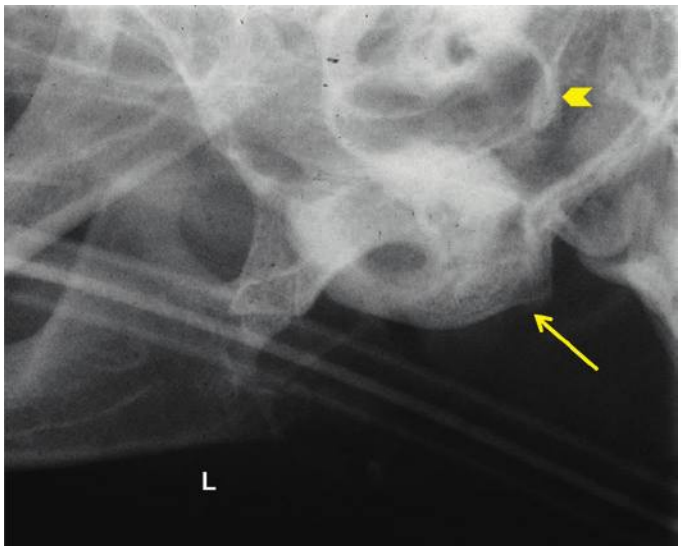

FIG. 17.19 Left lateral oblique radiograph of a dog with unilateral otitis media. Note the thickened wall of the left bulla *(arrow)* compared with the normal, thin-walled right bulla *(arrowhead)*.

views (Fig. 17.19) with the head tilted 10 to 15 degrees show individual bullae, whereas ventrodorsal or dorsoventral views show the external ear canals and the architecture of the petrous temporal bones. Lysis or periosteal reaction of the bullae and petrous temporal bone should increase suspicion of neoplasia. A soft tissue mass in the pharyngeal region on the lateral view may be noted in cats with inflammatory polyps. Ultrasound has been suggested as an adjunct to radiographic imaging of the tympanic bullae because it can be performed in dogs without the need for sedation or general anesthesia; however, in one study the sensitivity for detecting otitis media was low (21%).[5]

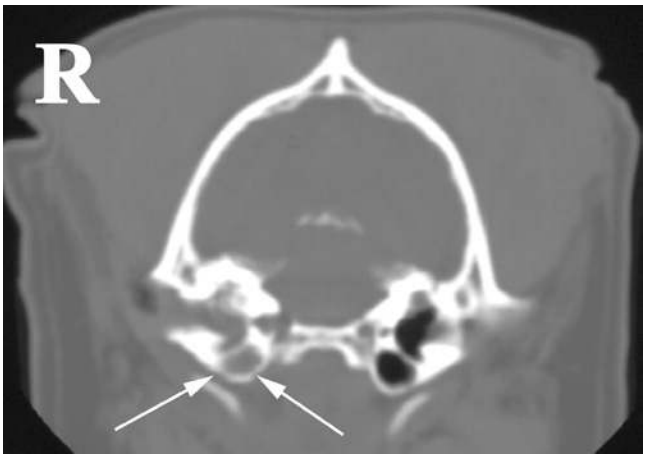

FIG. 17.20 Computed tomography axial image of a dog with otitis media. Soft tissue attenuating material is increased within the right tympanic bulla *(arrows)* without derangement of the bony aspect of the bulla.

CT is particularly useful for diagnosis of otitis media, evaluation of nasopharyngeal polyps, and determination of the extent of otitis externa or neoplasia (Fig. 17.20). Owing to collapse of the pharynx when the animal is under anesthesia, it may be difficult to identify a nasopharyngeal polyp using cross-sectional imaging techniques; reformatted sagittal images may be better. Direct visualization is always recommended after cross-sectional imaging examinations to better evaluate for the possibility of a nasopharyngeal polyp. On a well-positioned study, both bullae should appear symmetric. The tympanic bullae and external ear canal lumens should be filled with air, and the wall of the tympanic bulla should be thin and well defined. In animals with otitis media, thickening and irregularity of the tympanic bullae are often seen. Other findings may include lysis of the tympanic bulla, a soft tissue attenuating material within its lumen, and signs of otitis externa. Evaluation of the bone of the bullae is more difficult using magnetic resonance imaging, but it can be used to identify soft tissue changes that occur with otitis media and has the additional advantage of allowing evaluation of the brain in animals with signs of otitis interna. Middle ear disease may be an incidental finding on diagnostic imaging in cats that do not have clinical evidence of otitis media.

Laboratory Findings

Specific laboratory abnormalities are uncommon.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses for disease of the middle and inner ear cavity include bacterial, fungal, or yeast infection; inflammatory polyps; neoplasms; foreign body; trauma; sebaceous gland and ceruminous gland hyperplasia; paraoral abscess; trigeminal nerve disease; and idiopathic vestibular disease. Otitis media is common in animals with otitis externa, but because the clinical signs are similar, the former often goes unrecognized.

MEDICAL MANAGEMENT

The most important aspect of the treatment of otitis media is removal of infected tissues or exudate, neoplasms, polyps, or foreign bodies from the tympanic cavity. The external ear canal should be cleaned, and concurrent otitis externa must be treated (see p. 303). Medical management of animals with acute otitis media consists of myringotomy, cultures of middle ear contents, irrigation of the tympanic cavity, and topical and systemic antibiotics. Many veterinary dermatologists recommend starting oral fluoroquinolone pending culture and susceptibility results. If no improvement is seen in 3 to 4 weeks, ventral bulla osteotomy should be considered.

PSOM is a disease affecting predominantly Cavalier King Charles spaniels. Current treatment recommendations include repeated manual removal of the mucoid effusion from the tympanic cavity through a myringotomy incision and topical or systemic corticosteroids. Tympanostomy tubes have been placed by myringotomy incision in the pars tensa with the aid of an operating microscope. Clinical signs have resolved rapidly following this procedure, and it may be an acceptable alternative to repeated myringotomy for the treatment of PSOM.

SURGICAL TREATMENT

Surgery is often necessary to distinguish among the various possible causes of middle ear disease. Surgical treatment of otitis media caused by infection includes ventral bulla osteotomy, culture of affected tissue or exudate, drainage, and long-term antibiotics. Benign neoplastic or inflammatory lesions can usually be removed by a bulla osteotomy; however, Horner syndrome is a common, short-term complication of this procedure in cats (see p. 329). Neoplasia of the bulla warrants a poor prognosis.

NOTE If neurologic signs are present before surgery, be sure to warn the owner that they may persist after surgery.

Preoperative Management

Antibiotics may be given preoperatively; however, intraoperative cultures are often performed in animals with middle ear disease. In such patients, intravenous antibiotics should be given immediately after culture results have been obtained.

Anesthesia

See p. 302 and Table 17.1 for anesthetic recommendations for animals with ear disease. Chamber or mask induction should not be used in dyspneic animals (e.g., some cats with nasopharyngeal polyps).

Surgical Anatomy

The middle ear is composed of the tympanic cavity and its contents and the auditory tube. See p. 305 for a description of the surgical anatomy of the ear.

Positioning

The animal is positioned in lateral recumbency for an LBO and in dorsal recumbency for a ventral bulla osteotomy.

SURGICAL TECHNIQUE

Approach the middle ear by means of an LBO (see p. 309) in conjunction with TECA (see p. 308) or through a ventral bulla osteotomy (see p. 310).

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

See p. 310 for a description of surgical supplies necessary for a bulla osteotomy.

POSTOPERATIVE CARE AND ASSESSMENT

Cats with concurrent upper airway disease (e.g., nasopharyngeal polyps) may have respiratory distress after extubation and may require supplementary oxygen. Oxygen may be given by mask or nasal insufflation in these animals. Bilateral ventral bulla osteotomies, particularly in cats, may be associated with postoperative respiratory distress.

PROGNOSIS

Animals with bacterial otitis media may have persistent neurologic signs despite surgical treatment. Many cats with otitis interna before surgery will have permanent head tilts after surgery; however, these cats often have a normal level of activity despite their neurologic dysfunction. The prognosis for benign tumors is good, but surgical cure is rare with malignant tumors because of their extensive nature at the time of diagnosis. Inflammatory polyps may recur if they are simply removed from the external ear using traction (see p. 327). Recurrence is less likely if traction and bulla osteotomy are performed.

Although surgery can be curative, approximately half of dogs with aural cholesteatomas will have persistent or recurrent clinical signs. Dogs with chronic disease, temporal bone involvement, and neurologic signs tend to have a worse prognosis but can still be medically managed long-term with palliation of clinical signs.[6]

AURAL HEMATOMAS

DEFINITION

An **aural (auricular) hematoma** is a collection of blood within the cartilage plate of the ear.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Aural hematomas may occur in dogs or cats and are usually characterized as fluctuant swellings filled with hemorrhagic fluid, affecting part or all of the concave surface of the pinna. The cause of aural hematoma is not well understood; however, in many cases, it appears to be the result of head shaking or scratching at the ear caused by pain or irritation associated with otitis externa. The latter is usually bacterial in dogs and is due to *O. cynotis* infestation in cats. Head shaking may cause sinusoidal wave motions in the ear, resulting in fracture of the cartilage. The exact location of the source of hemorrhage is not known but is thought to come from branches of the great auricular arteries and veins within, under, or between the cartilage layers.

These vessels penetrate the scapha to supply the concave surface of the ear.

Some animals that develop aural hematomas do not have evidence of concurrent ear disease; hematoma formation in some patients may be associated with increased capillary fragility (e.g., Cushing disease). An additional theory with regard to etiology involves underlying autoimmune disease. Some dogs and cats with aural hematomas have been found to have a positive Coombs test in the serum and fluid retrieved from the pinna, whereas a small percentage had positive antinuclear antibody tests and identification of immunoglobulin G deposition at the dermo-epidermal junction.

DIAGNOSIS

Clinical Presentation

Signalment

Dogs and cats with otitis externa have a greater risk of developing aural hematoma.

History

A history of violent head shaking and/or acute or chronic otitis externa (see p. 312) may be noted; some animals may have no history of previous ear disease.

Physical Examination Findings

Hematomas initially appear fluid filled, soft, and fluctuant, but eventually may become firm and thickened as a result of fibrosis. The ear may develop a "cauliflower" appearance.

Diagnostic Imaging

Skull radiography or CT may be indicated if underlying otitis externa or media (or both) has predisposed the animal to aural hematoma.

Laboratory Findings

Specific laboratory abnormalities are uncommon.

DIFFERENTIAL DIAGNOSIS

An aural hematoma is diagnosed during the physical examination; however, the underlying ear disease must be diagnosed and treated to reduce the likelihood of recurrence.

MEDICAL MANAGEMENT

Simple needle aspiration to drain the hematoma can be performed, but recurrence is likely. When this pathway is chosen, daily drainage of the hematoma has been advocated to prevent early recurrence. The concave surface of the pinna should be clipped and prepped before a large (16–20 g) hypodermic needle is inserted in the most dependent part of the ear. Flushing with sterile saline can be performed to facilitate removal of clots and fibrin. Other methods of drainage have been described with variable outcomes (Box 17.6). Classically, drains are inserted and secured on the concave (inner) surface of the pinna.

The use of corticosteroids administered by a variety of routes has been described to treat aural hematomas. Daily intravenous administration of dexamethasone (0.5–2.0 mg/kg) results in resolution in over 85% of cases. Oral administration of antiinflammatory doses of prednisone can help decrease head shaking and scratching and may help treat inflammation associated with ear disease. Injection of dexamethasone, methylprednisolone, and triamcinolone (Box 17.7) directly into the hematoma cavity following drainage of fluid has successful resolution in over 90% of cases.

BOX 17.6 Methods of Aural Hematoma Drainage

Teat cannula
Silastic tubing
Penrose drain
Butterfly catheter (closed-suction drainage)

BOX 17.7 Reported Dosages of Intralesional Corticosteroids

Dexamethasone 0.2–0.4 mg in saline q24h for 1–5 days
Methylprednisolone 0.5–1.0 mL q7d for 1–3 weeks
Triamcinolone 0.1–1.0 mL q7d for 1–3 weeks

SURGICAL TREATMENT

Numerous techniques have been described for surgical treatment of aural hematomas. The goals of surgery are to remove the hematoma, prevent recurrence, and retain the natural appearance of the ear (i.e., minimize thickening and scarring). The most commonly used procedure involves incising the tissue overlying the hematoma, evacuating blood clots and fibrin, and holding the cartilage in apposition with sutures until scar tissue can form. To prevent enlargement or fibrosis, hematomas should be treated soon after they occur, preferably within several days.

Preoperative Management

Concurrent otitis externa (see p. 315) should be treated simultaneously. Appropriate cultures should be submitted and the ear canal cleaned and flushed.

Anesthesia

Animals with aural hematomas are usually healthy, and a variety of anesthetic protocols can be used. Tranquilization may be necessary on recovery from anesthesia once sufficient analgesics have been provided (see p. 303). See p. 302 for information on the anesthetic management of animals with ear disease.

Surgical Anatomy

Structural support of the pinna is provided by cartilage interposed between the two skin surfaces. Branches of the great auricular arteries and veins supply the pinna. These main vessels are located along the convex surface of the ear, and small branches penetrate the scapha to supply the concave surface. Sensory innervation to the ear is supplied by the second cervical nerve (convex surface) and by the auriculotemporal branches of the trigeminal nerve (concave surface).

Positioning

Patients are generally placed in lateral recumbency for aural hematoma and laceration repair.

SURGICAL TECHNIQUES

Aural Hematomas

Make an S-shaped incision on the concave surface of the ear and expose the hematoma and its contents from end to end (Fig. 17.21). Remove the fibrin clot and irrigate the cavity. Using 2-0 to 3-0 monofilament nonabsorbable suture (e.g., polypropylene, polybutester), place 0.75- to 1-cm long sutures through the skin on the concave surface of the ear and underlying cartilage. Place the sutures parallel to the major vessels (vertical rather than horizontal). They may be placed through the cartilage without incorporating the skin on the convex surface of the ear, or they may be full thickness. Place an ample number of sutures so that no pockets are left in which fluid can accumulate. Do not ligate the branches of the great auricular artery, visible on the convex surface of the ear. Do not suture the incision closed; it should gap slightly to allow for continued drainage. Place a light protective bandage over the ear, and support the ear over the animal's head (see p. 311, "Postoperative Care and Assessment"). Remove the bandage and sutures in 14 to 21 days.

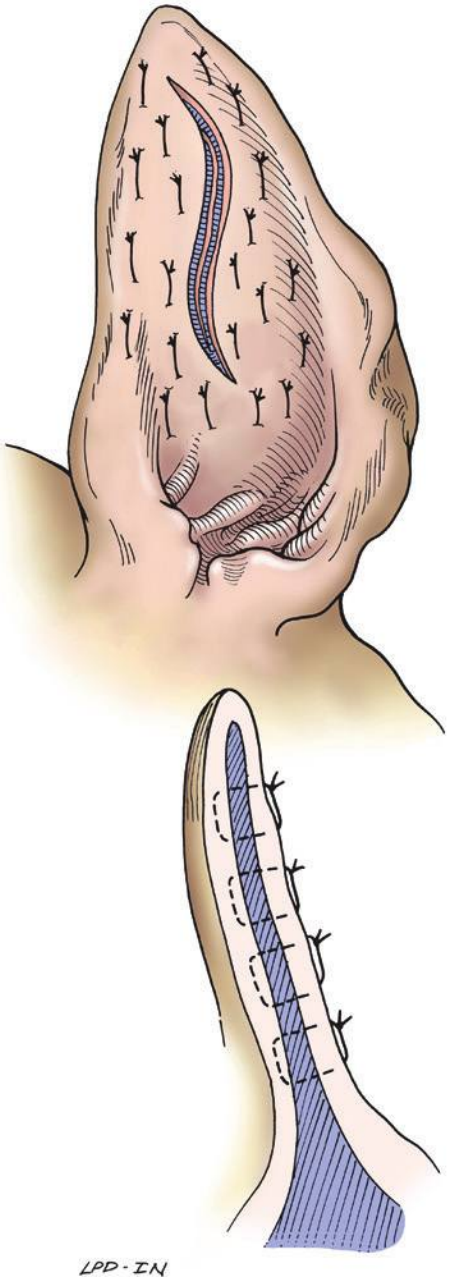

FIG. 17.21 Sutures should be placed vertically rather than horizontally for aural hematoma repair. They may be placed through the cartilage without incorporating the skin on the convex surface of the ear, or they may be full thickness.

An alternative surgical technique has recently been described in 23 dogs (Fig. 17.22).[7] No recurrence was documented in any of the dogs, and 91% had no auricular deformity. The advantages of this technique proposed by the authors include minimal need for aftercare, absence of discomfort or irritation caused by external sutures, and sutures that do not need to be removed.

Create a longitudinal incision on the concave surface of the pinna. Place several parallel suture lines intradermally on either side of the incision using monofilament absorbable suture (3-0 or 4-0 glycomer 631 or poliglecaprone 25).

Other surgical techniques described for treatment of aural hematomas involve the creation of circular fenestrations using either a 4-mm dermal biopsy punch or a CO_2 laser. When using a dermal punch, multiple partial-thickness circular plugs of tissue are removed approximately 0.5 to 1.0 cm apart from each other over the entire area of the hematoma. The skin edge of each incision is tacked through the cartilage using a 3-0 or 4-0 monofilament suture material in a simple interrupted pattern.

When using a CO_2 laser, a 1-cm circular partial-thickness incision is made in the most dependent part of the hematoma to facilitate drainage and flushing of the hematoma cavity. Multiple 1- to 2-mm full-thickness circular incisions are then made over the entire surface of the hematoma, with the goal being to stimulate adhesion formation between the cartilage layers due to fibrosis during cartilage healing. Outcomes and cosmetic appearance are reasonable, with no reports of hematoma recurrence.

A sutureless surgical technique for addressing aural hematomas is also available (Hematoma Repair System). Following the creation of the longitudinal incision on the concave surface of the pinna, preshaped silicon pads are placed on either side of

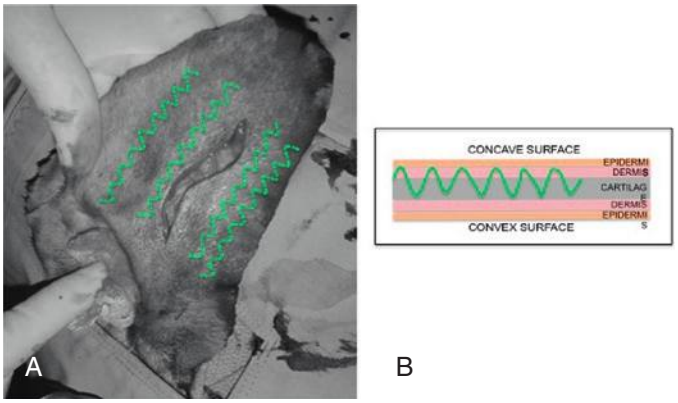

FIG. 17.22 Alterative internal suturing technique for aural hematomas. (A) One to three intradermal suture lines are placed parallel to the incision made in the concave surface of the pinna. (B) Longitudinal cross section of the pinna; the continuous suture line is placed from the concave dermis through the cartilage but not through to the convex surface.

the pinna. A needle is passed through the pad from medial to lateral, facilitating placement of locking clips and rings over the entire surface of the ear. Pads are left on for up to 3 weeks, but daily inspection is required to observe for evidence of pressure necrosis.

POSTOPERATIVE CARE AND ASSESSMENT

A bandage can be used to protect the ear from contamination and self-inflicted trauma after hematoma repair. Maintaining bandages on the head can be difficult. One method is to place short strips of tape on the rostral and caudal margin of the convex surface of the pinna (Fig. 17.23A). The tape should extend beyond the ear border. Longer pieces of tape are placed on the concave surface of the pinna so that these tape pieces contact the tape on the convex surface (see Fig. 17.23B). The ear is placed over the top of the head (cotton can be placed between the ear and the top of the head to support the ear), and a nonadherent pad is placed over the incision (see Fig. 17.23C). The long pieces of tape are applied to the skin. Cast padding and Kling are applied over the ear (the unaffected ear on the other side is not incorporated into the bandage), and Vetrap (3M) or stockinette (cut a hole for the unaffected ear) can be placed as the external layer (see Fig. 17.23D). The bandage can then be secured to the head cranially or caudally with Elastikon (Johnson & Johnson) or 1-inch (2.5 cm) tape that is applied to both the hair and the bandage.

Alternatively, the ear can be secured using a hematoma pad. The pad is secured to the ear using additional horizontal mattress sutures. Hematoma pads are available commercially (Buster Othaematoma Compress), but they can also be made using simple materials found in most veterinary hospitals (Box 17.8; Fig. 17.24).

NOTE Be sure to check head bandages periodically to ensure that they are not too tight and are not restricting breathing.

PROGNOSIS

Aural hematomas seldom recur if they are properly addressed and if any underlying ear disease is recognized and appropriately treated. There can be changes in the cosmetic appearance of the

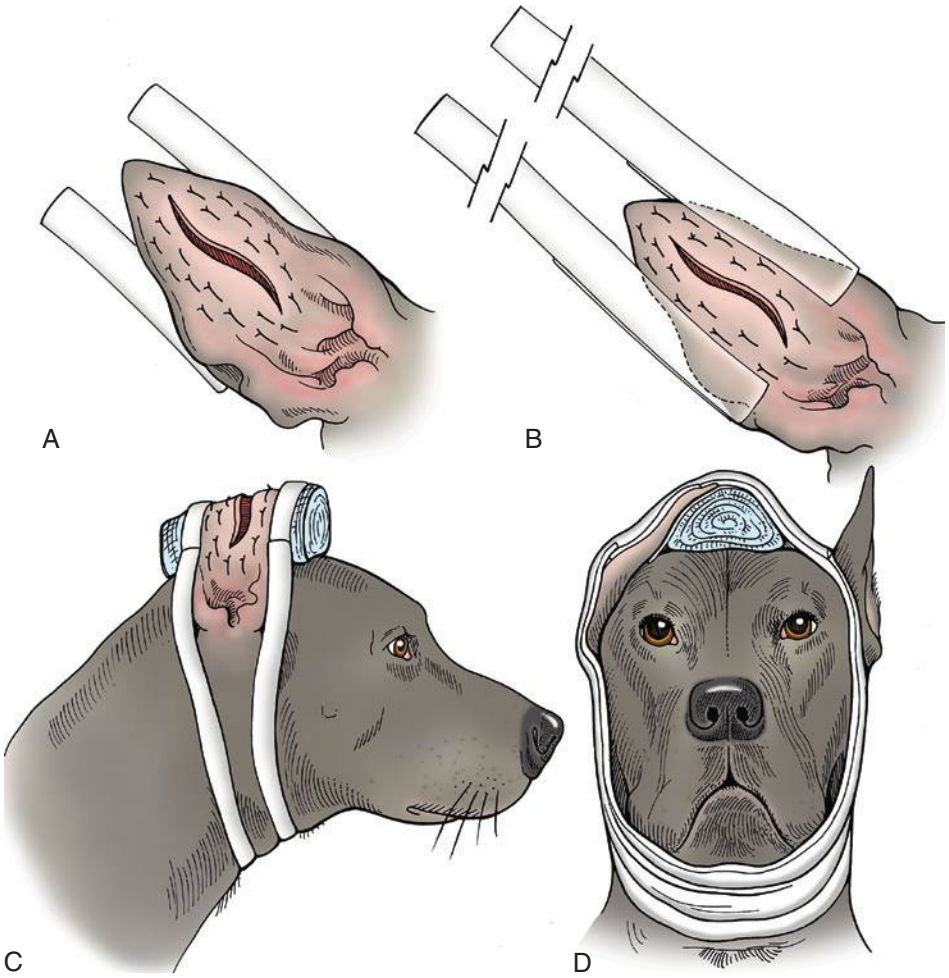

FIG. 17.23 Bandaging the ear after a surgical procedure. (A) Place short strips of tape on the rostral and caudal margins of the convex surface of the pinna. (B) Use longer pieces of tape on the concave surface of the pinna so that these tape pieces contact the tape on the convex surface. (C) Place the ear over the top of the head and place a nonadherent pad over the incision. (D) Apply cast padding and Kling over the ear, then use Vetrap or stockinette as an external layer.

BOX 17.8 Aural Hematoma Pad

Materials

- Piece of used radiographic film
- Used surgical scrub brushes
- Household cyanoacrylate (e.g., Super Glue)

Technique

1. Remove the sponge from the scrub brush and split it in half to decrease the thickness of the sponge.
2. Trace the outline of the pinna on the piece of radiographic film.
3. Glue the sponges to the radiographic film to completely cover the outline of the pinna.
4. Once the glue has dried, cut along the trace of the pinna outline.
5. Attach the aural hematoma pad to the concave aspect of the pinna with three or four full-thickness mattress sutures (see Fig. 17.24B–C).
6. The pad is removed in 3 days. The remaining sutures are removed in 3 weeks (see Fig. 17.24D).

pinna; cats or dogs with erect or semierect ears may lose carriage of the pinna.

TRAUMATIC LESIONS OF THE PINNA AND EAR CARTILAGE

The ear may be lacerated as a result of fighting or other trauma. These wounds may be superficial, involving the skin on one surface of the ear only, or may perforate the cartilage and involve both skin surfaces. Depending on the severity of the wounds, some may be left to heal by secondary intention, whereas others will have a more cosmetic appearance if sutures are placed. In rare cases, a portion of the ear may be avulsed, resulting in an unacceptable cosmetic deformity.

Traumatic separation of the annular and auricular cartilages may occur in dogs and cats; however, it is rare. Treatments have included TECA and LBO or vertical canal ablation. Primary

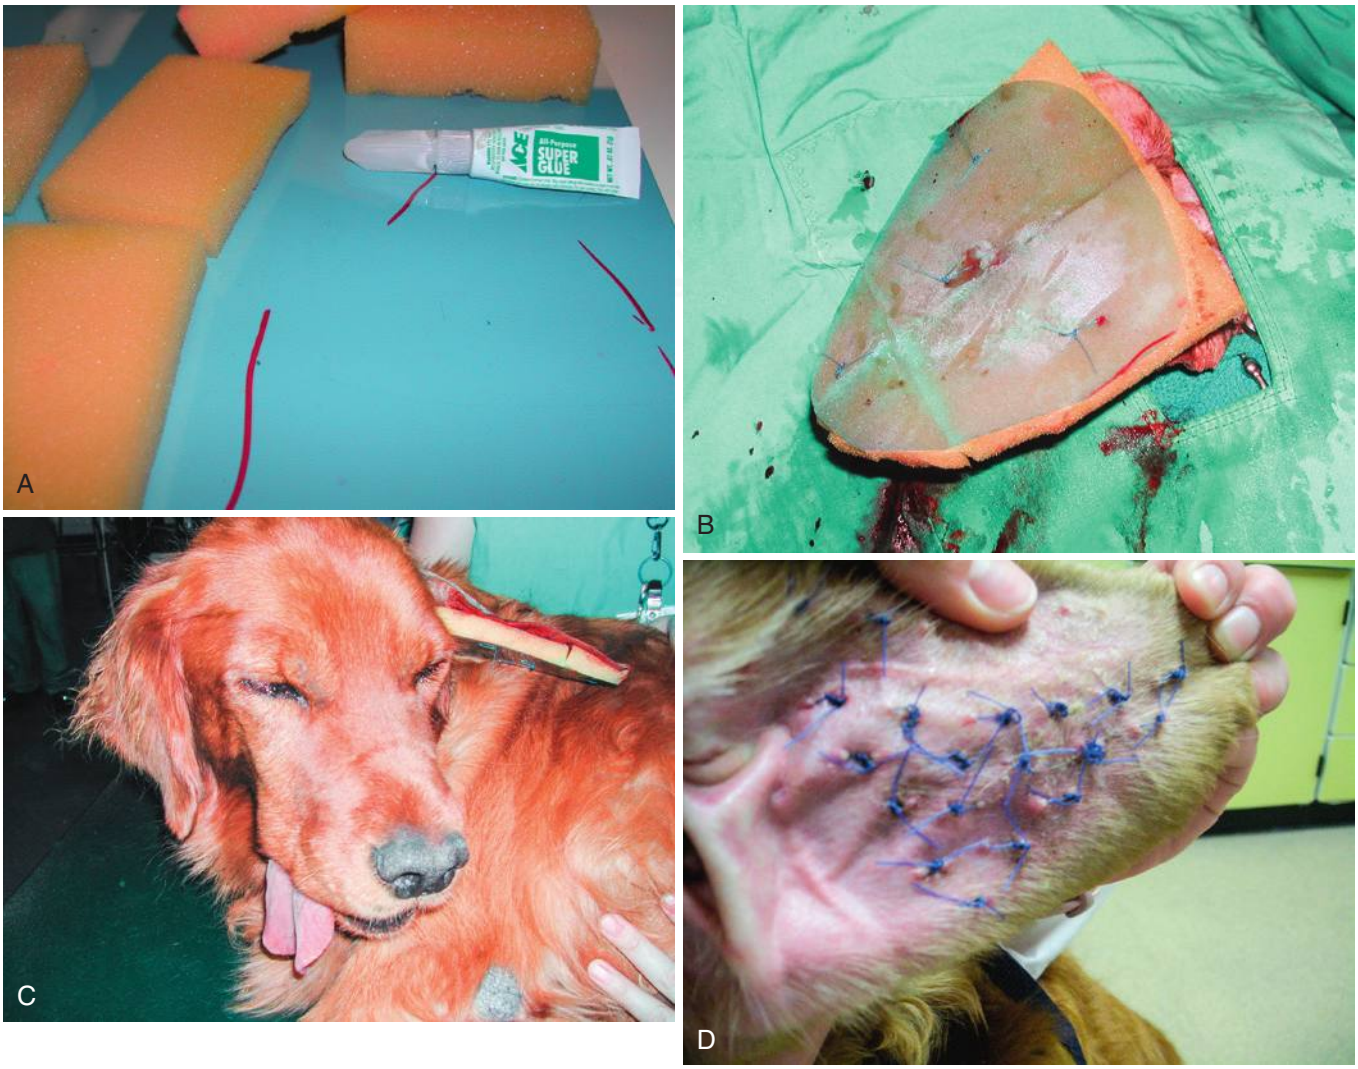

FIG. 17.24 The makings of an aural hematoma pad. (A) Materials needed include used surgical sponges, household cyanoacrylate glue, and used radiographic film. (B) The aural hematoma pad is attached directly to the concave aspect of the pinna with three to four full-thickness sutures. (C) The postoperative appearance following placement of an aural hematoma pad. (D) Appearance of the pinna following removal of the aural hematoma pad.

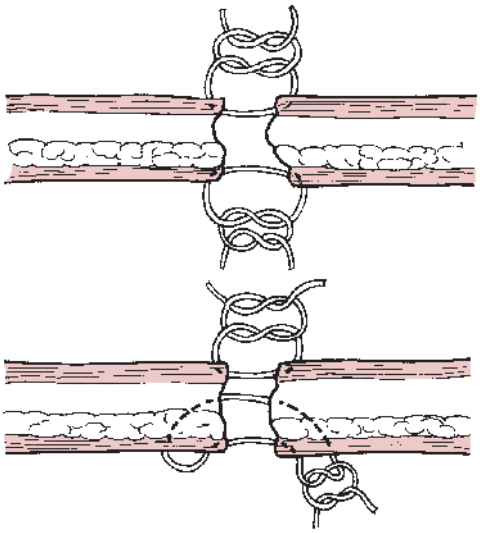

FIG. 17.25 Suture placement for repair of pinna lacerations.

repair of the traumatic injury using a caudal approach can be attempted.

Linear lacerations that involve only one skin surface may be left to heal by secondary intention or can be sutured. The laceration should be cleaned and the edges debrided if necrotic tissue is present. The skin margins can be apposed with simple interrupted sutures. If a flap of tissue has been elevated away from the cartilage, it should be sutured. Sutures are placed through the skin at the margins of the wound. Sutures also should be placed through the skin and cartilage at the center of the flap to obliterate any dead space where fluid might collect. Full-thickness injuries through the ear margin should be sutured. The skin on both sides of the defect may be sutured with simple interrupted sutures, or, as an alternative, a vertical mattress suture can be used to appose the skin and cartilage on one side of the ear and simple interrupted sutures used to appose the skin on the opposite side of the ear (Fig. 17.25).

Avulsions of the Ear Margin

Small avulsions of the ear margin may be treated by resecting surrounding tissue to restore a normal ear contour. The skin edges are sutured over the cartilage using a continuous suture pattern. Larger defects of the ear may be repaired using a pedicle flap obtained from the side of the neck in dogs with pendulous ears or from the dorsum of the head in dogs with erect ears.

NOTE Defects of the ear margins can be repaired for cosmetic reasons, but repair should be delayed after excision of neoplasms until it has been determined that recurrence is unlikely.

Prepare the ear and donor site for aseptic surgery. Debride the margins of the ear defect. Place the ear on the donor site and incise the skin, extending the limbs of the incision 0.5 to 1 cm longer than the defect (Fig. 17.26A). Suture the flap to the skin on the convex surface of the ear (see Fig. 17.26B). Place a nonadherent dressing over the wound and leave the ear bandaged for 10 to 14 days. Then, sever the flap from the donor site in the shape of the defect on the concave side of the ear (see Fig. 17.26C). Gently fold the flap over the ear margin and suture it to the skin (see Fig. 17.26D). Remove skin sutures in 10 to 14 days.

NEOPLASIA OF THE PINNA AND EXTERNAL EAR CANAL

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Neoplasms of the external ear canal are relatively uncommon in dogs and cats; however, they may arise from any structure that lines or supports the ear canal. Aural tumors in the dog and cat can be histologically benign or malignant. The most common malignant tumors of the external ear canal are ceruminous gland adenocarcinomas, squamous cell carcinomas, and carcinomas of undetermined origin. Benign aural conditions include inflammatory polyps (see p. 327), aural cholesteatomas (epidermoid cysts), basal cell tumors, papillomas, histiocytomas, fibromas, and ceruminous gland adenomas, among many others. Aural tumors tend to be more aggressive in cats than in dogs. Most canine ceruminous gland tumors are benign, but such tumors in cats are usually malignant.

Although tumors of the external ear canal are more common than those arising in the internal or middle ear cavity, clinical signs of middle or inner ear disease may predominate if these tumors extend through the tympanic membrane (see p. 317). Squamous cell carcinoma in the bullae with bone destruction may cause severe pain in the region of the temporomandibular joint. Neoplasms of the external ear are frequently associated with concurrent bacterial and yeast infections. It has been hypothesized that chronic otitis causes hyperplasia, which may eventually induce dysplastic and neoplastic changes. The mere presence of a tumor in the ear canal often obstructs drainage, resulting in otitis externa.

Any tumor that affects the skin may arise on the pinna, but the most common tumor of the pinna in cats is squamous cell carcinoma. These tumors are most often diagnosed in older cats, particularly white ones (Figs. 17.27 and 17.28). The association between lack of protective pigmentation and occurrence of these tumors suggests that solar radiation is a causative factor. Although these tumors are highly invasive, metastasis is uncommon. If metastasis does occur, it is usually seen in the regional lymph nodes and lungs. Tumors may be noted on the nares and eyelids.

Other tumors of the pinna of dogs and cats include melanoma, fibrosarcoma, basal cell tumor, fibroma, lymphoma, histiocytoma, papilloma, and mast cell tumor. A recent study found that dogs with mast cell tumors on the pinna, without evidence of gross metastasis, have a similar prognosis to mast cell tumors in other haired areas of the body following treatment with surgical excision, unlike mast cell tumors on other parts of the head.[8]

DIAGNOSIS

Clinical Presentation

Signalment

Most neoplastic lesions of the external ear are found in middle-aged or older animals. Older male cats may be at increased risk of developing ceruminous gland tumors of the ear canal. Squamous cell carcinoma of the pinna occurs almost exclusively in older white-eared cats or in multicolored cats with little pigmentation of the pinna.

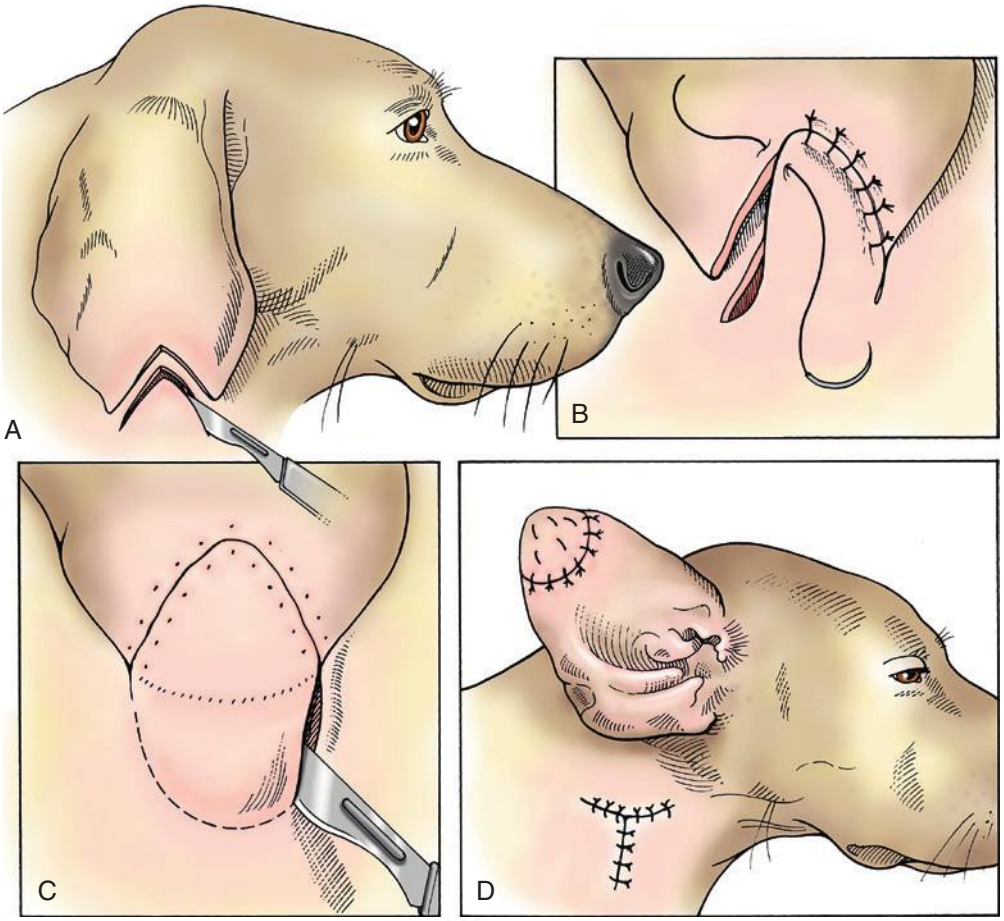

FIG. 17.26 Repair of pinnal defects. (A) Place the ear on the donor site and incise the skin, extending the limbs of the incision 0.5 to 1 cm longer than the defect. (B) Suture the flap to the skin on the convex surface of the ear. (C) After 10 to 14 days, sever the flap from the donor site in the shape of the defect on the concave side of the ear. (D) Gently fold the flap over the ear margin and suture it to the skin.

History

The history of a patient with a tumor arising from the external ear canal usually differs minimally from that of a patient with primary bacterial otitis externa (see p. 317). The history of cats with squamous cell carcinoma is often insidious and begins with the owner intermittently noticing crusty, eczematous lesions at the edge of the ear.

Physical Examination Findings

Small, pedunculated masses of the external ear canal suggest ceruminous gland hyperplasia or adenomas, papillomas, or inflammatory polyps. Infiltrative masses suggest ceruminous gland adenocarcinoma (Fig. 17.29). Squamous cell carcinoma usually originates on the tips of the ears, where little hair is present, and initially may appear as hyperemic skin. As the lesions progress, erosion, ulceration, crusting, and thickening become noticeable. The ear may bleed with mild trauma.

Diagnostic Imaging

Radiographic signs of neoplasia (i.e., bony lysis of the petrous temporal bone) may be noted on skull radiographs of animals with neoplasia of the external ear canal. CT is more sensitive for detection and evaluation of the extensiveness of lesions and is recommended (Fig. 17.30). Although metastasis usually occurs late in the course of the disease, pulmonary metastasis may be noted with some ear tumors; therefore thoracic radiographs are also recommended.

Laboratory Findings

Definitive diagnosis of ear neoplasia requires cytology or histopathology. Fine needle aspirate and cytopathology of external ear masses in the cat accurately distinguish inflammatory polyps from neoplasia. For differentiation of benign proliferation and malignant neoplasia, however, histopathology is recommended.

DIFFERENTIAL DIAGNOSIS

Neoplastic lesions of the ear pinna must be differentiated from nonneoplastic lesions, such as dermatitis caused by insect bites or immune-mediated lesions. Suspicious lesions should be biopsied to improve chances of early, complete resection.

MEDICAL MANAGEMENT

Squamous cell carcinoma may be prevented or reduced by applying sunscreen to nonpigmented areas of the ear and

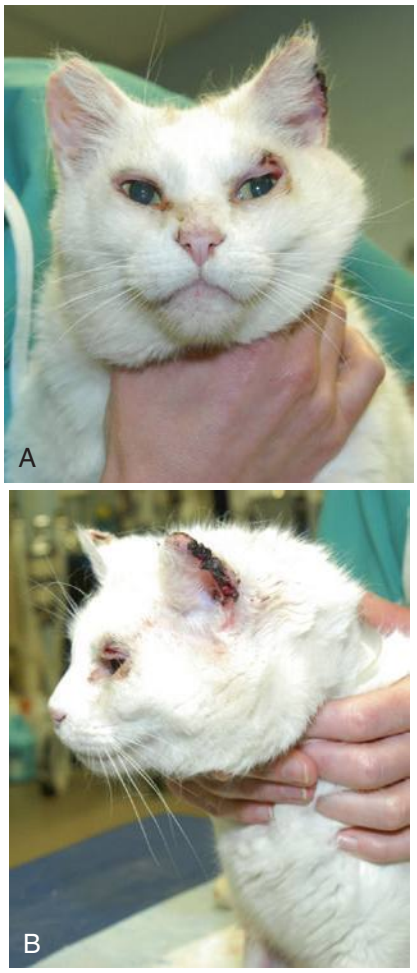

FIG. 17.27 Adult cat with squamous cell carcinoma of the pinnae and periorbital regions. (A) Rostral and (B) left lateral views.

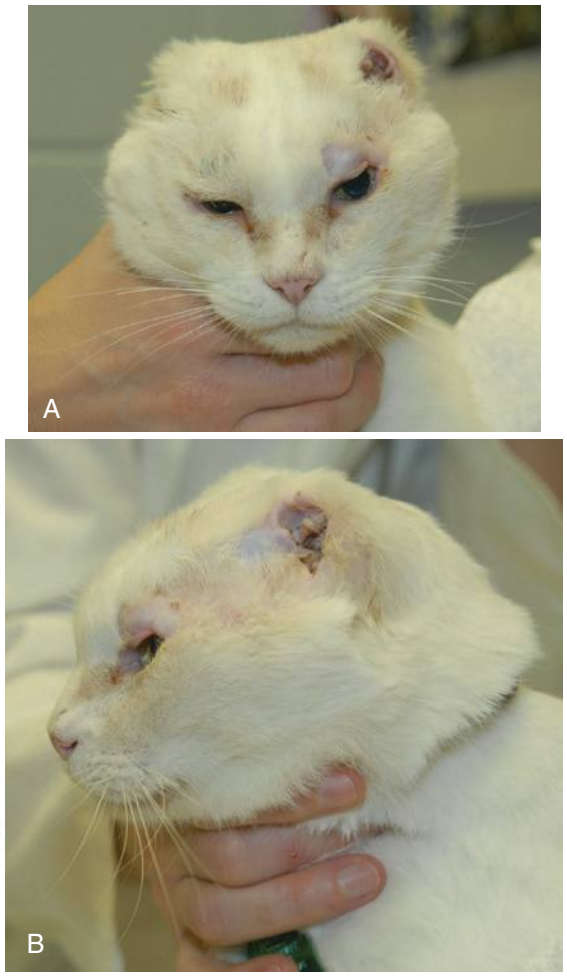

FIG. 17.28 Same cat in Fig. 17.27 1 month after bilateral pinnectomy and strontium therapy for squamous cell carcinoma. (A) Rostral and (B) left lateral views.

FIG. 17.29 Ceruminous gland adenocarcinoma on the pinna of a 6-year-old dog presented for treatment of chronic otitis externa.

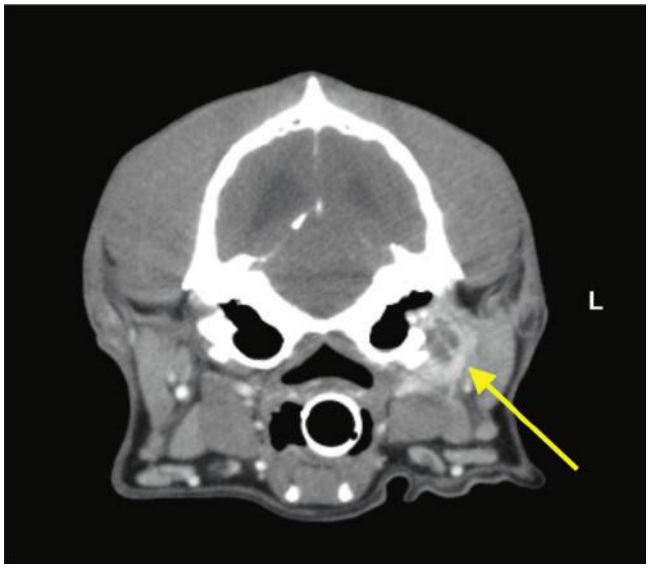

FIG. 17.30 Contrast-enhanced computed tomography axial image of a dog with an expansile neoplastic mass of the external and middle ear *(arrow)*.

preventing physical exposure to ultraviolet radiation. Cryotherapy and radiation are alternatives to surgical removal of the pinna. Cryotherapy may be curative in small, superficial tumors, but local recurrence is common. Radiation therapy is less disfiguring than surgical removal of lesions and is a viable alternative for small, superficial tumors and preneoplastic lesions.

SURGICAL TREATMENT

For neoplasms of the external ear canal, vertical ear canal ablation or TECA with LBO is usually required (see pp. 307–309). Local treatment options for squamous cell carcinoma of the pinna include surgical resection, cryosurgery, and photodynamic therapy. For cats with more aggressive or advanced disease, systemic chemotherapy may provide limited improvement in survival times. The aim of surgical treatment of malignancies of the pinna is to remove the neoplasm with a wide margin of normal surrounding skin. This may require pinnectomy alone or a vertical ear canal ablation and removal of the pinna. The owner should be prepared for the resulting cosmetic deformity.

Preoperative Management

If concurrent otitis externa is present, perioperative antibiotics based on culture results should be given. Preoperative cytologic studies can help determine whether radical resection is necessary when neoplasia is suspected.

Anesthesia

See p. 302 for anesthetic recommendations for animals with ear disease.

Surgical Anatomy

See p. 305 for a description of the surgical anatomy of the ear canal and pinna.

Positioning

Positioning for ear surgery is described in the discussion of surgical techniques on pp. 306 to 310.

SURGICAL TECHNIQUE

The most important aspect of surgery for ear neoplasms is achieving wide margins to prevent local recurrence; this may require removal of the entire pinna and ear canal. If aggressive surgical therapy cannot provide clean margins, adjunctive therapy (e.g., radiation) should be considered. See pp. 306 to 310 for a description of surgical techniques commonly used for diseased or neoplastic ears.

NOTE Malignant ear tumors must be excised with wide margins of normal tissue. The owner should be advised of the resulting cosmetic defect before surgery is planned.

For pinnectomy, remove the affected portion of the ear and suture the remaining skin over the exposed cartilage. For small tumors on the central portion of the convex surface of the pinna, resect the neoplasm and mobilize the skin around the defect by undermining between the cartilage and the skin. Suture the skin margins or, if necessary, leave the defect open to heal by secondary intention under a light bandage. For small tumors on the concave surface of the ear, repair the skin defect by elevating a flap from surrounding skin and rotating it into the defect. Suture the flap to the wound margins. After 10 to 14 days, transect the flap and suture the edge to the defect. Close the donor site primarily.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

See p. 310 for a discussion of suture materials and surgical instruments for ear surgery.

POSTOPERATIVE CARE AND ASSESSMENT

An Elizabethan collar or sidebar should be used to prevent the animal from scratching the ear after surgery. Ear surgery is painful, and perioperative analgesics such as hydromorphone or fentanyl or FLK CRI (see p. 144) should be provided (see also Table 17.1). If the animal appears dysphoric or anxious, tranquilizers may be given once the patient has received adequate postoperative analgesics (see p. 303 and Table 17.1).

PROGNOSIS

For malignant ceruminous gland tumors of the external ear, TECA with LBO is seldom curative, and adjunctive therapy (radiation therapy) should be considered. Local recurrence of squamous cell carcinoma is common if wide margins are not obtained at surgery. The prognosis is poor with squamous cell carcinoma of the middle and inner ear; however, amputation of the pinna for squamous cell carcinoma of the ear margin may be curative.

INFLAMMATORY POLYPS

DEFINITION

Inflammatory polyps are benign, fibrous, pedunculated masses that may be found in the oropharynx, middle ear, or external ear canal. They are also known as *nasopharyngeal, middle ear, otopharyngeal,* or *aural polyps.*

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Feline inflammatory polyps are benign growths that originate from the middle ear or the auditory tubes of young cats. True nasopharyngeal polyps extend into the pharyngeal cavity causing signs of upper airway obstruction, including stertor, nasal discharge, gagging, dysphagia, and dyspnea. Aural polyps extend from the middle ear through the tympanic membrane and into the external ear canal, resulting in symptoms of otitis externa. More severe signs include evidence of middle ear disease such as Horner syndrome or facial nerve paresis, or inner ear disease such as head tilting, ataxia, and nystagmus.

The exact origin and cause are unknown; however, it is thought that inflammatory polyps arise as a result of a prolonged inflammatory process. It is unclear whether this inflammation initiates or potentiates the development and growth of inflammatory polyps. Bacterial cultures are generally negative, and organisms are not usually seen on histopathology. A viral cause has been proposed as affected cats often have a history of upper respiratory infection.

DIAGNOSIS

Clinical Presentation

Signalment

Inflammatory polyps predominantly affect young cats; the reported mean age ranges from 14 months to 3 years. However, polyps have also been reported in older cats. No breed or sex predisposition has been identified. Although less commonly diagnosed, inflammatory polyps of the ear canal may occur in dogs.

History

Most cats present for evaluation of dysphagia or upper respiratory signs, such as stertorous respiration, nasal discharge, sneezing, voice change, and/or dyspnea. They may present for signs of otitis externa (head shaking and scratching at the ear). Occasionally, the animal may be seen for acute onset of head tilt, nystagmus, and/or vestibular imbalance. Clinical signs may be present for months before evaluation.

Physical Examination Findings

Most inflammatory polyps are unilateral, although they may be bilateral. Concurrent otic and nasopharyngeal polyps may be present. These masses tend to be pink and pedunculated but may be ulcerated to varying degrees. Polyp extension into the external canal may appear as a dark ceruminous mass on otoscopic examination, or may be red, pink, or white. These masses are often covered by mucus and/or blood. The tympanic membrane may appear distorted and discolored if the mass has not extended through it. Evidence of upper respiratory obstruction is present in some cats, and secondary infection, such as nasal discharge, rhinitis, and/or sinusitis, may also be noted.

The area dorsal to the soft palate can be evaluated by digital palpation of the soft palate and using a dental mirror and a spay hook, or by using a small-diameter flexible endoscopy tube that can be retroflexed over the soft palate (Fig. 17.31). The latter technique has the advantage of allowing excellent visualization and provides an opportunity to obtain biopsies and brush samples for cytology and culture if a mass is not present. Care should be taken when anesthetizing cats with possible upper airway obstruction due to the potential for respiratory decompensation.

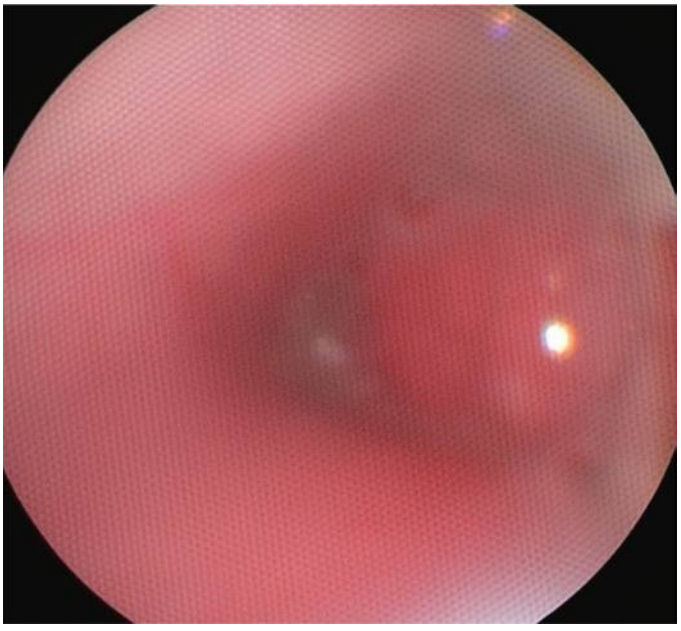

FIG. 17.31 Retroflexed endoscopic image of a nasopharyngeal inflammatory polyp in a 3-year-old cat.

Diagnostic Imaging

Well-positioned lateral radiographic images of the pharyngeal region are most useful for diagnosing nasopharyngeal polyps, yet CT is the gold standard for determining the extent of involvement and whether the condition is unilateral or bilateral before surgery (Fig. 17.32). On CT, a soft tissue attenuating mass may be seen extending from the middle ear into the lumen of the external ear canal. Alternatively, a soft tissue mass may be seen in the nasopharyngeal region (although collapse of the pharyngeal region during anesthesia can hinder this evaluation). Nasopharyngeal polyps, rather than neoplasia, should be suspected in young animals with a soft tissue mass in the nasopharyngeal region.

Thoracic radiographs are indicated to look for signs of lower airway disease and to rule out metastatic neoplasia in older cats. Echocardiography could be considered in cases of long-standing severe upper airway obstruction that could result in pulmonary hypertension.

Laboratory Findings

Specific laboratory abnormalities are uncommon.

DIFFERENTIAL DIAGNOSIS

Polyps should be differentiated from neoplastic masses, particularly in older cats. Other differentials include upper respiratory tract infections, nasal foreign bodies, otitis externa/media, and fungal diseases.

MEDICAL MANAGEMENT

Treatment of concurrent infection should be instituted after appropriate microbial cultures are performed. Surgical removal of the masses is indicated because medical management has been uniformly unsuccessful in eliminating these polyps. If traction-avulsion alone is used, concurrent treatment with an antiinflammatory (e.g., prednisolone, 1–2 mg/kg per day for 2 weeks followed by a tapered dose for an additional 2–4 weeks) may reduce the recurrence rate.

SURGICAL TREATMENT

Surgical procedures advocated for removal of polyps include traction-avulsion of the mass, traction-avulsion with direct endoscopic visualization, ventral bulla osteotomy, lateral ear canal resection, TECA combined with LBO, and myringotomy. Traction-avulsion is used as a first-line treatment to remove masses when there is no evidence of otitis media. Ventral bulla osteotomy should be performed if middle ear disease is evident from clinical signs or on radiography or CT. For cats with deep aural polyps, a lateral approach to the ear canal has been described.[9]

Preoperative Management

If severe respiratory obstruction is present, a temporary tracheostomy may be necessary; however, this is rarely required.

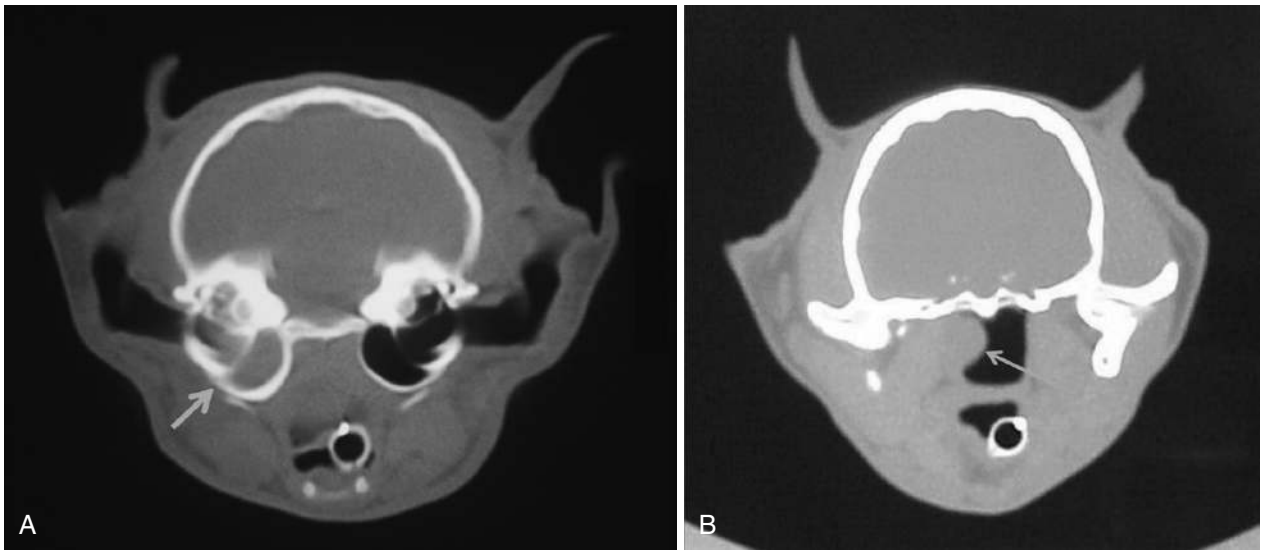

FIG. 17.32 Computed tomography axial image of the cat in Fig. 17.31 with soft tissue opacity within the tympanic bulla (*arrow*, A) and a soft tissue mass in the nasopharynx (*arrow*, B), consistent with an inflammatory polyp.

Antimicrobial therapy should await results of microbial cultures.

Anesthesia

Anesthetic management of animals undergoing ear surgery is provided on p. 302. If the patient is in respiratory distress, be prepared with monitors, airway devices, an anesthesia machine, and induction/emergency drugs before inducing anesthesia. Preoxygenating these patients for 3 to 5 minutes before induction can be helpful. When a patient resists preoxygenation with a mask, holding the anesthesia machine circuit with the oxygen at a high flow rate in front of the patient's nose and mouth will increase the inspired oxygen concentration enough to allow extra time to intubate the animal. Care must be used when intubating animals that have oropharyngeal masses; occasionally a smaller than expected endotracheal tube may be necessary. The cuff on the tube should be carefully checked to ensure its function and to prevent blood and other debris from entering the trachea during surgery.

Surgical Anatomy

Anatomy of the ear is detailed on p. 305.

Positioning

The animal is positioned in dorsal recumbency for ventral bulla osteotomy (see p. 310).

SURGICAL TECHNIQUES

Ventral bulla osteotomy is described on p. 310. In cats, the bullae should be entered through the larger ventromedial compartment. Most polyps are found in the dorsolateral compartment. Removal of the septum at its most lateral aspect may help prevent damage to the sympathetic trunk. Cultures should be taken of the bullae and the polyp. The polyp, epithelial lining, and associated exudate should be carefully removed with thumb forceps. The polyp should be submitted for histopathology.

Traction-avulsion of aural or nasopharyngeal polyps is the simplest technique and can be associated with limited recurrence rates if the entire polyp and stalk are removed, with or without administration of postprocedural corticosteroids.

For aural polyps, position the cat in lateral recumbency. Grasp the polyp using toothed grasping forceps such as Allis tissue forceps or alligator forceps. If necessary, use a small rigid endoscope with a biopsy channel to facilitate visualization.[10] *Alternatively, with a No. 11 scalpel blade, make a small stab incision into the vertical canal distal to the junction with the horizontal canal.*[9] *Place stay sutures on either side of the incision to improve visualization. Insert small curved hemostatic forceps into the canal and advance over the polyp. Grasp the polyp as close as possible to the external auditory meatus. Twist and pull with the forceps to avulse the polyp in its entirety. Close the canal using several simple interrupted sutures using 4-0 monofilament absorbable suture material. Close the rest of the incision routinely.*

For nasopharyngeal polyps, place the cat in dorsal or sternal recumbency. Retract the soft palate rostrally using a spay hook or stay sutures. It is rarely indicated to incise the soft palate on the midline to gain access to the nasopharynx (staphylotomy). *Grasp the polyp using toothed grasping forceps or a small towel clamp (e.g., 3.5 inch [9 cm] Backhaus towel clamp). Expect mild bleeding, but excessive hemorrhage is uncommon.*

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Ventral bulla osteotomy can be performed using a small Steinmann pin and a hand chuck or an air drill. The opening is typically enlarged with a rongeur (e.g., Kerrison, Lempert).

POSTOPERATIVE CARE AND ASSESSMENT

The animal should be evaluated for seroma formation after surgery. These seromas rarely require drainage. Surgical curettage of the tympanic cavity frequently causes transient Horner syndrome in cats, which usually resolves in 2 to 3 weeks (see

discussion on surgical anatomy, p. 305). Horner syndrome is rare in dogs after this procedure, probably reflecting the difference in the anatomy of the tympanic cavity between the two species.

PROGNOSIS

The prognosis is excellent with complete removal of the polyp. Nasopharyngeal polyps may be less likely to recur than aural ones. Horner syndrome typically resolves within a few weeks. Rarely, temporary or permanent vestibular signs (e.g., nystagmus, head tilt) may occur. Transient facial nerve paralysis is uncommon but may occur after bulla osteotomy (see p. 311).

Surgery of the Digestive System

Surgery of the Oral Cavity and Oropharynx

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Maxillectomy is removal of a portion of the maxilla, and **mandibulectomy** is removal of a portion of the mandible. **Tonsillectomy** is excision of one or both tonsils. **Glossectomy** is excision of a portion of the tongue. **Cheiloplasty** is performed to alter the shape of the lip, generally to reduce drooling. **Mucoceles** are subcutaneous collections of saliva or mucus (or both). **Ranulas** are collections of fluid from the mandibular or sublingual salivary glands that occur beneath the tongue on either side of the frenulum.

PREOPERATIVE CONCERNS

Surgical diseases of the oral cavity and oropharynx are common in dogs and cats. They include congenital and traumatic abnormalities, foreign bodies, neoplasia, salivary gland disease, and dental disease. Patients with oral cavity or oropharyngeal disease may have drooling, dysphagia, anorexia, bleeding from the mouth, and/or fetid breath. Some animals are asymptomatic until the lesions become large or are discovered on routine physical examination. Others are presented for treatment of a mass, oral hemorrhage, oral pain, difficulty eating, nasal regurgitation, chronic rhinitis, and/or dyspnea. Oropharyngeal disorders often present with a combination of upper airway and upper gastrointestinal (GI) tract signs, including cough, sneezing, dysphagia, and dyspnea if the laryngopharynx is involved. They may have a history of dental disease, weight loss, or trauma. The diagnosis is based on history, clinical signs, physical examination, cytologic studies, radiographs, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and/or biopsy.

Before major surgery is performed, a thorough physical examination, complete blood cell count (CBC), and serum biochemical profile should be performed; urinalysis and electrocardiogram (ECG) may be appropriate also. Animals undergoing maxillectomy or mandibulectomy and those predisposed to coagulopathies should have the coagulation system checked (i.e., platelet count and mucosal bleeding time) and blood cross matching done before surgery. Skull radiography, or preferably MRI or CT images, are indicated to determine the extent of the lesion. Thoracic radiographs or CT are indicated to evaluate for metastasis, cardiac size, and pulmonary disease. The teeth of animals with periodontal disease should be cleaned several days before major reconstructive surgery to improve tissue health and reduce oral bacterial numbers. Nutrition should be maintained by tube feeding if necessary (see Chapter 10). Animals with oronasal fistulae can be fed via feeding tubes to reduce the chances of rhinitis and inhalation pneumonia before surgery. Metabolic abnormalities should be corrected. Mature animals should be fasted for 12 to 18 hours before induction of anesthesia (pediatric patients are fasted for 4–8 hours). After induction and orotracheal intubation, the mouth should be flushed with dilute Betadine or chlorhexidine solution to reduce bacterial numbers.

ANESTHETIC CONSIDERATIONS

Preemptive analgesics and local nerve blocks (infraorbital, maxillary, mandibular, mental, or palatine nerves; bupivacaine 0.5%, 0.25–1 mL per site; see also Chapter 13) should be used to minimize pain associated with major oral reconstructive surgery. An orally placed endotracheal tube can sometimes hinder oral cavity and oropharyngeal surgery; in these cases, endotracheal intubation can be performed through a pharyngotomy (see p. 1044) or tracheotomy incision (see p. 842). It is important that the endotracheal tube and its cuff prevent blood and fluid from entering the lower airways. One or two gauze sponges can be placed in the oropharynx around the endotracheal tube to help absorb fluids; however, be sure to remove these sponges prior to waking the patient. Postoperative swelling of the oral mucous membranes may obstruct the glottis; this can be minimized by pretreatment with glucocorticoid (e.g., dexamethasone, 0.5–1 mg/kg given subcutaneously or intramuscularly before induction of anesthesia or intravenously at induction). Most animals with oral disease are healthy, and numerous anesthetic protocols can be used (Table 18.1). Because the oral cavity is highly vascular and hemostasis can sometimes be difficult, blood, hypertonic saline, and/or colloids should be available in the event of severe hemorrhage (see p. 32). Preoperative placement of two large cephalic catheters provides better venous access if volume replacement becomes necessary. Evaluation of blood pressure during surgery is warranted because of the risk of bleeding and subsequent hypotension.

ANTIBIOTICS

The oral cavity and oropharynx are contaminated (aerobic, facultative, and anaerobic bacteria); but saliva is antimicrobial

ABSTRACT

Complex surgery of the oral cavity is required to repair oronasal communications, including those that are congenital (cleft palate) and those acquired due to trauma or dental disease. Mass lesions of the oral cavity may be benign or malignant in dogs; most are malignant in cats. Salivary mucoceles are a common condition in dogs and are typically corrected with surgery. Surgery of the gastrointestinal tract requires adherence to a number of general principles to avoid complications. Surgery of the esophagus (e.g., for foreign bodies) is difficult because the esophagus heals poorly due to the lack of a serosa. The most common indication for surgery of the stomach and small intestine is ingested foreign material. Large intestinal surgery presents a challenge; the most common indications are for neoplasia and megacolon (in cats). Surgery of perineal and rectal masses, perineal hernias, and anal sac disease require attention to detail and carry the risk of incontinence.

TABLE 18.1 Anesthetic Considerations in the Healthy Patient Undergoing Oral or Rectal Surgery

Preoperative Considerations

Associated conditions	• Minimal; usually healthy if young patient • May have other comorbidities if older patient
Bloodwork	• HCT • TP • In patients older than 5–7 years, consider electrolytes, liver enzymes, BUN, and Cr • Calcium if rectal mass
Physical exam	• Depends on diagnosis

Premedications	• If patient is anxious give:
	  • Diazepam (0.2 mg/kg IV), *or*
	  • Midazolam (0.2 mg/kg IV, IM), *plus*
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM in dogs; 0.05–0.1 mg/kg IV, IM in cats), *or*
	  • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or*
	  • Morphine[b] (0.1–0.2 mg/kg IV or 0.2–0.4 mg/kg IM), *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM)

Intraoperative Considerations

Induction	• If premedicated, give:
	  • Propofol (2–4 mg/kg IV), *or*
	  • Alfaxalone (2–3 mg/kg IV)
	• If no premeds given, give:
	  • Propofol (4–8 mg/kg) IV), *or*
	  • Alfaxalone (2–5 mg/kg IV), *or*
	• Ketamine (5 mg/kg IV with diazepam or midazolam as above)

Maintenance	• Isoflurane or sevoflurane, *plus*
	  • Fentanyl (2–10 µg/kg IV PRN in dogs; 1–4 µg/kg IV PRN in cats) for short-term pain relief, *plus*
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV PRN in dogs; 0.05–0.1 mg/kg IV PRN in cats), *or*
	  • Morphine[b] (0.1–1 mg/kg IV PRN in dogs; 0.05–0.2 mg/kg IV PRN in cats), *or*
	  • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV PRN), *plus*
	  • Dexmedetomidine[d] (low dose) (0.5–1 µg/kg IV) *or*
	  • Medetomidine[d] (low dose) (1–2 µg/kg IV), *plus*
	  • Ketamine (low dose) (0.5–1 mg/kg IV), *or*
	  • Ketamine CRI (0.5 mg/kg IV loading dose then 10 µg/kg/min IV)

Fluid needs	• 5–10 mL/kg/h plus 3 × EBL • Two large IV catheters if potential for large EBL • Have blood or colloids available
Monitoring	• Blood pressure • HR • Respiratory rate • SpO_2 • Temperature

Blocks	• If oral surgery, 0.25–1.0 mL local anesthetic for infraorbital, maxillary, mandibular, or mental blocks[e]
	• If epidural for rectal surgery, then:
	  • Morphine (0.1 mg/kg preservative free), *or*
	  • Buprenorphine (0.003–0.005 mg/kg diluted in saline)

Postoperative Considerations

Analgesia	• Fentanyl CRI (1–10 µg/kg IV loading dose, then 2–20 µg/kg/h IV), *or* • Hydromorphone CRI (0.025–0.1 mg/kg/h IV in dogs), *or* • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM q3–4h in dogs 0.05–0.1 mg/kg IV, IM q3–4h in cats), *or* • Morphine[b] (0.1–1 mg/kg IV or 0.1–2 mg/kg IM q1–4h in dogs; 0.05–0.2 mg/kg IV or 0.1–0.5 mg/kg IM q1–4h in cats), *or* • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or* • Buprenorphine[c] (5–20 µg/kg IV, IM, SC q4–8h), *plus* • ± Ketamine CRI (2 µg/kg/min IV; if no previous loading dose, give 0.5 mg/kg IV prior to CRI), *plus* In dogs: • Carprofen (2.2 mg/kg q12h PO), *or* • Deracoxib (3–4 mg/kg q24h for <7 days PO), *or* • Meloxicam (0.1–0.2 mg/kg once SC, PO, then 0.1 mg/kg PO q24h) In cats: • Meloxicam[f] (0.15 mg/kg SC once; approved for doses up to 0.3 mg/kg SC; see also Table 34.3), *or* • Buprenorphine[c] (0.01–0.02 mg/kg OTM q6–12h)

TABLE 18.1 Anesthetic Considerations in the Healthy Patient Undergoing Oral or Rectal Surgery—cont'd

Monitoring	• SpO_2 • Blood pressure • HR • Respiratory rate • Temperature
Bloodwork	• HCT and TP if large blood loss
Estimated pain score	• Depends on procedure

[a]Monitor for hyperthermia in cats.
[b]Give slowly to prevent histamine release.
[c]Buprenorphine is a better analgesic than morphine in cats.
[d]Use only in young, healthy animals.
[e]Do not exceed maximum local anesthetic dose for very small dogs and cats.
[f]Black box warning added by the Food and Drug Administration in October 2010 identified cases of renal failure and death in cats with repeated uses of meloxicam. Meloxicam is approved for single use only in cats in the United States.
BUN, Blood urea nitrogen; *Cr,* creatinine; *CRI,* constant-rate infusion; *EBL,* estimated blood loss; *HCT,* hematocrit; *HR,* heart rate; *IM,* intramuscular; *IV,* intravenous; *OTM,* oral transmucosal; *PO,* orally; *PRN,* as needed; *SC,* subcutaneous; *SpO_2,* hemoglobin saturation with oxygen; *TP,* total protein.

BOX 18.1 Prophylactic and Therapeutic Antibiotics for Oral Surgery

Cefazolin (Ancef, Kefzol)
22 mg/kg IV q8–12h

Amoxicillin (Amoxi-Tabs, Amoxi-Drops, Amoxi-Inject)
22 mg/kg PO, IM or SC q8–12h

Clindamycin (Antirobe)
11–33 mg/kg PO q8–12h or 11 mg/kg IV q8–12h; when giving IV dilute and administer slowly

Metronidazole (Flagyl)
10–15 mg/kg PO q12h

IM, Intramuscular; *IV,* intravenous; *PO,* orally; *SC,* subcutaneous.

and blood supply to this region is excellent. For these reasons, infections after oral surgery are rare. One dose of a prophylactic antibiotic effective against gram-positive aerobes and anaerobes (e.g., ampicillin, clindamycin) may be given at anesthetic induction (Box 18.1). Therapeutic antibiotics (e.g., cefazolin plus metronidazole, amoxicillin plus clavulanic acid, or clindamycin; see Box 18.1) are indicated in debilitated or immunosuppressed patients and those with severe periodontal disease.

SURGICAL ANATOMY

The oral cavity is divided into the vestibule and the oral cavity proper. The vestibule is the cavity lying outside the teeth and gums but inside the lips and cheeks. The ducts of the parotid and zygomatic salivary glands open in the dorsocaudal part of the vestibule. The oral cavity proper is the area bounded by the hard palate and a small part of the soft palate dorsally, by the dental arches laterally and rostrally, and by the tongue and adjacent mucosa ventrally. The tongue is attached to the floor of the oral cavity by the lingual frenulum. The oropharynx extends from the level of the palatoglossal arches to the caudal border of the soft palate and the base of the epiglottis. The oropharynx is bounded dorsally by the soft palate and ventrally by the root of the tongue. The palatine tonsils are found in the lateral wall of the oropharynx.

The blood supply to this region originates from branches of the common carotid arteries. The paired major and minor palatine arteries are important (Fig. 18.1). Two or three vessels emerge from the major palatine foramen at the caudal edge of the fourth upper premolar and course rostrally, midway between the midline and the dental arcade. The right and left major palatine arteries anastomose caudal to the incisors. The minor palatine arteries enter the palate caudal to the last molar and lateral to the major palatine artery, then course caudomedially to ramify in the caudal hard palate and soft palate. The major blood supply to the mandible is via the mandibular alveolar artery, which enters the mandibular canal on the medial surface of the mandible (see Fig. 18.1). The entry point is where an oblique line connecting the last molar tooth and the angular (muscular) process (which is hidden beneath the pterygoid muscle) meet. The mandibular alveolar artery ends at the middle mental foramen, where it branches to form the caudal, middle, and rostral mental arteries and exits via the mental foramina. The mandibular canal also transmits the mandibular vein and the mandibular alveolar nerve.

NOTE Infection is rare and healing is rapid after surgery of the oral cavity because of its excellent blood supply.

SURGICAL TECHNIQUES

Atraumatic surgical technique is important for reducing tissue damage and swelling and encouraging rapid healing (Box 18.2). Hemorrhage is expected and should be controlled with pressure and vessel ligation. Electrosurgery should be used sparingly because excessive use delays healing and may cause dehiscence. Electrocoagulation should be applied only to discrete, isolated areas. The possibility exists that flammable gases (i.e., oxygen) leaking around the endotracheal tube could be ignited when electrosurgery or laser surgery is used.

Tension-free closure is imperative to prevent wound dehiscence and a subsequent oronasal fistula. Flaps created during reconstructive procedures should be approximately 2 to 4 mm larger than the defect, and major vessels entering these flaps must be preserved. Tension on these flaps should be minimized by adequate mobilization. Flaps should be manipulated with skin hooks or stay sutures to minimize trauma. Suture lines should be placed over connective tissue or bone, rather than the defect, to help support mucosal flaps. Cleanly incised edges of tissue should be apposed with a two-layer closure in an appositional suture pattern (simple interrupted, simple continuous, cruciate, or vertical

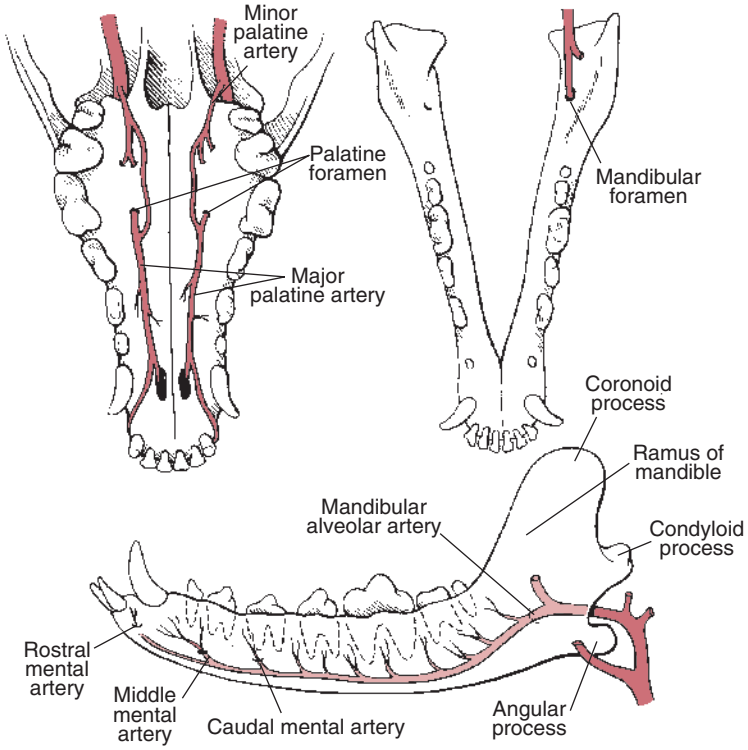

FIG. 18.1 The major blood supply to the maxilla is via the major and minor palatine arteries and to the mandible via the mandibular alveolar artery.

BOX 18.2 Principles of Oral Surgery

- Use atraumatic technique.
- Control hemorrhage using pressure and ligation.
- Avoid tension; make flaps 2–4 mm larger than the defect.
- Support flaps; do not suture over defects.
- Use appositional sutures (e.g., simple interrupted, simple continuous, cruciate, vertical mattress patterns).

mattress patterns). Monofilament suture material (i.e., 4-0 or 3-0 poliglecaprone 25, polyglyconate, polydioxanone, or polypropylene) minimizes wicking and tissue reaction. A temporary acrylic obturator can be cemented or wired to the teeth to protect healing tissues in the occasional case in which tongue or pharyngeal muscle activity is apt to break down the suture line.

Biopsy Techniques

Impression smears or aspirates should be obtained from oral lesions before incisional or excisional biopsy. Cytologic studies may allow a tentative diagnosis that will help in planning further diagnostics; however, it must be realized that most oral lesions have inflamed surfaces secondary to oral bacterial flora. Therefore one should routinely obtain deep samples, especially if inflamed, necrotic tissue is present. An incisional biopsy using a core needle or wedge biopsy technique should be performed if the definitive diagnosis will change the course of therapy. A Tru-Cut or Vim-Silverman needle can be used to obtain small cores from several areas of the mass, whereas wedge biopsies should be performed from nonnecrotic areas of the mass when larger pieces of tissue are needed. A loop or needle electrode of an electrosurgical unit is useful in obtaining oral biopsies. However, the specimen will be nondiagnostic if too much current is applied, especially to a small sample. Tissue coagulation can be prevented by keeping the power setting on the electrosurgical unit as low as possible. Diseased tissue is often friable and difficult to appose with sutures after a biopsy; however, pressure over the cut area is usually sufficient to control hemorrhage. Silver nitrate cautery can be used if necessary. Wide excision (e.g., partial maxillectomy, mandibulectomy, tonsillectomy, glossectomy, or lip resection) should be performed and the area reconstructed if the definitive histologic diagnosis will not alter the course of therapy. All specimens should be submitted for histologic evaluation.

NOTE Avoid areas of superficial necrosis when obtaining biopsies; sample deeper, viable tissues instead.

Temporary Carotid Artery Ligation

Some surgeons perform temporary carotid artery occlusion before maxillectomy to minimize blood loss.

To do so, place the animal in dorsal recumbency and prepare the ventral cervical area for surgery. Expose the trachea through a 5- to 8-cm ventral cervical midline incision. Palpate the carotid pulse and exteriorize the carotid sheath. Separate the common carotid artery from the vagosympathetic trunk and internal jugular vein. Temporarily occlude the carotid artery with a vascular clamp or tie. Repeat the procedure on the opposite carotid artery. Temporarily appose skin with a continuous suture pattern or staples during the maxillectomy procedure. After the maxillectomy, reopen the cervical wound and remove the vascular clamps or ties. Lavage the area thoroughly and appose the sternohyoid muscles, subcutaneous tissue, and skin in separate layers.

NOTE Temporary carotid artery ligation may not be safe in cats or in severely anemic dogs. Perform with caution!

Partial Maxillectomy

Maxillectomy is most often performed to resect an oral neoplasm (Fig. 18.2). Varying amounts of the maxilla and hard palate may be excised, depending on the gross and radiographic, CT, or MRI extent of the lesion. Depending on the area being resected, partial maxillectomies may be classified as hemimaxillectomies (rostral, central, or caudal) or premaxillectomies (bilateral rostral) (Figs. 18.3 and 18.4). Hemimaxillectomy, without a definition of site, usually refers to removal of one entire maxilla. Partial maxillectomies can be combined with nasal planectomy and dorsolateral approaches through the skin. Partial maxillectomy is limited by the surgeon's ability to reconstruct the oronasal defect; lesions that cross the midline of the palate are difficult to reconstruct.

FIG. 18.2 An odontogenic tumor involving the maxillary dental arcade, palate, and maxilla.

Clip and aseptically prepare the maxillary and nasal skin. Flush the mouth with antiseptic solution. Place the patient in dorsal recumbency for lesions of the premaxilla and open the mouth to its maximum extent by placing a mouth speculum or by taping the mouth open. Place the patient in lateral or dorsal recumbency for lesions caudal to the premaxilla. Determine the extent of resection based on the size of the soft tissue lesion and the radiographic, CT, or MRI degree of bony involvement. Generally, excise the mass and a minimum of 1 to 2 cm of normal soft tissue and bone on all borders. Remove the mass en bloc by first making mucosal incisions (buccal, gingival, and hard palate) around the tissue to be resected. Avoid rectangular excision because the corners are susceptible to dehiscence. Using a periosteal elevator, undermine and reflect the gingival and palatal mucosa.

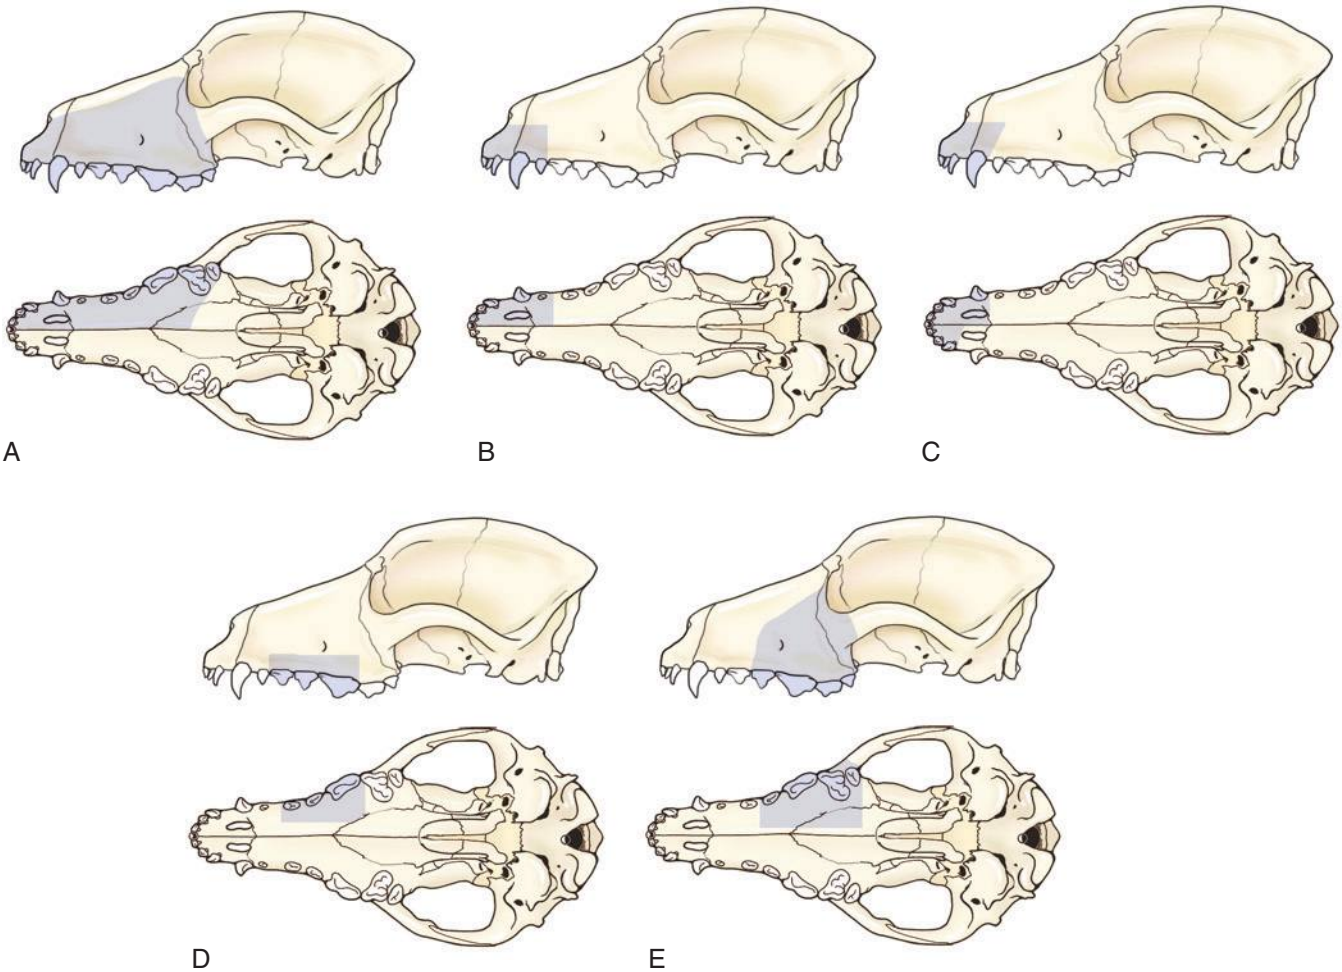

FIG. 18.3 Areas resected with partial maxillectomy techniques. (A) Hemimaxillectomy. (B) Rostral hemimaxillectomy. (C) Premaxillectomy (bilateral rostral hemimaxillectomy). (D) Central hemimaxillectomy. (E) Caudal hemimaxillectomy.

FIG. 18.4 Appearance of the oral cavity of a dog after a rostral hemimaxillectomy. A buccal flap has been advanced across the defect and secured with apposition sutures.

FIG. 18.6 A buccal mucosal flap was advanced over the defect evident in Fig. 18.5 and secured with approximating sutures.

FIG. 18.5 A central hemimaxillectomy was performed to remove the lesion shown in Fig. 18.2 and an additional 1 to 2 cm of normal tissue. Note that the nasal cavity is exposed.

FIG. 18.7 Postoperative appearance after rostral mandibulectomy. Note that the tongue is barely apparent despite the short mandible.

Use an oscillating saw or an osteotome and mallet to cut the maxilla, incisive bone, and/or palate. Resect all premolar and molar teeth for lesions extending to the third premolar because of the outward turn of the dental arch. When performing a caudal maxillectomy, remove a portion of the zygomatic arch and orbit if necessary to obtain clean borders. Elevate the tissue block and sever any remaining soft tissue attachments to complete the resection and expose the nasal cavity (Fig. 18.5). Remove involved nasal turbinates with rongeurs and hemostats if disease extends into the nasal cavity. Control hemorrhage by ligating identifiable vessels and applying pressure to other areas. Isolate and ligate the major palatine and infraorbital artery and vein if they are included in the resection site. Use bone wax or electrofulguration to help control bone hemorrhage. Lavage and inspect the defect to ensure that all grossly diseased tissue has been excised. Close the defect by elevating a buccal mucosal flap from the adjacent cheek or lip (Fig. 18.6). Elevate enough buccal mucosa and submucosa to allow a tension-free approximation with the gingival and palatal mucosa. Place the first layer of simple interrupted sutures in the submucosa, with the knot directed toward the nasal cavity. Place a second layer of interrupted approximating sutures (i.e., simple, cruciate, vertical mattress) to accurately appose buccal mucosa to the palatal and gingival mucosa. A double-flap technique may be used to close premaxillectomy defects to provide mucosa on both the nasal and oral surfaces. However, an epithelial surface on the nasal aspect of the flap is not necessary because the connective tissue surface of the flap is covered with respiratory epithelium within 1 to 2 weeks. *If carotid artery occlusion was performed, release the occlusion after the defect has been closed.*

Partial Mandibulectomy

Mandibulectomy is most often performed to resect an oral neoplasm. Occasionally mandibular fractures are also treated by partial mandibulectomy. Varying amounts of mandible may be excised, depending on the extent of the tumor or lesion (Fig. 18.7). Depending on the extent of resection, hemimandibulectomies may be classified as rostral, rostral-bilateral, central, caudal, or total (Fig. 18.8). These techniques may be combined when more extensive resection is necessary. After mandibulectomy, cheiloplasty (commissuroplasty) may be performed to minimize excessive drooling and lateral protrusion of the tongue (Fig. 18.9). It is accomplished by removing the mucocutaneous junction of the upper and lower lip to the level of the second premolar or canine tooth. The commissure is advanced rostrally during closure. The upper and lower lip

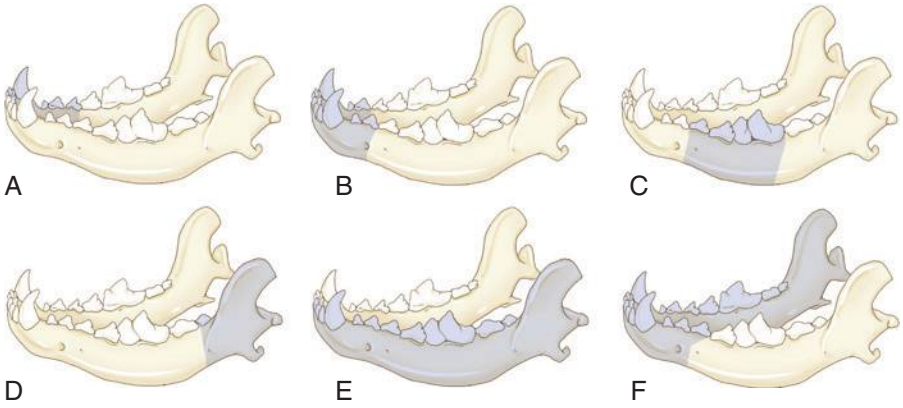

FIG. 18.8 Areas resected with partial mandibulectomy techniques. (A) Rostral hemimandibulectomy (unilateral rostral hemimandibulectomy). (B) Rostral mandibulectomy (bilateral rostral hemimandibulectomy). (C) Central hemimandibulectomy. (D) Caudal hemimandibulectomy. (E) Total hemimandibulectomy. (F) Three-quarter mandibulectomy.

FIG. 18.9 Postoperative appearance after hemimandibulectomy in which cheiloplasty was not performed. Although the tongue is movable, it protrudes from the oral cavity.

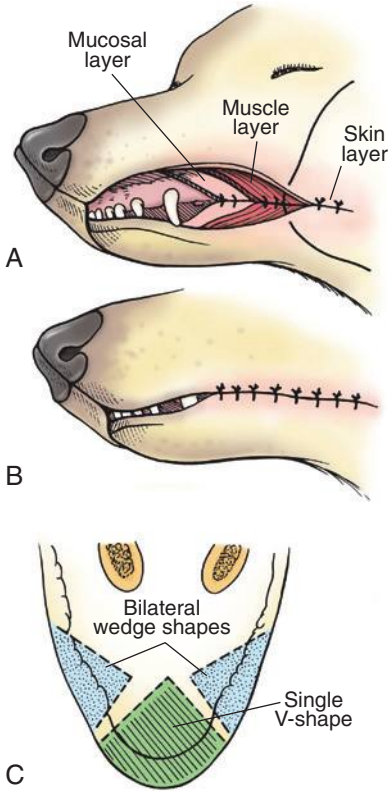

FIG. 18.10 Cheiloplasty. (A) Excise the lip margins to the level of the second premolar. (A–B) Appose the incised lip margins in three layers (oral mucosa, muscle and connective tissue, and skin). (C) To improve cosmesis after rostral mandibulectomy, excise redundant skin from one or more of the indicated sites.

margins are apposed in three layers (oral mucosa, muscle and connective tissue, and skin) (Fig. 18.10). Opening the mouth fully during the first 2 weeks may cause dehiscence. Tension-relieving button sutures or a loose tape muzzle may be used to help prevent this. During rostral mandibulectomies, redundant skin and mucosa may be eliminated by excising and apposing V-shaped wedges. The base of the V is along the mucocutaneous junction (see Fig. 18.10).

Position the patient in lateral, sternal, or dorsal recumbency with the neck extended (Figs. 18.11A and 18.12A). Clip and aseptically prepare the skin of the lateral face and ventral mandible. Flush the mouth with antiseptic solution. Determine the amount to be resected based on the size of the soft tissue lesion and the radiographic, CT, or MRI evidence of bony involvement. Generally, excise the mass and a minimum of 1 to 2 cm of normal soft tissue and bone on all borders. Retract the commissure and lip to give maximum exposure. If necessary, improve visualization by incising the commissure to the level of the mandibular angle (see Fig. 18.12B). Begin en bloc resection by first incising mucosa (buccal, gingival, and sublingual) around the diseased area (see Figs. 18.11B and 18.12B). Using a periosteal elevator, undermine and reflect the gingival mucosa to expose the lateral and ventral aspects of the mandible. Transect or elevate and retract muscles (mentalis, orbicularis oris, buccinator, mylohyoideus, geniohyoideus, genioglossus, masseter, digastricus, temporalis, and pterygoideus) attached to the portion of the mandible being resected (see Figs. 18.11B and 18.12C–D). Use an oscillating saw or an osteotome and mallet to

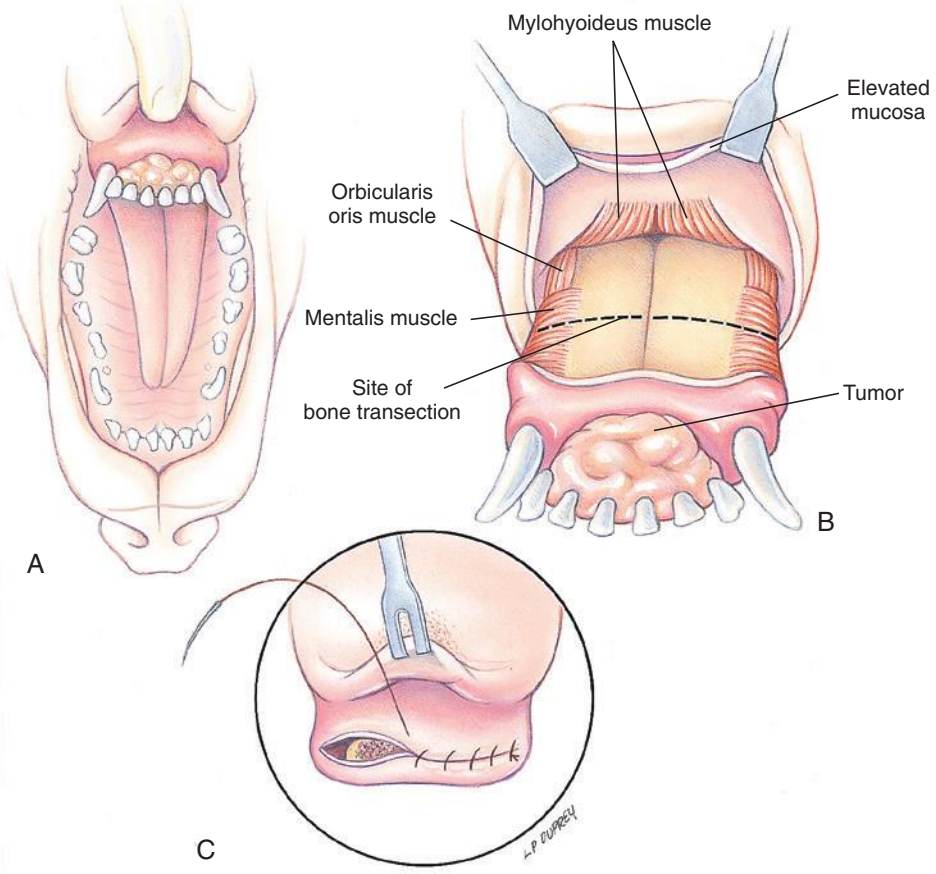

FIG. 18.11 Rostral mandibulectomy. (A) Position the patient in dorsal recumbency. (B) Incise the mucosa 1–2 cm from the lesion, exposing the underlying muscles. Elevate the muscles and transect the bone *(dashed line)*. (C) Appose the labial and sublingual mucosa after en bloc excision.

transect the mandible and separate the symphysis. As an alternative, use a Gigli wire to transect the mandible. Complete a total hemimandibulectomy by incising the joint capsule and disarticulating the temporomandibular joint (see Fig. 18.12C). Locate the temporomandibular joint by rotating the mandible and palpating the articulation. Ligate or cauterize the mandibular artery (see Fig. 18.12D). Sever any remaining soft tissue attachments to complete the resection. Avoid traumatizing the lingual frenulum or sublingual and mandibular salivary ducts. Contour the ostectomy sites with bone rongeurs, removing sharp bone and tapering the edges to facilitate closure. Close the defect by elevating a mucosal flap from the adjacent lip or cheek (see Figs. 18.11C and 18.12E). Elevate enough mucosa and submucosa to allow a tension-free approximation with the gingival and sublingual mucosa. Place the first layer of simple interrupted sutures in the submucosa with the knots buried. Place a second layer of interrupted approximating sutures (simple, cruciate, or vertical mattress) to accurately appose the labial, sublingual, and gingival mucosa. As an alternative, use a single-layer, simple continuous or interrupted suture pattern.

NOTE It is not necessary to stabilize the remaining mandible after mandibulectomy. However, cortical bone grafts have been used to improve the animal's appearance.

Mandibular Rim Excision

Mandibular rim excision may be considered for small, minimally invasive tumors of the mandible in large dogs in which the tooth roots do not approach the mandibular canal. Advanced imaging is strongly recommended to help ensure complete excision of mass lesions using this technique. *Incise the mucoperiosteum in a curvilinear pattern, 1 cm around the mass and associated teeth. Elevate the attached gingiva and excise the mandibular segment with a handpiece that irrigates but does not insufflate. Be certain that no tooth roots remain. Smooth the osteotomy site and reattach the mucosa over the bony defect with monofilament absorbable suture.*

Tonsillectomy

When neoplasia of the palatine tonsils is suspected, they should be biopsied or removed. Squamous cell carcinoma (SCC) and lymphosarcoma are the most common tumors of the tonsils, and neither are generally cured. Enlarged tonsils are occasionally removed if they contribute to airway obstruction or dysphagia and in cases of unresponsive chronic tonsillitis. However, tonsillitis is usually secondary to other diseases (e.g., esophageal dysfunction), and removing the tonsils rarely effects a cure.

Administer dexamethasone (0.1–0.2 mg/kg IV [intravenous]) at the time of induction to minimize postoperative swelling and

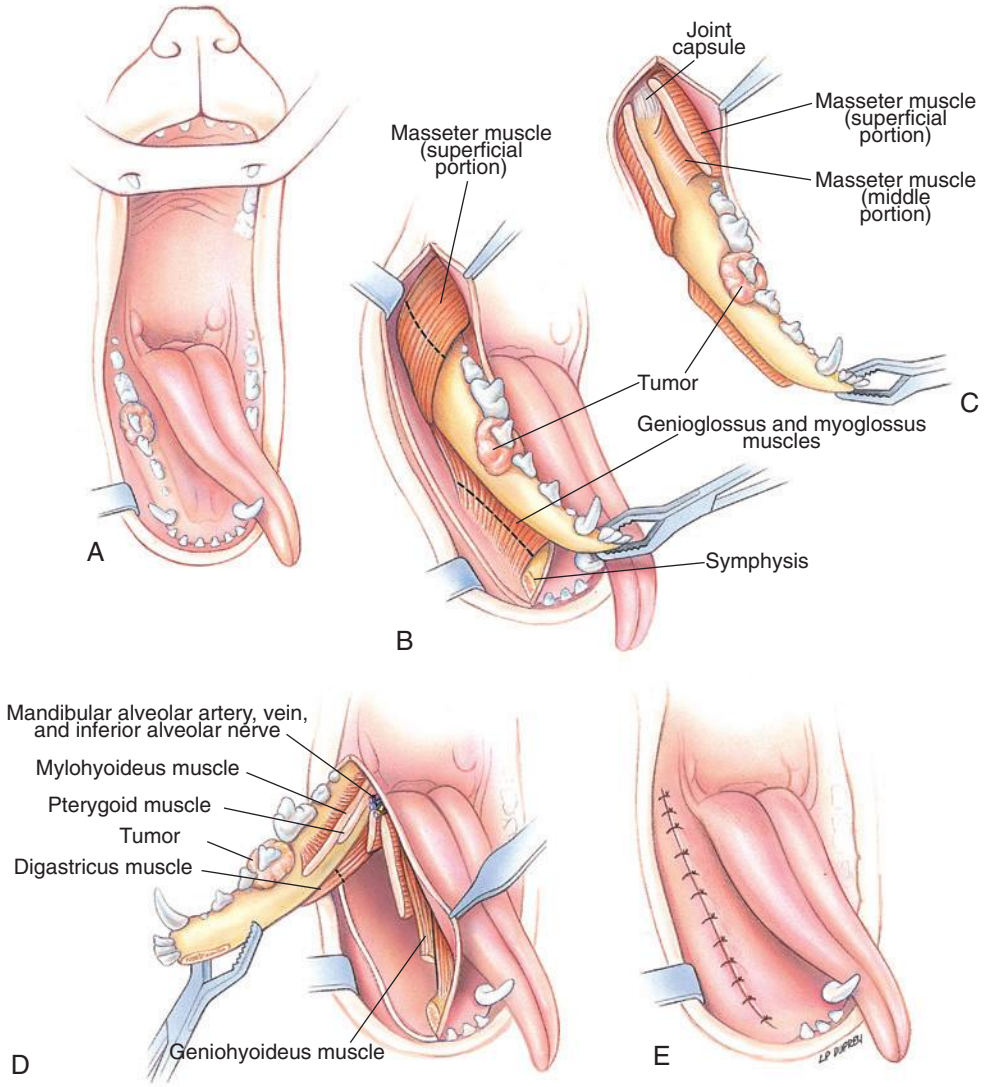

FIG. 18.12 Total hemimandibulectomy. (A) Position the patient in ventral recumbency. (B) Incise the mucosa 1 to 2 cm from the lesion. Incise the commissure to allow better exposure of the caudal mandible. Separate the mandibular symphysis and identify and transect *(dashed line)* the muscles. (C) Dissect and transect the lateral mandibular muscles and expose the temporomandibular joint. (D) Dissect and transect the medial muscles of the mandible and identify the mandibular artery entering the mandibular foramen. Ligate the mandibular vessels, disarticulate, and remove the mandible. (E) Appose the buccal and sublingual mucosa with approximating sutures.

edema. Position the animal in ventral recumbency with the maxilla suspended from an IV stand or similar device. Open the mouth maximally and secure it open with tape or gauze. Locate the tonsil in the tonsillar fossa or crypt on the dorsolateral wall of the oropharynx just caudal to the palatoglossal arch (Fig. 18.13). Retract the edge of the tonsillar crypt caudodorsally to expose the tonsil. Grasp the tonsil at its base with an Allis tissue forceps or hemostat and retract it from the crypt. Transect the hilar mucosa at the base of the tonsil with Metzenbaum scissors or a tonsillectomy snare. Ligate the tonsillar artery as it enters the caudal aspect of the tonsil. Some surgeons excise the tonsil using electrosurgery or laser surgery. *Appose the edges of the tonsillar crypt with a simple continuous suture pattern of 3-0 or 4-0 monofilament absorbable suture to minimize hemorrhage.*

Glossectomy

The primary reason for partial tongue amputation is neoplasia, which usually occurs on the margin or base of the tongue. The most common lingual tumor is SCC (Fig. 18.14), but others include malignant melanoma, granular cell myeloblastoma, and mast cell tumor. Most lingual lacerations are amenable to repair with a one- or two-layer closure rather than amputation. Other reasons for tongue surgery include abscess drainage, glossitis, severe trauma, and congenital ankyloglossia (limited tongue movement). Tongue lesions are associated with signs of drooling, malodor, dysphagia, and sometimes dyspnea.

Glossectomies are classified as partial (involving only the free tongue), subtotal (entire free tongue and part of the genioglossus and geniohyoideus muscles), near total (greater than 75% of

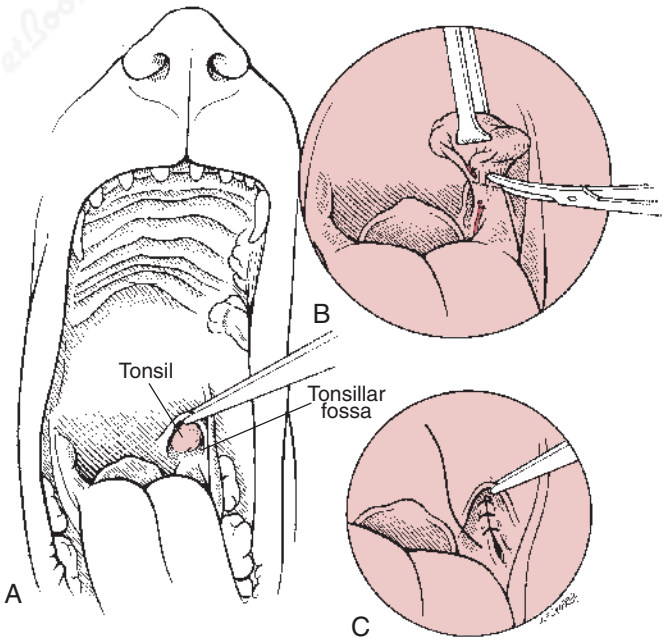

FIG. 18.13 Tonsillectomy. (A) The palatine tonsils are located in the dorsolateral pharynx. (B) During tonsillectomy evert the tonsil from the crypt, ligate the tonsillar vessels, and begin transection along the base. (C) Close the crypt with a simple continuous pattern to help control hemorrhage.

FIG. 18.14 Appearance of a squamous cell carcinoma of the tongue in a dog.

tongue), and total (100% of tongue). Glossectomy is considered major if more than the free portion of the tongue is removed. Amputation of 40% to 60% of the rostral tongue is usually well tolerated. Amputation at the base of the tongue or total glossectomy makes eating and drinking difficult; however, the animal can learn to suck in food and water, or chunks of food can be tossed to the base of the tongue. Ptyalism following major glossectomy occasionally occurs; improvement may be seen with bilateral sialoadenectomy. When total glossectomy is performed, a clamp is not used. *Wedge the incision so that slightly more tongue muscle than dorsal or ventral mucosa is excised. Control hemorrhage by ligation, pressure, or electrosurgery. Use through-and-through horizontal mattress sutures as needed to control hemorrhage.*

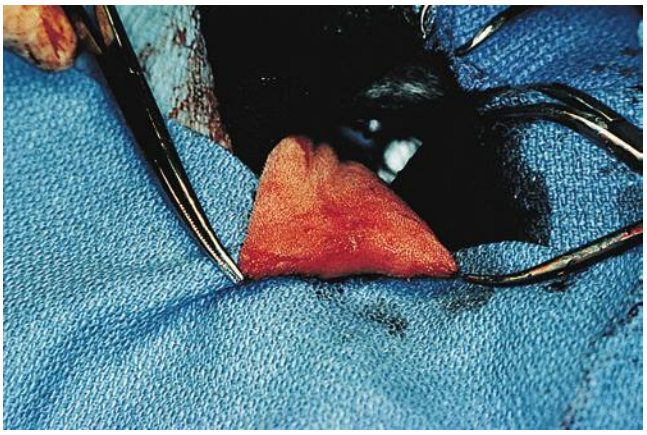

FIG. 18.15 Postoperative appearance of the tongue in Fig. 18.14 after partial glossectomy. The glossectomy was completed by apposing epithelial edges with a simple continuous suture pattern.

Appose the epithelial edges with a simple continuous suture pattern using 3-0 or 4-0 monofilament absorbable suture (Fig. 18.15). Place a feeding tube when major glossectomies are performed (see pp. 94–102).

NOTE Dogs seem to adapt better than cats to tongue amputation. A feeding tube may be required until the animal learns to eat after the procedure.

Pharyngotomy

Pharyngotomy may be performed to allow endotracheal intubation if the tube is in the surgeon's way when placed via the oral cavity. For a description of the technique, please see p. 1044.

Salivary Gland Excision

The salivary glands are most often removed to treat salivary mucoceles or neoplasia, and the mandibular and sublingual salivary glands are most often removed to treat cervical, sublingual, and pharyngeal salivary mucoceles. Neoplasms (usually adenocarcinomas or carcinomas) occur most frequently in the parotid (~50% dogs, ~20% cats) and the mandibular (~30% dogs, ~60% cats) salivary glands. Salivary gland excision is described on pp. 361 to 363.

HEALING OF THE ORAL CAVITY AND OROPHARYNX

The oral cavity and oropharyngeal mucosa heal more rapidly than skin because phagocytic activity (primarily monocytes rather than polymorphonuclear leukocytes) and epithelialization are more extensive and occur earlier in mucosa. An excellent mucosal blood supply, warmer temperatures, higher metabolic activity, and a higher mitotic rate contribute to rapid healing of mucosa. Apposed wounds reepithelialize within a few days, and defects heal by second intention.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Special instruments that may facilitate surgical procedures of the oral cavity include periosteal elevators, an oscillating saw or osteotome and mallet, Gigli wire, rongeurs or bone cutters,

vascular bulldog clamps, vascular ties, tissue hooks, Metzenbaum scissors, noncrushing clamps (Doyen intestinal forceps), and Penrose drains. Piezoelectric bone surgery has been reported for maxillectomy and mandibulectomy, as well as dental surgery.[1] Proposed advantages include decreased soft tissue trauma and blood loss, improved precision of osteotomies, and decreased thermal bone damage, edema, and inflammation. Disadvantages include the cost of the equipment, learning curve, and slower osteotomy speed. Although many suture materials may be used in the oral cavity and oropharynx, 3-0 or 4-0 polydioxanone, polyglyconate, or poliglecaprone 25 (monofilament absorbable) and 3-0 or 4-0 polypropylene or nylon (monofilament nonabsorbable) are often suggested; however, many surgeons utilize polyglactin 910 (multifilament absorbable) because of its softness and presumed decreased postoperative irritation.

POSTOPERATIVE CARE AND ASSESSMENT

After oral surgery, gauze sponges should be removed from the caudal pharynx and the nasopharynx should be suctioned. Extubation should be delayed until a well-developed swallowing reflex is present. Patients should be recovered in a slightly head-down position, and the tube should be removed with the cuff slightly inflated to help ensure blood clots are expelled through the mouth rather than being aspirated or swallowed. These patients should be monitored for airway obstruction or pain, and analgesics should be provided as needed (for dosages of opioid analgesics, see Tables 12.1 and 13.2; for dosages of nonsteroidal antiinflammatory drugs [NSAIDs], see Table 13.2). Elizabethan collars or similar restraining devices should be used on some animals to prevent disruption of the surgical site. Occasionally an acrylic oral splint is used to protect the surgical site.

NOTE Be sure to suction the oral cavity and oropharynx before extubation, extubate with the cuff inflated, and monitor for airway obstruction during recovery.

Oral intake should not be allowed for the first 8 to 12 hours after surgery (except in pediatric patients at risk for hypoglycemia); hydration should be maintained with IV fluids. Water should be offered after 12 hours and the animal observed for signs of dysphagia, pain, or regurgitation. If no serious problems are identified, soft food may be offered between 12 and 24 hours after surgery. Gruel is unnecessary and may seep between sutures, inhibiting healing. Hand feeding (tossing meatballs) and watering may be necessary for 1 to 2 weeks following major glossectomy, until the animal is trained to suck water and prehend food without a tongue. Feeding through a gastrostomy or esophagostomy tube is occasionally necessary for animals with severe wounds or those unwilling to eat within 3 days of surgery (see Chapter 10). Soft food should be fed and the animal prevented from chewing on sticks, toys, or other hard items until the wound has healed. Healing should be evaluated at 3 to 5 days, 2 weeks, and 4 weeks after surgery. Additional reconstruction may be necessary if areas of partial dehiscence do not heal by second intention or if an oronasal fistula remains after 4 to 6 weeks. Animals with neoplasia should be evaluated every 3 to 6 months for tumor recurrence.

Epistaxis, serous to mucoid nasal discharge, and pain are expected after maxillectomy. Crusting of the nares and epiphora may occur when the nasolacrimal duct is transected. Subcutaneous emphysema occasionally occurs when a large portion of the nasal cavity is exposed. Emphysema, crusting, and nasal discharge are short-term sequelae that usually resolve in days to weeks. Cosmesis is usually good, with a slight facial concavity and lip elevation after lateral maxillectomy. Removal of a canine tooth causes more noticeable concavity. Premaxillectomies involving all incisors and one or both canine teeth produce ventral drooping of the nose and displacement of the maxillary lip caudal to the mandibular canine teeth unless further reconstruction (e.g., cantilever technique) is performed. Extensive premaxillectomies (caudal to the first premolar) shorten the nose and may cause an obvious prognathic appearance (protrusion of the lower jaw).

NOTE Dogs do better after hemimandibulectomies than do cats. Warn owners that some cats refuse to eat after this procedure and may require a feeding tube.

Cosmesis and function after partial mandibulectomy are good (see Fig. 18.7). Mandibular "drift" and instability occur more often when the osteotomy is caudal to the second premolar. The remaining hemimandible may deviate medially, producing malocclusion, clicking of the teeth, and/or trauma to the palatal or gingival mucosa. Most animals adapt and serious problems seldom occur. The involved canine tooth may be pulled or shortened if erosion or ulceration develops. Alternatively, use of orthodontic elastic chain attached to the ipsilateral canine and maxillary fourth premolar has been shown to decrease mandibular drift in a small number of patients. Significant client compliance is required in changing the chain weekly for 4 to 6 weeks, but indefinite use has been considered for prevention of mandibular drift. Rostral mandibulectomy (bilateral) caudal to the third or fourth premolar may cause difficulty with prehension and is less cosmetic. Aggressive rostral mandibulectomy may be combined with reconstruction using a plate and matrix combination; however, advanced imaging and 3D printing of the skull are required and dehiscence may require reoperation.[2] Tongue protrusion may occur, but most patients are able to keep the tongue retracted. Cheiloplasty may decrease drooling and lateral tongue protrusion in animals after partial mandibulectomies or maxillectomies.

COMPLICATIONS

Minor swelling of the skin and mucous membranes should be expected after partial maxillectomy or mandibulectomy but should resolve within 2 to 3 days. Infection is possible because the oral cavity is contaminated. However, infection is rare if the blood supply is maintained and good surgical technique is used. Partial dehiscence may occur 3 to 5 days after surgery if tissue is severely traumatized, blood supply is inadequate, or excessive motion or tension affects any area of the repair. Sometimes appearances that are unacceptable to owners may be modified with further cosmetic reconstruction following maxillectomy or mandibulectomy. Zygomatic mucocele has been reported after caudal hemimaxillectomy. The most common postoperative complication after tonsillectomy is hemorrhage. Regrowth of tonsillar tissue may occur if excision is incomplete. Apparent hyperptyalism following major glossectomy occasionally occurs;

improvement may be seen with bilateral sialoadenectomy. Tumor recurrence or metastasis is always possible after any oncologic surgery.

SPECIAL AGE CONSIDERATIONS

Pediatric patients with congenital cleft palate should be fed with a tube until they are 8 to 12 weeks old and may be more safely anesthetized. Refer to the anesthesia section in Chapter 26 (see p. 722) for discussion of special concerns with pediatric patients. Pediatric patients are at higher risk of hypothermia and hypoglycemia; therefore they should not be fasted for more than 4 to 8 hours. Neoplasia is more common in geriatric patients; they should be thoroughly evaluated before surgery for concurrent disease and metastasis.

SPECIFIC DISEASES

CONGENITAL ORONASAL FISTULA (CLEFT PALATE)

DEFINITIONS

A **congenital oronasal fistula** is an abnormal communication between the oral and nasal cavities, involving the soft palate, hard palate, premaxilla, and/or lip. The **primary palate** consists of the lip and premaxilla. Incomplete closure of the primary palate is a **primary cleft** or **cleft lip** (harelip). The **secondary palate** consists of the hard and soft palates. Incomplete closure of either of these structures is a **secondary cleft** or **cleft palate.** Animals may also have unilateral or bilateral failure of the soft palate to fuse with the nasopharyngeal wall; this is termed a **lateral cleft of the soft palate** or **hypoplastic soft palate**.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Congenital palatal defects result when the two palatine shelves fail to fuse during fetal development (Fig. 18.16). The most critical time for development and closure of the fetal palate appears to be 25 to 28 days of gestation in dogs. Incomplete closure of either the primary or secondary palate is attributed to inherited (recessive or irregular dominant, polygenic traits), nutritional (inadequate folic acid), hormonal (steroids), mechanical (in utero trauma), and toxic (including viral) factors. Primary cleft palate alone is rare (Fig. 18.17); however, secondary cleft palate may occur alone or in combination with primary clefts. Some affected neonates are unable to nurse effectively and die soon after birth. Others contaminate their nasal cavity with saliva and food. Signs of rhinitis and other respiratory infections are common. Middle ear disease that is often clinically unrecognized is sometimes associated with congenital clefts.

DIAGNOSIS

Clinical Presentation

Signalment

Dogs, particularly brachycephalic breeds, are more commonly affected with cleft palate than cats. Purebred dogs have a higher incidence than mixed breeds. Breeds at high risk for cleft palate include Boston terriers, Pekingese, bulldogs, miniature schnauzers, beagles, cocker spaniels, and dachshunds. Siamese cats have a higher incidence than other cat breeds. Females are more commonly affected than males. The cleft is present at birth, although it is not always recognized immediately.

History

A history of difficulty nursing, nasal regurgitation, nasal discharge, and failure to thrive are common problems. Signs related to incomplete separation of the oral and nasal cavity include drainage of milk from the nares during or after nursing; gagging, coughing, or sneezing (or all three) while eating; poor growth; and respiratory infection (i.e., rhinitis, aspiration pneumonia).

Physical Examination Findings

All puppies and kittens should be checked on initial presentation for evidence of a cleft palate. Diagnosis of congenital oronasal fistula is made by visual examination. Incomplete closure of the lip is easily recognized when the patient is first examined; however, a thorough oral examination is required to identify incomplete closure of the premaxilla, hard palate, or soft palate. Anesthesia may be necessary to thoroughly assess the soft palate. A secondary cleft may occur without a primary cleft. Patients may be thin and stunted. Abnormal respiratory sounds are auscultated if aspiration pneumonia is present.

FIG. 18.16 A puppy with a cleft extending through the primary and secondary palate.

FIG. 18.17 Primary cleft palate in a young shih tzu involving the lip, premaxilla, and nostril.

NOTE Be sure to thoroughly evaluate affected neonates for concurrent congenital anomalies.

Diagnostic Imaging

Radiographic examination of the skull is not necessary; however, thoracic radiographs are useful in evaluating for aspiration pneumonia, typically characterized by interstitial to alveolar infiltrates within the ventral aspect of the lungs. It should be noted that middle ear disease can be seen in association with defects in the palate; thus imaging of the tympanic bullae may be indicated. Advanced imaging may also be considered for dramatic palatal abnormalities and for acquired defects.

Laboratory Findings

Laboratory abnormalities are not present unless the animal has aspiration pneumonia or is cachectic.

DIFFERENTIAL DIAGNOSIS

Traumatic or acquired clefts, rhinitis, nasal foreign body, and aspiration pneumonia are potential differential or concurrent diagnoses.

MEDICAL MANAGEMENT

Affected patients should be tube fed to maintain an adequate nutritional status and reduce the incidence of aspiration pneumonia until they are old enough for surgery. Aspiration pneumonia may be treated with antibiotics, fluids, oxygen, bronchodilators, and/or expectorants. Use of glucocorticoids for acute aspiration is controversial and clearly has no place in chronic aspiration. A tracheal wash or brushing for culture and sensitivity testing should be performed if aspiration pneumonia is severe. Broad-spectrum antibiotics with efficacy against anaerobes (Box 18.3) are indicated for severe aspiration or purulent rhinitis. Animals with severe rhinitis may benefit from having the nasal infection treated before surgical closure of the defect. Cultures should be obtained from the nasal cavity after anesthetizing the patient and the nose and oral cavity flushed of debris and exudate. To prevent recontamination of the nasal cavity with food, the animal should be given nothing by mouth for 10 to 14 days. Nutrition can be provided via tube feeding (e.g., esophagostomy or gastrostomy tube; see pp. 95 and 97, respectively) during this time.

SURGICAL TREATMENT

Most animals with defects of the primary and secondary palate are euthanized or die. Surgical treatment is generally delayed until the patient is at least 8 to 12 weeks of age to allow growth and easier access to the palate. Older patients seem to have less friable tissue that holds suture better. Palatoplasty performed before 16 weeks of age may hinder maxillofacial growth and development. Although rare, a narrower maxilla and occlusal problems may result. The primary goal of repairing a cleft palate is to reconstruct the nasal floor. Several procedures may be necessary before the entire cleft is permanently reconstructed. This is a hereditary defect; affected patients should be neutered.

Preoperative Management

Pediatric patients should not be fasted longer than 4 to 8 hours. After induction of anesthesia and placement of a cuffed endotracheal tube, the nasal and oral cavities should be flushed with saline and a dilute antiseptic solution. Perioperative antibiotics may be given intravenously at anesthetic induction if the animal is not already receiving them. Poorly nourished animals should be fed through a gastrostomy or esophagostomy tube for several days before surgery.

BOX 18.3 Antibiotic Treatment of Aspiration Pneumonia

Chloramphenicol (Chloromycetin)
Dogs: 50 mg/kg PO; 10–15 mg/kg IV q8h
Cats: 20–40 mg/kg PO, IM, SC, or IV q12h

Cefazolin (Ancef, Kefzol)
22 mg/kg IV q8h

Enrofloxacin (Baytril)
Dogs: 7–20 mg/kg PO or IV q24h (must be given diluted and slowly over 30 min)
Cats: 5 mg/kg PO or IV q24h (must be given diluted and slowly over 30 min)[a]

Ampicillin
22 mg/kg PO, IV, IM, or SC q6–8h

Amikacin (Amiglyde-V)
Dogs: 15–22 mg/kg IV q24h
Cats: 10–14 mg/kg IV q24h

Clindamycin (Antirobe, Cleocin)
Dogs: 11–33 mg/kg PO q8–12h, *or* 11 mg/kg IV q8–12h; when giving IV dilute and administer slowly
Cats: 5–33 mg/kg PO or SC q12–24h

Ampicillin Sodium & Sulbactam Sodium (Unasyn)
15–30 mg/kg IV q6–8h (off-label use)

[a]Can cause blindness in cats receiving high doses.
IM, Intramuscular; *IV,* intravenous; *PO,* orally; *SC,* subcutaneous.

Anesthesia

Puppies and kittens are better able to metabolize drugs after 8 weeks of age, making them better anesthetic risks. Special precautions should be taken to prevent hypothermia and hypoglycemia in young patients. Refer to the anesthesia section in Chapter 26 (see p. 722) for discussion of special concerns with pediatric patients. Intubation through a pharyngotomy (see p. 1044) or tracheotomy incision (see p. 842) may facilitate repair of secondary clefts. Pharyngotomy is generally preferred if it allows adequate visualization of the defect. General anesthetic recommendations for animals undergoing oral surgery are provided on p. 331. Guarded tracheostomy tubes should be used to prevent kinking during the procedure. Care should be taken to prevent and recognize dislodgment of the anesthetic tubing from the endotracheal tube during oral manipulations.

Surgical Anatomy

The major palatine arteries emerge from the major palatine foramen midway between the midline and caudal edge of the upper fourth premolar (see Fig. 18.1). The main artery courses rostrally, equidistant between the lingual border of the teeth and the palatal midline, to anastomose with the major palatine artery of the contralateral side caudal to the incisors. The minor palatine arteries enter the palate at the level of the last molar, caudal and

slightly lateral to the major palatine foramen. The minor palatine arteries course caudomedially and ramify in the caudal hard palate and soft palate. The soft palate is also supplied by branches of the ascending pharyngeal artery.

POSITIONING

To facilitate repair of a secondary palate defect, the animal should be positioned in dorsal recumbency with the mouth maximally opened. Ventral or dorsal recumbency may be used for a primary palate repair.

SURGICAL TECHNIQUES

The first step in the repair of combined primary and secondary clefts is to separate the oral and nasal cavities by reconstructing the nasal floor. After separation, the lip defect is reconstructed. Areas where flaps were harvested for closure of primary or secondary clefts are allowed to heal by second intention. Granulation and epithelialization are usually complete within 2 to 3 weeks.

Closure of Hard Palate Defects

AP The two procedures most often used to repair secondary clefts are sliding bipedicle flaps and overlapping flap techniques. Sliding bipedicle flaps (von Langenbeck technique) are created to close hard palate defects. The disadvantage of this technique is that the repair is unsupported and directly over the defect. Staged repair can be done to increase coverage of palatal defects.[3] In a study of six dogs, dental extractions with repair of the alveolar defects was done first, followed by double flap closure over the defect 4 weeks later. Successful repair was reported in three dogs; two dogs required surgical revision, and in one failure, further surgery was declined by the owner.

Incise the margins of the defect and make bilateral releasing incisions along the margins of the dental arcade (Fig. 18.18A). Elevate the mucoperiosteal layer on both sides of the defect with a periosteal elevator (see Fig. 18.18B). Avoid damaging the major palatine arteries. Control hemorrhage with pressure and suction. Appose the nasal mucosal edges or periosteum at the margin of the defect with buried interrupted sutures (knots within the nasal cavity) if possible. Slide the elevated mucoperiosteal flaps across the defect and appose with simple interrupted sutures (see Fig. 18.18C–D). Allow the denuded hard palate near the dental arcades to heal by secondary intention. A variation of this technique, in which a partial-thickness rather than a full-thickness incision of the mucoperiosteum is made without exposure of the palatal bone, may reduce maxillofacial deformity.

An alternate technique for repair of hard palate defects is the overlapping "sandwich" technique (Figs. 18.19 and 18.20). This

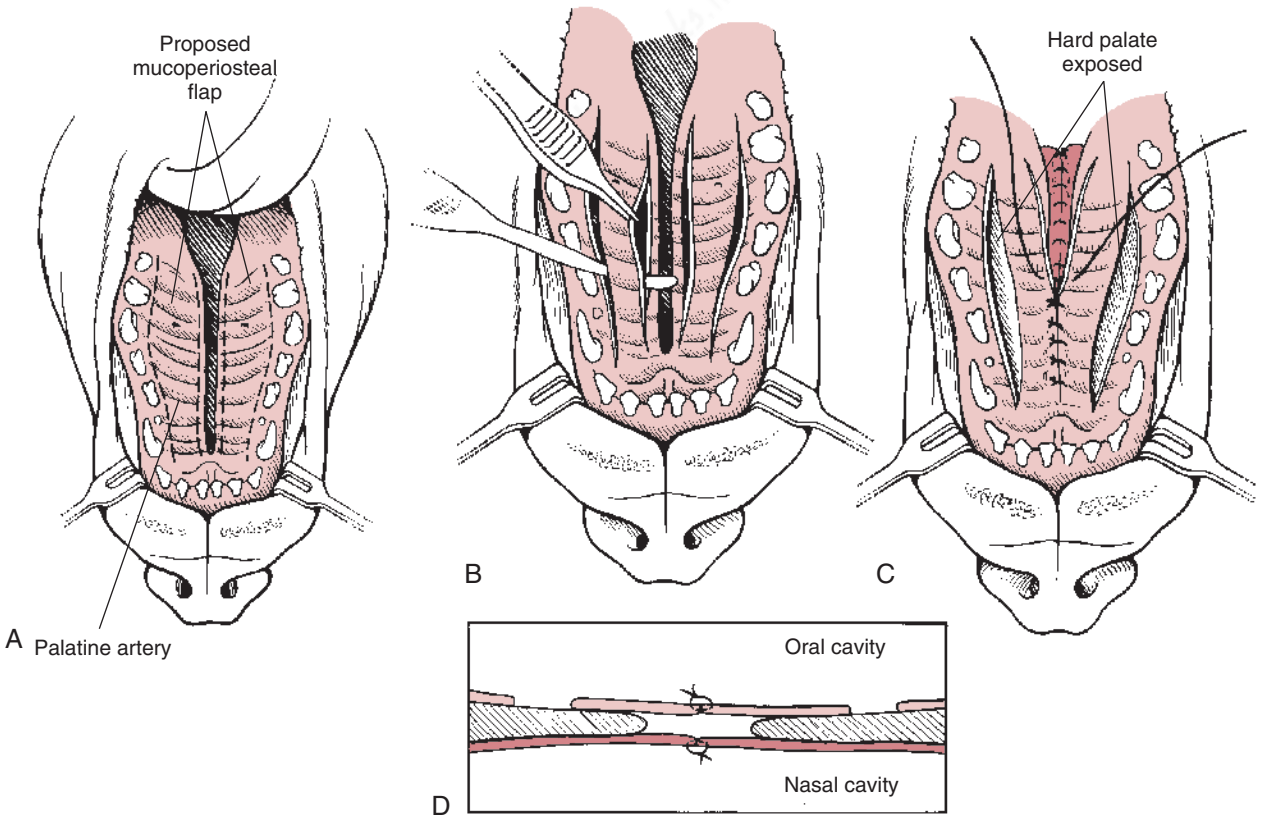

FIG. 18.18 A sliding bipedicle flap repair may be used to repair a congenital oronasal fistula. (A) The *dashed lines* represent the mucoperiosteal incisions necessary to create two sliding flaps. (B) The mucoperiosteum is elevated from the hard palate with the major palatine artery. (C) The nasal mucosa and mucoperiosteum are apposed in two layers over the defect in the hard palate. (D) Cross-sectional view of the repair.

FIG. 18.19 The secondary palate of the puppy in Fig. 18.16 was repaired with an overlapping flap technique. The defect over the hard palate was allowed to heal by second intention.

technique is advantageous because it does not place the repair over the palate defect. *Incise one margin of the defect separating the oral and nasal mucosa (see Fig. 18.20A). Elevate the mucoperiosteum at this edge by approximately 5 mm. At the opposite side of the defect, create a mucoperiosteal rotational flap large enough to cover the defect with its base hinged at the margin of the palatal defect (see Fig. 18.20B). Begin the incision near and parallel to the dental arcade, creating a flap 2 to 4 mm larger than the defect. Make perpendicular incisions at the rostral and caudal end of the incision extending to the cleft. Elevate this mucoperiosteal flap, taking care not to disrupt the margin of the defect (see Fig. 18.20B). Dissect carefully around the palatine artery to release it from fibrous tissue. Rotate the flap across the defect (see Fig. 18.20C). Place the edge of the flap under the mucoperiosteal flap on the opposite side. Preplace and then tie a series of horizontal mattress sutures to secure the flaps in position (see Fig. 18.20D).*

NOTE Warn owners that several operations may be needed to completely close large hard palate defects.

Closure of Soft Palate Defects

Incise the margins of the cleft to separate the oral and nasal mucosae. Continue incisions made in the margins of hard palate clefts caudally into the soft palate (see Fig. 18.20D). Isolate the nasal mucosa, palatal muscles, and oral mucosa. Appose the palatal edges in three layers, beginning caudally and working rostrally to a point adjacent to the caudal or midpoint of the tonsil. First appose the nasal mucosa using a series of simple interrupted sutures with nasally oriented knots or use a simple continuous pattern. Then appose the palatal muscle and connective tissue with a simple continuous suture pattern. Last, appose the oral mucosa with a simple continuous or interrupted suture pattern. Make tension-relieving incisions in the oral mucosa from the lingual aspect of the last molar to near the tip of the soft palate.

An overlapping flap technique, rotational flaps from the hard or soft palate, and nasal or nasopharyngeal mucosal flaps can also be used to repair soft palate defects. Correction of lateral soft palate clefts generally includes an oropharyngeal/nasopharyngeal mucosal flap. Some surgeons fracture the pterygoid hamulus (where the palatal muscles attach) with an osteotome to reduce tension on the soft palate.

Reconstruction of Soft Palate Hypoplasia

Bilateral pharyngeal mucosal flaps may be used to reconstruct a hypoplastic soft palate. *Create two random-pattern flaps from the right and left pharyngeal walls that are based laterally and extend into the nasopharynx.* The base of each flap is at the caudal aspect of the last molar and extends caudally to the rostral margin of the tonsillar crypt. *Create a flap of hard palate mucoperiosteum, extending from the lateral aspects of the hard palate medial to the dental arcades, taking care to preserve the palatine arteries and attachment at the caudal border of the hard palate.* Caudal rotation of the mucoperiosteum results in the mucosa facing the new floor of the soft palate. *Suture the edges of the flap to the lateral walls of the pharynx. Suture the ends of the lateral pharyngeal flaps together on the midline to form the oral mucosal surface of the soft palate. Suture the rostral border of the lateral pharyngeal flaps to the base of the hard palate and the caudal aspect of the three flaps in separate rows of simple continuous patterns.*

Closure of Primary Clefts

AP Cosmetic repair of primary clefts can be very complicated, requiring elaborate planning to achieve a successful outcome (Fig. 18.21A).

Create a mucosal flap to separate the nasal cavity from the oral cavity (see Fig. 18.21B). If the cleft extends into the premaxilla, evaluate the gingival mucosa of the deciduous incisors and pull them if necessary. Suture the buccal or gingival mucosal flap to the nasal mucosa. Use a freehand modified Z-plasty for reconstruction of the lip defect (see Fig. 18.21C). Close the lip defect so that the distance from the ventral nostril to the free ventral edge of the lip is the same on both sides. Make multiple small flaps, if necessary, for a cosmetic closure. Place a layer of sutures in the fibromuscular layer (orbicularis oris muscle and connective tissue) before skin closure.

POSTOPERATIVE CARE AND ASSESSMENT

Soft food should be fed for a minimum of 2 weeks after surgery, and chewing on hard objects (e.g., bones, sticks, chew toys) should be prevented. Esophagostomy feeding for 7 to 14 days may facilitate healing. Reevaluation at 2 weeks may require anesthesia to identify small defects.

COMPLICATIONS

Dehiscence and subsequent incomplete healing of oronasal fistulae are the most common complications. Dehiscence usually occurs within 3 to 5 days of surgery but may occur later. Early dehiscence may occur if tension is excessive, blood supply is poor, or the tissue is traumatized. Motion of the tongue against the repair and particulate matter in the surgical site can also lead to dehiscence. Early dehiscence of the lip occurs if the orbicularis oris muscle has not been apposed. Contraction of the unapposed muscle during lip movement causes excess tension on the suture line. Tissues are friable after dehiscence; therefore repair of early dehiscence should be delayed for 4 to 6 weeks to allow tissues to revascularize and regain strength. Late dehiscence is a result of growth-induced stress on the repair and is best treated after the patient matures.

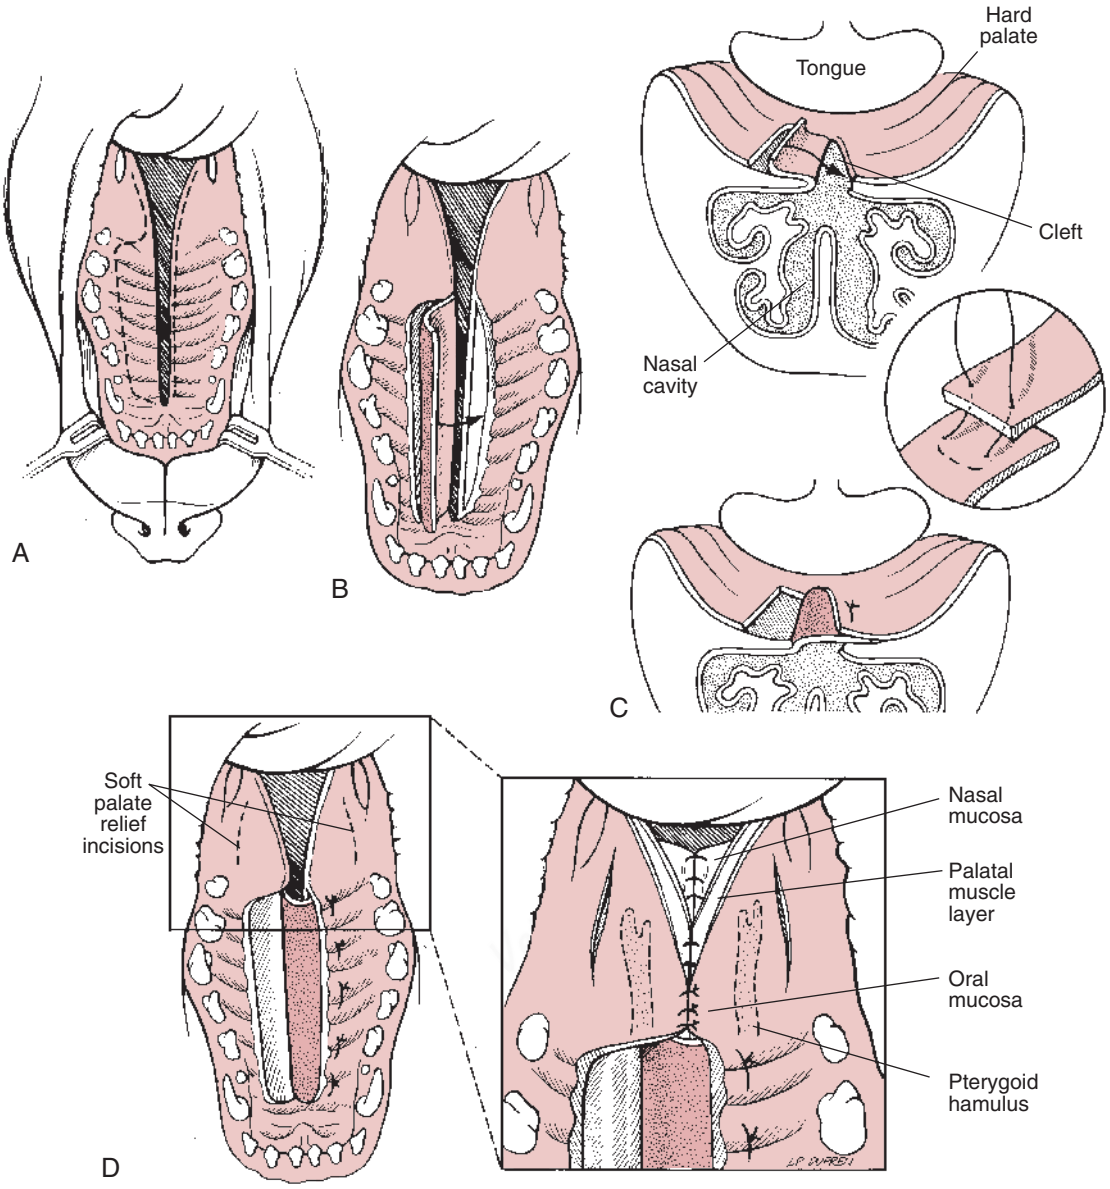

FIG. 18.20 A congenital oronasal fistula may be repaired with an overlapping flap technique. (A) The *dotted lines* represent the incisions necessary to allow soft tissue closure. (B) Elevate the mucoperiosteal flap and rotate it medially to cover the hard palate defect. (C) Insert the edge of this flap between the hard palate and the mucoperiosteum on the opposite side of the defect. Secure the flaps in position with horizontal mattress sutures *(insert)*. (D) Complete the repair by apposing the incised edges of the cleft soft palate in three layers. Make lateral relief incisions *(broken lines)* to reduce tension on the repair.

PROGNOSIS

The prognosis is good for animals with successful cleft palate repair; however, several operations may be required. Chronic rhinitis and aspiration pneumonia persist if large defects are not repaired. Untreated patients with small clefts may have few clinical signs.

ACQUIRED ORONASAL FISTULAE

DEFINITION/SYNONYMS

Acquired oronasal fistulae (traumatic cleft palate, palatal defect) are abnormal communications between the nasal and oral cavities caused by trauma or disease.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Acquired palatal defects are most often caused by dental disease (Fig. 18.22). An oronasal fistula results when a deep maxillary periodontal pocket progresses to the apex of the tooth, lysing bone between the apex of the alveolus and the nasal cavity or maxillary sinus. A fistula may also result from trauma (i.e., bite wounds, gunshot wounds, blunt trauma to the head, electrical burns) or may be a complication of surgery (e.g., mass excision or ventral rhinotomy), radiation, or hyperthermic treatment of oral lesions. Foreign bodies lodged between the dental arcades may cause pressure necrosis of the hard palate and subsequent development of an oronasal fistula (Fig. 18.23). Ingested food

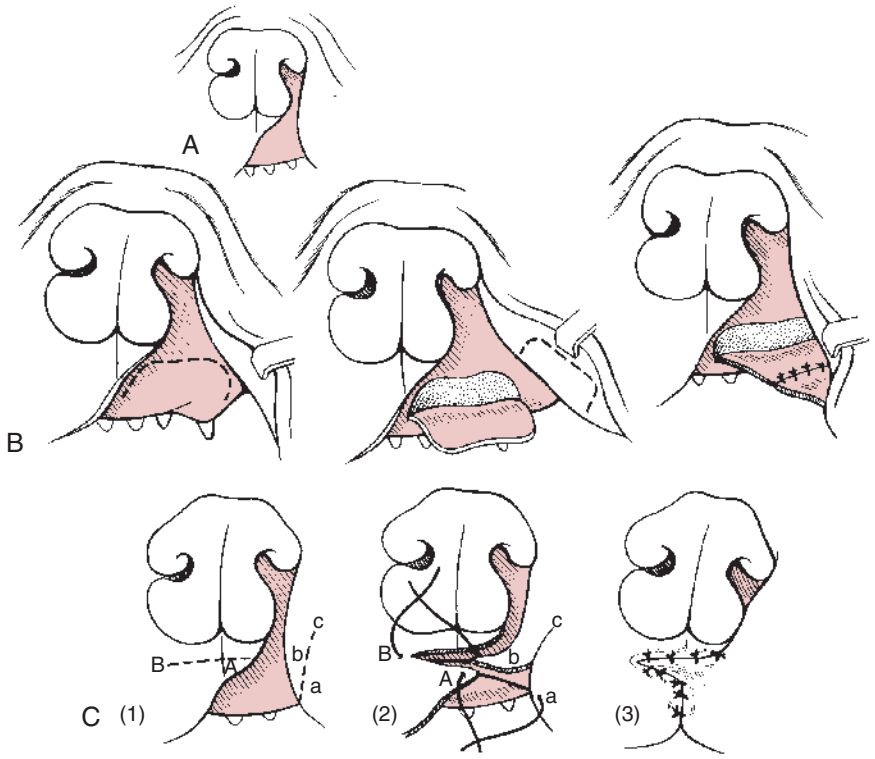

FIG. 18.21 (A) Schematic drawing of a repair of a primary cleft palate involving the lip, premaxilla, and nostril. (B) Create a flap from the nasal wall and suture it to a labial mucosal flap to separate the nasal cavity from the oral cavity. (C) Repair the cleft lip with one or a series of Z-plasties: *(1)* make incisions from A to B and a to c; *(2)* place a suture between A and a and B and b to transpose the flaps; *(3)* place additional sutures as needed.

FIG. 18.22 An oronasal fistula that occurred from loss of the canine tooth.

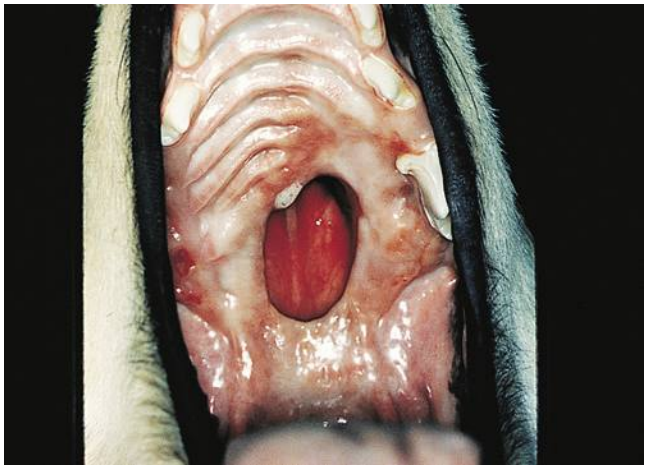

FIG. 18.23 An acquired oronasal fistula caused by a foreign body that lodged between the dental arcades.

that passes through the fistula into the nasal cavity may be expelled from the nostril by sneezing. Chronic rhinitis is common.

DIAGNOSIS

Clinical Presentation

Signalment

Any breed or sex may acquire an oronasal fistula. Oronasal fistulae that occur secondary to dental disease or tumors are seen more often in middle-aged and older animals. Oronasal fistulae that develop secondary to trauma may occur at any age.

History

An oronasal fistula should be suspected in patients with chronic rhinitis and a history of dental disease, trauma, or previously treated oral tumors. Common clinical signs are sneezing and chronic unilateral serous or mucopurulent nasal discharge.

Physical Examination Findings

The diagnosis of an oronasal fistula can be made by identifying an abnormal communication between the oral and nasal cavities

(see Figs. 18.22 and 18.23). Small fistulae associated with periodontal disease are not easily identified unless the area around the involved tooth is explored with a narrow dental probe. If passing the probe into the gingival pocket causes epistaxis, a fistula is present. The palatal aspect of the maxillary canine tooth is a common site for an oronasal fistula. Anesthesia is generally required to probe periodontal pockets.

Diagnostic Imaging

Skull radiography or cross-sectional imaging may identify underlying causes of fistulae, such as periapical abscesses, advanced periodontal disease, maxillary neoplasia (see p. 352), or broken or retained tooth roots. Lysis, especially of the laminae dura around tooth roots, is indicative of periapical abscesses.

Laboratory Findings

Inflammatory changes on a CBC may be seen secondary to rhinitis or aspiration pneumonia.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses include any disease that causes chronic rhinitis (e.g., fungal disease, nasal foreign body, congenital oronasal fistula, invasive oral neoplasia) and congenital clefts. These conditions can generally be differentiated based on physical examination, imaging, and/or histopathologic examination. Histopathologic evaluation should be performed to distinguish fistulae that occur secondary to neoplasia from those associated with infection or trauma.

MEDICAL MANAGEMENT

Broad-spectrum antibiotics effective against anaerobes (e.g., chloramphenicol, amoxicillin plus clavulanic acid, clindamycin) should be given if severe purulent rhinitis is present (see Box 18.3). Such animals may benefit from having the nasal infection treated before closure of the defect. With the patient under general anesthesia, cultures should be obtained from the nasal cavity, and the nose and oral cavity flushed of debris and exudate. To prevent recontamination of the nasal cavity with food, the animal should be given nothing by mouth for 10 to 14 days. Nutrition can be provided via tube feeding (e.g., tube gastrostomy, p. 97, or esophagostomy, p. 95) during this time.

SURGICAL TREATMENT

Most oronasal fistulae require surgical reconstruction, although small or traumatic fistulae occasionally heal spontaneously. A variety of surgical techniques have been described for repair, including simple suturing of the fistula edges, mucosal flaps, mucoperiosteal flaps, double reposition flaps, orbicularis oris axial pattern flaps, palatal island flaps, and two-staged tongue flaps. Successful repair of oronasal fistulae requires a well-supported, air-tight, tension-free closure. Flap techniques are more successful than direct apposition of the fistula edges because there is less tension and increased support for the repair. Teeth involved in the fistula should be extracted several weeks before reconstruction of the defect. Central lesions may require that normal teeth be extracted to allow creation of adequate mucosal flaps. If the fistula is of dental origin, it may be necessary to perform a limited maxillectomy (at least 5 mm from each margin) to remove necrotic or diseased bone. Traumatic oronasal fistulae may require stabilization of the maxilla and hard palate with small pins or wire. Interdental wiring (see p. 1045) using the carnassial teeth or the canine teeth (or both) can help bring bone edges into apposition. Areas where flaps were harvested heal by second intention in 2 to 3 weeks. Acrylic, Silastic, or metal obturators may also be fitted over the defect.

Preoperative Management

Pediatric patients should not be fasted for longer than 4 to 8 hours. After anesthetic induction, the nasal and oral cavities should be flushed with saline-diluted antiseptic solution. Aggressive management of rhinitis (see Medical Management, presented earlier) may reduce infection and improve the tissues' ability to hold suture.

Anesthesia

General anesthetic recommendations for animals undergoing oral surgery are provided on p. 331 (see Table 18.1). Intubation through a pharyngotomy (see p. 1044) or tracheotomy incision (see p. 842) may facilitate repair of large or centrally located oronasal fistulae. Pharyngotomy is generally preferred if it allows adequate visualization of the defect. Care should be taken to prevent and recognize dislodgment of the anesthetic tubing from the endotracheal tube during oral manipulations.

> **NOTE** Use guarded tracheostomy tubes to prevent kinking during oral procedures.

Surgical Anatomy

The surgical anatomy of the hard palate is discussed on p. 343.

Positioning

The patient should be positioned in lateral recumbency for repair of oronasal fistulae associated with the dental arcade. Dorsal recumbency with the mouth opened maximally facilitates repair of more centrally located fistulae involving the secondary palate.

SURGICAL TECHNIQUES

Direct Apposition

Direct apposition of the fistula should be performed only if the fistula is very small. *Debride the fistula to healthy, bleeding mucosal edges (Fig. 18.24A–B). Incise or debride the margin of the fistula and elevate the edges enough to allow approximation without excess tension. Appose the mucosa with interrupted appositional sutures (i.e., simple, cruciate, or vertical mattress pattern) (see Fig. 18.24C).*

Single-Layer Flap Repair

AP *Debride the epithelial margin of the fistula (Fig. 18.25A). Incise the gingival and buccal mucosa to outline a flap 2 to 4 mm larger than the debrided fistula (see Fig. 18.25B). Make these incisions perpendicular to the dental arcade. Elevate the gingival mucosa with a periosteal elevator. Then undermine the buccal mucosa until the flap can be advanced across the defect without tension (see Fig. 18.25C). Using a rongeur, remove infected alveolar and maxillary bone. Expose approximately 1 to 2 mm of the hard palate at the medial aspect of the fistula by excising 1 to 2 mm of mucoperiosteum. Lavage the surgical site with saline. Suture the gingival-buccal flap to the mucoperiosteum of the hard palate in an interrupted approximating pattern (i.e., simple, cruciate, or vertical mattress) using monofilament, absorbable (3-0 to 4-0)*

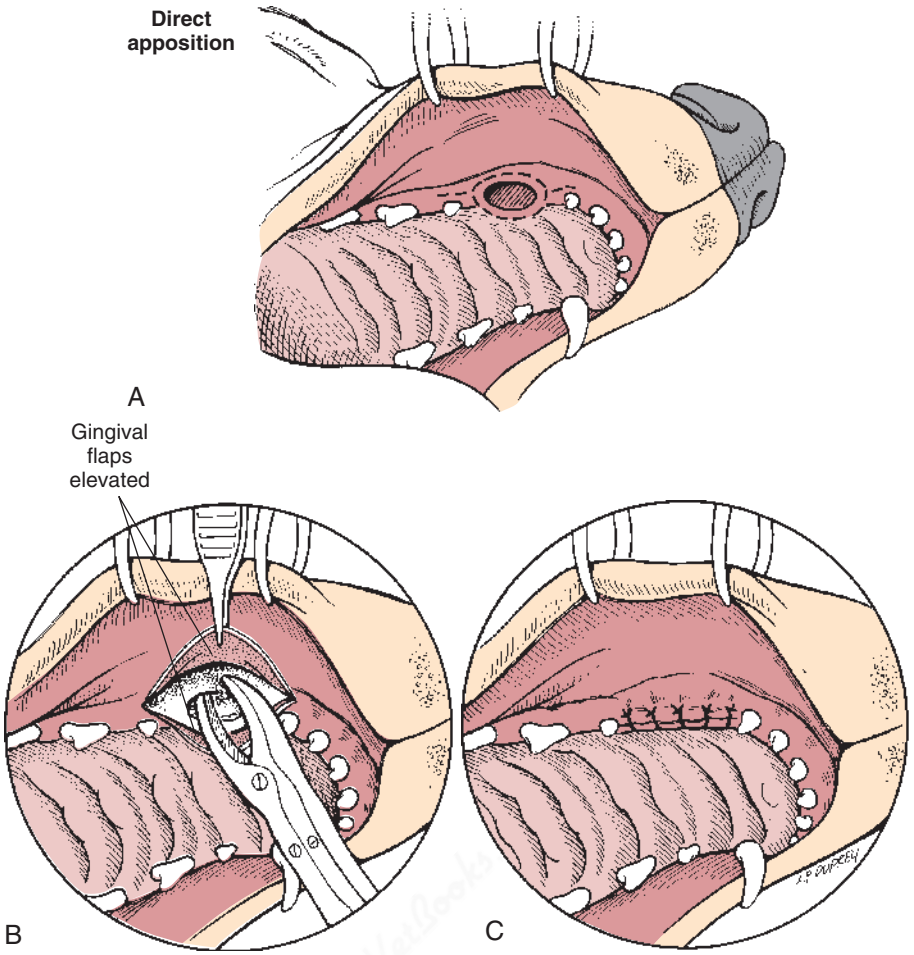

FIG. 18.24 Small fistulae may be repaired with a direct appositional technique. (A) Incise the mucosa around the fistula. (B) Elevate the gingival flaps and debride the edges of the fistula. (C) Appose the mucosa over the defect.

sutures. Inclusion of the angularis oris artery, which arises from the facial artery caudal to the commissure of the lips, during flap creation yields a mobile, strong flap with a good blood supply that may extend to the ipsilateral canine or across the palate to the opposite dental arcade.

Rotational Flap Repair

A rotational or advancement flap may be created from the hard or soft palate (see Fig. 18.25D–G), or an overlapping technique similar to that described for repair of congenital oronasal fistulae may be used (see p. 346). *Create a flap 2 to 4 mm larger than the debrided fistula. To ensure a good blood supply, incorporate the major or minor palatine artery in palatal flaps. Transpose and suture the flap over the defect (see Fig. 18.25D–G).*

NOTE Granulation tissue fills the defect over the hard palate, and the area reepithelializes within a few weeks.

Double-Flap Repair

Double-flap techniques may be used with large dental fistulae and fistulae located in more central areas of the palate. Double-flap techniques provide a mucosal surface on both the oral and nasal sides of the fistula. If buccal flaps are planned to close large central defects, extraction of teeth may be necessary. The extraction sites should be allowed to heal before reconstruction. Do not debride the palatal epithelial margin during debridement of the fistula, because this edge serves as the base of the mucoperiosteal flap and must remain continuous with the nasal mucosa to be effective.

Create a flap in the mucoperiosteum 2 to 4 mm larger than the debrided fistula (Figs. 18.26–18.28). Elevate the flap without disrupting the palatal margin of the fistula. Fold the flap over the defect and suture it to the gingival mucosa with interrupted, approximating, monofilament, absorbable sutures for the first layer of closure (see Fig. 18.26). This flap provides "nasal" mucosa. *Create a rotational mucoperiosteal flap 2 to 4 mm larger than the defect for the second layer of closure (see Fig. 18.26). Appose this flap to the gingival mucosa with approximating 3-0 to 4-0 sutures. To ensure a good blood supply, incorporate the major palatine artery in palatal flaps. As an alternative, create one or two mucoperiosteal flaps 2 to 4 mm larger than the defect (see Fig. 18.28A). Transpose and suture the flap in place for the first layer of the closure (see Fig. 18.28B) to provide the "nasal" mucosa. Cover this layer with a mucosal flap (gingival and buccal) to provide the "oral" mucosal layer of the closure (see Fig. 18.28C–D). Allow the denuded hard palate to heal by second intention.*

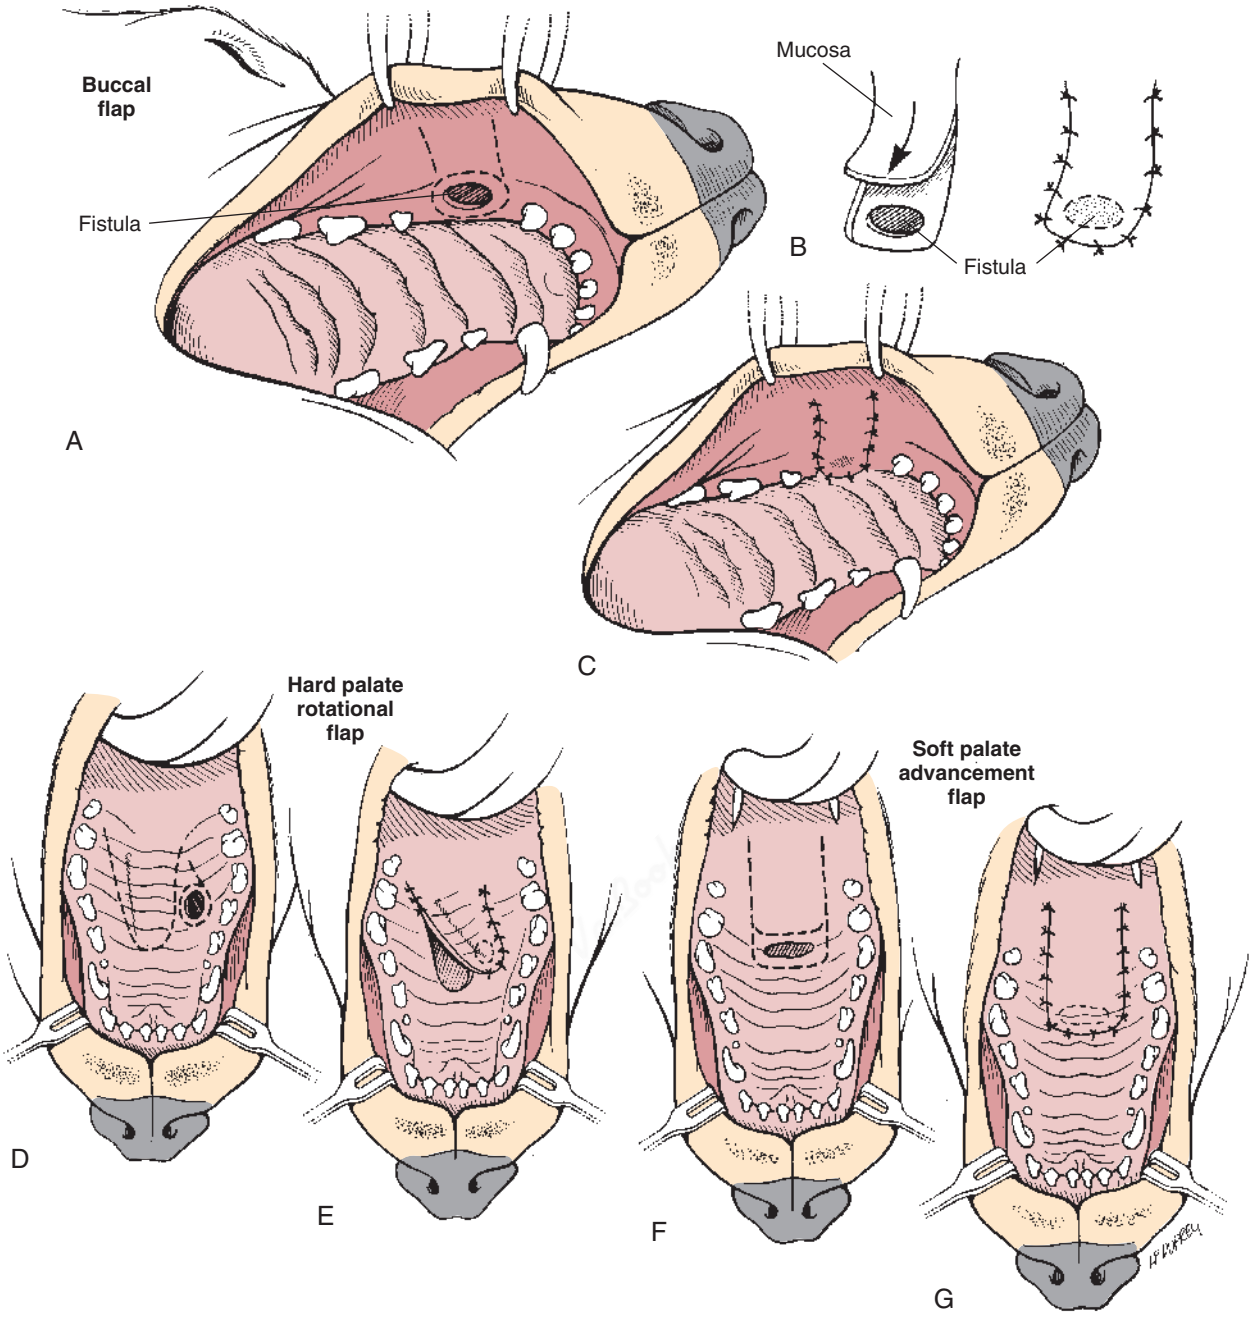

FIG. 18.25 Single-flap technique for fistula repair. (A) Incise mucosa around the fistula to create the buccal flap *(dashed line),* then debride the fistula. (B–C) Advance a buccal flap over the defect and suture into place. (D–E) After debriding the fistula, create a hard palate rotational flap *(dashed line)* and rotate the mucoperiosteal hard palate flap over the defect. Suture the flap to surrounding mucoperiosteum. (F–G) To repair lesions at the junction of the hard and soft palates, debride the defect, then create and close the defect with a soft palate advancement flap *(caudal dashed line).*

Conchal Cartilage Graft Repair

Repair of oronasal fistulae may be accomplished using auricular cartilage in cats with small, central defects of the hard palate. *Incise the skin over the caudoventral surface of the pinna, excise a round piece of the scapha of the pinna leaving the rostral skin intact (Fig. 18.29). Elevate the hard palate mucoperiosteum approximately 2 to 3 mm around the oronasal fistula to accommodate the graft. Insert the graft and suture it to the surrounding palate with simple interrupted sutures rostrally and caudally.*

Vertical Ear Canal Graft Repair

Excise the lateral two-thirds of the vertical ear canal and suture the skin to the mucosa of the horizontal ear canal (Fig. 18.30).

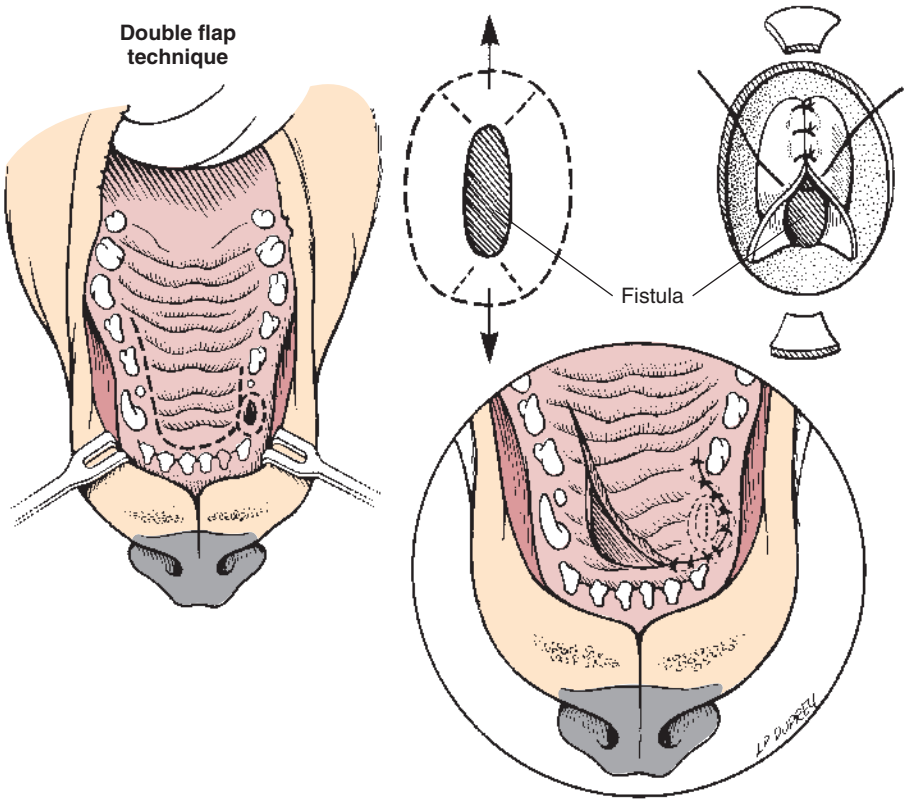

FIG. 18.26 A double-layer flap technique may be performed using tissue surrounding the fistula and a flap from the mucoperiosteum of the hard palate. Create the first flap *(gingival dashed line)* by rotating the gingival margins of the fistula medially and apposing with sutures *(top inset)*. Cover this flap *(bottom insert)* with a rotational mucoperiosteal hard palate flap *(palatal dashed line)*.

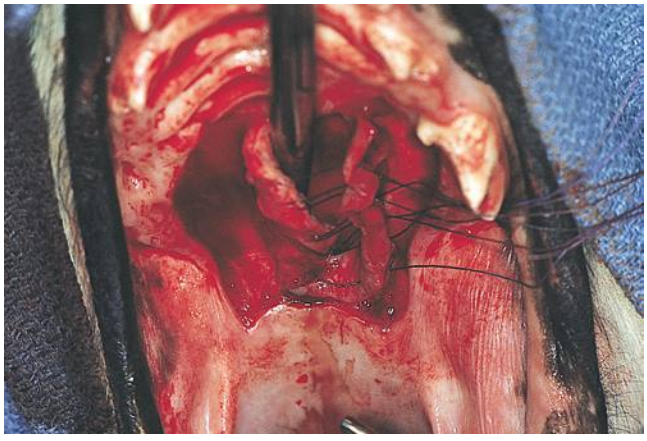

FIG. 18.27 Intraoperative image showing repair of an oronasal fistula using a double-layer flap technique. The margins of the fistula have been elevated and rotated medially to cover the defect. This flap was later covered with a flap created from the buccal mucosa.

Unfold the harvested cartilage, sharply excise the mucosa, and position the mucosal surface dorsally into the nasal cavity. Elevate the mucoperiosteum of the hard palate approximately 2 to 3 mm around the fistula to create a pocket for the graft and to create mucosal flaps to cover as much of the cartilage graft as possible. Secure the graft to the palate with 3-0 polydioxanone (PDS) vertical mattress sutures at each corner and midway between corners.

POSTOPERATIVE CARE AND ASSESSMENT

IV fluids should be provided until the animal begins eating and drinking (usually within 24 hours of surgery). Soft food should be fed for 2 to 3 weeks, and chewing on hard objects (i.e., toys, sticks) must be prevented to avoid dehiscence or perforation of the flap separating the oral and nasal cavities. If the animal paws at the mouth, an Elizabethan collar should be used. Severe rhinitis should be treated with antibiotics (see Box 18.3). Healing should be evaluated 2 and 4 weeks after surgery.

COMPLICATIONS

Most oronasal fistulae are successfully repaired if flaps can be apposed without tension and with a good blood supply. Dehiscence and recurrence of the oronasal fistula are expected if conditions for healing are not ideal. Motion of the tongue against the repair and particulate matter in the surgical site can also lead to dehiscence. Tension, poor blood supply, infection, poor debridement, lack of flap support, and traumatic technique may inhibit healing. Additional attempts to repair recurring fistulae should be delayed by 4 to 6 weeks to allow sites of previous flap harvesting to heal, revascularize, and mature before additional flaps are created. Rhinitis should resolve after the fistula has healed if irreversible mucosal changes have not occurred.

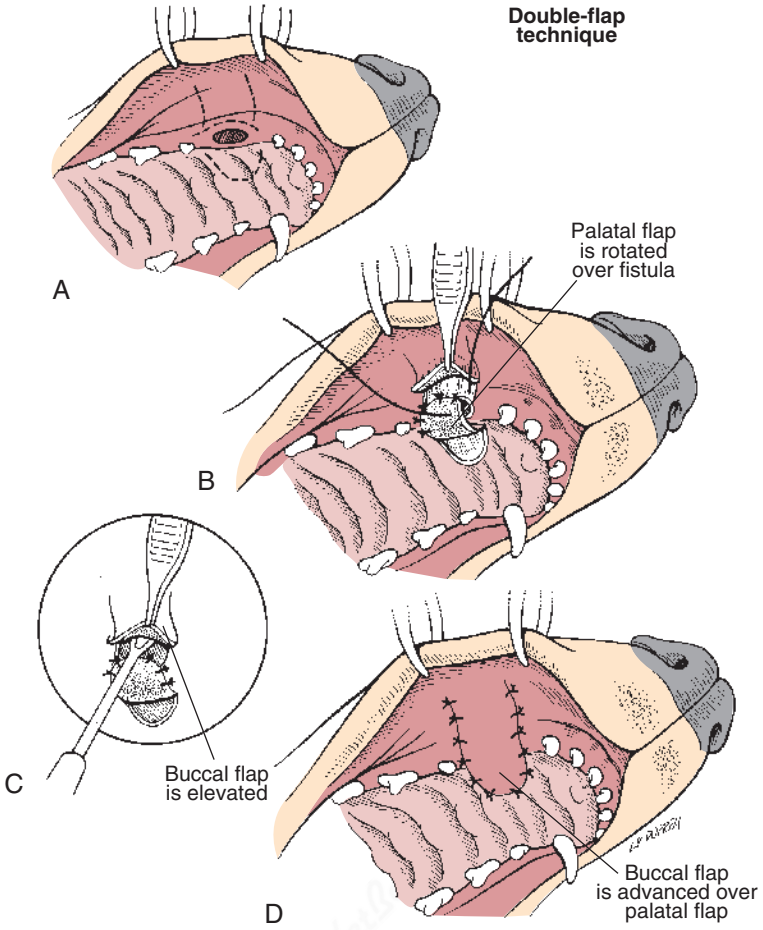

FIG. 18.28 A double-layer flap technique for fistula repair may be performed using a mucoperiosteal hard palate flap *(palatal dashed line)* and a buccal flap *(buccal dashed lines).* (A–B) Create a flap from the mucoperiosteum of the hard palate *(palatal and gingival dashed lines)* rotate and suture to gingival margin. (C–D) Cover it with a second flap created from the buccal mucosa *(inset),* then advanced and sutured over the first flap.

PROGNOSIS

Traumatic clefts may heal spontaneously in 2 to 4 weeks. Signs of rhinitis caused by regurgitation of food into the nasal cavity may be controlled with chronic antibiotic therapy. The long-term prognosis for most patients with nontraumatic fistulae is poor when surgical correction is not possible because fistulae do not heal without surgical reconstruction.

ORAL TUMORS

DEFINITIONS

Oral tumors encompass those neoplasms that arise from the gingiva, buccal mucosa, labial mucosa, tongue, tonsils, or dental elements. Malignant melanoma is also known as *melanosarcoma;* ameloblastoma is also referred to as *adamantinoma.*

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

The oral cavity is the fourth most common site of neoplasia in dogs and cats; oral tumors account for 5% (dogs) to 7% (cats) of all malignant tumors in these species. Oral tumors occur 2.6 times more often in dogs than cats. Malignant oral tumors have a higher relative risk of occurring in male than in female dogs. Oral tumors originate from the mucosa, tongue, periodontium, odontogenic tissue, mandible, maxilla, tonsils, and lips, spreading by direct extension or invasion of adjacent bone and cartilaginous tissue. Metastasis occurs by lymphatics or blood to the regional lymph nodes and lungs. All tumors should be clinically staged according to the TNM classification system (primary tumor, regional lymph nodes, and metastasis) described by the World Health Organization (Table 18.2).

The most common malignant canine tumors are malignant melanoma, SCC, and fibrosarcoma, whereas SCC is the most common malignant oral tumor in cats. Other malignancies are listed in Box 18.4. Benign oral tumors are rare in cats. The most common benign oral neoplasms in dogs are epulides; other benign oral lesions are listed in Box 18.4.

Malignant melanomas are the most common malignant oral tumor in dogs; they rarely occur in cats (Box 18.5). Melanomas are rapidly growing, white-gray or brown-black tumors that are firm and vascular. They usually occur on the gingiva and are characterized by early local invasion. Some types are easily mistaken histologically for fibrosarcoma. Metastasis to the regional

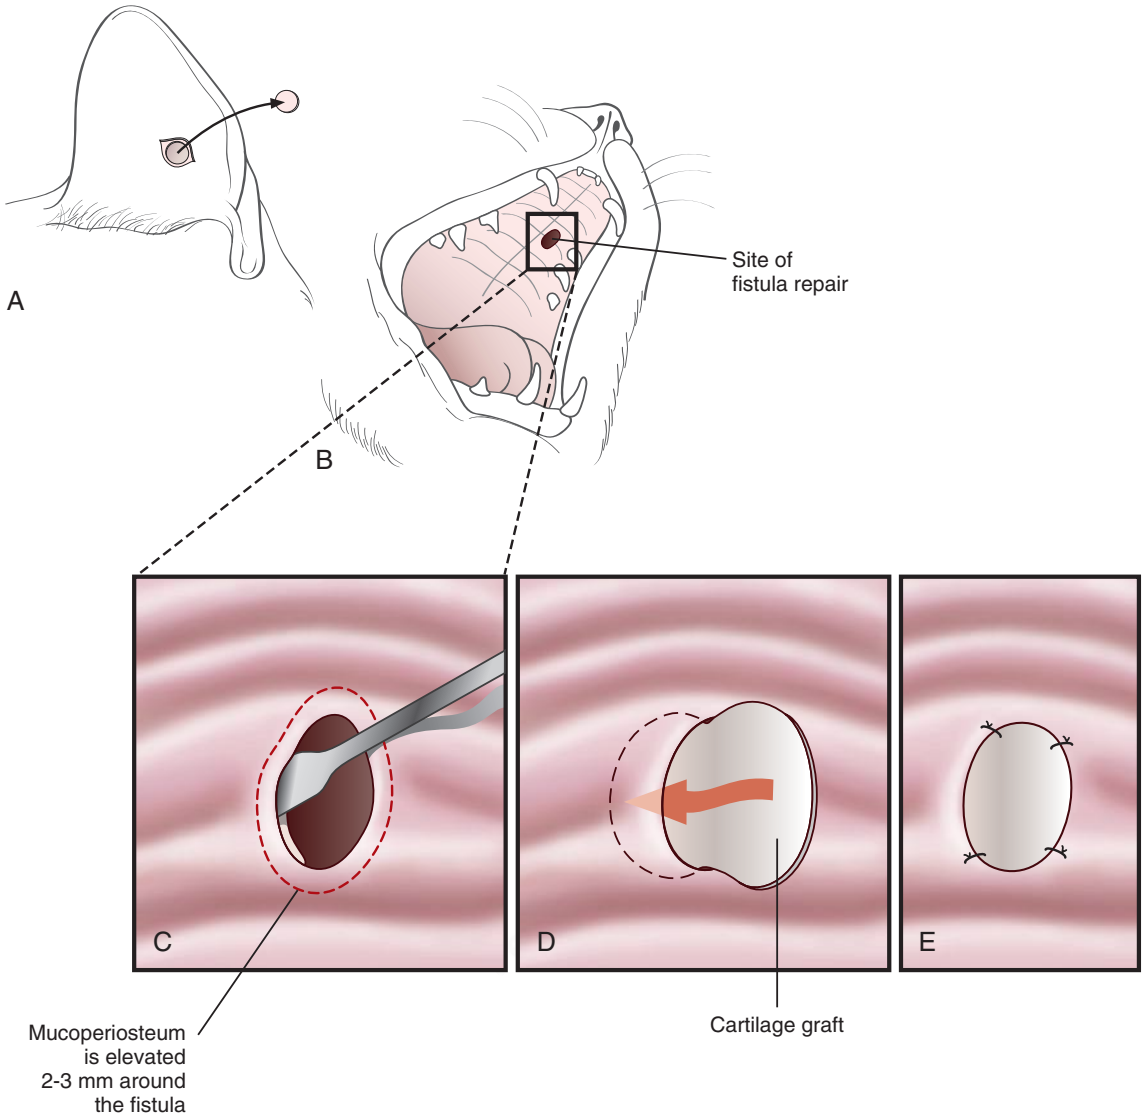

FIG. 18.29 Conchal cartilage graft repair. (A) Excise a round piece of the scapha of the pinna. (B) and (C) Elevate the mucoperiosteum. (D) Insert the cartilage. (E) Suture it to the surrounding tissues.

lymph nodes and lungs occurs in 80% of cases. Wide surgical excision using partial maxillectomy, mandibulectomy, tonsillectomy, or glossectomy is recommended. Radiation therapy may be used, but there is a high rate of recurrence. The response to radiotherapy may be better if concurrent hyperthermia is used, but the high rate of metastasis makes long-term survival unlikely. Administering cisplatin or carboplatin prior to radiation therapy provides better local control than radiation therapy alone. Chemotherapy and immunotherapy are of minimal benefit in treating malignant melanomas. A vaccine for canine melanoma is available, but its efficacy is uncertain at the time of this writing.

SCC is the most common malignant oral tumor in cats and the second most common malignant oral tumor in dogs (Box 18.6). Increased risk of SCC in cats has been associated with flea control products, diet, and environmental tobacco smoke. These tumors occur on the gingiva, lip, tongue, or tonsil. The masses are red, friable, vascular, and sometimes ulcerated. Most tumors in the rostral oropharynx are locally invasive, often invading bone and having a low metastatic potential, whereas those in the caudal oropharynx tend to be more infiltrative and metastasize more rapidly. Canine gingival SCC tends to be highly invasive and osteolytic but has a low rate of metastasis. Feline gingival SCC has a poorer prognosis than canine SCC. Wide resection is recommended for gingival tumors. They are radiosensitive, and combining radiotherapy with hyperthermia has been effective in palliating these tumors. Investigations into the use of chemotherapy alone or as an adjunct to surgery continue. Piroxicam may be helpful in controlling some SCCs. Tonsillar SCC grows rapidly and is associated with early local invasion and a high rate of lymph node and lung metastasis. It can also spread to the contralateral tonsil. These tumors occur most often in male urban dogs; tonsillar SCC has rarely been reported in cats. The prognosis for these tumors is guarded. SCCs may also occur on the tongue.

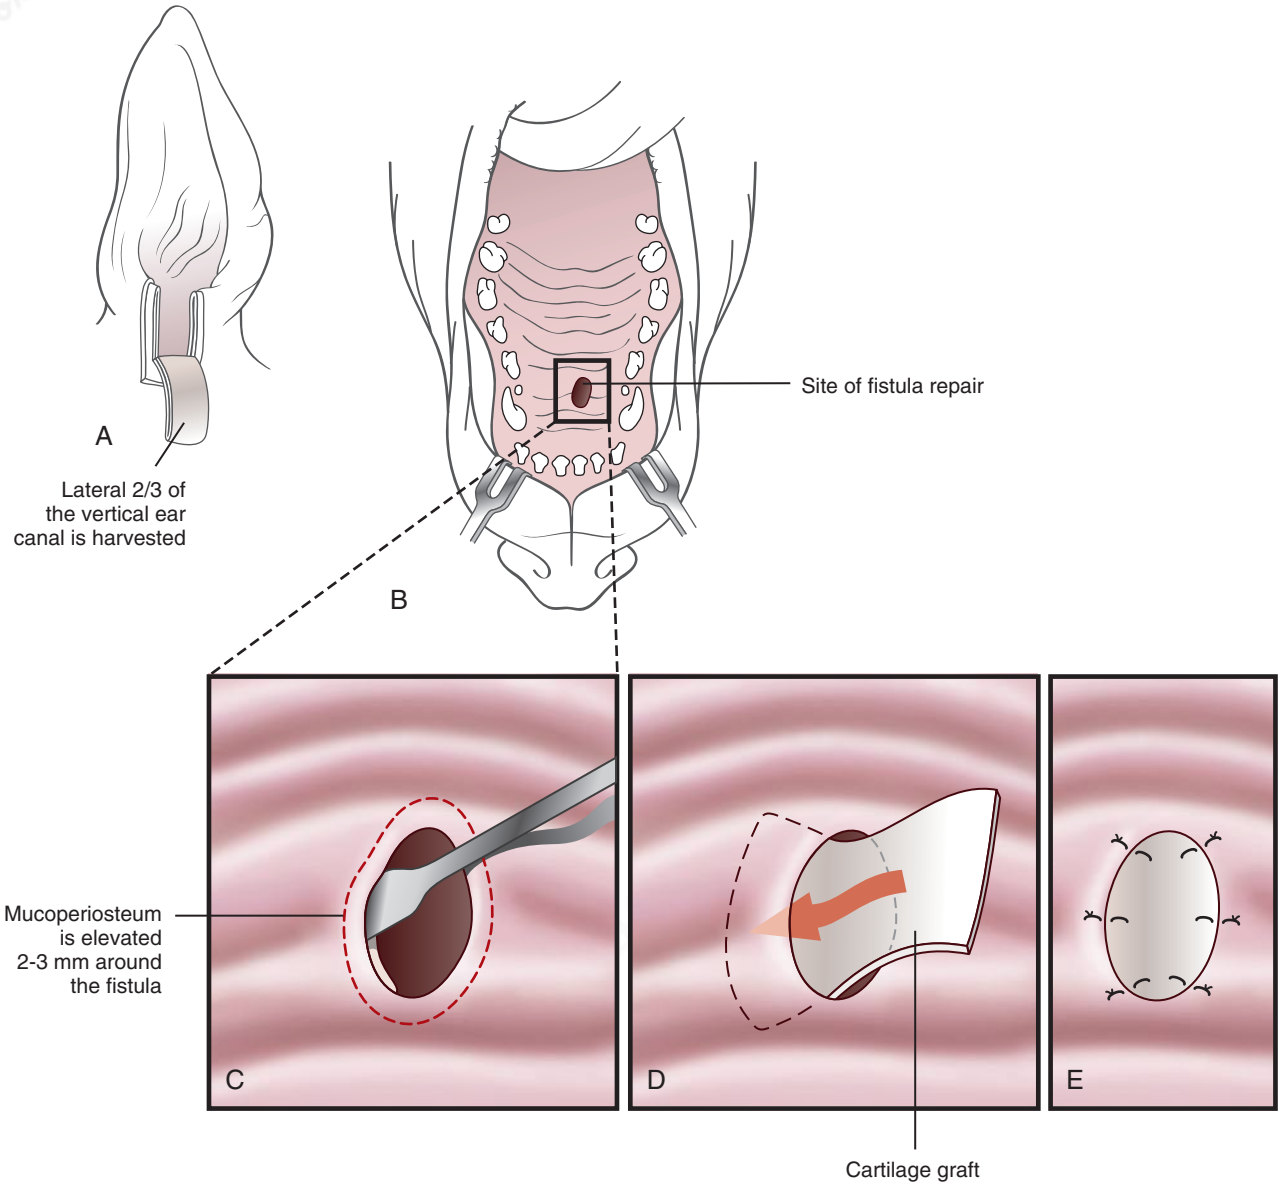

FIG. 18.30 Vertical ear canal graft repair. (A) Excise the lateral two-thirds of the vertical ear canal. (B) and (C) Elevate the mucoperiosteum around the fistula. (D–E) Position the mucosal surface of the cartilage dorsally into the nasal cavity. (E) Suture it to the surrounding tissues.

Fibrosarcomas are found primarily in dogs (Box 18.7). They most commonly occur on the maxillary gingiva and hard palate and appear as pink-red, firm, smooth, multilobulated masses that are often attached to underlying tissue. Local infiltration with bony involvement is common, but distant metastasis is uncommon. Local recurrence is high with any treatment; wide surgical resection is recommended. Most fibrosarcomas are poorly responsive to chemotherapy. Fibrosarcomas are generally radioresistant, although the median tumor control time with radiation alone may be as long as 12 months. Aggressive postoperative radiation therapy has improved survival times, but cryotherapy is believed to stimulate recurrence.

Osteosarcomas account for approximately 10% of canine mandibular and maxillary tumors. They are locally aggressive and have a high metastatic potential. The response to conventional therapies (i.e., surgery, radiation, chemotherapy) is poor, although survival is longer than with appendicular osteosarcoma.

The epulides are the most common benign oral neoplasms, accounting for 30% of all canine oral neoplasms (Box 18.8). They are rare in cats. These tumors are firm gingival masses that arise from the periodontal ligament. There are three types of epulides: fibromatous, ossifying, and acanthomatous. *Fibromatous epulides* are noninvasive, firm, smooth, pink masses that originate at the gingival sulcus and may be single or multiple, and pedunculated or sessile (Fig. 18.31). The primary cell type is periodontal ligament stroma. *Ossifying epulides* are similar to fibromatous epulides except that they have large amounts of osteoid matrix in the stroma of the periodontal ligament. They are firm and difficult to cut. Malignant transformation to osteosarcoma has been reported. *Acanthomatous epulides* are classified as benign

TABLE 18.2 Clinical Stage Classification System for Canine and Feline Tumors of the Oral Cavity[a]

Minimum Requirements for Assessing T, N, and M Categories (If These Cannot Be Met, Tx, Nx, and Mx Should Be Used)

T categories: Clinical and surgical examination
N categories: Clinical and surgical examination
M categories: Clinical and surgical examination, radiography of the thorax
T: Primary tumor
Tis—Preinvasive carcinoma (carcinoma in situ)
T0—No evidence of tumor
T1—Tumor <2 cm maximum diameter
T1a—Without bone invasion
T1b—With bone invasion
T2—Tumor 2–4 cm maximum diameter
T2a—Without bone invasion
T2b—With bone invasion
T3—Tumor >4 cm maximum diameter
T3a—Without bone invasion
T3b—With bone invasion
The symbol m added to the appropriate T category indicates multiple tumors.
N: Regional lymph nodes (RLN)[b]
N0—No evidence of regional lymph node involvement
N1—Movable ipsilateral nodes
N1a—Nodes not considered to contain growth[c]
N1b—Nodes considered to contain growth[c]
N2—Movable contralateral or bilateral nodes
N2a—Nodes not considered to contain growth[c]
N2b—Nodes considered to contain growth[c]
N3—Fixed nodes
M: Distant metastasis
M0—No evidence of metastasis
M1—Distant metastasis (including distant nodes) detected; specify site or sites

Stage Grouping

I	T	N	M
	T1	N0, N1a, or N2a	M0
II	T2	N0, N1a, or N2a	M0
III[d]	T3	N0, N1a, or N2a	M0
	Any T	N1b	
IV	Any T	Any N2b or N3	M0
	Any T	Any N	M1

[a]Modified from document VPH/CMO/80.20, World Health Organization, 1980.
[b]Regional lymph nodes are the cervical, submandibular, and parotid nodes.
[c](–), Histologically negative; (+), histologically positive.
[d]Any bone involvement.

FIG. 18.31 Appearance of a fibromatous epulis surrounding the maxillary incisors in a dog.

BOX 18.4 Types of Oral Tumors

Malignant

- Malignant melanoma
- Squamous cell carcinoma
- Fibrosarcoma
- Osteosarcoma
- Lymphosarcoma
- Mast cell tumor
- Gingival hemangiosarcoma
- Neurofibrosarcoma
- Anaplastic sarcoma
- Chondrosarcoma
- Myxosarcoma
- Invasive nasal tumors
- Transmissible venereal tumor
- Histiocytic neoplasia

Benign

- Epulides
- Viral papillomatosis
- Odontogenic tumors: adamantinoma[a] (ameloblastoma)
- Fibroma
- Peripheral giant cell granuloma
- Chondroma
- Lipoma
- Hemangioma
- Plasma cell tumor

[a]Biological behavior is unpredictable.

BOX 18.5 Characteristics of Oral Malignant Melanomas

- Most common malignant oral tumor in dogs (approximately 20%)
- Rare in cats
- Most common on gingiva
- More common in male dogs
- Mean age of affected animals is 9–11 years (average, 10.3 years)
- Breeds with pigmented oral mucosa, cocker spaniels, and German shepherds may be predisposed
- Metastasis is common
- Prognosis is poor; median survival is 8–9 months

BOX 18.6 Characteristics of Oral Squamous Cell Carcinomas

- Most common tumor in cats (approximately 70%)
- Second most common tumor in dogs (with fibrosarcoma) (approximately 15%)
- Occur on the gingiva, lip, tongue, or tonsil
- Biological behavior varies with location and species; regional lymph node involvement is common with tongue and tonsillar squamous cell carcinomas

BOX 18.7 Characteristics of Oral Fibrosarcomas

- Second most common malignant oral tumors in dogs (with squamous cell carcinoma)
- Occur most commonly on the gingiva and hard palate
- More common in large breeds (>20 kg) and male dogs
- Younger dogs may be affected (mean age <7 years)
- Locally invasive; high metastatic potential in dogs <2 years of age

BOX 18.8 Characteristics of Epulides

- Most common oral tumor in dogs (approximately 30%)
- Mean age approximately 8.2 years
- More common in large-breed dogs (>20 kg)
- Do not metastasize
- Acanthomatous epulis is most common form

masses, but they are often locally aggressive and sometimes difficult to differentiate histologically from SCC. They are the most common type of epulis and frequently infiltrate bone, causing lysis. Acanthomatous epulides most often occur rostral to the mandibular canine teeth. They are composed primarily of epithelial cells arranged in sheets and cords, intimately associated with the underlying stroma and invading bone. Wide surgical excision is recommended even though they are radiosensitive. They recur locally if not treated adequately.

Ameloblastomas (adamantinoma) are benign tumors that arise from the dental lamina. They usually occur in younger dogs and involve the rostral mandible. Ameloblastomas develop as intraosseous tumors and are locally invasive and nonmetastasizing. *Odontomas* are rare, benign odontogenic tumors that arise from the dental follicle and cause induction of both enamel and dentin in the lesion. *Dentigerous cysts* appear as closed cavities or sacs with one or more teeth embedded in the cyst wall. They arise within islands of odontogenic epithelium and are described as benign, nonneoplastic lesions; however, they may represent an early stage of malignant epithelial tumor development.

Oral papillomas are benign tumors caused by a papillomavirus or papovavirus in young dogs. They occur primarily on the buccal and gingival mucosa, appearing as multiple gray-white pedunculated lesions. Papillomas spontaneously regress within 2 months in most dogs as immunity to the viral agent develops. Surgical resection is necessary only to confirm the diagnosis or in dogs that are dysphagic as a result of many large papillomas. Some animals have been treated with autogenous vaccines, but this is not recommended because malignant skin tumors may develop at the site of inoculation.

DIAGNOSIS

Clinical Presentation

Signalment

Breeds that appear to be predisposed to oral tumors include boxers, German shepherds, golden retrievers, cocker spaniels, poodles, German shorthaired pointers, collies, old English sheepdogs, and Weimaraners. Oral tumors are generally observed in middle-aged or older animals (older than 7–10 years). Exceptions to this include oral papillomatosis (typically occurring in dogs 1 year old or younger) and fibrosarcoma (mean age of occurrence of approximately 5 years).

Melanomas are more common in males (the reported male to female ratio has been as high as 4:1), with an average age of onset of 9 to 11 years. Breeds with pigmented oral mucosa, cocker spaniels, and German shepherds appear to have an increased incidence. SCCs usually occur in cats of either sex older than 10 years of age. Nontonsillar SCCs are most common in small-breed dogs of either sex between 8 and 10 years of age. Fibrosarcomas occur more commonly in large-breed dogs, particularly Doberman pinschers and golden retrievers. Males are affected more often than females (2:1). For fibrosarcomas the age of onset is younger (4–5 years) in large-breed dogs (more than 25 kg) than in smaller dogs (8 years or older). Oral osteosarcomas most often affect the mandible and occur in females more often than males (1.8:1). Fibromatous epulides are common in boxers.

NOTE Remember, not all melanomas are pigmented; amelanotic melanomas may be easily confused with other oral tumors.

History

Oral tumors are often large when recognized by an owner; however, some are found during yearly examinations or routine dentistry. Neoplasia should be suspected during dentistry if teeth are excessively mobile. Affected animals are frequently presented for evaluation of a visible mass, oral bleeding, difficulty eating, or halitosis. Anorexia, weight loss, loose or displaced teeth, salivation, facial deformity, and/or nasal discharge may also be noted. A history of recent tooth extraction may precede rapid growth of a mass at the extraction site. Clinical signs in dogs with tonsillar SCC may be related to oropharyngeal obstruction (i.e., dyspnea, anorexia, cough, or drooling), and a large ventral cervical swelling may be associated with lymph node metastasis.

Physical Examination Findings

Oral tumors arising from the rostral portion of the oral cavity are generally easily visualized; however, examination for tonsillar or caudal oropharyngeal tumors may require sedation or anesthesia. General anesthesia is often necessary to define the extent of disease. The surface of growing neoplasms may appear ulcerated, infected, and necrotic. Regional lymph nodes should be evaluated for evidence of enlargement, nodularity, and adherence to surrounding tissue.

NOTE When you first observe the tumor, measure it, record its location, and photograph it, particularly if treatment is to be delayed.

Diagnostic Imaging

Three-view thoracic radiographs or thoracic CT should be performed to look for pulmonary metastasis and concurrent pulmonary or cardiovascular disease. Ventrodorsal and both lateral radiographic views should be taken because tumors may be missed on a single lateral view due to recumbent atelectasis. Further therapy may not be indicated if metastasis is noted. Skull radiographs, CT, or MRI are performed with the patient under general anesthesia and are used to assess the extent of the lesion and bony involvement. Malignant tumors show a tendency for irregular, destructive, or aggressive bone loss, whereas bone production predominates in benign tumors. Contrast enhancement with adjacent osteolysis is common on CT studies of cats with oral SCC.

Laboratory Findings

Laboratory examination of animals with oral tumors should include a CBC, chemistry profile, and bleeding time. In older dogs and those with evidence of renal or cardiac disease, urinalysis and ECG are appropriate. Other than anemia of chronic blood loss, abnormalities related to the tumor are uncommon.

DIFFERENTIAL DIAGNOSIS

Granulation tissue secondary to foreign body, trauma, or infection; eosinophilic granuloma complex; and gingival hyperplasia and dental disease are primary differential diagnoses. Fluctuant swellings in the sublingual and pharyngeal area may be salivary mucoceles (see p. 358) or congenital cysts. Other differential diagnoses include nasopharyngeal polyp, osteomyelitis, and feline plasma cell gingivitis-pharyngitis. Cytologic or histologic analysis of masses may be necessary to differentiate neoplastic from some nonneoplastic oral lesions.

MEDICAL MANAGEMENT

Cytologic analysis of the tumor and draining lymph nodes is indicated before surgery. Excisional or incisional biopsy (see p. 633) is usually necessary to determine the prognosis and treatment. Treatment modalities other than surgery that have been used alone or in combination for oral tumors include radiotherapy, hyperthermia, chemotherapy, cryosurgery, immunotherapy, and photodynamic therapy. SCCs are radiosensitive and are successfully treated by radiotherapy. Piroxicam is sometimes helpful in treating SCC. Fibrosarcomas are radioresistant. Melanomas may be sensitive to radiotherapy, but distant metastasis frequently renders it ineffective. Radiation-induced tumors occur in up to 20% of the irradiated sites. A vaccine for canine melanoma is available, but of uncertain efficacy. Refer to an oncology text for additional information about these techniques.

SURGICAL TREATMENT

Treatment protocols must be based on the tumor type, site, extent, and stage; the patient's age and health; and treatment limitations. Early, aggressive therapy offers the best chance of success in treating oral malignancies. Aggressive surgical excision (e.g., mandibulectomy, maxillectomy) may be curative for gingival tumors if resection is completed before metastasis occurs. Because most gingival tumors invade bone, mandibulectomy or maxillectomy is usually necessary. Shaving the tumor down to bone invariably results in recurrence. Caudal tumors and those crossing the midline may be unresectable, or the area may be difficult to reconstruct successfully with flaps. Excision of the middle and caudal maxilla is limited by the size of mucosal flap that can be created. Mandibulectomy is limited by the medial and caudal extent of the tumor (see p. 336). Tumors invading the sublingual musculature and caudal pharynx may not be resectable. Tumor extension into the lip necessitates full-thickness lip resection with partial maxillectomy (see p. 335) or mandibulectomy.

NOTE Owners often think that their pets will be unacceptably disfigured after major oral resections. It may help to show them pictures of animals that have had procedures similar to the one you are recommending for their pet.

Preoperative Management

Perioperative antibiotics are indicated for oral tumors, which often have focal areas of necrosis and infection (see p. 331). Debilitated animals may require IV fluids and enteral or parenteral hyperalimentation before surgery.

Anesthesia

General anesthetic protocols for animals undergoing oral surgery are given on p. 331 (see Table 18.1). Sedation or general anesthesia may be required for fine needle aspiration, depending on the location of the tumor and the animal's disposition. General anesthesia is generally recommended for biopsy because of subsequent bleeding. Surgical excision of tumors requires general anesthesia with inhalant anesthetics. Because most affected animals are old, isoflurane is the inhalant anesthetic of choice. Cuffed endotracheal tubes, preferably guarded to prevent kinking, should be used. Intubation may be accomplished through a pharyngotomy (see p. 1044) or tracheotomy (see p. 842) if necessary to facilitate surgery. Nerve blocks provide analgesia and reduce the amount of other anesthetic drugs needed during surgery (see Chapter 13).

NOTE Sterile sponges should be placed in the caudal oropharynx to prevent aspiration of blood; however, remember to remove these sponges prior to waking the patient.

Surgical Anatomy

The surgical anatomy of the oropharynx is discussed on p. 333.

Positioning

Mandibular lesions are usually resected with the patient in lateral recumbency. Maxillary lesions may be resected with the patient in lateral or ventral recumbency.

SURGICAL TECHNIQUE

AP Identify the soft tissue and/or bone to be resected and remove it according to the techniques for maxillectomy, mandibulectomy, glossectomy, and tonsillectomy described on pp. 335 to 340. Radiographing the excised segment before wound closure may help determine whether adequate bone was removed; however, tumor growth up the mandibular foramen may necessitate wider margins than radiographic evaluation of bone destruction might predict. Intraoperative cytologic evaluation is often more beneficial in determining the adequacy of resection. Submit excised tissues for histologic analysis. If additional bone is excised, mark the caudal border to allow determination of whether additional resection is needed (i.e., if this margin contains tumor). Concurrent or prior excision of regional lymph nodes (mandibular, parotid, and medial retropharyngeal) is important in staging the disease.

POSTOPERATIVE CARE AND ASSESSMENT

Sponges should be removed from the caudal oropharynx, and the oral cavity and nasopharynx suctioned before anesthetic recovery. Analgesics (i.e., hydromorphone, butorphanol, or buprenorphine; see Table 13.2) should be provided postoperatively. Soft food and water may be offered the day after surgery. IV fluids may be discontinued when the animal maintains hydration by drinking. Dogs are seldom reluctant to eat after surgery; however, cats may require 2 to 3 days to adapt. The patient should be reevaluated 1 and 2 weeks after surgery to assess healing. Sutures are usually extruded or sloughed 2 to 4 weeks postoperatively. Facial swelling usually resolves within 3 to 7 days after surgery. Thoracic radiographs may be taken at 3, 6, and 12 months postoperatively to evaluate for metastases, and oral examinations should be performed regularly to look for tumor recurrence. After partial maxillectomy or

mandibulectomy, excessive dental tartar may accumulate on the teeth of the opposite dental arch. Owner satisfaction after partial mandibulectomy or maxillectomy is usually good.

COMPLICATIONS

Tumor recurrence and dehiscence are the most common complications after major oral reconstruction. Overall, tumor recurrence after resection with tumor-free margins is less than 40%. Recurrence in these cases is due to the presence of a multifocal tumor, development of a new tumor, or inadequate pathologic assessment. Dehiscence occurs in less than one-third of cases with major reconstruction. Suture line tension, excessive use of electrocautery, ischemic necrosis of a mucosal flap, excessive flap movement, infection, and tumor recurrence are major causes of dehiscence. Dehiscence occurs more often if surgery is combined with radiotherapy or chemotherapy because these adjuvant therapies may inhibit wound healing.

PROGNOSIS

The prognosis for oral tumors depends on the type of tumor, its biological behavior, and the stage of disease. The prognosis is good for benign oral tumors, whereas the prognosis for malignant oral tumors is poor. The best chance for cure or control of malignant or benign oral tumors is surgical resection and reconstruction. Elimination of local disease is essential. Overall, the 1-year survival rate is approximately 50% with a median survival time of 8 months for dogs with malignant maxillary tumors. For malignant mandibular tumors, the overall 1-year survival rate is 45% with a median survival time of 11 months. Dogs with tumors rostral to the maxillary canine or the first mandibular premolar teeth have a better prognosis. This may be because of earlier recognition, altered tumor behavior based on location, or prevalence of tumor type.

SCCs respond best to surgery because they are localized and have not usually metastasized. In dogs, more than 50% of SCCs are controlled locally for a year or more, and the mean survival time is approximately 12 to 18 months. Cats with oral SCC have a poor prognosis, with a median survival time of approximately 2 months regardless of the form of therapy. Fibrosarcomas are localized but locally aggressive and difficult to resect completely. Most recur within the first year after resection, and 1-year survival rates vary from 20% to 50%. Melanomas have the poorest prognosis because they metastasize early. Fewer than 20% of affected animals are disease-free 1 year after surgery. Median survival times vary from 8 to 10 months. Tumors arising from the tongue have a poor prognosis. They are controlled locally in only approximately one-fourth of animals 1 year after resection or radiation therapy. Osteosarcoma of the mandible treated with surgical excision and in some cases chemotherapy was associated with a 58% metastatic rate, most often to the lungs (69%) and also to the lymph nodes, spinal column, long bones, and skin.[4] Median survival time was 525 days, with 50% surviving 1 year. Higher tumor grade was associated with a greater metastatic rate and lower percentage surviving 1 year.

SALIVARY MUCOCELES

DEFINITIONS

A **salivary mucocele** *(sialocele, salivary cyst, honey cyst)* is a collection of saliva that has leaked from a damaged salivary gland or duct and is surrounded by granulation tissue. A **cervical mucocele** is a collection of saliva in the deeper structures of the intermandibular space, the angle of the jaw, or the upper cervical region. **A sublingual mucocele (ranula)** is a collection of saliva in the sublingual tissue caudal to the openings of the sublingual and mandibular ducts, and a **pharyngeal mucocele** is a collection of saliva in the tissues adjacent to the pharynx. A **zygomatic mucocele** is a collection of saliva ventral to the globe. **Complex mucoceles**, consisting of two or more types, occur in some animals. **Marsupialization** is the process of incising a mucocele and suturing the edges to the mucosa. The interior of the mucocele suppurates and gradually closes by granulation.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Tearing of a salivary gland or duct results in leakage of saliva into the surrounding tissue. Salivary mucoceles are not cysts. Cysts are cavities lined by epithelium, whereas the granulation tissue lining of a mucocele is produced secondary to inflammation caused by free saliva in the tissues. The cause of salivary mucoceles is rarely identified, although blunt trauma (choke chains), foreign bodies, and sialoliths have been suggested. The sublingual salivary gland is most commonly involved. Saliva takes the path of least resistance, most commonly accumulating in the cranial cervical or intermandibular tissue (Fig. 18.32), sublingual tissue (Fig. 18.33), or pharyngeal tissue (Fig. 18.34). Saliva irritates the tissue and causes inflammation. The swelling may be firm and painful initially, but the animal is usually asymptomatic. Granulation tissue forms in response to the inflammation and prevents saliva from migrating further. The diagnosis of salivary mucocele is based primarily on the history, clinical signs, and cytologic findings. Radiographs may determine which gland is involved, and histopathologic examination is diagnostic.

DIAGNOSIS

Clinical Presentation

Signalment

Dogs are more frequently affected than cats. All breeds are susceptible, but some reports indicate that poodles, German shepherds, dachshunds, and Australian silky terriers are more commonly affected. There is a slight predisposition for males to be affected. An animal of any age may develop a mucocele.

History

Clinical signs depend on the location of the mucocele. Most dogs have cervical or intermandibular mucoceles and are asymptomatic. These animals are usually presented for treatment with a history of a gradually developing, fluctuant, painless mass. Patients with a sublingual mucocele (i.e., ranula) may have abnormal prehension and oral bleeding, which is caused by trauma during chewing. Respiratory distress and dysphagia are common in patients with pharyngeal mucoceles due to the sublingual salivary gland. Swelling in the oropharyngeal area may cause abnormal tongue movements and may interfere with eating or breathing, and swelling in the orbital area with zygomatic mucoceles may cause enophthalmos and divergent strabismus. Dogs with pharyngeal mucoceles can have concurrent cervical mucoceles.[5]

FIG. 18.32 Cervical mucocele in a dog. (A) Appearance of the mucocele on physical examination. (B) Viscosity of material aspirated from a cervical mucocele.

FIG. 18.33 Intraoperative appearance of a sublingual mucocele (ranula) located lateral to the tongue in the sublingual tissue. Note the ulcer from mucosal entrapment between teeth.

NOTE Ask the owners where they first noticed the swelling, because this may help you determine the affected side.

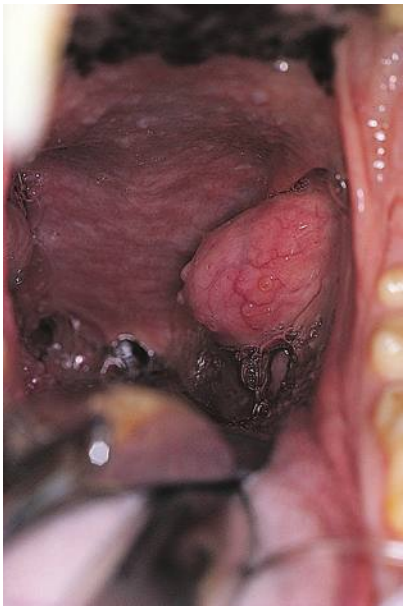

FIG. 18.34 Pharyngeal mucocele in a dog.

Physical Examination Findings

The parotid and mandibular glands are easily palpated. The sublingual gland is occasionally palpable in a cooperative or sedated patient. Palpation of the glands is expected to be normal and without discomfort. Most mucoceles are soft and fluctuant, whereas tumors and abscesses are generally firm. Mucoceles are painless except during the acute phase of swelling. It is sometimes difficult to identify the affected side when mucoceles are located on the ventral midline or intermandibular space. Examining these animals in dorsal recumbency often allows the mucocele

to gravitate to the affected side. Palpation of some cervical mucoceles causes the sublingual tissues to bulge on the affected side. Concurrent sublingual and cervical mucoceles originate from the side where the sublingual mucocele is found. Blood-tinged saliva may occur in patients with sublingual mucoceles because teeth often traumatize the mucocele. Periorbital facial swelling, enophthalmos, and periocular pain are signs of a zygomatic mucocele. Optic neuropathy may occur secondary to pressure from zygomatic mucoceles.

NOTE Animals with pharyngeal mucoceles are often presented in acute respiratory distress. Institute appropriate therapy rapidly or they may die!

Diagnostic Imaging

Survey radiographs rarely help, except in cases involving sialoliths, some foreign bodies, or neoplasia. Thoracic radiographs are indicated to evaluate for metastasis if neoplasia is suspected. Sialography (i.e., injecting iodinated, water-soluble contrast agent into a salivary duct) to confirm the diagnosis or determine the site of origin is difficult and usually unnecessary. In some cases, particularly pharyngeal mucoceles, cross-sectional imaging can be used to better evaluate the location and extensiveness of the lesion. Advanced imaging is important for diagnosing zygomatic salivary disease.[6] Fluid can be differentiated from tissue, and aspirates can be taken for cytologic evaluation to differentiate between infection and mucocele.

Laboratory Findings

Laboratory abnormalities are rare. Salivary gland function and duct patency can be evaluated by placing a drop of topical ophthalmic atropine solution on the tongue to stimulate saliva flow; however, it may be difficult to distinguish flow from individual ducts. Paracentesis should be performed under aseptic conditions to prevent infection of the mucocele. Aspiration of a clear, yellowish, or blood-tinged, ropy, mucoid fluid with a low cell count is consistent with saliva (see Fig. 28.32B). Staining a smear with a mucus-specific stain, such as periodic acid-Schiff, confirms the presence of saliva. An elevated white blood cell count may indicate concurrent sialoadenitis.

DIFFERENTIAL DIAGNOSIS

Sialoadenitis, sialadenosis, salivary neoplasia, sialolith (calcium phosphate or carbonate), cervical abscess, foreign body, hematoma, cystic or neoplastic lymph nodes, tonsil cyst, thyroglossal cyst, cystic Rathke's pouch, or branchial cysts may cause swellings in the same region as mucoceles. Occasionally mucoceles may be difficult to distinguish from cysts or tumors. Histopathologic examination is necessary to diagnose salivary gland tumors and to differentiate a congenital cyst from a mucocele. Congenital cysts have an epithelial lining, whereas mucoceles are lined by granulation tissue.

Salivary neoplasia presents as a mass in older animals and may be associated with halitosis, weight loss, dysphagia, exophthalmos, Horner's syndrome, sneezing, and dysphonia. The mandibular gland is most commonly affected in cats and the parotid in dogs, and simple adenocarcinoma is the most common histologic type.

Animals presenting with chronic oropharyngeal abscesses typically have draining tracts, cervical swelling, dysphagia, and oral pain. A history of fighting, penetrating trauma, or chewing on sticks is common with abscesses.

MEDICAL MANAGEMENT

Emergency aspiration of the mucocele may be necessary for animals in respiratory distress (especially pharyngeal mucoceles). Repeated drainage or injection of cauterizing or antiinflammatory agents does not eliminate mucoceles; however, it complicates subsequent surgery by leading to abscessation or fibrosis. Use of a sclerosing agent injected into the mucocele has been suggested, but this procedure is rarely performed.[7] Mucoceles rarely resolve without surgery.

SURGICAL TREATMENT

Complete excision of the involved gland-duct complex and drainage of the mucocele are curative. The side of origin of the mucocele may be determined by oral examination, palpation, sialography, or exploration of the mucocele.

NOTE If you are having trouble identifying the affected side in an animal with a cervical mucocele, place the animal on its back. The contents of the mucocele often gravitate to the side of the affected gland.

Preoperative Management

Animals with pharyngeal mucoceles may be presented for treatment in acute respiratory distress and rapid intubation may be necessary. Intubation may not be possible through the mouth, and a temporary tracheostomy may be required. These animals are generally stable once they have been intubated, and surgical excision of the salivary glands and drainage of the mucocele can be delayed while further diagnostics are performed if necessary. IV antibiotics may be given at induction of anesthesia but are not essential.

Anesthesia

Most animals undergoing salivary gland excision for mucoceles are healthy, and a variety of anesthetic protocols can be used (see Table 18.1). General anesthetic recommendations for animals undergoing oral surgery (i.e., for ranulas or pharyngeal mucoceles) are provided on p. 331.

Open-mouth breathing, abducted forelimbs, labored breathing, and restlessness indicate moderate to severe respiratory distress that may require emergency therapy. Minimal restraint should be used with severely dyspneic patients, and they should be allowed to maintain the position in which they feel most comfortable. Premedication with any drug that causes hypoventilation is contraindicated (see Box 28.2 on p. 834). Additionally, every attempt should be made to minimize stress to the patient prior to induction. Oxygen support, even while placing an IV catheter, may be necessary. Pulse oximetry with a sensor that can be secured to the tail can be especially helpful with perioperative monitoring of patients in respiratory distress. Prior to induction, the anesthesia provider should be prepared with airway devices, anesthesia machine, and monitors, as well as induction and emergency drugs. Preoxygenating the patient for 3 to 5 minutes prior to induction with flow-by or a loose face mask should be followed with a rapid induction and intubation. Propofol is recommended

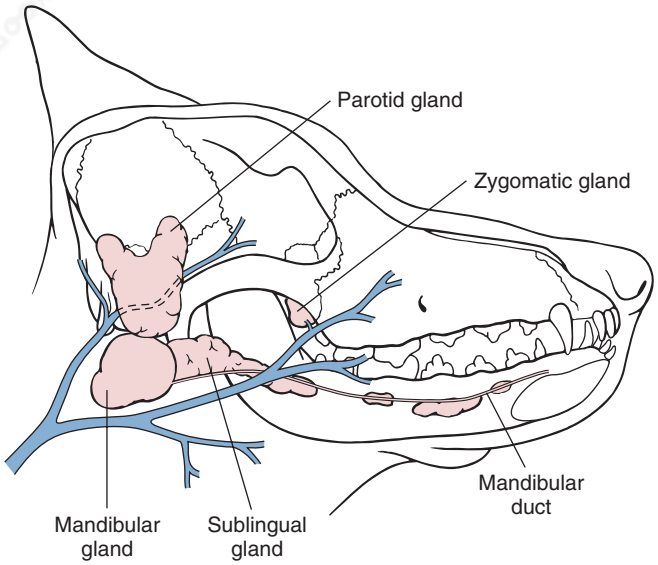

FIG. 18.35 Surgical anatomy of the salivary glands. The parotid gland lies ventral to the ear canal. The mandibular gland is ventral to the parotid gland, lying between the maxillary and linguofacial veins. The sublingual gland follows the rostral course of the mandibular duct toward the oral cavity. The zygomatic gland is protected by the zygomatic arch.

for induction because it has a rapid onset of action and is short-acting. Oral intubation may be difficult in patients with large pharyngeal mucoceles (discussed previously), and placement of the endotracheal tube by means of tracheostomy often is necessary to allow adequate visualization of the lesion. Once intubation has been accomplished, a more thorough exam may be done.

Surgical Anatomy

Dogs and cats have four major pairs of salivary glands of surgical significance (Fig. 18.35). They are the parotid, mandibular, sublingual, and zygomatic glands. The parotid gland is a triangular-shaped serous gland located ventral to the horizontal ear canal. Numerous arteries, veins, and nerves are closely associated with the medial aspect of the gland. The parotid duct papilla is located on the mucosal surface of the cheek at the level of the upper carnassial tooth (fourth premolar). The mandibular gland is large and ovoid and lies within a fibrous capsule, caudal and ventral to the parotid gland. It is located between the linguofacial and maxillary veins as they merge to join the external jugular vein. The mandibular duct runs with the sublingual gland toward the floor of the mouth and opens on a small papilla lateral to the rostral border of the frenulum (Box 18.9). The sublingual gland is divided into monostomatic and polystomatic portions. The monostomatic portion originates on the rostroventral border of the mandibular gland. The ducts from this portion of the sublingual gland course with the mandibular duct but often open on separate papillae. The polystomatic portion is divided into several loosely connected lobules that surround the mandibular duct and lie immediately beneath the oral mucosa, secreting directly into the oral cavity. The zygomatic gland, an irregularly ovoid gland, is located on the floor of the orbit ventrocaudal to the eye and medial to the zygomatic arch. The zygomatic gland has several ducts that run ventrally and open on a fold of mucosa lateral to the last upper molar tooth. The major zygomatic duct can usually be identified at this location, approximately 1 cm caudal to the parotid papilla.

BOX 18.9 Oral Openings of the Salivary Gland Ducts

Parotid Duct
- Labial mucosa at level of upper carnassial tooth

Mandibular Duct
- Papilla lateral to the rostral border of the frenulum

Sublingual Duct
- Opens with the mandibular duct near the lingual frenulum

Zygomatic Gland
- Lateral to the last upper molar tooth

Positioning

Salivary gland excision is performed with the animal in lateral recumbency. Ventral recumbency and maximum opening of the mouth facilitate marsupialization of pharyngeal mucoceles and ranulas.

SURGICAL TECHNIQUES

Mandibular and Sublingual Salivary Gland Excision

The mandibular and sublingual salivary glands are excised together because the sublingual gland is intimately associated with the mandibular salivary gland duct; removal of one would traumatize the other. Removal of glands on the involved side is all that is necessary for mucocele resolution; however, both pairs of mandibular and sublingual glands may be resected without risk of xerostomia. If it is not clear from which side the mucocele originated, make a stab incision in the mucocele and digitally palpate the lumen. The unaffected side is rounded and smooth. The affected side has a tract or tunnel toward the site of leakage.

Position the patient in lateral recumbency. Place a pad under the neck to rotate the ventral aspect dorsally and fix the neck in an extended position. Locate the mandibular salivary gland between the linguofacial and maxillary veins as they join the external jugular vein (Fig. 18.36A). Incise the skin, subcutaneous tissue, and platysma muscle from the angle of the mandible caudally to the external jugular vein to expose the fibrous capsule of the mandibular gland (see Fig. 18.36B). Avoiding the branch of the second cervical nerve that crosses the capsule, incise the capsule and dissect it away from the mandibular and monostomatic sublingual salivary glands. Ligate the artery (branch of the great auricular artery) and vein as they are encountered on the dorsomedial aspect of the gland. Continue dissecting cranially, following the mandibular duct, sublingual duct, and polystomatic sublingual glands toward the mouth (see Fig. 18.36B). Incise the fascia between the masseter and digastricus muscles. Expose the entire mandibular and sublingual salivary gland complex by retracting the digastricus muscle and applying caudal traction on the mandibular gland. If necessary, perform digastricus muscle myotomy or tunnel the caudal sublingual gland duct complex under the digastricus muscle to improve visualization. Dissect (digital and sharp) rostrally until the lingual branch of the trigeminal nerve is identified and only ducts remain in the complex. Avoid traumatizing the lingual or hypoglossal nerves. Try to identify the gland-duct defect causing the mucocele, because failure to identify

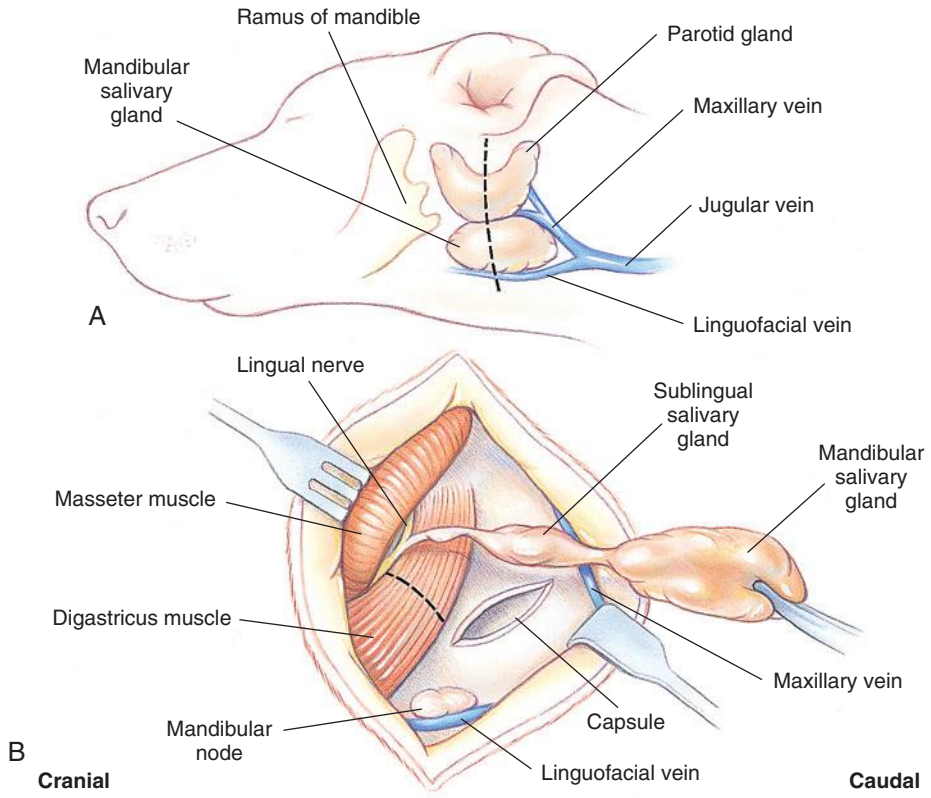

FIG. 18.36 Excision of the mandibular and sublingual salivary glands. (A) Make an incision ventral to the external ear canal and over the mandibular salivary gland at the junction of the linguofacial and maxillary veins. (B) Dissect the mandibular salivary gland after incising the capsule. Apply caudal traction on the mandibular gland and dissect the duct and sublingual gland until the lingual nerve has been identified. Transect the digastricus muscle *(dashed line)* to aid dissection if necessary.

FIG. 18.37 Mandibular and sublingual glandular tissue removed from the dog in Fig. 18.32.

this defect may indicate that the mucocele originated from the contralateral gland-duct complex (Fig. 18.37). Ligate and transect the mandibular sublingual gland-duct complex just caudal to the lingual nerve.

Traction on the gland-duct complex may cause the ducts to tear. If this occurs near the point of proposed transection or on the oral aspect of the gland-duct defect, no further dissection is needed. However, if the tear occurs before the gland-duct defect or when the defect has not yet been identified and glandular tissue is identified oral to the tear, further resection of glandular tissue is recommended to prevent recurrence.

Lavage the surgical site before closure. Appose the digastricus muscle if it has been incised with horizontal mattress or cruciate sutures. Close the dead space with a few sutures in the capsule and deep tissue. Routinely appose superficial muscles, subcutaneous tissue, and skin. Following excision, submit the glands and ducts to rule out neoplasia and submit a portion of the mucocele wall to rule out congenital cysts.

Drain cervical mucoceles by making a stab incision at the most dependent point; place a closed suction or Penrose drain if desired. Protect the drain with an absorbent bandage. Change the bandage and cleanse discharge from the neck as needed to prevent excoriation of the skin. Maintain the drain for 1 to 5 days, removing it when there is minimal discharge. Allow the stab incision to heal by second intention. Redundant skin resumes its normal appearance within several weeks. *Drain sublingual mucoceles (ranulas) by excising an elliptical, full-thickness section of the mucocele wall. Suture the granulation tissue lining to the sublingual mucosa (marsupialization) to encourage drainage for several days (Fig. 18.38). Drain pharyngeal mucoceles by aspiration or marsupialization. Excise redundant pharyngeal tissue to prevent airway obstruction after the mucocele has been evacuated.*

Marsupialized ranulas contract and heal quickly by second intention. After bilateral mandibular and sublingual salivary

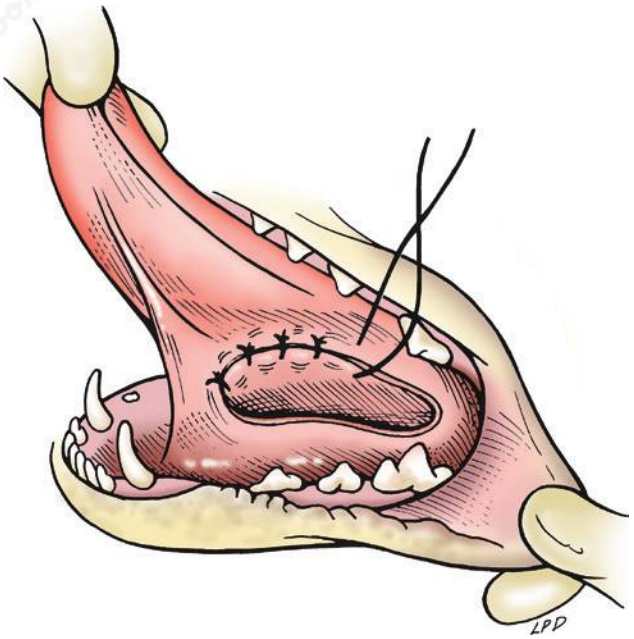

FIG. 18.38 Marsupialization of a ranula. After excising an elliptical piece of mucosa and granulation tissue from the mucocele wall, suture the mucosa to the lining of the mucocele.

gland excision, dogs still have sufficient saliva to adequately moisten their food.

Zygomatic Gland Excision

AP Zygomatic gland excision is required for zygomatic mucoceles, unresponsive infections, inflammatory conditions, and neoplasia.

Position the patient in lateral or ventral recumbency. Protect the animal's eye from irritants with ophthalmic ointment. Incise the skin and subcutaneous tissues over the dorsal rim of the zygomatic arch. Incise the palpebral fascia, retractor anguli oculi muscle, and orbital ligament, and elevate them dorsally with the skin and globe. Further expose the gland by partly removing the zygomatic arch with rongeurs or by osteotomy. Retract the globe dorsally to expose the periorbital fat and underlying zygomatic gland. Remove the gland by blunt dissection (the gland is friable). Avoid the ventrally located anastomotic branch between the deep facial and external ophthalmic veins. Drain the mucocele if present. If possible, replace the zygomatic arch by securing the bone with suture placed through predrilled holes. Lavage the area and appose the palpebral fascia to the zygomatic periosteum with sutures. Close subcutaneous tissues and skin.

Parotid Gland Excision

AP Parotid gland excision is occasionally performed for neoplasia, fistula, chronic infection, or mucocele. The triangular-shaped gland is located at the base of the auricular cartilage.

Position the patient in lateral recumbency. Incise the skin from 1 to 2 cm ventral to the external acoustic meatus to a point midway between the ramus of the mandible and the bifurcation of the jugular vein. Incise the platysma muscle to expose the parotidoauricularis muscle, vertical ear canal, and parotid salivary gland. Sever and retract the parotidoauricularis muscle from its vertical ear canal attachment. Ligate and divide the caudal auricular vein. Begin dissection of the parotid gland at its dorsocaudal angle. Separate the parotid from the mandibular gland ventrally. Continue dissection between the gland and the vertical ear canal. Avoid traumatizing the facial nerve at the base of the horizontal ear canal. Ligate and divide the superficial temporal vein (a branch of the maxillary vein) coursing through the gland. Cauterize or ligate small vessels on the gland's medial surface. Ligate and transect the parotid duct as it leaves the gland. Lavage the area. Reappose the parotidoauricularis muscle. Complete the closure by apposing subcutaneous tissues and skin. Ligation of the parotid duct may be an alternative treatment for parotid mucoceles or fistulae. Ligating the duct proximal to the disruption, near the body of the gland, causes glandular atrophy.

POSTOPERATIVE CARE AND ASSESSMENT

Histologic assessment of the excised gland rules out neoplasia as a cause of the mucocele. Change bandages daily if a Penrose drain has been placed. Depending on the amount of drainage, remove the drain 24 to 72 hours after surgery or when drainage is minimal. Allow the drain site to heal by second intention. Soft food should be fed for 3 to 5 days after ranula marsupialization or drainage of pharyngeal mucoceles.

COMPLICATIONS

Postoperative complications after salivary gland resection are uncommon but may include seroma formation, infection, and mucocele recurrence. Seromas can form in the dead space created by removal of the glands; they typically resorb and do not need aspiration or drainage. Infection is rare if aseptic technique is used. Mucoceles recur if the side of mucocele origin was misdiagnosed or if an inadequate portion of the gland was excised. Regional lymph nodes are sometimes mistaken for salivary glands. Dissection may be difficult if the mucocele was previously infected or injected. Attention to anatomic detail during surgery should minimize recurrence and complications associated with salivary gland excision.

PROGNOSIS

In rare cases a mucocele resolves without surgery. The prognosis is excellent if the disease is accurately diagnosed and excision is complete.

OROPHARYNGEAL PENETRATING TRAUMA

DEFINITION

Oropharyngeal penetrating trauma (OPT) is an injury of the oropharynx, palate, and adjacent cervical structures caused by foreign material.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Sticks are the most common material associated with OPT in dogs, likely because of play behavior. Direct trauma to the pharyngeal structures with bacterial inoculation of associated cervical structures results in local signs of inflammation and infection, with possible subsequent abscessation. Airway compromise resulting from local inflammation or systemic signs of septic shock can

occur, depending on the duration of time between injury and presentation and the severity of the associated infection.

DIAGNOSIS

Clinical Presentation

Signalment

Dogs are more likely to have OPT due to indiscriminate eating and play behaviors, compared with cats. Any breed of dog can be affected; however, commonly reported breeds include the border collie, mixed breed, English springer spaniel, and Labrador retriever. Cats, having a tendency to play and hunt, more commonly have string or needle foreign bodies than bones. Foreign bodies may occur in an animal of any age but are most common during the first 3 years of life.

History

Known trauma results in acute vocalization, gagging, and pawing at the mouth.

Physical Exam Findings

The most commonly observed clinical signs are ptyalism, depression, and pain with cervical flexion or opening the mouth; bloody saliva and collapse are less commonly seen. Mediastinal involvement may result in fever, dyspnea, and tachycardia.

Diagnostic Imaging

Emphysema and soft tissue swelling may be present on radiographs (Figs. 18.39 and 18.40). Wood material may not be readily identified radiographically, but ultrasound may show hyperechoic linear material with shadowing.

Laboratory Findings

Penetrating trauma and associated infection may result in neutrophilic leukocytosis. Hypoglycemia may be seen in young patients that are unable to eat or that have systemic inflammatory response syndrome (SIRS).

DIFFERENTIAL DIAGNOSIS

Mass lesions, strictures, esophagitis, cricopharyngeal dysfunction, and other possibilities of ptyalism and dysphagia should be ruled out. Thoracic radiographs should be performed to rule out pneumomediastinum (see Fig. 18.40), pneumothorax, and/or pleural effusion if concurrent esophageal trauma is suspected.

SURGICAL TREATMENT

Surgical exploration of the oropharynx and neck are done via an oral and ventral cervical approach, respectively. One study used rigid endoscopy for minimally invasive removal of foreign material via the original entry tract.[8] Fluid irrigation was used to dilate the original wound and tract during foreign body extraction using flexible instruments via the endoscope instrument channel. Care should be taken to avoid pressurization of the irrigation solution; cervical swelling occurred in one of nine dogs, and the outcome was successful with no recurrences in any dog.

Preoperative Management

Therapy to correct significant dehydration and electrolyte and acid-base imbalances should be initiated before surgery. Prophylactic antibiotics should be given (see p. 331).

FIG. 18.39 Radiographs of a dog with known oropharyngeal penetrating trauma. (A) Lateral image showing emphysema surrounding the pharynx and esophagus. (B) Ventrodorsal image showing emphysema on the left side of the pharynx and esophagus *(arrows)*.

Anesthesia

Deep general anesthesia and/or muscle relaxants should be considered, as oropharyngeal stimulation results in vigorous responses and motion. Opioids (e.g., fentanyl, hydromorphone) obtund oropharyngeal reflexes and may also be administered.

Surgical Anatomy

The surgical anatomy of the pharynx, tongue, and esophagus is described on pp. 333 and 369.

SURGICAL TECHNIQUE

Oral wounds should be examined and foreign material removed if present. Subsequent debridement, lavage, and closure are done for pharyngeal wounds; however, not all palatal wounds require immediate closure (Fig. 18.41). Lingual abscessation has been reported following presumptive foreign body penetration of the

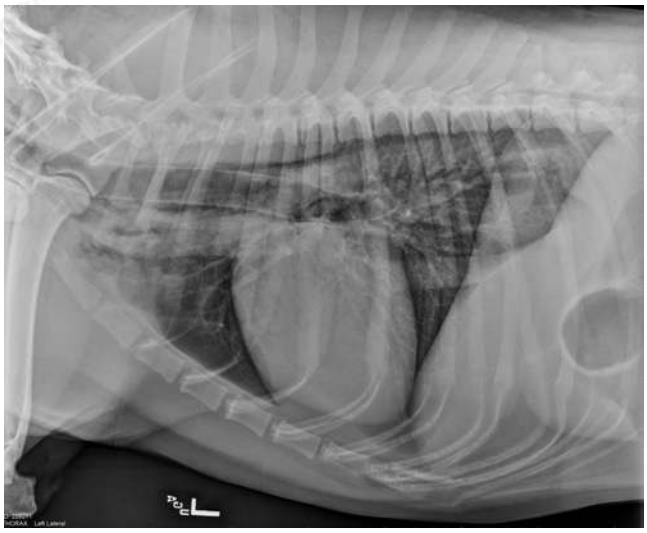

FIG. 18.40 Lateral thoracic radiograph of the dog in Fig. 18.39 showing cranial mediastinal emphysema.

FIG. 18.41 Left-sided palatal trauma of the dog in Figs. 18.39 and 18.40.

tongue, and drainage, debridement, and lavage should be done with consideration of drain placement in large, sublingual abscesses. *Explore subcutaneous cervical emphysema via a ventral midline approach, as described for esophageal foreign bodies (p. 378); take care to closely evaluate the retropharyngeal region. Place a closed suction drain if dead space cannot be closed because of anatomic considerations of neurovascular structures. Consider concurrent gastrostomy or esophagostomy tube placement for postoperative nutritional support.*

POSTOPERATIVE CARE AND ASSESSMENT

All patients should be observed carefully for 2 to 3 days for signs of pain and dehiscence. Analgesia with opioids and NSAIDs may be beneficial to reduce pain and encourage oral intake of food and water if a gastrostomy tube has not been placed. In such cases, small balls of canned food that require minimal prehension (representing preformed food boluses) are recommended. Repeat thoracic radiographs should be performed in animals with preoperative mediastinal widening or emphysema, pneumomediastinum, pneumothorax, and/or pleural effusion and in cases that fail to improve following surgery.

BOX 18.10 Possible Surgical Diseases of the Esophagus

- Foreign bodies
- Tumors
- Perforation
- Hiatal hernia
- Fistulae[a]
- Gastroesophageal intussusception[a]
- Diverticula[a]
- Cricopharyngeal achalasia[a]
- Strictures

[a]Rare.

COMPLICATIONS

Draining tracts, abscessation, and extension into the mediastinum can result from persistent infection or unidentified foreign material. Persistent clinical signs may signify remaining foreign material and the need for repeated evaluation and possible surgery.

PROGNOSIS

Early diagnosis and removal of a foreign material is essential, resulting in a good prognosis. Involvement of the mediastinum may cause significant inflammation and can be fatal.

Surgery of the Esophagus

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Esophagotomy is an incision into the esophageal lumen; **esophagectomy** is partial resection of the esophagus. **Esophagostomy** is the creation of an opening in the esophagus for placement of a feeding tube. **Regurgitation** is the passive expulsion of undigested food or fluid from the pharynx or esophagus. **Vomiting** is a centrally mediated reflex that causes expulsion of food or fluid from the stomach or intestines or both.

PREOPERATIVE CONCERNS

The esophagus carries food, water, and saliva from the pharynx to the stomach. Although less common than intestinal obstruction, esophageal obstruction associated with foreign bodies, strictures, or masses may occur in dogs and cats. Esophageal surgery may be indicated if function is interrupted by obstruction or perforation (Box 18.10).

Diagnosis of esophageal disorders is based on history, clinical signs, imaging, and/or endoscopy. The predominant clinical signs of esophageal pathology are typically regurgitation or dysphagia (Box 18.11). The history can be used to try to distinguish vomiting from regurgitation, but this is not always easy to do. Regurgitation is classically a passive process, whereas vomiting is usually preceded by salivation, vigorous retching, and abdominal contractions. Regurgitated material generally consists of undigested food

BOX 18.11 Clinical Signs of Esophageal Disease

- Regurgitation
- Coughing
- Dysphagia
- Dyspnea
- Ptyalism
- Fever
- Altered appetite
- Weight loss

and saliva, whereas vomited material may contain bile or digested blood. However, some animals vomit material that looks just like regurgitated material, and not all vomiting animals have the previously listed signs. If a patient has the classic signs of vomiting, then it is usually vomiting. However, if it does not have the classic signs of vomiting, it can be hard to know whether it is vomiting or regurgitating.

Some patients with esophageal disease present with respiratory signs (especially coughing, but also pulmonary crackles, mucopurulent nasal discharge, and/or fever suggestive of aspiration pneumonia) without any history of regurgitation or spitting up. Anytime a dog presents with pneumonia, aspiration must be a differential even if there is no history of throwing up. A patient with esophageal disease may have a normal, ravenous, or depressed appetite, and some patients lose weight.

Distention of the cervical esophagus may occur in patients with severe esophageal weakness. Some patients with severe weakness of the cervical esophagus will have a bellows-like effect; expirations will be associated with a ballooning in the neck when the cervical esophagus fills with air that is expelled from the thoracic esophagus. The same signs can sometimes be accomplished by compressing the thorax while the nostrils are occluded (this was an old way of diagnosing megaesophagus). Abnormalities of prehension and swallowing may sometimes be noted by observing the animal while it is eating. Masses and foreign bodies may sometimes be palpated in the cervical esophagus. Rarely, esophageal perforations may cause septic mediastinitis, producing fever, mediastinal or pleural effusion, respiratory distress, and eventual death.

Definitively diagnosing esophageal disease and then defining the type may require a variety of techniques. Thoracic and cervical radiographs, including the esophagus from the caudal portion of the oral cavity to the stomach, should be assessed for foreign bodies, esophageal dilatation with gas or liquid, periesophageal fluid or gas opacities, and aspiration pneumonia. The esophagus is not radiographically visible in most normal dogs and cats; however, small amounts of swallowed air may sometimes be seen in the cranial cervical and cranial thoracic esophagus of normal animals. Mediastinitis, pneumomediastinum, and/or pleural effusion suggest esophageal perforation. Barium contrast radiographs of the esophagus are often helpful if survey radiographs are nondiagnostic; a reasonable number of dogs with esophageal weakness do not have obvious abnormalities on plain radiographic studies. Contrast fluoroscopic examination of the esophagus allows evaluation of swallowing, motility, and gastroesophageal sphincter function. Fluoroscopy is needed to best assess motility. Barium sulfate paste may cause complications if aspirated. Liquid barium sulfate is the preferred preparation when performing esophagrams and is relatively safe if aspirated (unless it is aspirated in large quantities or if there is preexisting pneumonia). Food mixed with barium may reveal some partial obstructions that would be missed with liquid or paste barium sulfate.

BOX 18.12 Preoperative Management of Patients With Esophageal Disorders

- Withhold food: mature animals, 12–18 hours; pediatric animals, 4–8 hours
- Correct fluid, electrolyte, and acid-base imbalances
- Give prophylactic antibiotics (i.e., ampicillin, cephalosporins), if appropriate
- Support nutrition
- Treat esophagitis and aspiration pneumonia

BOX 18.13 Treatment of Esophagitis

Omeprazole (Prilosec)
1–2 mg/kg PO q12–24h

Esomeprazole (Nexium)
1 mg/kg IV q12–24h[a]

Pantoprazole (Protonix)
1 mg/kg IV q12–24h[a]

Metoclopramide (Reglan)
0.2–0.4 mg/kg PO, SC, or IV q8h

Cisapride (Pharmacy Compounded)
0.1–0.5 mg/kg PO q8–12h

Sucralfate[b] (Carafate Suspension, Not Tablets)
0.5–1 g PO q6–8h

[a]Dose is anecdotal.
[b]Carafate impairs absorption and/or reduces bioavailability of some drugs; give at different intervals.
IV, Intravenous; *PO,* orally; *SC,* subcutaneous.

NOTE Use aqueous iodinated contrast if esophageal perforation is suspected. Do not use barium sulfate in such cases. Nonionic iodinated contrast agents (such as iohexol or iopamidol) are the safest. Hypertonic iodinated contrast can cause fulminant pulmonary edema if aspirated.

Lateral body position typically used for restraint during esophagography prolongs transit time in the cervical esophagus and decreases the percentage of boluses producing primary esophageal peristaltic waves. Secondary waves are not affected by body position. Functional abnormalities of the esophagus are best evaluated with dogs in sternal recumbency during fluoroscopic examination of barium swallows.

Esophagoscopy is indicated if plain or contrast radiographs reveal what may be a mass or foreign body or if esophageal obstruction, tumor, hiatal hernia, or inflammation is suspected. During esophagoscopy, mucosal lesions may be identified and biopsied, and foreign bodies can be removed or advanced into the stomach. Esophagotomy may be performed as a diagnostic and therapeutic procedure if a definitive diagnosis cannot be made by other means (see p. 370). Esophagectomy and esophageal resection/anastomosis should be avoided, if possible.

Treatment for aspiration pneumonia, esophagitis, and nutritional debilitation should be initiated before surgery (Box 18.12). For mild esophagitis, antacids (e.g., proton pump inhibitors; Box 18.13) with or without gastric prokinetics (e.g., metoclopramide; see Box 18.13) are administered, and food and water

are withheld for 24 to 48 hours to reduce esophageal irritation. Water should be offered first. If there is no regurgitation, a low-fat, high-protein gruel that will enhance lower esophageal high-pressure zone tone, speed gastric emptying, and reduce reflux should be fed for 3 to 4 days. Soft food should be fed for an additional 5 to 7 days, and then the animal should be gradually returned to its normal diet. For moderate to severe esophagitis, a proton pump inhibitor (see Box 18.13) and more potent gastric prokinetic therapy (e.g., cisapride; see Box 18.13) are often necessary. Oral intake of food and water may need to be withheld for days in the case of very severe esophagitis. Hydration should be maintained with IV fluids; nutritional support may require a gastrostomy tube (see p. 97). Oral feeding with a low-fat gruel should be initiated as described for mild esophagitis and continued for 10 to 14 days. Oral administration of sucralfate suspension may help alleviate discomfort in patients with reflux esophagitis (see Box 18.13). If oral pain is so severe that the patient refuses even to swallow saliva, oral administration of viscous lidocaine (over the counter) may help. Antibiotics effective against oral contaminants (e.g., ampicillin, amoxicillin, clindamycin; Box 18.14) are of dubious effectiveness. Concurrent glucocorticoid therapy (e.g., prednisolone, 1.1 mg/kg given orally once daily) might reduce the risk of obstruction due to cicatrix secondary to severe esophagitis; however, the benefit of this therapy is dubious.

Treatment of aspiration pneumonia should be started before esophageal surgery, unless there is an esophageal foreign object, in which case the foreign object should be removed as soon as possible. If aspiration is observed while the animal is anesthetized, the airway should be suctioned to remove irritants. Fluid therapy is indicated for animals that are severely dyspneic or in shock. Nasal oxygen supplementation should be provided to dyspneic animals, and positive pressure ventilation may be needed in unresponsive patients. Bronchodilators (i.e., theophylline, aminophylline, terbutaline sulfate) may reduce bronchospasms and ventilatory muscle fatigue in these patients (see Box 18.14). Glucocorticoids such as dexamethasone (0.02 mg/kg IV) are rarely used and should only be considered if the animal acutely aspirates and is severely dyspneic. Expectorants (e.g., guaifenesin) are occasionally used in animals with productive coughs. Systemic antibiotic therapy is indicated in animals with pulmonary infection or sepsis. Broad-spectrum antibiotics (or combinations of antibiotics) effective against gram-negative and anaerobic bacteria should be used (e.g., clindamycin or ampicillin plus either enrofloxacin or amikacin; see Box 18.14). Culture and sensitivity should be done, if possible. Aerosol therapy and coupage facilitate both delivery of antibiotics to the respiratory tree and elimination of excessive respiratory secretions.

BOX 18.14 Treatment of Aspiration Pneumonia

Bronchodilators

Aminophylline

Dogs: 10 mg/kg PO, IM, IV (if given IV, give slowly over 5 min) q6–8h
Cats: 5 mg/kg PO q12h

Theophylline (Extended Release)

Dogs: 10 mg/kg PO q12h, dose may vary with product
Cats: 20–25 mg/kg PO q24–48h, dose may vary with product

Terbutaline (Brethine, Bricanyl)

Dogs: 1.25–5 mg/dog PO q8–12h
Cats: 100–125 mg/cat PO q12h

Antimicrobials

Ampicillin

22 mg/kg IV, IM, SC q6–12h

Clindamycin (Antirobe, Cleocin)

Dogs: 11–33 mg/kg PO q8–12h, *or* 11 mg/kg IV q8–12h; when giving IV dilute and administer slowly
Cats: 11–33 mg/kg PO or SC q12–24h

Enrofloxacin (Baytril)

Dogs: 7–20 mg/kg PO, IV q24h (diluted and given slowly over 30 min)
Cats: 5 mg/kg PO or IM q24h

Amikacin (Amiglyde-V)

Dogs: 15–2 mg/kg IV or SC q24h
Cats: 10–14 mg/kg IV or SC q24h

IM, Intramuscular; *IV,* intravenous; *PO,* orally; *SC,* subcutaneous.

ANESTHETIC CONSIDERATIONS

Fluid, electrolyte, and acid-base imbalances should be corrected before induction of anesthesia. If feasible, mature animals should be fasted for 12 to 18 hours before esophageal surgery; however, young puppies and kittens may be fasted for shorter periods (4–8 hours) to prevent hypoglycemia. Refer to the anesthesia section in Chapter 26 (see p. 722) for discussion of special concerns with pediatric patients. Selected anesthetic protocols for patients in a stable condition undergoing cervical esophageal surgery are listed in Table 18.3.

Procedures on the thoracic esophagus require modification of general anesthetic protocols to accommodate compromised function of the respiratory and cardiovascular systems. General recommendations for anesthesia in patients undergoing thoracic surgery are provided in the anesthesia section of Chapter 29 on p. 884, Table 29.1, and Table 30.3. Aspiration at induction is of primary concern (see Table 18.3). Although this is an uncommon complication in dogs and cats, esophageal disease puts the patient at increased risk. Many of these patients have previously aspirated. Inducing general anesthesia with the subsequent obtunding of airway reflexes enhances the risk of aspiration. Have suction turned on and immediately available. Have an assistant elevate the patient's head to aid in keeping esophageal secretions out of the oropharynx until the endotracheal tube has been secured, the cuff inflated, and the anesthesia circuit attached. The patient should be preoxygenated for 3 to 5 minutes prior to induction, followed by rapid induction and intubation. Propofol is recommended for induction because of its rapid onset of action and short duration. Once intubation is complete, the head can be lowered. A mechanical ventilator is recommended. If the patient has aspiration pneumonia, positive pressure ventilation should be performed with lower tidal volumes, normal peak ventilation pressures, and higher respiratory rates. The tidal volume (6–10 mL/kg) must be adequate to expand the lungs during thoracotomy without overdistending alveoli. The inspiratory time should be kept between 1 and 1.5 seconds because a prolonged inspiratory time may collapse alveolar capillaries and impede venous return. The respiratory rate should be 10 to 20 breaths per minute. Nitrous oxide (rarely used) is comparatively less soluble in plasma than are oxygen and other inhalation anesthetics; therefore it rapidly diffuses into the alveoli when it is discontinued, resulting in diffusion hypoxia if the nitrous oxide

TABLE 18.3 Anesthetic Considerations in the Patient With Esophageal Disease

Preoperative Considerations

Associated conditions	• ± Aspiration pneumonia
Bloodwork	• CBC • Electrolytes • BUN • Cr
Physical exam	• Dysphagia • Regurgitation • Crackles or areas of dullness with auscultation of lungs and fever if aspiration pneumonia present
Other diagnostics	• Blood pressure • ECG • Radiographs (cervical, thoracic, abdominal) • ± Fluoroscopy • ± Barium
Premedications	• Avoid moderate to heavy sedation. Patient needs to maintain strong laryngeal reflexes until intubated

Intraoperative Considerations

Induction	• Preoxygenate 3–5 minutes
	• Be prepared for regurgitation; have suction turned on and immediately available; induce with patient sternal and head up; head can be lowered after intubation, cuff inflation, and circuit attachment
	• Rapidly induce so that endotracheal tube can be quickly placed:
	  • Propofol (4–8 mg/kg) IV, *or*
	  • Alfaxalone (2–5 mg/kg IV), *or*
	  • Midazolam (0.2 mg/kg) IV followed by propofol (2–6 mg/kg IV), *or*
	  • Fentanyl (2–10 µg/kg) IV followed by propofol (2–6 mg/kg IV)

Maintenance	• Isoflurane or sevoflurane, *plus*
	  • Fentanyl (2–10 µg/kg IV PRN in dogs; 1–4 µg/kg IV PRN in cats) for short-term pain relief, *plus*
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV PRN in dogs; 0.05–0.1 mg/kg IV PRN in cats), *or*
	  • Morphine[b] (0.1–1 mg/kg IV PRN in dogs; 0.05–0.2 mg/kg IV PRN in cats), *or*
	  • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV PRN), *plus*
	  • Ketamine (low dose) (0.5–1 mg/kg IV), *or*
	  • Ketamine CRI (0.5 mg/kg IV loading dose then 10 µg/kg/min IV)
	  • For hypotension (to keep MAP 60–80 mm Hg) give phenylephrine, ephedrine, norepinephrine, or dopamine as needed

Fluid needs	• 10 mL/kg/h plus 3 × EBL
Monitoring	• Blood pressure • ECG • Respiratory rate • SpO_2 • $EtCO_2$ • Temperature • U/O

Blocks	If thoracic surgery, consider:
	• Epidural:
	  • Morphine (0.1 mg/kg preservative free), *or*
	  • Buprenorphine (0.003–0.005 mg/kg diluted in saline), *plus*
	• Local anesthetics (see Box 30.2 and Chapter 13)
	  • Intercostal nerve blocks with local anesthetics (see Box 30.2 and Chapter 13), *plus*
	  • Incisional block with local anesthetic (see Box 30.2 and Chapter 13)

Postoperative Considerations

Analgesia	• Fentanyl CRI (1–10 µg/kg IV loading dose then 2–20 µg/kg/h IV), *or* • Morphine[b] (0.1–1 mg/kg IV or 0.1–2 mg/kg IM q1–4h in dogs; 0.05–0.2 mg/kg IV or 0.1–0.5 mg/kg IM q1–4h in cats), *or* • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM q3–4h in dogs; 0.05–0.1 mg/kg IV, IM q3–4h in cats), *or* • Hydromorphone CRI (0.025–0.1 mg/kg/h IV in dogs), *or* • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or* • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM q4–8h; 0.01–0.02 mg/kg OTM q6–12h in cats), *plus* • ± Ketamine CRI (2 µg/kg/min IV. If no previous loading dose, give 0.5 mg/kg IV prior to CRI)
Monitoring	• Blood pressure • ECG • Respiratory rate • SpO_2 • $EtCO_2$ • Temperature
Bloodwork	• HCT if significant blood loss • Repeat abnormal preoperative bloodwork
Estimated pain score	• Moderate to severe if open thoracic surgery

[a]Monitor for hyperthermia in cats.
[b]Give slowly to prevent histamine release.
[c]Buprenorphine is a better analgesic than morphine in cats.
BUN, Blood urea nitrogen; *CBC,* complete blood cell count; *Cr,* creatinine; *CRI,* constant-rate infusion; *EBL,* estimated blood loss; *ECG,* electrocardiogram; *$EtCO_2$,* end-tidal CO_2; *HCT,* hematocrit; *IM,* intramuscular; *IV,* intravenous; *MAP,* mean arterial pressure; *OTM,* oral transmucosal; *PRN,* as needed; *SpO_2,* hemoglobin saturation with oxygen; *U/O,* urine output.

is not turned off 5 to 10 minutes prior to extubation. Once surgery is completed, extubation should not be rushed. Suction the oropharynx well. Make sure the patient is awake and not overly sedated, respirations are adequate, and the patient is comfortable prior to extubation.

See Table 29.1 for recommendations of analgesics for patients undergoing thoracotomy. After induction of anesthesia, suctioning secretions and ingesta from the obstructed esophagus may help prevent aspiration and minimize contamination of the surgical site.

ANTIBIOTICS

Perioperative antibiotics may be given to prevent infection of periesophageal tissues. Prophylactic IV antibiotics should be given when anesthesia is induced and repeated 2 to 3 hours later. A third dose may be given 8 hours after the second dose. Broad-spectrum antibiotics effective against anaerobes are recommended (i.e., clindamycin, cefoxitin). Animals with preoperative perforation or severe esophageal trauma should be treated with therapeutic antibiotics (see Box 18.14). Specimens collected from the surgical site or perforation should be submitted for bacterial culture and susceptibility testing. The duration of antibiotic therapy varies according to the source of infection and the contaminating organisms, but they should generally be continued for a minimum of 2 weeks.

SURGICAL ANATOMY

The cervical and proximal thoracic portions of the esophagus lie to the left of the midline; however, the esophagus lies slightly to the right of the midline from the tracheal bifurcation to the stomach. The layers of the esophageal wall include the mucosa, submucosa, muscularis, and adventitia. The submucosa is the holding layer of the esophagus and must be incorporated with all sutures. The normal canine esophagus has linear mucosal striations throughout its length. The distal portion of the feline esophagus usually has circular mucosal folds that form a herringbone pattern with positive contrast.

NOTE Because the esophagus lacks a serosal layer, early fibrin sealing of esophagotomy sites may occur more slowly than in other areas of the gastrointestinal tract.

The vascular supply of the cervical esophagus is from branches of the thyroid and subclavian arteries. Bronchoesophageal arteries and segmental branches from the aorta supply the thoracic esophagus. The abdominal esophagus is supplied by branches from the left gastric and left phrenic arteries. Intramural branches ramify and anastomose in the submucosal layer. Collateral blood flow from the cervical and abdominal portions of the esophagus can provide the thoracic esophagus with adequate blood flow if the intramural esophageal vascular system is intact.

SURGICAL TECHNIQUES

Abnormalities of the cervical esophagus are approached using a ventral midline cervical incision. Thoracic esophageal abnormalities at the base of the heart are approached using a right lateral thoracotomy and those cranial or caudal to the heart with a left cranial or caudal thoracotomy. The abdominal esophagus is approached through a ventral midline celiotomy. Hair should be clipped from the entire ventral cervical area for surgery of the cervical esophagus and from the entire hemithorax for approaches to the thoracic esophagus. The skin should be aseptically prepared for surgery. Atraumatic meticulous technique must be employed to ensure rapid healing without dehiscence or stricture (Box 18.15).

BOX 18.15 Principles of Esophageal Surgery

- Use atraumatic meticulous technique; healing is challenged by: no serosa, no omentum, segmental blood supply, constant motion and bolus distention, and intolerance of longitudinal stretching
- Choose the most advantageous approach
- Preserve vasculature; dissect sparingly
- Suction the lumen prior to incising
- Make incision through healthy tissue
- Make longitudinal esophagotomy incisions
- Inspect for contralateral perforations or necrosis
- Resect only 3 to 5 cm during esophagectomy
- Incorporate submucosa with all sutures
- One-layer closure—keep knots extraluminal
- Two-layer closure—inner layer: intraluminal knots; outer layer: extraluminal knots
- Tension-relieving techniques: circumferential myotomy, gastric advancement, phrenic nerve interruption, pexy sutures
- Seal and support with a harvested omental flap or muscle flap
- Treat esophagitis with proton pump inhibitors and/or gastric prokinetics

Approach to the Cervical Esophagus

Position the patient in dorsal recumbency (Fig. 18.42A). Incise the skin on the midline, beginning at the larynx and extending caudally to the manubrium. Incise and retract the platysma muscle and subcutaneous tissues. Separate the paired sternohyoid muscles along the midline to expose the underlying trachea (see Fig. 18.42B). Retract the thyroidea ima vein with the sternohyoid muscle or ligate it. If access to the caudal cervical esophagus is needed, separate and retract the sternocephalicus muscles. Retract the trachea to the right to expose the adjacent anatomic structures, including the esophagus, the thyroid gland, the cranial and caudal thyroid vessels, the recurrent laryngeal nerve, and the carotid sheath (vagosympathetic trunk, carotid artery, and internal jugular vein) (see Fig. 18.42C). Pass a stomach tube or esophageal stethoscope to facilitate identification of the esophagus and lesion. After completing the definitive procedure, lavage the surgical site with warm sterile saline and return the trachea to its normal position. Close the incision by apposing the sternohyoid muscles using absorbable suture (3-0 or 4-0) in a simple continuous pattern. Appose subcutaneous tissues in a simple continuous pattern with 3-0 or 4-0 absorbable suture. Use nonabsorbable suture (3-0 or 4-0 monofilament) and an appositional suture pattern to appose the skin.

Approach to the Cranial Thoracic Esophagus via a Lateral Intercostal Thoracotomy

Position the patient in right lateral recumbency over a rolled towel placed perpendicular to the long axis of the body (Fig. 18.43A). Choose the appropriate intercostal space incision based on the radiographic location of the abnormality (see Fig. 18.43B–D). Most abnormalities cranial to the base of the heart can be accessed through an incision in the left third or fourth intercostal space (the technique for thoracotomy is described on p. 889). *Identify*

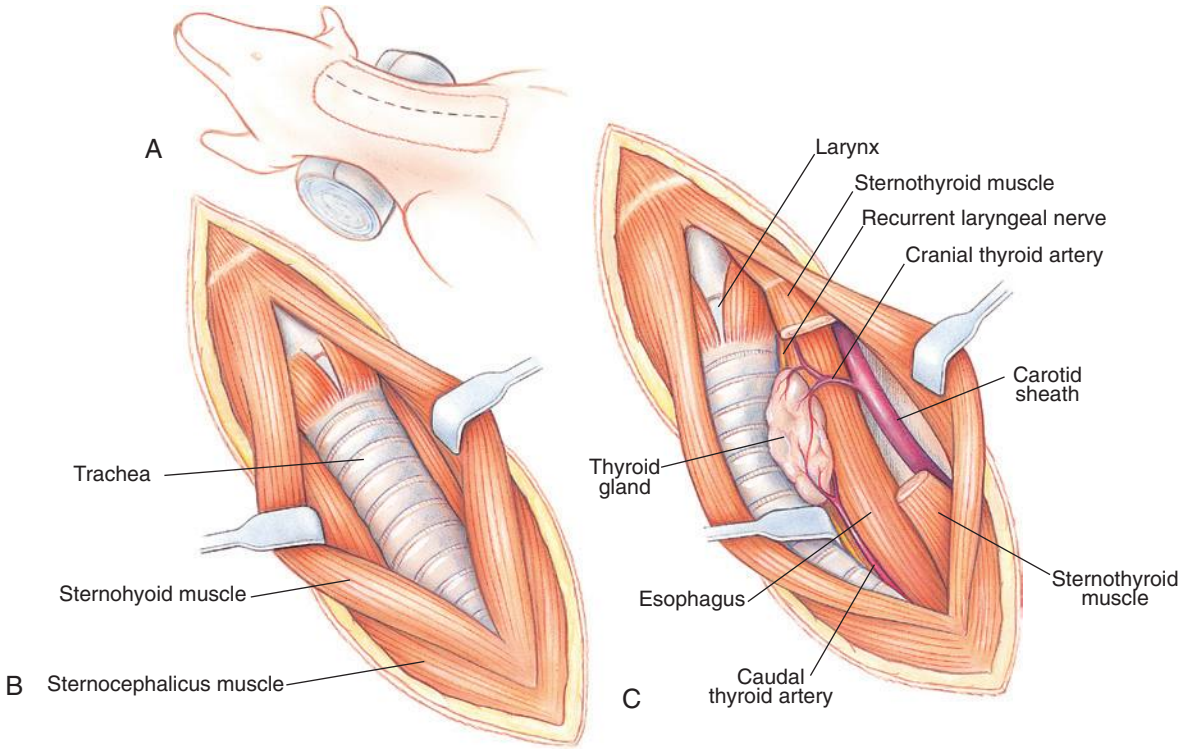

FIG. 18.42 Approach to the cervical esophagus. (A) Position the patient in dorsal recumbency with the neck resting on a rolled towel. (B) Incise the skin from the larynx to the manubrium, and separate the sternohyoid muscles to expose the trachea. (C) Retract the trachea to the right to expose the esophagus, thyroid, carotid sheath, and recurrent laryngeal nerve.

the esophagus in the mediastinum dorsal to the brachiocephalic trunk (see Fig. 18.43E). Identification may be aided by passage of a stomach tube or by palpating the abnormality. Dissect the mediastinal pleura overlapping the esophagus to just above and below the proposed surgical site. Preserve the branch of the internal thoracic vein and the costocervical vein, which cross the cranial esophagus.

Approach to the Esophagus at the Heart Base via a Right Lateral Thoracotomy

The approach is the same as that for the cranial esophagus except that the incision is made through the right fourth or fifth intercostal space (Fig. 18.44A–B). *Identify the esophagus, located just dorsal to the trachea in the mediastinum (see Fig. 18.44C). Dissect and retract the azygos vein from the esophagus to allow adequate exposure. Ligate the azygos vein if necessary to adequately expose the esophagus. Closure is the same as for cranial thoracotomy.*

Approach to the Caudal Esophagus via a Caudal Lateral Thoracotomy

Position the patient in lateral recumbency as described previously for cranial lateral thoracotomy. Perform a caudal lateral thoracotomy (Fig. 18.45A). Although the caudal esophagus can be approached through an incision in either the left or right eighth or ninth intercostal space, the left ninth space is preferred. *Expose the caudal esophagus by transecting the pulmonary ligament and packing the caudal lung lobes cranially. Identify the esophagus, which is just ventral to the aorta (see Fig. 18.45B). Identify the dorsal and ventral vagal nerve branches on the lateral aspect of the esophagus and protect them.*

Esophagotomy

Pack off the esophagus from the remainder of the field with moistened laparotomy pads. Suction material from the cranial esophagus before making the esophagotomy incision to minimize contamination of the surgical site. If ingesta and secretions have not been completely suctioned, occlude the lumen cranial and caudal to the proposed esophagotomy site with fingers or noncrushing forceps. Place stay sutures adjacent to the proposed incision site to stabilize, aid manipulation, and avoid trauma to the esophageal edges. Make a stab incision into the lumen of the esophagus, and extend the incision longitudinally as necessary to remove the foreign body or observe the lumen. Make the incision over the foreign body if the esophageal wall appears normal. If the wall appears compromised, make the incision caudal to the lesion or foreign body. Remove foreign bodies with forceps, taking care to avoid further esophageal trauma (tearing or perforation). Examine the esophageal lumen. Obtain culture specimens from necrotic and perforated areas. Debride and close perforations surrounded by healthy tissue that involve less than one-fourth the circumference of the esophagus. Identify large necrotic areas or extensive perforations and perform a resection and anastomosis (discussed later).

Esophagotomy incisions may be closed with a one- or two-layer closure. A two-layer simple interrupted closure results in greater immediate wound strength, better tissue apposition, and improved healing after esophagotomy but takes longer to perform than single-layer techniques. *Place each suture approximately 2 mm*

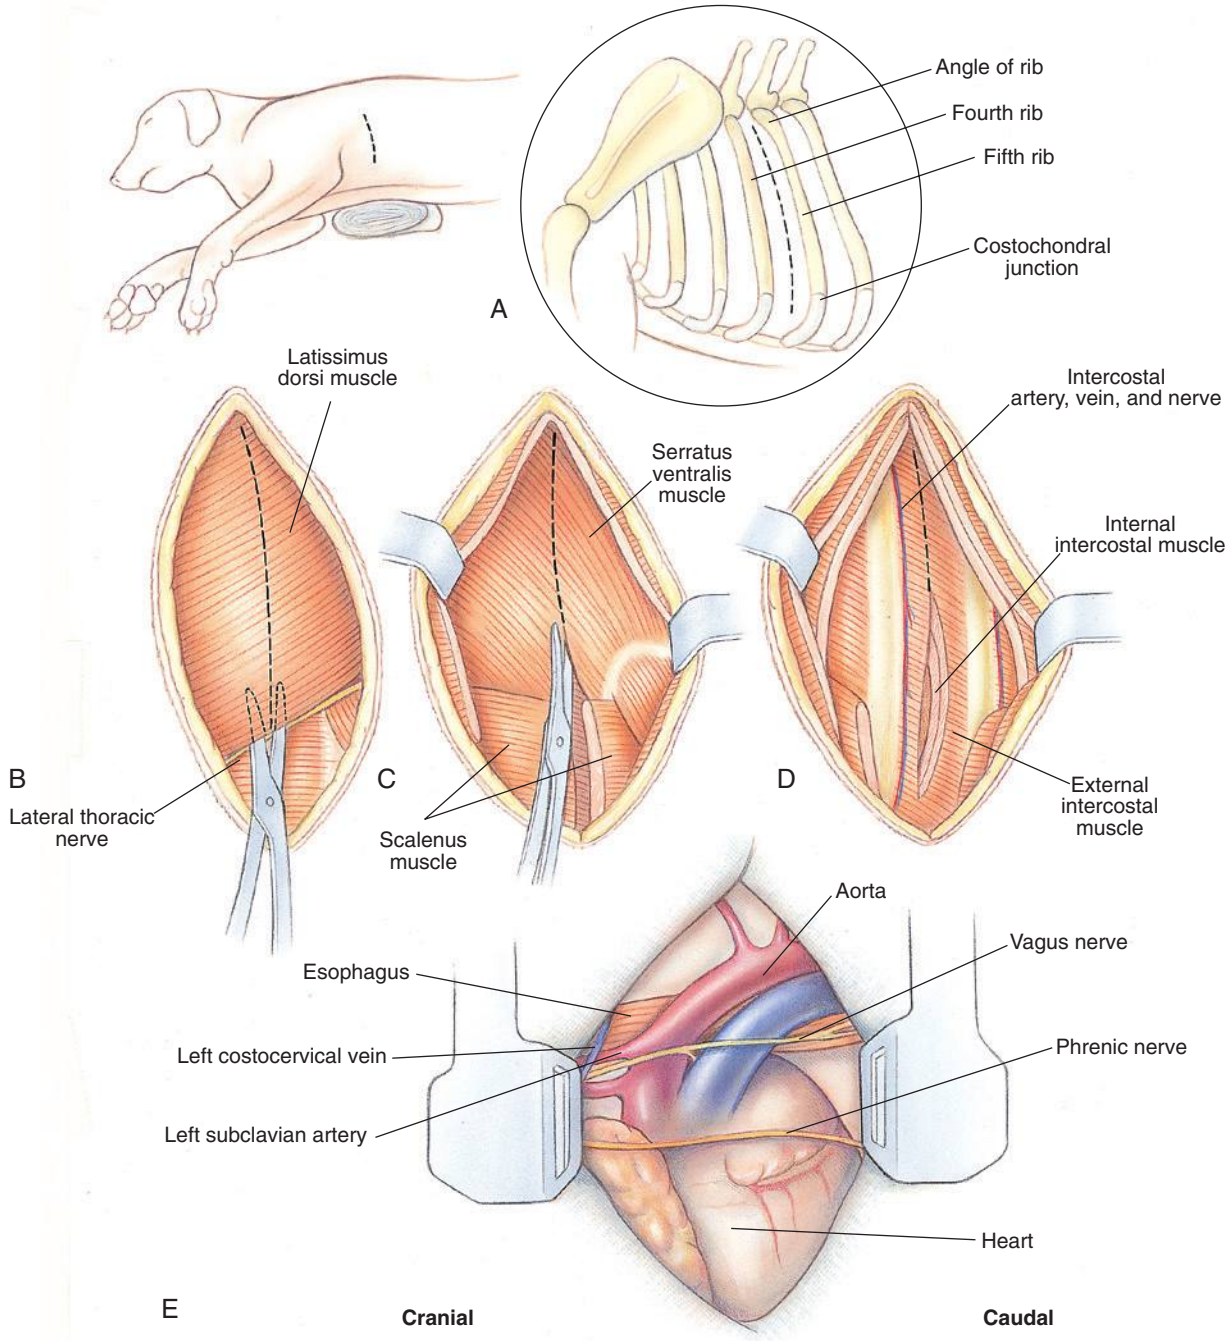

FIG. 18.43 Approach to the cranial thoracic esophagus. (A) Position the patient in right lateral recumbency over a rolled towel placed perpendicular to the long axis of the body. Select the appropriate incision site based on the radiographic location of the lesion *(inset)*. (B) Identify and transect the latissimus dorsi muscle *(dashed line)*. (C) Identify and transect or retract the serratus ventralis *(dashed line)* and scalenus muscles. (D) Expose and incise the intercostal muscles *(dashed line)*. (E) Position rib retractors and identify the thoracic viscera.

from the edge and 2 mm apart. Incorporate the mucosa and submucosa in the first layer of a two-layer simple interrupted closure. Place sutures so that the knots are within the esophageal lumen (Fig. 18.46A–B). Incorporate the adventitia, muscularis, and submucosa in the second layer of sutures with the knots tied extraluminally (see Fig. 18.46C). When a one-layer closure is used, pass each suture through all layers of the esophageal wall, and tie the knots on the extraluminal surface. Check closure integrity by occluding the lumen, injecting saline, applying pressure, and observing for leakage between sutures.

Partial Esophagectomy

Esophagectomy is performed to remove devitalized or diseased esophageal segments. Benign strictures should be dilated

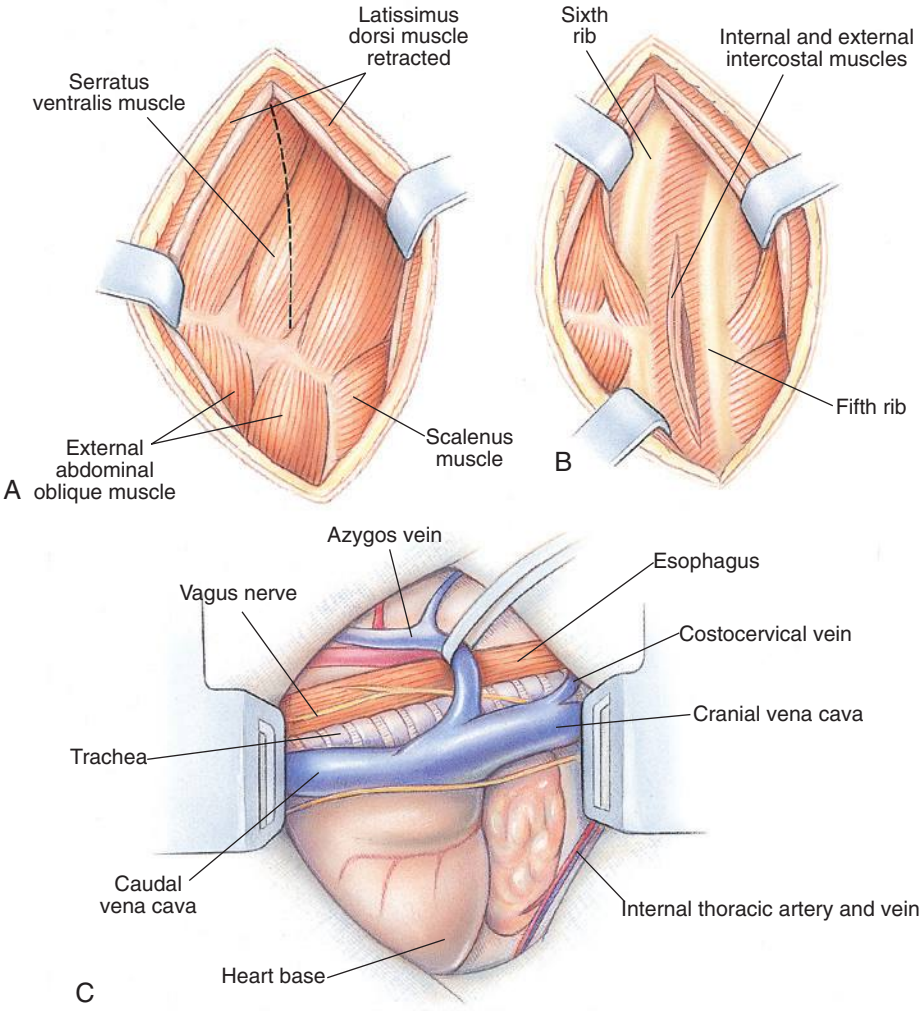

FIG. 18.44 Approach to the esophagus at the heart base. (A) Make an incision through the right fourth or fifth intercostal space. Identify and transect or retract the latissimus dorsi, serratus ventralis *(dashed line),* scalenus, and external abdominal oblique muscles. (B) Incise the intercostal muscles. (C) Expose the thoracic viscera.

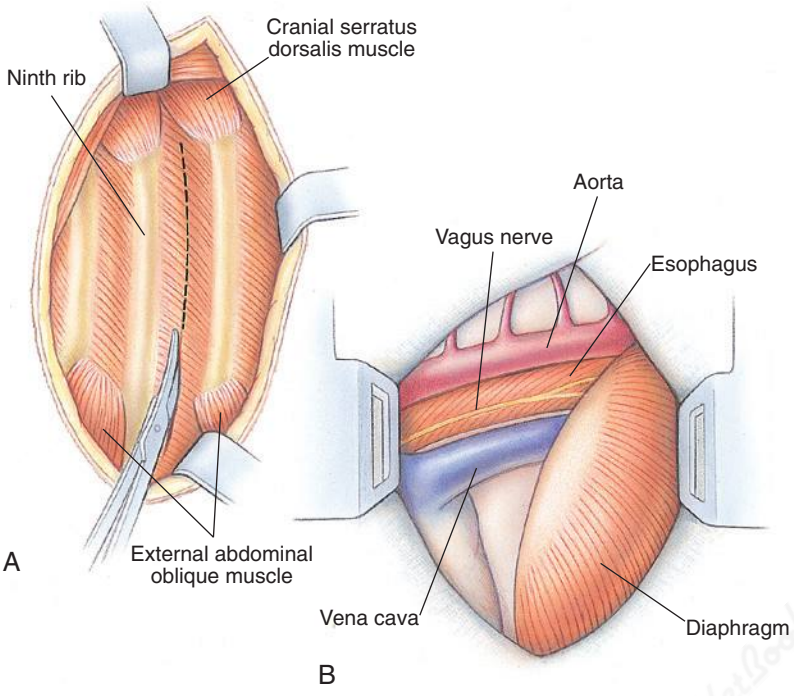

FIG. 18.45 To approach the caudal thoracic esophagus, position the animal in right lateral recumbency and make an eighth or ninth intercostal space incision. (A) Identify and transect or retract the latissimus dorsi, cranial serratus dorsalis, external abdominal oblique, and intercostal muscles *(dashed line).* (B) Identify the diaphragm and other thoracic viscera.

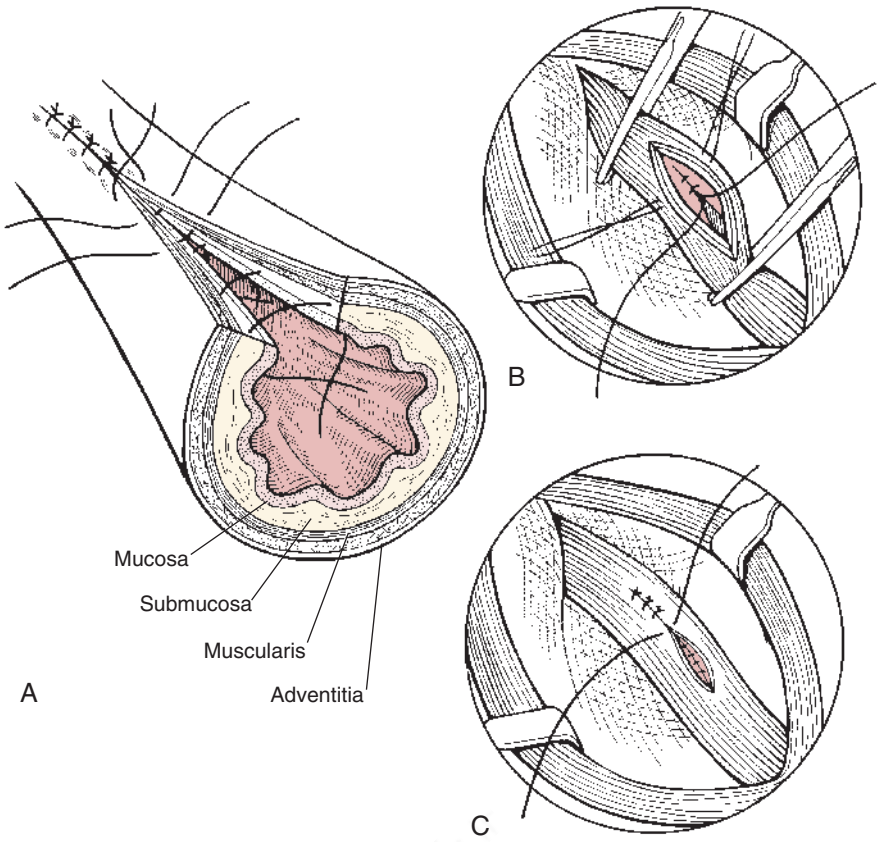

FIG. 18.46 Esophagotomy closure. (A–B) Close the mucosa and submucosa with simple interrupted sutures so that the knots are intraluminal. (A) and (C) Appose the adventitia and muscularis with a second layer of simple interrupted sutures oriented with extraluminal knots.

endoscopically if possible, with surgery reserved as a salvage procedure. Periesophageal tissues must be dissected from around the abnormal area to allow resection of diseased tissue and mobilization of normal esophagus; however, extensive dissection should be avoided to preserve vasculature. Excessive tension along the anastomosis may cause dehiscence. Although 20% to 50% of the esophagus has been resected and primarily anastomosed without tension-relieving techniques, resection of more than 3 to 5 cm risks anastomotic dehiscence. Partial myotomy is recommended to relieve anastomotic tension when resecting large segments of esophagus (Fig. 18.47). Circumferential myotomy is a partial-thickness myotomy through the longitudinal muscle layers, 2 to 3 cm cranial and caudal to the anastomosis. The inner circular muscle layers are not incised to avoid damaging the submucosal blood supply. Injection of saline into the muscularis may aid identification of the different muscle layers. The myotomy gap heals by second intention without stricture or dilatation. Mobilizing the stomach cranially through an enlarged esophageal hiatus can also help reduce tension across the anastomosis. Other tension-relieving techniques include interruption of the phrenic nerve and placement of "pexy" sutures between the esophagus and the prevertebral fascia. Esophageal replacement may be necessary if segments of more than 3 to 5 cm are resected. Many replacement techniques have been described, including microvascular anastomosis of the colon or small intestine to the esophagus, gastric tubes, skin tubes, and various prostheses. Replacement of the esophagus requires specialized training, techniques, and equipment.

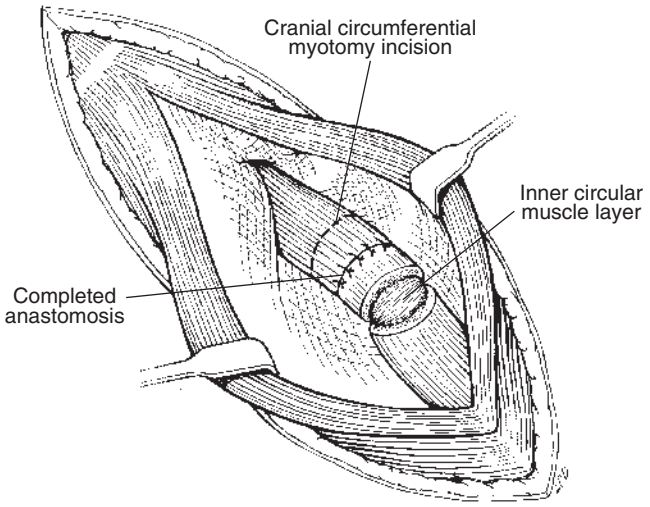

FIG. 18.47 Tension-relieving esophageal myotomy is performed 2 to 3 cm cranial and caudal to the anastomosis.

For esophagectomy, occlude and stabilize the esophagus with fingers (scissor action of middle and index fingers) or noncrushing forceps. Resect the diseased portion of the esophagus (Fig. 18.48).

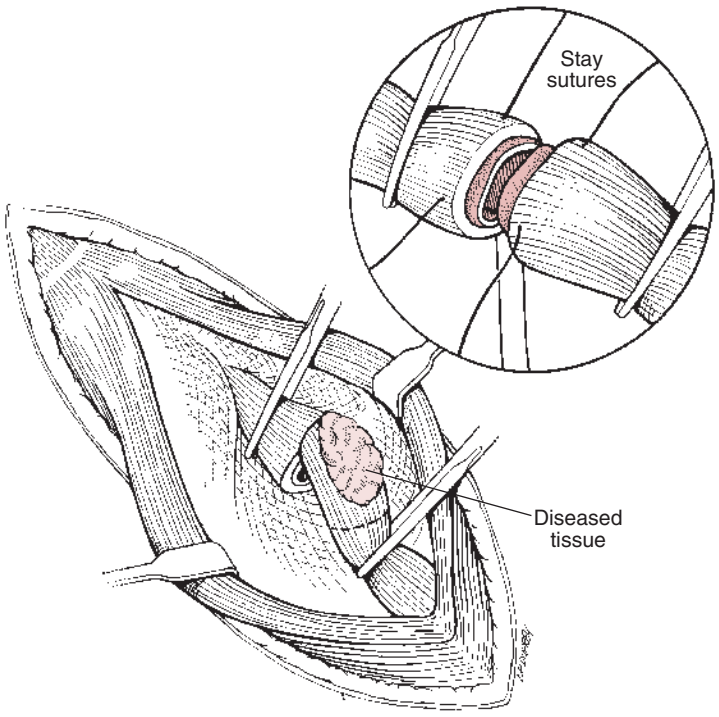

FIG. 18.48 For partial esophagectomy, occlude the esophageal lumen with noncrushing forceps and mobilize and resect the diseased esophagus *(dashed line)*. Place stay sutures to manipulate the esophageal ends *(inset)*. Anastomose the ends as shown in Fig. 18.46.

Suction debris from the lumen of the remaining esophagus. Place three equally spaced stay sutures at each end of the remaining esophagus to facilitate gentle handling of the esophagus and help maintain apposition and alignment of the transected ends (see Fig. 18.48). Bring the esophageal ends into apposition with the stay sutures and suture the ends together using a one- or two-layer closure, as described for esophagotomy. Place sutures in the contralateral (far) wall first and then in the more accessible ipsilateral (near) wall. When using a two-layer closure, appose the esophagus in the following four steps: (1) appose the adventitia and muscularis of the contralateral wall around approximately half of the esophageal circumference (Fig. 18.49A); (2) appose the mucosa and submucosa of the contralateral wall (see Fig. 18.49B); (3) appose the mucosa and submucosa of the ipsilateral wall (see Fig. 18.49C); and (4) appose the adventitia and muscularis of the ipsilateral wall (see Fig. 18.49D). Check the integrity of the closure by occluding the lumen, injecting saline, applying pressure, and observing for leakage between sutures.

An end-to-end circular stapling device may reduce operating time and contamination of the surgical field, but this technique may have a greater potential for stricture formation. *Place a purse-string suture in the cranial esophageal remnant. Insert the anvil and tie the purse string around the instrument shaft. Place a second purse-string suture around the distal resection site and secure it. Appose the esophageal ends by tightening the stapler's wing nut. Activate the instrument and then remove it with a rotating motion. Close the access incision for placement of the stapling device with a linear stapler (p. 445).*

Support or Patching Techniques

Augmentation of esophagotomy or esophagectomy sites with omentum or muscle can aid healing by supporting, sealing, and revascularizing the surgical site. Muscle pedicles from the sternohyoid, sternothyroid, intercostal, diaphragm, or epaxial muscles can be mobilized and sutured over the primary repair or esophageal defect (Fig. 18.50A). As an alternative, omentum can be mobilized from the abdomen, brought through a rent in the diaphragm, and sutured over the esophageal site (see Fig. 18.50B). Pedicles from the gastric wall and pericardium have also been used.

Esophagostomy

Feeding tubes placed in the midcervical esophagus are associated with fewer complications than pharyngostomy or nasogastric feeding tubes. The technique for esophagostomy tube placement is described on p. 95. The distal end of the tube is positioned rostral to the gastroesophageal junction to reduce gastroesophageal reflux. Ostomy wounds typically heal by second intention after removal of the tube, without stricture or esophagocutaneous fistula formation.

HEALING OF THE ESOPHAGUS

The esophagus is subject to constant movement from swallowing and respiration. This continuous motion may interfere with healing and must be overcome with good surgical technique. Although large segments of the esophagus have been resected successfully, the esophagus does not tolerate longitudinal stretching well and may dehisce if tension is excessive. Complications (especially dehiscence, stricture, fistulization) are common after esophageal surgery. The high complication rate has been blamed on the lack of serosal covering, lack of omentum, segmental blood supply, constant motion, and distention with passage of food boluses. Careful surgical technique and patient management can minimize most of the possible complicating factors.

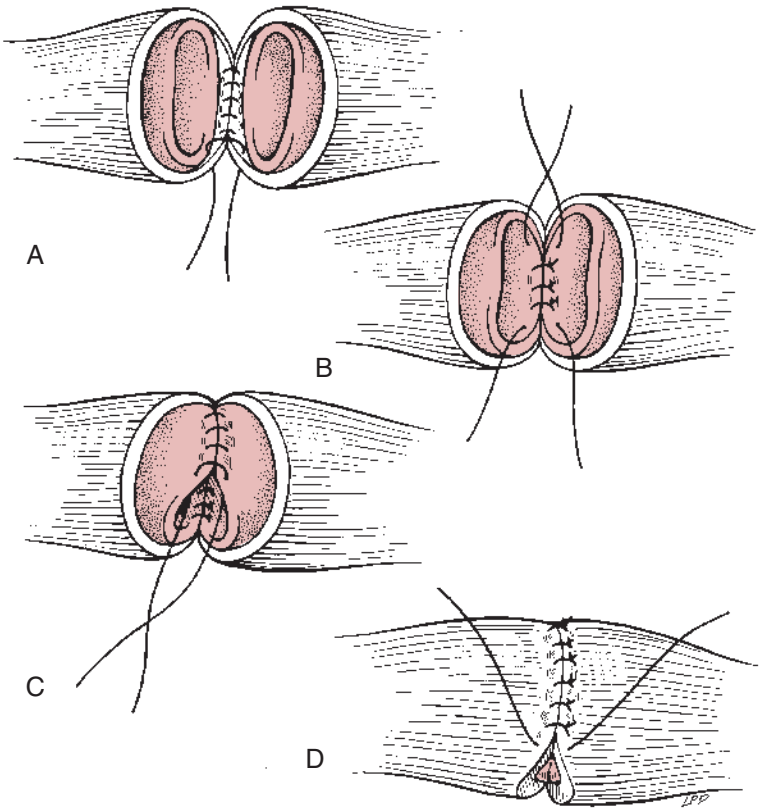

FIG. 18.49 During partial esophagectomy, appose the ends with two layers of sutures in a four-step procedure. (A) First, appose the adventitia and muscularis on the far side with simple interrupted sutures and extraluminal knots. (B) Second, appose the submucosa and mucosa on the far side with simple interrupted sutures using intraluminal knots. (C) Third, appose the nearside submucosa and mucosa. (D) Last, appose the nearside muscularis and adventitia.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

In addition to a general pack, other requirements may include special forceps (i.e., noncrushing Doyen forceps), delicate hemostats (i.e., Adson), Metzenbaum scissors, retractors (Gelpi retractors for the cervical approach; Finochietto retractors for the thoracic approach; malleable retractors), and tubes (chest tube, gastrostomy tube, stomach tube). A suction unit and laparotomy pads should also be available. Surgical stapling equipment (e.g., linear stapler, circular end-to-end stapler, ligate-and-divide vascular stapler, skin stapler) is beneficial but optional. Monofilament absorbable suture (polydioxanone, polyglyconate, or poliglecaprone 25 with a swaged-on taper point needle) and nonabsorbable suture (polypropylene, nylon with a reverse cutting needle) (3-0 or 4-0) are recommended in the esophagus.

POSTOPERATIVE CARE AND ASSESSMENT

After esophageal surgery, analgesics should be provided as described for thoracotomy patients on p. 886. Air and fluid must be evacuated via a thoracostomy tube or needle thoracentesis after thoracic procedures. Unless periesophageal or thoracic infection is anticipated, thoracostomy tubes can generally be removed within 8 to 12 hours after esophageal surgery. Nasal oxygen may benefit animals after thoracotomy (see Table 4.4).

Oral intake should be withheld for 24 to 48 hours. IV fluids should be continued until oral intake resumes. Water may be offered 24 hours postoperatively if the esophagus is in good condition and regurgitation or vomiting does not occur. Blenderized food (gruel) may be offered during the next 24 hours if no vomiting or regurgitation occurs after water consumption. Blenderized food should be continued for 5 to 7 days, then the animal should be gradually returned to its normal diet over the next week. If oral intake is not anticipated or possible within 48 to 72 hours after surgery, feeding should be performed via a gastrostomy tube (see p. 97).

Esophagitis and aspiration pneumonia should be treated as described in the discussion on Preoperative Concerns (p. 365). Patients undergoing esophageal surgery should be closely monitored for fever and neutrophilia, which may indicate infection secondary to leakage. Dysphagia and regurgitation that occur 3 to 6 weeks after surgery may indicate esophageal stricture formation. It is extremely important that clients be informed of possible complications before and after surgery (Box 18.16).

COMPLICATIONS

Infection, regurgitation, pneumonia, esophagitis, dehiscence, fistula, stricture, and recurrence of disease are possible complications of esophageal surgery. Common errors in treating esophageal disorders include delayed identification of esophageal foreign

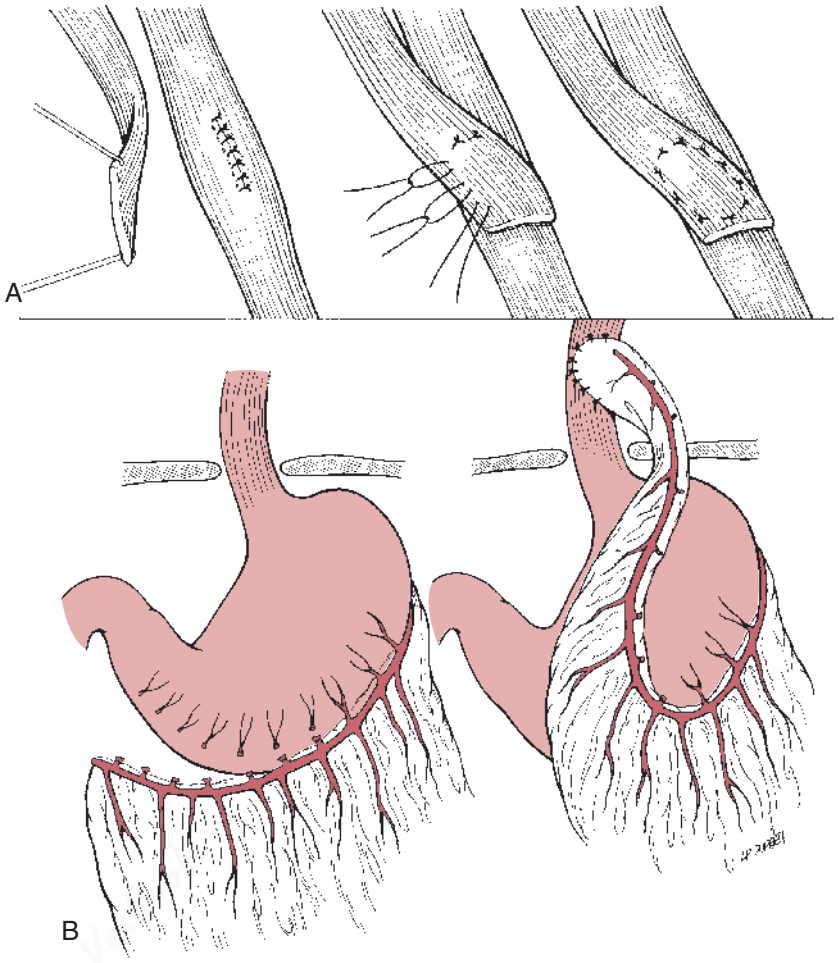

FIG. 18.50 Patching the esophagus. (A) Mobilize muscle adjacent to the esophagus and suture it over an esophageal incision to create an esophageal patch. (B) As an alternative, mobilize omentum from the greater curvature of the stomach, pass it through an incision in the diaphragm, and suture it over the esophageal closure to create an omental patch.

BOX 18.16 Client Education and Communication for Patients Undergoing Esophageal Surgery

- Regurgitating or vomiting can cause aspiration pneumonia, which can be fatal if not controlled.
- Surgery may not resolve all clinical signs of esophageal disease.
- Preventing oral intake, tube feeding, or feeding from an elevated platform such that the patient must be near vertical to the floor may be necessary.
- Esophageal healing is poor compared with other parts of the gastrointestinal tract; therefore leakage, infection, dehiscence, and stricture are more common.
- Foreign bodies may perforate the esophagus or great vessels during extraction, with fatal results.
- Dogs should not be fed bones.

bodies, perforation, or aspiration pneumonia; failure to control esophagitis; inappropriate surgical approach; and failure to patch or support the esophagus appropriately.

SPECIAL AGE CONSIDERATIONS

Care must be used in anesthetizing young animals for esophageal surgery. Surgery is often performed in animals with persistent right aortic arches (PRAAs; see p. 394) or hiatal hernias (see p. 386) at 8 to 16 weeks of age. Perioperative hypothermia and hypoglycemia are common problems in these pediatric patients and may be life-threatening.

SPECIFIC DISEASES

ESOPHAGEAL FOREIGN BODIES

DEFINITION

Foreign bodies are inanimate objects that may obstruct the esophageal lumen to varying degrees.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

The most common foreign bodies found in the esophagi of dogs and cats are bones, although sharp metal objects (e.g., needles and fishhooks), rawhide chew toys, balls, string, and an assortment of other objects have lodged there. Foreign bodies lodge in the esophagus because they are too large to pass or they have sharp edges that become embedded in the esophageal mucosa. Foreign bodies are most commonly found at the thoracic inlet, the base of the heart, or in the epiphrenic (diaphragm) area because extraesophageal structures limit esophageal dilatation at these sites. The persistence of a foreign body (acting as a bolus) in the esophagus stimulates peristaltic activity. If the foreign body puts excessive pressure on the esophagus or if it remains at one location, pressure necrosis may occur and in some cases can cause

perforation within 3 to 4 days. If esophagitis occurs, it may interfere with esophageal motility and lower esophageal high-pressure zone function. Food that does not pass the obstruction accumulates and may be regurgitated or may cause proximal esophageal distention. Prolonged distention disrupts normal neuromuscular function and reduces peristalsis. Esophageal perforation and aspiration pneumonia (see p. 367) are the major complications possible.

Sharp objects may abrade or lacerate the esophageal mucosa, causing irritation and inflammation of the underlying tissues (esophagitis) or hemorrhage. Sharp objects may also perforate the esophageal wall and allow bacteria, ingesta, and secretions to contaminate the periesophageal tissues. Occasionally sharp objects perforate the esophageal wall and one of the great vessels at the base of the heart, causing severe hemorrhage into the mediastinum. Foreign bodies may penetrate the esophageal wall and establish a fistula with the trachea, bronchi, pulmonary parenchyma, or skin (Box 18.17).

DIAGNOSIS

Clinical Presentation

Signalment

Indiscriminate eaters (dogs) are more commonly affected than more particular eaters (cats). Although any breed of dog or cat may have an esophageal foreign body, small-breed dogs are more frequently affected because their esophagus is smaller. Yorkshire terriers and West Highland white terriers may be overrepresented compared with hospital populations.[9] Cats, having a tendency to play and hunt, more commonly have string or needle foreign bodies than bones. Foreign bodies may occur in an animal of any age but are most common during the first 3 years of life.

History

Animals may be presented for treatment within minutes of foreign body ingestion (especially when it is seen, as commonly occurs with fishhooks) or days later. An acute onset of pawing at the mouth, oral or cervical pain, dysphagia, and/or regurgitation are the most common initial signs. Other signs may include gagging, excessive salivation, retching, hyporexia, restlessness, depression, dehydration, and respiratory distress. Clinical signs vary somewhat depending on the duration, location, and type of obstruction. Patients with acute obstructions generally show excess salivation and gag or regurgitate soon after eating. Weight loss and emaciation are sometimes seen in patients with long-term esophageal obstruction. Patients with complete obstruction regurgitate both solids and liquids, whereas those with partial obstruction may retain liquids. Esophageal pain may cause anorexia. Foreign bodies that impinge on the upper airways may cause acute respiratory distress. Sharp foreign bodies or those that have caused necrosis of the esophageal wall allow leakage of saliva and ingesta into the surrounding tissues, causing inflammation and infection. These patients are likely to be hyporexic, febrile, and/or dyspneic as a result of pleural effusion. Hypovolemic shock can occur if a foreign body penetrates a major vessel adjacent to the esophagus. A history of being fed bones, getting into garbage, or roaming is consistent with foreign body ingestion. Fishhook ingestion is typically obvious from the history.

NOTE Strive to differentiate between vomiting and regurgitation; acute-onset regurgitation strongly suggests the presence of an esophageal foreign body.

Physical Examination Findings

Patients may be normal or depressed and dehydrated on physical examination. If the foreign body is lodged in the cervical esophagus, it may sometimes be palpated. Poor body condition may be a factor if the patient has been anorexic or regurgitating for weeks. Abnormal lung sounds may be auscultated in patients with aspiration pneumonia. Animals that are in great pain may drool because they refuse to swallow.

Diagnostic Imaging

Most foreign bodies can be seen on good quality survey radiographs (Fig. 18.51) provided that they are radio-opaque, but it is not always obvious that they are in the esophagus. Esophageal masses and foreign bodies may be poorly demarcated densities that closely resemble pulmonary masses. Foreign bodies are usually found at or cranial to the thoracic inlet, the base of the heart (approximately 10%), and the diaphragm (approximately

BOX 18.17 Esophageal Foreign Bodies: Key Points

- History of roaming or garbage eating is a diagnostic clue
- Common location: thoracic inlet, heart base, or diaphragm
- Suspect perforation, pressure necrosis, aspiration pneumonia, fistula
- Most are identified or suspected from survey radiographs
- Most patients with esophageal perforations will have pleural effusion, pneumothorax, or pneumomediastinum; contrast radiographs are rarely necessary
- If you use contrast radiographs to find perforations, use iodinated contrast media
- Most can be removed during esophagoscopy; do not use force
- Fatal hemorrhage can occur if a sharp object penetrates the wall
- If the mass cannot be retrieved per mouth, then advance object into stomach if possible
- Radiograph the patient after endoscopic removal to look for signs of perforation (pneumothorax)
- Feeding tubes may be required
- Postoperative strictures may occur with or without surgery

FIG. 18.51 Lateral thoracic radiograph showing a treble fishing hook esophageal foreign body at the base of the heart in a dog.

85%). In addition to the foreign body, there may be an adjacent soft tissue opacity and cervical subcutaneous emphysema, and a dilated, air-filled cranial esophagus may be seen. Pneumonia and tracheal distortion may also be present. Radiographs should be closely examined for signs of pneumomediastinum, pneumothorax, and pleural effusion, each of which suggests esophageal perforation. If pleural effusion is present, it must be examined cytologically to see if there is evidence of inflammation or infection.

Esophagrams are rarely necessary to identify foreign bodies and perforations. If contrast radiographs will be performed to look for esophageal perforation, water-soluble, organic, iodine contrast materials or iohexol are recommended. Isotonic iodinated contrast agents are the safest as they will not cause pulmonary edema if aspirated or if there is a bronchoesophageal fistula. Hypertonic iodinated contrast agents should be avoided in these situations. However, one does not generally do a contrast radiograph to look for perforation (see the discussion on endoscopy presented later), and the presence of a foreign body may mask identification of a perforation during an esophagram. If a bronchoesophageal fistula is suspected, a hypertonic iodinated contrast agent should not be used because its hypertonicity may cause pulmonary edema. Foreign bodies can also be diagnosed endoscopically, which is usually the next step after finding a suggestive density on plain radiographs.

NOTE If available, endoscopy is generally of greater value than radiographic contrast studies in diagnosing esophageal foreign bodies because the foreign body can potentially be removed during the endoscopic procedure.

Laboratory Findings

Laboratory findings are normal with acute obstructions. Perforations usually cause neutrophilic leukocytosis. Hypoglycemia may be seen in young patients that are unable to eat or in SIRS (or both).

DIFFERENTIAL DIAGNOSIS

Vascular ring anomalies, extraluminal masses, esophageal neoplasia, strictures, esophagitis, gastroesophageal intussusception, esophageal diverticula, hiatal hernias, megaesophagus, and cricopharyngeal dysfunction are other possible causes of regurgitation that must be differentiated from esophageal foreign bodies. Radiographs of pulmonary tumors and esophageal masses can perfectly mimic radiographs of esophageal foreign bodies.

SURGICAL TREATMENT

It is very important to take a radiograph just before induction of anesthesia to ensure that the foreign body has not moved and that there is no sudden evidence of perforation; this is true for endoscopy as well as surgery.

Most esophageal foreign bodies can be successfully removed endoscopically (see also Chapter 14). Rigid endoscopes (i.e., colonoscopes) are preferred, assuming that they are long enough. Rigid endoscopes allow one to use rigid grasping forceps, which in turn allow better manipulation and grasping than is available with forceps inserted through flexible endoscopes. The rigid scopes also offer some degree of protection to the esophagus; the foreign body is partially drawn up into the scope during removal so that it does not traumatize the esophageal mucosa. The major advantage to flexible endoscopes is that some esophageal foreign bodies are out of reach of rigid scopes; but the retrieval devices used in flexible endoscopes do not offer the operator as much control or power as do the rigid endoscopic forceps. Surgical removal of esophageal foreign bodies should be elected if (1) there is pneumothorax or pleural exudate suggesting perforation, (2) endoscopy cannot retrieve the foreign body, or (3) if a fishhook is deeply embedded such that the point and barb are obviously completely through the wall of the esophagus and free to lacerate intrathoracic vessels. After removal of the foreign body, the esophagus must be carefully reevaluated endoscopically and the chest re-radiographed to look for evidence of perforation (i.e., pneumothorax). Be careful when insufflating air; it is possible to cause a tension pneumothorax if there is a perforation. Perforations should generally be managed with debridement and surgical closure (see p. 370); however, small perforations occasionally may be allowed to close on their own.

Preoperative Management

Therapy to correct significant dehydration and electrolyte and acid-base imbalances should be initiated before surgery. Prophylactic antibiotics should be given (see p. 369).

Anesthesia

Anesthetic management of patients undergoing esophageal surgery is described on p. 367 and in Table 18.3. Deep general anesthesia or muscle relaxants that reduce esophageal tone facilitate endoscopic manipulations. Nitrous oxide should not be used in these patients. Most animals should be preoxygenated before induction. If the patient has aspiration pneumonia, positive pressure ventilation should be performed with lower tidal volumes, normal peak ventilation pressures, and higher respiratory rates.

Surgical Anatomy

The surgical anatomy of the esophagus is described on p. 369.

SURGICAL TECHNIQUE

Foreign bodies may be removed by extracting them endoscopically with grasping instruments, pulling them out using a balloon-type catheter (e.g., Foley), advancing them into the stomach where they can dissolve or be removed by gastrotomy (see p. 401), or by performing an esophagotomy (see p. 370), or a partial esophagectomy (see p. 371).

Endoscopic Removal of Esophageal Foreign Bodies

Endoscopic removal of esophageal foreign bodies is generally preferred unless there is a good reason to the contrary; it is successful in removing foreign bodies in the majority of affected animals. *After examining the radiograph taken just before anesthetic induction, carefully advance the rigid endoscope down the esophagus to the level of the foreign body.* The larger the diameter of endoscope, the better the visualization and the more the esophageal lumen will be dilated (which can aid in removing the foreign object). *Position the patient such that the neck is extended so that the endoscope will not put undue pressure on the trachea or the nearby vessels (if a flexible scope is used, positioning of the neck is not as important). Only advance the scope while observing through it so as not to push the scope into the foreign object and cause further trauma. Insufflate with minimal amounts of air and only if necessary; insufflating too much air might rupture weakened*

areas in the esophagus, cause a gastric dilatation that cannot be relieved by stomach tube because of obstruction of the esophagus, or cause tension pneumothorax. Once the foreign object is found, aspirate any fluid or debris surrounding it to enhance visualization. After examining the object, grasp it firmly and then carefully manipulate it to free it from the esophagus (there are typically points where the foreign object protrudes into esophageal mucosal defects). Once it is freed, draw it as far as possible up into the rigid scope, and then remove the scope and foreign object as one unit. If there is severe trauma to the esophageal mucosa, place a gastrostomy tube (see p. 97).

If the foreign object cannot be grasped, it can sometimes be pushed into the stomach *if* the endoscopist *knows* that there are no sharp objects or structures that could cause perforation. If necessary, a water-soluble lubricant can be applied around the foreign object to facilitate this maneuver. Forcefully pushing an object that is firmly embedded in the esophageal wall is contraindicated because doing so may cause perforation or enlargement of a preexisting perforation. Once in the stomach, the foreign object may be removed by gastrotomy (see p. 401) or, in the case of bones, allowed to dissolve. **However, do not administer antacids or the stomach will not be able to dissolve the bone**.

Fishhooks can usually be removed with rigid scopes, depending on the size of the barb (hooks with very large barbs often cannot be torn out of the mucosa) and whether the barb has been pushed all the way through the wall of the esophagus such that it could lacerate thoracic vessels when it is pulled back into the esophagus. The technique varies a little, depending on whether the point of the hook is pointed craniad or caudad. *If the point of the hook is pointed caudad, then firmly grasp the hook at the bend such that when it is pulled, the point of the hook is pulled straight out, parallel with the esophageal lumen.* The barb will tear through the esophageal wall, leaving a small defect. *If the point of the hook is pointed craniad, firmly grasp the eye of the hook with the rigid forceps. Next, advance the rigid endoscope until the rim of the rigid scope rests on the bend of the hook. Then, holding the eye of the hook so that the shaft remains parallel with the lumen of the esophagus and the rigid scope, advance the scope and the rigid grasping forceps as one unit, tearing the hook out of the mucosa.*

Balloon Catheter-Assisted Removal of Foreign Objects

An alternative to grasping the foreign body is to pass a balloon catheter distal to the object (Figs. 18.52 and 18.53). The esophageal lumen is then dilated beyond its normal size by inflating the balloon, and the object is disengaged from the esophageal wall by endoscopic manipulation if necessary and removed as the catheter is pulled out through the mouth. This procedure is advisable only for foreign bodies with a relatively smooth contour. After nonsurgical foreign body removal, radiographs may be taken to look for evidence of perforation (e.g., pneumomediastinum and pneumothorax).

Surgical Removal of Esophageal Foreign Objects

Foreign bodies can be surgically removed by performing an esophagotomy (see p. 370) or a partial esophagectomy (see p. 371). Distal esophageal foreign bodies are occasionally removed by a gastrotomy. *Make an incision midway between the greater and lesser curvature, direct a forceps into the distal esophagus and grasp the object, pull into the stomach, and remove it.* An esophagotomy or a partial esophagectomy is performed when foreign bodies cannot be removed by other means, when the risk of esophageal

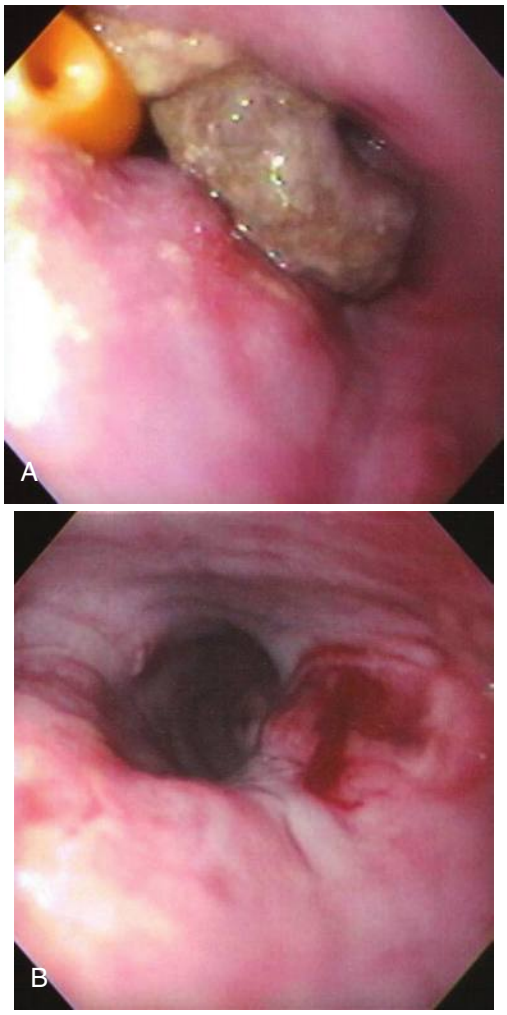

FIG. 18.52 (A) Endoscopic appearance of a piece of liver lodged in the esophagus. Note the tip of a Foley catheter, which is being passed to retrieve it. (B) After retrieval of the foreign body, ulceration of the mucosa was identified.

FIG. 18.53 Smooth esophageal foreign bodies can be removed by balloon retraction during endoscopy. Dilate the esophagus, pass the catheter distal to the foreign body, then inflate the balloon and withdraw the catheter and foreign body.

perforation or laceration is high, or when there is evidence of mediastinitis, pleuritis, or esophageal necrosis. *Debride all esophageal disruptions if necessary and close in one or two layers as for esophagotomy.* Abnormal communications between the alimentary and respiratory tracts (i.e., bronchoesophageal or tracheoesophageal fistula) must be closed. Partial or complete pulmonary lobectomy (see p. 894) is required with some bronchoesophageal fistulae.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Endoscopes (both flexible and rigid, but preferably rigid), endoscopic grasping forceps, or balloon-tipped catheters (i.e., Foley catheter) are needed for nonsurgical foreign body removal. Thoracic retractors are needed for surgical removal of intrathoracic foreign bodies. Noncrushing intestinal forceps to occlude the esophageal lumen may be needed for esophagotomy or esophagectomy procedures.

POSTOPERATIVE CARE AND ASSESSMENT

All patients should be observed carefully for 2 to 3 days for signs of esophageal leakage and infection. Esophagitis and aspiration pneumonia should be treated as described on pp. 366–367. Antibiotics should be continued for several days if the esophageal mucosa is severely eroded or lacerated, especially if a fishhook was removed. IV fluids should be continued until feeding resumes. To avoid delays in healing, all oral intake (food, water, medications) should be withheld for a minimum of 24 hours after removal of foreign bodies causing substantial erosion or ulceration. If no regurgitation is observed, water and then a bland gruel should be introduced gradually. Animals with minimal esophageal trauma may be offered water within 24 to 48 hours, followed by small meals of gruel. After 3 to 7 days of gruel feeding, soft, moist food should then be offered for 5 to 7 days, followed by a gradual return to a normal diet. Animals with moderate to severe esophageal trauma should avoid oral intake for 3 to 7 days. In debilitated patients or those requiring no oral intake for longer than 3 days, gastrostomy feeding tubes should be placed (see p. 97). Severe esophagitis should be treated with proton pump inhibitors to reduce gastric acidity. Sucralfate or viscous lidocaine may be considered if pain relief is needed. Antibiotics effective against oral anaerobes (ampicillin, amoxicillin, clindamycin; see Box 18.14) are used, and glucocorticoids may help prevent cicatrix formation (controversial).

COMPLICATIONS

Complications of foreign body removal include esophagitis, ischemic necrosis, dehiscence, leakage, infection, fistulae, esophageal diverticula, and stricture formation. Esophageal perforation may lead to mediastinitis, pleuritis, and/or pyothorax. Prolonged duration of clinical signs and increased numbers of immature neutrophils may suggest esophageal perforation; however, perforation is best diagnosed radiographically. Complications are more common in small dogs (<10 kg) and cases in which foreign material is present for more than 3 days. Dogs with foreign bodies that are removed within 24 hours or less tend to have fewer complications.

PROGNOSIS

Removal of the foreign body is essential. The prognosis is good if perforation has not occurred; however, it is guarded if perforation has resulted in either mediastinitis or pyothorax (or both). Ischemic necrosis or perforation of the esophagus may occur after foreign body removal. Leakage of saliva and ingesta into the mediastinum or pleural cavity usually causes severe inflammation, infection, and death. Severe, circumferential damage to the mucosa may produce cicatrix.

ESOPHAGEAL STRICTURES

DEFINITION

Benign esophageal strictures (*stenosis, cicatrix*) are bands of intraluminal or intramural fibrous tissue that may completely or partly obstruct the esophagus.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Benign esophageal strictures may be caused by esophagitis secondary to esophageal foreign bodies, gastroesophageal reflux during anesthesia, surgery, trauma, or caustic agents (e.g., doxycycline, acid, clindamycin, ciprofloxacin). The risk of developing a stricture after an anesthetic episode is low (probably less than 1%), whereas more than half of animals presenting with strictures have recently undergone anesthesia. Most strictures are single, but occasionally they are multiple, and most occur near the lower esophageal high-pressure zone (Box 18.18). Strictures occur more commonly after circumferential esophageal trauma. To produce a stricture, esophageal damage must generally involve the muscular layers and affect most of the circumference in a focal area. The mucosal defect is then replaced by epithelial migration. The gap in the muscle is filled by fibrous connective tissue, and wound contraction and collagen remodeling reduce the width of the scar. This leads to narrowing of the esophageal lumen, which may cause obstruction. The degree of obstruction varies, depending on the severity of the original lesion. Peristaltic waves carrying food boluses are disrupted by the obstruction. In cases of partial obstruction, part of each bolus passes the obstruction and moves down the esophagus. The other portion of the bolus accumulates proximal to the obstruction, and the proximal esophagus may

BOX 18.18 Esophageal Strictures: Key Points

- Strictures form when the mucosa is traumatized
- Suspect if there has been an anesthetic episode during the previous month or the patient has been receiving tetracycline, doxycycline, nonsteroidal antiinflammatory drugs, or ciprofloxacin
- Signs may begin immediately after injury
- Often missed by survey radiography and sometimes by contrast radiography
- Esophagoscopy is diagnostic, but inexperienced endoscopists can miss lesions in larger animals or lesions near the lower esophageal sphincter
- Strictures may be multiple or single and may be very short or several centimeters long
- Most occur near the lower esophageal high-pressure zone
- Treat for esophagitis and pneumonia if indicated
- Balloon dilatation results in a satisfactory outcome in many patients, but some patients (especially those with long strictures) often need multiple balloonings and may never respond well
- Most can eat canned or dry food after treatment
- Strictures may recur

eventually distend. If distention occurs and is severe, it may disrupt normal neuromuscular function and reduce peristalsis. The accumulated food and secretions are frequently regurgitated.

Factors related to the development and severity of esophagitis following reflux include the duration of esophageal contact, acidity and presence of enzymes such as pepsin, effectiveness of esophageal clearance, and mucosal resistance to injury. Once esophagitis develops, a vicious circle can occur in that esophageal inflammation decreases lower esophageal high-pressure zone tone predisposing to more reflux, which exacerbates the inflammation, and so on. Gastroesophageal reflux may occur during general anesthesia when protective mechanisms are diminished and the gastroesophageal sphincter loses tone. There is no consensus on what constitutes a major risk factor for anesthesia-associated reflux with subsequent cicatrix. Gastric acid can damage the esophagus severely if not neutralized by saliva or removed by peristalsis within a few minutes. Signs of regurgitation may become evident within a few days or weeks after surgery because of stricture formation.

DIAGNOSIS

Clinical Presentation

Signalment

Any age, breed, or sex of dog or cat may be affected.

History

Regurgitation is the most common presenting sign, and stricture should be suspected in animals experiencing frequent regurgitation with a history of previous esophageal trauma, surgery, anesthetic episode, vomiting, or treatment with various drugs (i.e., tetracyclines, NSAIDs, ciprofloxacin, clindamycin). Some animals retain fluids but regurgitate solids. Pain may be experienced when solid food becomes lodged in the stricture by forceful esophageal peristaltic waves. Regurgitation or vomiting often begins within 2 weeks of an anesthetic episode. Vomiting and regurgitation are often associated with eating, ptyalism, gagging, and dysphagia. Weight loss, coughing, and aerophagia may also be recognized.

Physical Examination Findings

Although animals with esophageal strictures may be thin and depressed, physical examination is usually normal. Occasionally the cervical esophagus is dilated. There may be putrid breath secondary to decay of material retained in the esophagus. Patients with aspiration pneumonia may be febrile and have increased respiratory rate and effort, crackles, wheezes, and increased lung sounds.

Diagnostic Imaging

Care is required to identify esophageal strictures radiographically. Positive contrast esophagrams are required (Fig. 18.54). Partial strictures are more readily identified if barium is mixed with food and observed fluoroscopically. There may or may not be dilatation of the esophagus proximal to an abrupt narrowing. It may be difficult to determine the extent of a stricture radiographically.

Esophagoscopy

Esophagoscopy allows visualization of the lesion. The mucosa may be inflamed and eroded, or it may appear relatively normal but with a compromised diameter (Fig. 18.55). Occasionally the stricture is a ring of white fibrous tissue that narrows the esophageal lumen and fails to distend with insufflation. In severe cases, it may be impossible to advance the scope beyond the stricture, and gastric overdistention can be a significant complication of esophagoscopy if the scope cannot be passed into the stomach to suction air that was insufflated into the patient. Biopsy and histologic examination rule out stricture secondary to neoplasia.

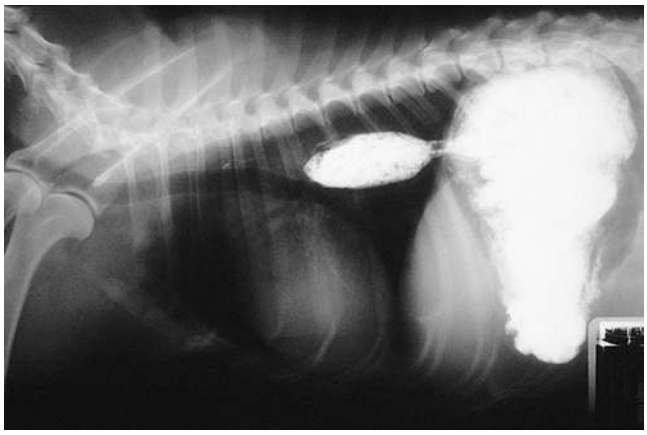

FIG. 18.54 Radiographic appearance of an esophageal stricture after the administration of barium. Notice the accumulation of contrast in the distal thoracic esophagus just cranial to the diaphragm.

FIG. 18.55 Endoscopic appearance of a distal esophageal stricture subsequent to anesthesia and surgery to remove mammary tumors.

Laboratory Findings

Animals with esophageal strictures show no specific laboratory abnormalities unless aspiration pneumonia is present.

DIFFERENTIAL DIAGNOSIS

Vascular ring anomalies, extraluminal masses, esophageal neoplasia, foreign bodies, esophagitis, gastroesophageal intussusception, esophageal diverticulum, hiatal hernias, megaesophagus,

and cricopharyngeal dysfunction are other possible causes of regurgitation that must be differentiated from esophageal stricture.

MEDICAL TREATMENT

The goal of treatment is to resolve regurgitation and maintain nutrition and hydration by oral feeding. Treat esophagitis (see p. 366) and aspiration pneumonia (see p. 367) as previously described (see Boxes 18.13 and 18.14). Sometimes one can soften the food by adding water until it is liquid enough to pass through the obstruction. A gastrostomy tube will allow feeding if the stricture is severe. Alter the environment so foreign bodies, which may become lodged at the stricture, are avoided.

SURGICAL TREATMENT

Strictures are treated by correcting the cause and then expanding the narrowed segment with balloon catheter dilatation or bougienage. Balloon catheter dilatation is typically preferred because there is less chance of perforation, but clinicians trained in bougienage can be just as successful as those using balloons. Electrocautery or laser incision of the scar tissue at three or four equidistant sites around the circumference of the stricture, intralesional injections of repositol steroids, topical application of mitomycin C after dilatation, insertion of stents, and/or use of balloon-esophagoscopy tubes can promote successful dilatation in many patients. Partial esophagectomy is usually not necessary and may not be possible, depending on the length of the stricture. Resistant cervical strictures may be corrected by the creation of a traction diverticulum.

Preoperative Management

Animals should be fasted before esophageal dilatation. Treatment for esophagitis and aspiration pneumonia should be initiated as needed, before stricture treatment (see pp. 366–367). Dilatation of esophageal strictures is associated with bacteremia in people, and preprocedural antibiotics are recommended, although there are no data on their effect on outcome in dogs and cats.

Anesthesia

General anesthesia is required for esophageal dilatation or bougienage. Recommendations for anesthesia in patients with esophageal disorders are given on p. 367 and Table 18.3.

Surgical Anatomy

The surgical anatomy of the esophagus is discussed on p. 369.

Positioning

Balloon dilatation and bougienage are generally performed with the patient in lateral recumbency.

SURGICAL TECHNIQUE

Bougienage

Bougienage involves the dilatation of a stricture using blunt dilators that are graduated in size. A lubricated, tapered probe (dilator) is pushed through the stricture. The initial dilator is followed by a graduated series of successively larger probes until the desired lumen size is achieved or excess resistance is encountered. Some types of dilators are passed over guide wires. The esophagus should be as straight as possible during the procedure. This technique is best done under direct endoscopic visualization or with fluoroscopic guidance. Bougienage also exerts a longitudinal shearing force at the stricture site that can be more traumatic than is usual with balloon dilatation; however, success is more related to the training of the endoscopist than the type of equipment (i.e., bougienage vs. balloon dilatation) used.

> **NOTE** It is advised that you are trained in this technique before attempting it, as it is possible to perforate the esophagus if you do it improperly.

Balloon Dilatation

There are two main techniques: placing a balloon catheter through the biopsy channel of the endoscope, and running the balloon catheter down and over a previously placed guide wire.

Guide wires may be placed endoscopically or fluoroscopically. It is safer to use a guide wire than to try to advance the balloon catheter down the esophagus without a guide wire. *First, place a guide wire through the stricture site. Use a wire that is stiff at one end and floppy at the other. If an endoscope is used, insert the floppy end of the wire through the scope's biopsy channel and through the stricture. Then, withdraw the endoscope from the patient while continually feeding the wire into the patient, thus removing the endoscope from around the wire while the latter is kept in the stricture. Next, place the balloon in the stricture by running the balloon catheter over the wire while observing it endoscopically. Once the balloon is positioned so that the middle of it is near the center of the stricture, inflate the balloon with fluid or air (depending on the type of balloon) and deflate it after a minute.* If (1) the stricture is very mature and thick and the balloon cannot rupture the stricture, or (2) ballooning is typically associated with excessive trauma and reformation of the stricture, it may be advantageous to incise mature fibrotic strictures at three or four sites around the circumference of the esophagus using an electrosurgical or laser unit prior to dilatation. This hopefully causes the stricture to rupture more evenly at three or four sites as opposed to causing a major, deep rupture at just one site.

The balloon must stay in the stricture during this process. If the balloon is not correctly positioned, it will migrate out of the stricture as it is inflated and the stricture will not be dilated. Progressively larger balloons may be used until the desired degree of dilatation has been achieved. The amount of dilatation necessary is subjective and should not be overly ambitious. Most small animals will be functional if the esophageal lumen is opened up to 10 mm; larger animals may need to be opened up to 15 or even 20 mm. Repeat the dilatation as often as necessary to attain a satisfactory outcome. Many animals only require 1 dilation, but some require 15 or more. If multiple dilations are required, they are usually done two to three times weekly until the stricture no longer reforms.

> **NOTE** Cause as little trauma as possible during dilation to lessen the likelihood of stricture reformation. Try not to tear off or aspirate any more esophageal mucosa than is absolutely necessary.

To inhibit scarring and reformation of the stricture postdilatation, one may topically apply mitomycin C. *Reconstitute 5 mg*

of mitomycin C in 10 mL of sterile water. Soak a gauze sponge in this solution, grasp it with endoscopic forceps that have already been placed through the endoscope, and then pass the scope, forceps, and sponge into the esophagus, taking care to minimize application of the mitomycin to other parts of the esophagus. Leave the gauze that is soaked in the mitomycin for 5 minutes on the sites where the mucosa is torn and on the submucosa. Then remove the sponge and wash the site with 50 mL of sterile water, which is then aspirated by the endoscope. Follow routine precautions for chemotherapeutic drugs.

Another technique is to inject repositol steroids (e.g., triamcinolone acetate). A needle catheter designed to be placed through the biopsy channel of the endoscope is used to place a total dose of 1 to 2 mL of the steroid in three to four spots around the circumference of the site. The steroids may be injected before or after dilatation. The author prefers to inject after the dilatation procedure.

The goal is to open the stricture just enough so that the patient is functional and can eat soft food, not just gruel. It is often not possible to completely eliminate the stricture. These patients are often at risk for esophageal foreign bodies at the site of the stricture, as usually some degree of lumen compromise remains.

Covered, nonbiodegradable stents have been used successfully in some dogs. Biodegradable, metallic, and plastic stents have been described in the treatment of refractory canine esophageal strictures.[10] Stenting followed attempts at treating with balloon dilatation and included polydioxanone, polyurethane, and nitinol stents. The majority were sutured in place to prevent migration, and complications included ptyalism, regurgitation, dysphagia, vomiting, megaesophagus, gagging, and stent migration in the short term. Despite improvement in dysphagia score, complications long term included restructure following stent dissolution, migration, vomiting, regurgitation, hyperplastic tissue growth, and tracheoesophageal fistula formation. Half of the dogs were euthanized due to stent-related complications. Failure of dilatory therapy may necessitate esophageal resection or replacement. A relatively new technique involves placing an esophagostomy tube that also has a balloon at the distal end. After initial dilation of the stricture, the tube is placed much like any esophagostomy tube but with care taken to ensure that the balloon is present in the stricture. The dog is then sent home, and the owner inflates the balloon once or twice daily for 4 to 6 weeks. Care must be taken to select clients that are able to perform the needed dilations and care for the tube.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

When dilating an esophageal stricture, balloons specifically designed for use in the esophagus should be used (e.g., MaxForce TTS High Performance Balloon Dilatation Catheter). Electrocautery snares and injection needles for use through endoscopes are available (e.g., Olympus Corp.). Stents custom built for specific animals may be ordered (e.g., Infinity Corp.). An electrosurgical unit adaptable to laparoscopic sites or a laser unit is advantageous with mature fibrotic strictures.

POSTOPERATIVE CARE AND ASSESSMENT

Continue to monitor for regurgitation and aspiration pneumonia. Superficial mucosal tears are expected following dilation. However, patients should be monitored closely for signs of perforation, which include dysphagia, subcutaneous emphysema, pneumothorax, pneumomediastinum, and mediastinitis. Nasal oxygen may benefit these animals postoperatively, and analgesics (see Chapter 13) should be provided if necessary (esophageal lesions are surprisingly painful). If perforation is suspected, one should verify with thoracic radiographs. A small rupture may be treated by placing a gastrostomy tube and administering antibiotics. A major rupture will require surgical closure. Monitor for hemorrhage, which, although rare, can require transfusion. Diverticulum formation is another complication that may develop (see later discussion).

If the procedure has caused a substantial mucosal tear, therapy for esophagitis (antacids, prokinetics, sucralfate, antibiotics) may be administered (see Boxes 18.13 and 18.14). Antibiotic therapy intuitively makes sense, but there are no data showing that it has an effect on outcome. Glucocorticoid (e.g., prednisolone, 1.1 mg/kg given orally once a day) may be administered to help prevent stricture reformation, but the effect of systemic treatment on outcome is unknown, whereas some data suggest intralesional steroids are effective. Preexisting esophagitis and aspiration pneumonia should be treated as described on pp. 366 to 367. Placement of a gastrostomy tube (see p. 97) may be beneficial in these patients so that oral feeding can be avoided for 7 to 10 days but the patient can be kept in a positive nitrogen balance during healing. When oral feeding is resumed, feed small, frequent meals of a soft (not gruel) consistency.

PROGNOSIS

Most patients (approximately 85%) with esophageal strictures can be helped by dilatation, but strictures may reform. Most are able to tolerate canned or dry food without regurgitation, but some require gruel. Thin stricture bands may require only a single dilatation; however, patients with severe or long strictures often require multiple dilatations. There is a more guarded prognosis if strictures are several centimeters long; if there is dense, thick, mature fibrous tissue; or if severe esophagitis is persistent. Prognosis is worse if perforation occurs. Resection of long strictures may result in dehiscence caused by excessive anastomotic tension. Bougienage is commonly associated with a good outcome in a majority of dogs and cats, but multiple sessions are typically required and one-quarter to one-third of animals treated with this technique may have a poor outcome.

ESOPHAGEAL DIVERTICULA

DEFINITIONS

Esophageal diverticula are saclike dilatations that produce pouches in the wall of the esophagus. A **pulsion diverticulum** is a herniation of the mucosa through the muscular layers of the esophagus. These diverticula are produced by exaggerated intraluminal pressure in association with abnormal regional peristalsis or when obstruction interferes with normal peristalsis. **Traction diverticula** are distortions, angulations, or funnel-shaped bulges of the full-thickness wall of the esophagus caused by adhesions resulting from an external lesion.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Esophageal diverticula are rare. They may be acquired or congenital and are most commonly found in the distal cervical esophagus cranial to the thoracic inlet or in the distal thoracic esophagus just cranial to the diaphragm (epiphrenic). *Congenital diverticula* are believed to develop as a result of a congenital weakness of the esophageal wall, abnormal separation of tracheal and esophageal embryonic buds, or eccentric vacuole formation in the esophagus. Acquired forms are classified as pulsion or traction diverticula based on their cause. *Pulsion diverticula* are most common in the epiphrenic area but can form cranial to any diseased esophageal segment. Many conditions may initiate the formation of diverticula, including esophagitis, esophageal stenosis, foreign bodies, vascular ring anomalies, neuromuscular dysfunction, and hiatal hernias. The esophageal mucosa herniates secondary to increased intraluminal pressure, accumulation of food, and esophageal inflammation. The wall of a pulsion diverticulum consists of only esophageal epithelium and connective tissue.

Traction diverticula occur after an inflammatory process involving the trachea, bronchi, lymph nodes, or other extraesophageal structures. Inflammation causes fibrous tissue to form between the esophagus and the diseased structure. As the fibrous tissue matures, it contracts and pulls an area of the esophagus outward to form a pouch. Most traction diverticula occur in the cranial and midthoracic esophagus. The wall of a traction diverticulum consists of adventitia, muscle, submucosa, and mucosa.

DIAGNOSIS

Clinical Presentation

Signalment

Any age, breed, or sex of dog or cat may be affected.

History

Small diverticula can be asymptomatic. Large, multilobulated diverticula are usually associated with clinical signs. Diverticula may result in esophageal impaction, chronic esophagitis, and rupture of the diverticulum wall, with resultant mediastinitis or the formation of an esophagotracheal-bronchial fistula. Clinical signs may include distress or gasping after eating, postprandial regurgitation, intermittent anorexia, fever, weight loss, thoracic or abdominal pain, and respiratory distress.

Physical Examination Findings

The physical examination is normal if the diverticulum is asymptomatic. Abnormal lung sounds may be auscultated if aspiration pneumonia has developed.

Diagnostic Imaging

Contrast radiographs are required. Be sure not to confuse the normal esophageal redundancy, seen in brachycephalic breeds and shar peis, with esophageal pathology. Diverticula appear as air-filled or food-filled masses in the area of the esophagus. An esophagram usually demonstrates a deviation or outpouching of the esophageal lumen that fills partly or completely with contrast material. Esophagoscopy is helpful in confirming the radiographic diagnosis and identifying associated esophagitis, strictures, or other abnormalities. The esophageal wall may be very thin, and esophagoscopy must be performed with care.

NOTE Dogs and cats with generalized megaesophagus tend to have greater outpouching of the esophageal wall cranial to the base of the heart. Brachycephalic dogs and shar peis often have a loop of redundant esophagus cranial to the base of the heart. Do not misdiagnose these animals as having diverticula.

Laboratory Findings

Esophageal diverticula do not produce any specific laboratory abnormalities. Laboratory findings consistent with pyothorax (see p. 949) may result if the diverticulum has ruptured. Neutrophilia may be present if aspiration pneumonia has developed.

DIFFERENTIAL DIAGNOSIS

Esophageal hiatal hernia, gastroesophageal intussusception, stricture, neoplasia, extraluminal masses, vascular ring anomalies, esophageal foreign body, esophagitis, and megaesophagus are other possible causes of regurgitation.

SURGICAL TREATMENT

Persistent underlying causes of the diverticula must be identified and treated. Asymptomatic, small diverticula may be treated by feeding a soft, bland diet with the animal in an upright position to avoid food accumulation in the pouch. Large diverticula should be surgically excised.

Preoperative Management

Esophagitis and aspiration pneumonia should be treated preoperatively as described on pp. 366 to 367. Prophylactic antibiotics are indicated if esophageal resection is considered likely.

Anesthesia

Anesthetic recommendations for animals undergoing cervical esophageal surgery are discussed on p. 367 and in Table 18.3. Anesthetic recommendations for thoracotomy are given on p. 884, Table 29.1, and Table 30.3.

Surgical Anatomy

The surgical anatomy of the esophagus is described on p. 369.

Positioning

Patients are positioned in dorsal or lateral recumbency, depending on the site of the diverticulum. Radiographs are important to help determine the best surgical approach. Diverticula in the cervical esophagus are approached via a ventral cervical midline incision with the animal in dorsal recumbency. Thoracic diverticula are usually approached via a lateral thoracotomy. Occasionally a median sternotomy or thoracic wall flap may be necessary to approach diverticula at the thoracic inlet or cranial mediastinum.

SURGICAL TECHNIQUE

After identifying the diverticulum, isolate it from surrounding structures with blunt and sharp dissection and then pack it off with laparotomy pads. Partial lung lobectomy may be necessary if adhesions cannot be easily separated. *Position a thoracoabdominal (TA; linear) or GIA (gastrointestinal anastomosis) stapling device along the base of the diverticulum and fire. Transect and*

remove the diverticulum without contaminating the surgical site. If stapling equipment is not available, suction the esophageal lumen and place noncrushing forceps across the proposed transection site. Transect the diverticulum and appose the edges as for esophagotomy with a one- or two-layer simple appositional pattern (see p. 370). Lavage the surgical site and, if possible, mobilize and place omentum over the incision. Thoracostomy tubes may be placed in animals having thoracotomies to evacuate residual air and fluid.

POSTOPERATIVE CARE AND ASSESSMENT

After surgery, these patients should be monitored for esophagitis and aspiration pneumonia and treated appropriately (see pp. 366–367). Postoperative esophagoscopy and esophagrams may be indicated if problems are detected. Regurgitation that occurs secondary to persistent esophagitis is a possible problem. Infection as a result of contamination of the surrounding tissues during surgery, dehiscence, or leakage at the surgical site are other possible problems. Postoperative analgesics should be provided to control pain (see p. 886 for recommendations after thoracotomy).

PROGNOSIS

Asymptomatic patients often continue to do well without surgery; feeding them in an upright position to avoid food accumulation in the diverticula may help. Clinical signs may be difficult to control in symptomatic patients with medical therapy alone. If surgery is not possible, such patients should be treated for esophagitis and fed soft food in an upright position. The prognosis with surgical correction is good if thoracic contamination is avoided and good esophageal apposition is achieved.

ESOPHAGEAL NEOPLASIA

DEFINITION

Esophageal neoplasia is any abnormal, noninflammatory proliferation of cells in the esophagus.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Esophageal neoplasia is rare and usually malignant. Tumors are often locally invasive and metastasize through lymphatic and hematogenous routes. The most common types of tumors are sarcomas, SCCs, and leiomyomas. Leiomyomas have been reported at the lower esophageal high-pressure zone in aged beagles. These tumors are usually advanced by the time clinical signs are recognized. Primary esophageal carcinomas are of unknown etiology. Primary esophageal sarcomas (osteosarcoma, fibrosarcoma) are often located in the vicinity of parasitic granulomas caused by *Spirocerca lupi*. The life cycle of *S. lupi* involves a coprophagous beetle that the dog has eaten or a transport host that the dog subsequently eats. Tumors from the thyroid, thymus, heart base, or lung may invade the esophagus secondarily.

Esophageal tumors initially cause partial obstruction of the esophagus, which may interfere with motility and lead to dilatation of the proximal esophagus. As the tumor enlarges, signs of complete esophageal obstruction become apparent. Most esophageal tumors are locally invasive and metastasize to draining lymph nodes.

DIAGNOSIS

Clinical Presentation

Signalment

In cats, SCCs are usually seen in females in the middle third of the esophagus just caudal to the thoracic inlet. Most esophageal tumors occur in dogs and cats over 6 to 8 years of age.

History

Chronic progressive signs of obstructive esophageal disease in middle-aged and older animals suggest esophageal neoplasia. Animals with primary tumors may be asymptomatic until the mass becomes large enough to cause near complete obstruction. These animals may be presented for regurgitation, lethargy, depression, drooling, dysphagia, anorexia, weight loss, and/or fetid breath. In animals with secondary tumors, clinical signs may include regurgitation, dyspnea, palpable masses, and/or systemic and local tumor effects.

Physical Examination Findings

The physical examination is usually normal. Some animals are thin, and a dilated cervical esophagus may be identified. Hypertrophic osteopathy and spondylosis deformans may be noted, especially with *S. lupi*–induced sarcomas. Some will have pyrexia, submandibular swelling, pale mucous membranes, melena, salivation, cough, neurologic signs, and weight loss. Crackles from aspiration pneumonia may be detected.

Diagnostic Imaging

Aerophagia (swallowing of air), displacement of the esophagus, and megaesophagus may be signs of esophageal neoplasia. Survey thoracic radiographs may be normal or may reveal a soft tissue opacity in the plane of the esophagus or mediastinum (Fig. 18.56). This density may be impossible to distinguish from esophageal foreign body in some cases. The esophagus may retain air cranial to the tumor, or megaesophagus may be present.[11] The lungs should be evaluated for metastatic lesions. Contrast esophagrams may demonstrate an intraluminal mass (mucosal irregularities, filling defects, or stricture) with primary tumors, or an impinging

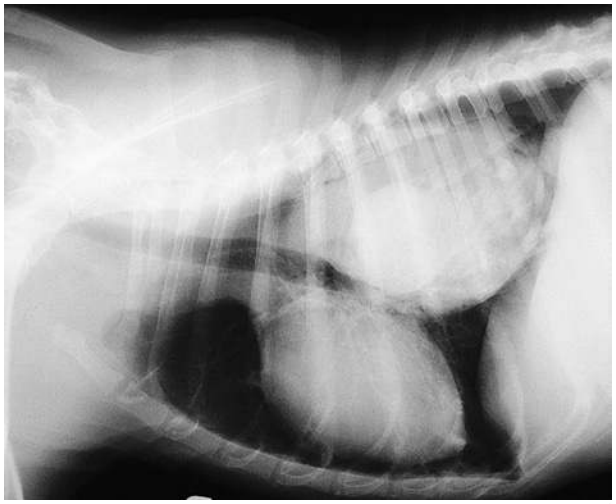

FIG. 18.56 Lateral thoracic radiograph of an 8-year-old dog with a large esophageal carcinoma. Notice the soft tissue opacity mass in the plane of the distal thoracic esophagus.

FIG. 18.57 Appearance of an intraluminal mass on esophagoscopy. Esophagoscopy allows biopsy of such masses.

mural or extraluminal mass with smooth mucosal margins and no filling defect with secondary tumors. Fluoroscopic studies may reveal abnormal motility. Signs of spondylosis and spondylitis may be detected at the ventral aspect of the cervical and thoracic vertebrae. Dogs with *S. lupi* infestation commonly have spondylosis deformans or spondylitis of the cervical or thoracic vertebrae with or without hypertrophic osteopathy. CT scans may help determine the degree of esophageal wall involvement. Esophagoscopy allows direct visualization of intraluminal masses and biopsy for definitive diagnosis (Fig. 18.57). An adult *S. lupi* worm is occasionally seen protruding into the lumen from the mass. Identification of a granuloma with a nipple-like orifice is characteristic of spirocercosis. Extraluminal masses cannot be visualized unless they have eroded into the lumen. It is difficult to inflate the lumen if it is impinged on or has been invaded by extraluminal masses.

Laboratory Findings

Laboratory values may indicate chronic disease or paraneoplastic syndromes. Animals with spirocercosis-associated sarcomas may have neutrophilic leukocytosis (82%) and microcytic anemia (30%). *S. lupi* eggs may be detected on a fecal sedimentation test but are usually difficult to find. A histologic diagnosis of esophageal sarcoma in addition to detecting *S. lupi* eggs in feces, esophageal nodular granulomas, or spondylitis of the caudal thoracic vertebrae is considered diagnostic of spirocercosis-associated sarcomas.

DIFFERENTIAL DIAGNOSIS

Esophageal stricture, extraluminal masses, vascular ring anomalies, esophageal foreign body, esophagitis, gastroesophageal intussusception, esophageal diverticulum, hiatal hernia, and megaesophagus are other possible causes of regurgitation. The clinical signs of ptyalism, odynophagia, and sialadenopathy associated with *Spirocerca* lesions appear similar to the clinical signs in dogs with salivary gland necrosis and necrotizing sialometaplasia syndrome.

SURGICAL TREATMENT

Early diagnosis is important, before metastasis or extensive esophageal involvement has occurred. Partial esophagectomy with end-to-end anastomosis is indicated when approximation can be accomplished without excess tension. Endoscopic mass ablation has been described in a series of dogs.[12] Complications included esophageal perforation, excess mucosal resection, and esophageal hemorrhage. Short-term treatment of an esophageal tumor with a metallic stent has also been described.[13]

Preoperative Management

S. lupi–associated esophageal granulomas often resolve after treatment with doramectin (200 mg/kg given subcutaneously at 14-day intervals for three treatments). Complete resolution of the esophageal nodules is possible, and adverse drug effects are not expected. Chemotherapy, radiation therapy, or photodynamic therapy may be beneficial in some animals.

Anesthesia

Anesthetic recommendations for animals undergoing cervical esophageal surgery are provided on p. 367 and in Table 18.3. Selected anesthetic protocols for animals undergoing thoracic surgery are provided on p. 884, Table 29.1, and Table 30.3.

Surgical Anatomy

The surgical anatomy of the esophagus is described on p. 369.

SURGICAL TECHNIQUE

Esophagectomy is described on p. 371. Refer to p. 375 for a description of suture material and special instruments for esophageal surgery.

POSTOPERATIVE CARE AND ASSESSMENT

The patient should be monitored for esophagitis and aspiration pneumonia and treated as needed postoperatively (see pp. 366–367). Nasal oxygen may benefit these animals, and analgesics should be provided to control pain. See p. 375 for recommendations for postoperative care of animals undergoing esophageal surgery. Dehiscence caused by excessive tension at the anastomosis and tumor recurrence are possible complications of esophageal surgery. Continue doramectin treatment in animals with spirocercosis.

PROGNOSIS

Most esophageal tumors are advanced at the time of diagnosis and do not respond well to radiation therapy or chemotherapy. Radiation therapy may be palliative, but radiation-induced esophagitis or damage to the heart, lungs, and great vessels are possible sequelae that are poorly tolerated. Photodynamic therapy may palliate some nonresectable tumors. Resection may be curative for leiomyomas, but the prognosis for other malignancies is guarded for cure or palliation because resection is difficult due to the advanced nature of most tumors at the time of detection.

HIATAL HERNIA

DEFINITION

Hiatal hernias are protrusions of the abdominal esophagus, gastroesophageal junction, and sometimes a portion of the gastric fundus through the esophageal hiatus into the caudal mediastinum cranial to the diaphragm.

BOX 18.19 Hiatal Hernia: Key Points

- Most are congenital rather than acquired
- Shar peis and English bulldogs are most commonly affected
- Some are asymptomatic
- Symptomatic animals often have regurgitation and esophagitis
- Herniation may be intermittent, making radiographic diagnosis challenging
- Herniorrhaphy includes hiatal reduction, esophagopexy, and left-sided gastropexy
- Surgery is usually most appropriate for younger symptomatic animals; older symptomatic animals are usually best treated medically
- Treat for esophagitis initially after surgery
- Prognosis is usually good after repair

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Hiatal hernias usually are caused by congenital abnormalities of the hiatus that allow cranial movement of the abdominal esophagus and stomach (Box 18.19). The phrenicoesophageal ligament is lax or stretched and allows the gastroesophageal junction to be displaced through the hiatus into the caudal mediastinum. Malpositioning or lack of support of the gastroesophageal sphincter reduces gastroesophageal sphincter pressure and leads to gastroesophageal reflux. Gastroesophageal reflux and subsequent esophagitis and megaesophagus are responsible for most of the clinical signs. Hiatal hernia occasionally occurs secondary to trauma and has occurred concurrently with severe respiratory distress. Trauma may damage diaphragmatic nerves and muscles, resulting in hiatal laxity and subsequent herniation. In patients with upper respiratory obstruction, reduced intrathoracic pressure during inspiration has been theorized to contribute to esophageal reflux and visceral herniation. Hiatal hernia has been reported with tetanus.

With hiatal hernias, the stomach commonly slides in and out of the thorax. If the hernia is large enough, other abdominal viscera may also be cranially displaced into the thorax. Various types of hiatal abnormalities have been described (Fig. 18.58). In patients with sliding or axial hiatal hernias, the gastroesophageal junction is located within the thoracic cavity. In patients with paraesophageal or rolling hiatal hernias, the gastroesophageal junction is usually located in a normal position, and the gastric fundus or other abdominal viscera are displaced through the hiatus and located in the thorax. Some hiatal hernias are a combination of sliding and paraesophageal hernias, with the gastroesophageal junction and gastric fundus both displaced.

DIAGNOSIS

Clinical Presentation

Signalment

Hiatal hernias may occur in a variety of dog and cat breeds; however, males, Shar Peis, and brachycephalic dogs appear to be predisposed. Hiatal hernia was diagnosed in 76% of golden retrievers with muscular dystrophy[14] and in one-third of cats evaluated for dysphagia.[15] Most symptomatic animals have signs relating to congenital hiatal hernia before reaching 1 year of age, although diagnosis may occur later. Patients with acquired hernias may develop signs at any age.

History

Regurgitation is the primary clinical sign in symptomatic individuals, but many patients are asymptomatic. Other signs may include vomiting, hypersalivation, dysphagia, respiratory distress, hematemesis, anorexia, and weight loss. Severe dyspnea or trauma may have occurred.

Physical Examination Findings

Affected patients may be thin on physical examination. Abnormal lung sounds are ausculted with aspiration pneumonia.

Diagnostic Imaging

Hiatal hernias usually appear as a soft tissue or soft tissue/gas–filled mass near the esophageal hiatus in the caudodorsal thoracic region on survey radiographs (Fig. 18.59). However, with sliding hernias, several radiographs may be necessary to identify the herniation, which may be intermittent. Intermittent hernias are particularly common in cats. The presence of gas in the herniated portion aids in identification of the mass as herniated stomach. Varying degrees of megaesophagus and pneumonia may be noted. A positive contrast esophagram should show the gastroesophageal junction, rugal folds, or both, cranial to the hiatus. Occasionally, strictures may be identified. Fluoroscopy may demonstrate hypomotility, delayed clearing of the distal esophagus, or gastroesophageal reflux. Compressing the abdomen during fluoroscopy may help identify hernias. Esophagoscopy can sometimes detect the hernia (i.e., gastric mucosa that has entered the thoracic cavity), as well as esophagitis (inflammation, mucosal erosion), gastric reflux, and strictures. Some hiatal hernias are intermittent (sliding) and require multiple radiographs or fluoroscopy (or both) to diagnose. Do not confuse hiatal hernias with peritoneopericardial (see p. 931) or traumatic (see p. 926) diaphragmatic hernias, despite their sometimes having a similar radiographic appearance. Hiatal hernias are typically located in the plane of the caudal mediastinum.

Laboratory Findings

Hematologic and serum chemistry results are nonspecific in affected animals.

DIFFERENTIAL DIAGNOSIS

Esophageal stricture, neoplasia, extraluminal masses, vascular ring anomalies, esophageal foreign body or perforation, esophagitis, esophageal intussusception, esophageal diverticulum, and megaesophagus are other possible causes of regurgitation.

SURGICAL TREATMENT

Affected patients may benefit from medical treatment for gastroesophageal reflux or esophagitis (see p. 366) because hiatal hernias may be "innocent bystanders" in a patient with symptoms resulting from other problems. Surgery is generally recommended in symptomatic, young animals with congenital disease that does not respond to appropriate medical treatment. A number of surgical techniques have been described for correcting hiatal hernias. Diaphragmatic hiatal reduction and plication, esophagopexy, and left-sided fundic gastropexy are described here. Gastropexy is probably the most important step in the repair. Displacing the terminal esophagus slightly caudally with a left-sided gastropexy increases barrier pressure at the gastroesophageal

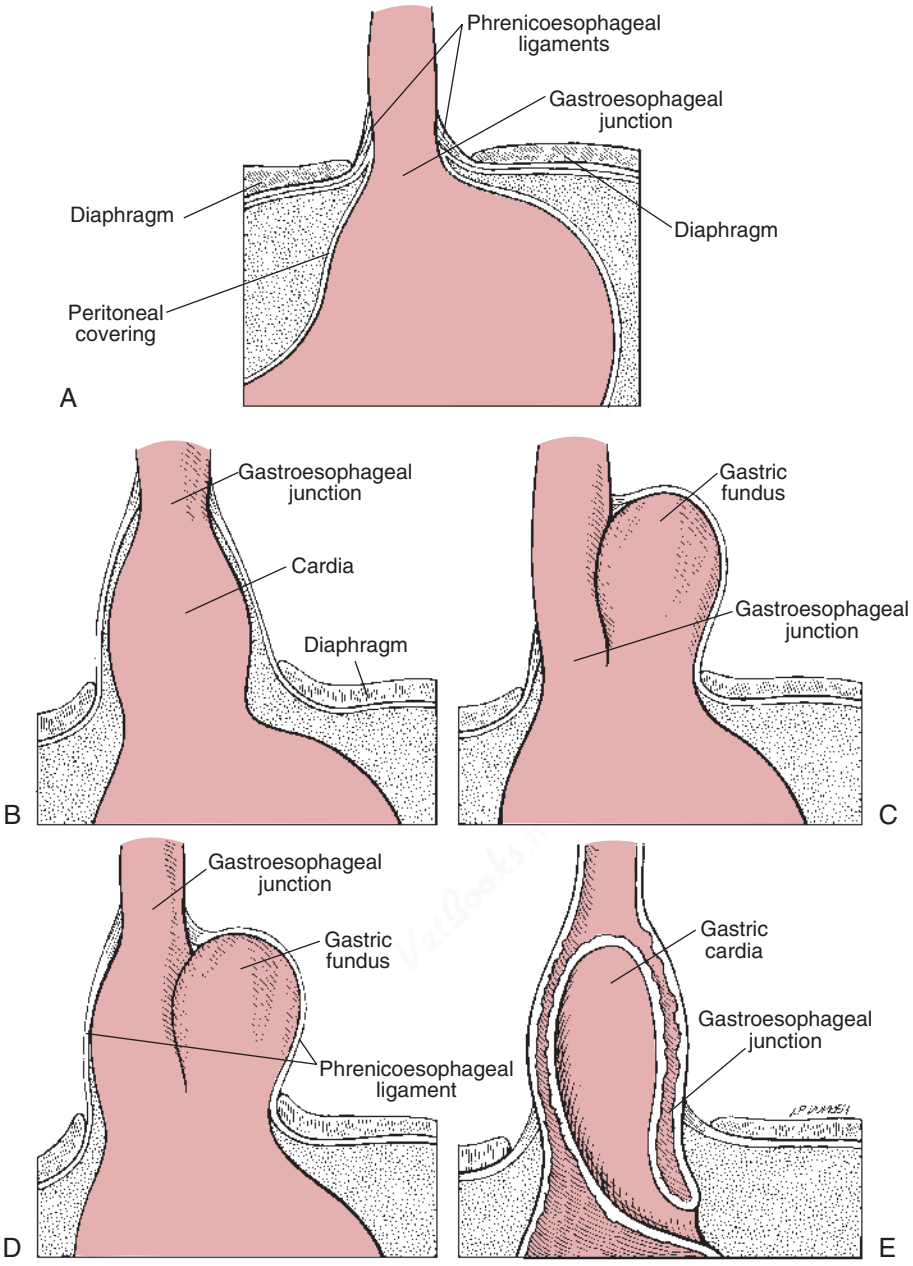

FIG. 18.58 Diagrams of a (A) normal gastroesophageal junction and (B–E) hiatal abnormalities. (B) Sliding or axial hiatal hernia. (C) Paraesophageal or rolling hiatal hernia. (D) Combination sliding and paraesophageal hernia. (E) Gastroesophageal intussusception.

junction, and reflux disease often resolves after the procedure. If esophagitis is severe and oral intake is to be withheld for several days, a gastrostomy tube (see p. 97) allows early alimentation without further esophageal irritation. Some surgeons perform sphincter-enhancing procedures, such as a Nissen fundoplication (antireflux procedure), instead of the aforementioned techniques. However, fundoplication or other antireflux procedures are only indicated in patients with evidence of gastroesophageal reflux. In dogs and cats, primary incompetence of the caudal esophageal sphincter has not been documented in association with hiatal hernia; therefore antireflux procedures are not routinely recommended.

Preoperative Management

Reflux esophagitis and aspiration pneumonia should be treated before induction of anesthesia (see pp. 366–367). Feeding frequent, small meals of high-protein/low-fat foods may be beneficial. If megaesophagus is present, feeding affected animals in a standing, upright position may reduce regurgitation.

Anesthesia

Positive-pressure ventilation may be necessary if pneumothorax is created during hiatal manipulations. Nitrous oxide should not be used in these patients. Negative intrathoracic pressure is reestablished by thoracentesis or tube thoracostomy after hiatal

manipulations are complete. See p. 367 and Table 18.3 for anesthetic recommendations for patients undergoing esophageal surgery and p. 884, Table 29.1, and Table 30.3 for recommendations for patients undergoing thoracic surgery.

Surgical Anatomy

The esophageal hiatus is one of three openings in the diaphragm. The esophageal hiatus is more centrally located than the caval foramen (located ventrally) or aortic hiatus (located dorsally). The esophagus passes through the esophageal hiatus, along with the vagal nerve trunks and esophageal vessels. The esophageal hiatus is surrounded by the phrenicoesophageal ligament, the thickened collagen fibers of which are weakened, stretched, or in some way defective in hiatal hernias. The terminal 1 to 2 cm of the esophagus is expected to lie within the abdominal cavity caudal to the diaphragm. The esophagogastric junction and gastroesophageal sphincter, which are in the abdomen, regulate movement of ingesta between the esophagus and the stomach.

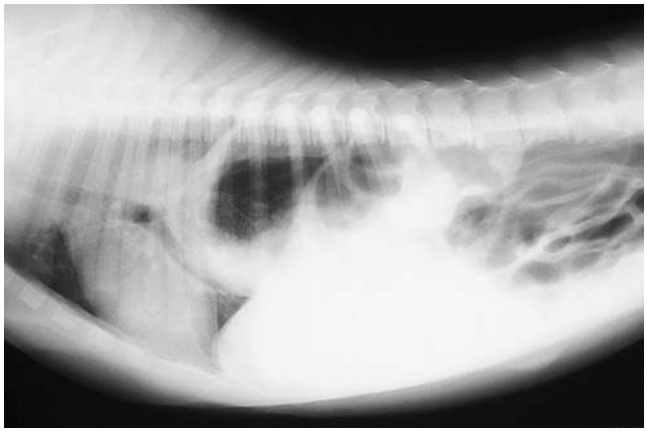

FIG. 18.59 Lateral radiograph of a 12-week-old shar pei with a hiatal hernia. Note the air-filled mass (stomach) in the caudal thorax.

Positioning

Patients are positioned in dorsal recumbency, and the caudal thorax and ventral abdomen are prepared for aseptic surgery.

SURGICAL TECHNIQUE

Make a cranial ventral midline incision extending caudal to the umbilicus to expose the diaphragm and stomach. Retract the left lobes of the liver medially to expose the esophageal hiatus. Pass a stomach tube (28- to 32-Fr) to help identify and manipulate the esophagus. Grasp the stomach and reduce the hernia with gentle traction. Examine the hiatus. Dissect the phrenicoesophageal membrane, freeing the esophagus from the diaphragm ventrally. Preserve the vagal trunks and esophageal vessels during dissection. Place an umbilical tape sling around the abdominal esophagus to displace it caudally and facilitate manipulations. Perform a diaphragmatic hiatal plication-reduction, esophagopexy, and left-sided fundic gastropexy. Accomplish diaphragmatic hiatal plication-reduction by excoriating or debriding the margins of the hiatus and then place three to five sutures (2-0 polydioxanone or polypropylene) to appose the edges and narrow the hiatus (Fig. 18.60).

Perform plication around a large stomach tube (28- to 32-Fr) (see Fig. 18.60). Reduce the hiatus to 1 or 2 cm, a size that allows passage of one finger. Accomplish esophagopexy by placing sutures (3-0 or 2-0 polydioxanone or polypropylene) from the remaining margin of the hiatus through the adventitia and muscular layers of the abdominal esophagus. Complete the repair with either a left-sided tube gastropexy or incisional gastropexy (see pp. 406–408). Fix the fundus with slight to moderate caudal traction to prevent cranial movement of the gastroesophageal junction into the thorax. Evacuate air from the chest by thoracentesis or tube thoracostomy and lavage and close the abdomen.

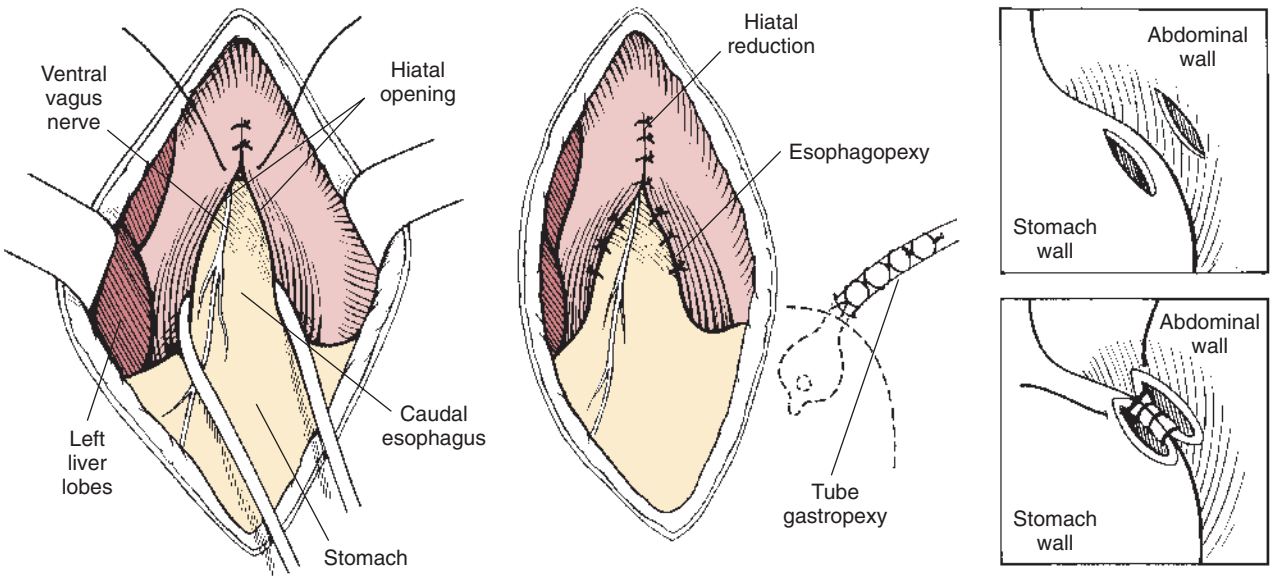

FIG. 18.60 Reduce hiatal hernias and reduce the size of the esophageal hiatus with plicating sutures. Suture the esophagus to the diaphragm (esophagopexy) and perform a tube or incisional gastropexy *(insets)* at the fundus.

POSTOPERATIVE CARE AND ASSESSMENT

Patients should be monitored after surgery for dyspnea caused by pneumothorax, and air should be evacuated from the thorax as necessary. Nasal oxygen may benefit dyspneic animals. Analgesics should be provided as necessary to control pain (see Table 13.2). Affected animals may continue to regurgitate after surgery because of persistent esophagitis or reflux or if the repair caused obstruction at the lower esophageal high-pressure zone. Treatment of esophagitis and aspiration pneumonia should be continued postoperatively (see pp. 366–367). Feed small portions of low-fat, high-protein, softened or liquefied food three to five times a day. Feeding from an elevated platform may be beneficial in animals with concurrent esophageal weakness. Postoperative esophagoscopy may benefit patients with persistent clinical signs by identifying persistent herniation, obstruction, or ulceration.

COMPLICATIONS

Dysphagia is common for several days; however, if it continues beyond that time, the hiatus may have been overreduced, requiring reoperation. Infection may occur if the esophageal or gastric lumen is penetrated with sutures or tubes. Possible problems after antireflux procedures include gastric dilatation, necrotic gastritis, and acute death.

PROGNOSIS

The prognosis without surgery is good in asymptomatic patients and those that respond to medical therapy; however, symptomatic patients that do not respond to medical therapy and are not surgically repaired may develop severe esophagitis and stricture. The prognosis is good; however, aspiration pneumonia must be controlled for a favorable outcome. Patients with gastroesophageal sphincter incompetence may benefit from additional antireflux procedures.

GASTROESOPHAGEAL INTUSSUSCEPTION

DEFINITION

Gastroesophageal intussusception (*esophageal intussusception, gastroesophageal invagination, esophageal invagination*) is the invagination of the gastric cardia into the distal esophagus with or without the spleen, duodenum, pancreas, and omentum.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Gastroesophageal intussusception is a rare condition that can be confused with esophageal hiatal hernia (see Fig. 18.58E). Most reports in the literature are of solitary cases. The gastroesophageal junction does not move cranially into the thorax as with a sliding hiatal hernia, and the cardia is within the esophageal lumen rather than external to the esophagus as with a paraesophageal hiatal hernia. Gastroesophageal intussusception usually occurs in immature animals with megaesophagus. The etiology of gastroesophageal intussusception is unknown. Idiopathic megaesophagus or incompetency of the gastroesophageal sphincter mechanism or abnormal esophageal motility and subsequent regurgitation may predispose an animal to this disorder. Vomiting and retching cause the esophagus to dilate. Experimental work in puppies has shown that vomiting can cause invagination of the gastric cardia into the esophagus. A large or lax esophageal hiatus may be necessary to allow the gastric cardia to move cranially into the esophagus. Entrapment or strangulation of the invaginated stomach occurs, causing esophageal obstruction, continued regurgitation, and rapid fluid loss. Discomfort is caused by stretching of gastric mesenteric attachments and esophagitis. Severe respiratory distress is caused by the greatly enlarged esophagus compressing the pulmonary parenchyma or by aspiration pneumonia (or both). Cardiovascular collapse occurs secondary to obstruction of venous return and eventually of the arterial blood supply. The resulting congestion, inflammation, and necrosis contribute to the animal's deterioration. The condition is even rarer in cats, but has been seen in conjunction with megaesophagus.

DIAGNOSIS

Clinical Presentation

Signalment

Although several breeds have been reported with gastroesophageal intussusception, German shepherds and other large-breed dogs seem to be at increased risk. More cases have been reported in males than in females. The condition is most common in young dogs, usually under 3 months of age. Gastroesophageal intussusception has been reported in cats.

History

In most cases there is acute onset of clinical signs (e.g., regurgitation, vomiting, dyspnea, hematemesis, abdominal discomfort, rapid deterioration, death) with rapid deterioration and death within 1 to 3 days if the condition is not treated immediately. Signs may mimic those of aspiration pneumonia, making the diagnosis difficult. Approximately half of affected animals have a history of esophageal disease, and a few have been reported with chronic, intermittent clinical signs including recurrent vomiting and regurgitation and lethargy. These chronic cases may be secondary to a sliding intussusception.

Physical Examination Findings

Animals may be thin and show pain on abdominal palpation. Signs of shock may be noted (i.e., poor capillary refill, pale mucous membranes, labored breathing, tachycardia, and thready pulse).

Diagnostic Imaging

Radiographs show a dilated distal esophagus with a luminal soft tissue mass (Fig. 18.61). Rugal folds may be associated with the soft tissue mass. The trachea may be deviated ventrally, and signs of aspiration pneumonia may be apparent. The normal gastric gas bubble usually seen in the cranial abdomen may be absent or diminished in size. The intussusception can be outlined by either positive or negative contrast studies; however, this may be difficult to perform, as these patients are often severely dyspneic. Esophagoscopy reveals a dilated esophagus with a large soft tissue mass having gastric rugal folds in the distal esophageal lumen. Esophagitis may be apparent. It may not be possible to advance the endoscope into the distal esophagus or stomach.

Laboratory Findings

Laboratory findings are nonspecific and related to dehydration and shock.

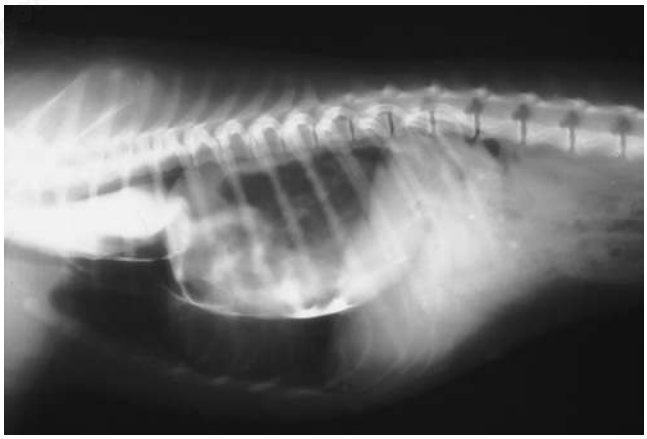

FIG. 18.61 Radiograph of a dog with a gastroesophageal intussusception. Note the luminal soft tissue mass in the dilated distal esophagus.

DIFFERENTIAL DIAGNOSIS

Esophageal hiatal hernia, neoplasia, extraluminal masses, esophageal foreign body, and esophageal diverticulum are differential diagnoses.

SURGICAL TREATMENT

Surgical intervention should be performed as soon as possible after diagnosis. Stabilization of the patient's condition and treatment for shock should be performed before induction of anesthesia; however, surgical treatment should not be delayed in acute cases. A single report of endoscopic reduction and treatment with a percutaneous endoscopic gastrostomy tube has been reported in one dog.[16]

Preoperative Management

Before induction of anesthesia, shock treatment should be initiated (i.e., aggressive fluid therapy and broad-spectrum antibiotics), and electrolyte and acid-base abnormalities should be identified and corrected if possible. An ECG also should be performed before the induction of anesthesia.

Anesthesia

Anesthetic recommendations for animals undergoing esophageal surgery are provided on p. 367 and in Table 18.3.

Surgical Anatomy

The surgical anatomy of the esophageal hiatus is discussed on p. 369.

Positioning

The animal is positioned in dorsal recumbency, and the caudal thorax and ventral abdomen are prepared for aseptic surgery.

SURGICAL TECHNIQUE

Make a ventral midline abdominal incision from the xiphoid process to several centimeters caudal to the umbilicus. Explore the abdomen and locate the duodenum and stomach. Apply gentle traction on the duodenum and stomach to reduce the intussusception. If necessary, digitally dilate or enlarge the esophageal hiatus to allow complete reduction of the intussusception. Examine the distal esophagus, the stomach, and any other involved viscera for evidence of vascular thrombosis, avulsion, ischemia, or necrosis. Resect devitalized tissue. Reduce the size of the esophageal hiatus to 1 to 2 cm if it is too large or lax (see p. 389). Perform an incisional gastropexy (see p. 408) at the gastric fundus to prevent recurrence. In addition to the fundic gastropexy, an incisional right or pyloric antrum gastropexy is sometimes performed. *Lavage and close the abdomen. Place a feeding tube if esophageal disease is severe.*

POSTOPERATIVE CARE AND ASSESSMENT

Fluids should be continued after surgery and acid-base and electrolyte imbalances corrected. Nasal oxygen may benefit dyspneic animals. Postoperative analgesics should be provided (see Table 13.2), and oral intake withheld initially to encourage resolution of esophagitis and gastritis (see p. 366). After 24 to 48 hours, water can be offered. If vomiting or regurgitation does not occur, small amounts of low-fat, high-protein gruel can be offered several times a day. If megaesophagus is present, the animal should be fed in an upright position or through a gastrostomy tube. However, esophageal weakness may not resolve, especially in young animals. Treat esophagitis as needed (see Box 18.13). A gastrostomy tube feeding may be helpful. Deterioration and death may occur if the condition is not recognized and treated promptly. Devitalization of a portion of the esophagus or stomach may occur as a result of preoperative vascular compromise. Dysphagia is common for several days after surgery; however, persistent dysphagia may occur if the hiatus is overly narrowed by surgery. Such patients require reoperation.

PROGNOSIS

Antemortem diagnosis is rare in acute cases (mortality approaches 95%); therefore few cases of gastroesophageal intussusception have been diagnosed and treated successfully. Recurrence is not expected if incisional gastropexy is performed and esophagitis is controlled. Prognosis in chronic intermittent cases is fair if reduction is maintained and esophageal disease manageable.

CRICOPHARYNGEAL ACHALASIA

DEFINITION

Cricopharyngeal achalasia (*congenital cricopharyngeal achalasia, cricopharyngeal dysphagia, cricopharyngeal dysfunction, cricopharyngeal asynchrony*) is one type of pharyngeal dysphagia. The condition is characterized by the interruption of passage of a bolus from the oropharynx through the cranial esophageal sphincter into the cervical esophagus because of failure of the sphincter to open or failure of the opening to coordinate with orophayrngeal swallowing.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Cricopharyngeal achalasia is a rare cause of dysphagia; however, it is important to differentiate it from other forms of oropharyngeal dysphagia because the former is treatable with surgery. There are a number of swallowing disorders and their treatment varies. The cause of cricopharyngeal achalasia is unknown but appears to be a congenital derangement in the coordination of

the swallowing reflex. The cause is probably neurologic, because transecting the pharyngeal branch of the tenth cranial nerve can reproduce the disorder. Cricopharyngeal achalasia is characterized by inadequate relaxation of the cricopharyngeal muscle and/or lack of coordination with pharyngeal muscle contractions during swallowing. This disrupts the cricopharyngeal phase of swallowing, causing food to remain in the pharynx and produce gagging, regurgitation, aspiration, and coughing. Repeated attempts to swallow are made until retained pharyngeal contents are swallowed, regurgitated, or aspirated. Food remaining in the pharynx may be aspirated into the trachea during inspiration, eliciting a cough and causing pneumonia. The small amount of food that succeeds in passing from the oropharynx into the proximal esophagus passes normally into the stomach.

In normal swallowing, food is grasped by the teeth and formed into a bolus by rapid tongue movements. The bolus is pushed up and back by the base of the tongue into the oropharynx. The hypopharyngeal, pterygopharyngeal, and palatopharyngeal muscles contract and force the bolus through the relaxed upper esophageal sphincter (cricopharyngeal, thyropharyngeal muscles) into the cervical portion of the esophagus. The cricopharyngeal muscle contracts after the bolus passes. Cricopharyngeal muscle tone is linked to deglutition and the respiratory cycle. During swallowing, the airways are protected by the soft palate (which closes the nasopharynx) and the epiglottis (which flips back to close the glottis).

DIAGNOSIS

Clinical Presentation

Signalment

The condition is rare. It seems to be more common in springer and cocker spaniels and miniature poodles but has been seen in a variety of breeds. Signs of dysphagia begin at weaning, although in rare cases animals may not be diagnosed until they are older.

History

Most dogs appear normal until they begin eating solid food. At that time, repeated unsuccessful attempts to swallow are noted, with gagging, retching, and expulsion of saliva-covered food. Regurgitation occurs immediately after swallowing. Other signs may include aspiration, coughing, excess salivation, and nasal reflux during eating. Most patients have a voracious appetite, but some fail to thrive, become anorexic, and lose weight.

Physical Examination Findings

Affected animals may appear normal or stunted at the time of examination. Some patients are emaciated. The animal should be observed eating and drinking to confirm dysphagia and to characterize it as oral or pharyngeal. Patients with oral dysphagia have difficulty with prehension and bolus formation. Those with pharyngeal dysphagia have difficulty transporting the bolus into the esophagus. Patients with cricopharyngeal dysphagia usually have more difficulty with solid food, whereas those with other types of pharyngeal dysphagia may have more difficulty (i.e., may aspirate more readily) when swallowing liquids. Swallowing attempts may trigger the animal to cough, gag, and choke. A neurologic examination should be performed to rule out cranial nerve deficits and concurrent neuromuscular abnormalities. Signs of concurrent aspiration pneumonia, rhinitis, laryngeal paralysis, or megaesophagus may be present.

Diagnostic Imaging

Survey thoracic radiographs should be evaluated for aspiration pneumonia and esophageal size. Definitive diagnosis requires fluoroscopic or cinefluoroscopic evaluation of swallowing barium sulfate. Use liquid barium or paste barium sulfate mixed with food unless aspiration is anticipated. An experienced radiologist may be needed to differentiate cricopharyngeal achalasia from pharyngeal dysphagia. Affected animals will have several ineffectual attempts by the tongue to force the bolus from the pharynx and inadequate relaxation of the cricopharyngeal muscle, prohibiting bolus entry into the proximal esophagus. In normal dogs, the time between onset of swallowing and opening of the upper esophageal sphincter following a bolus of liquid barium is approximately 0.10 seconds; opening in those with cricopharyngeal achalasia is delayed (approximately 0.17–0.45 seconds). A thin stream of contrast may be seen passing through the sphincter. Some contrast may be seen refluxing into the nasopharynx or being aspirated into the airway. Patients with cricopharyngeal achalasia have adequate pharyngeal strength to push the food bolus into the esophagus, but the cricopharyngeal sphincter stays shut or opens at the wrong time during the swallowing reflex. Patients with pharyngeal dysphagia do not have adequate oropharyngeal strength or coordination of the pharyngeal muscles to properly push the food bolus into the esophagus. Positive contrast in the trachea or outlining airways indicates aspiration. Esophageal motility should be evaluated during fluoroscopic studies to identify concurrent problems because many animals with pharyngeal dysphagia have concurrent esophageal dysfunction, and for these patients, cricopharyngeal surgery is absolutely contraindicated. Endoscopic examination of the pharynx and esophagus is normal.

Laboratory Findings

Laboratory findings are normal unless the patient is severely debilitated or has aspiration pneumonia. Then they may have a neutrophilia or hypoproteinemia.

DIFFERENTIAL DIAGNOSIS

Pharyngeal dysphagia caused by inadequate pharyngeal contraction can be challenging to differentiate from cricopharyngeal achalasia. Pharyngeal dysphagia tends to occur in older dogs, whereas cricopharyngeal dysfunction tends to occur in younger dogs, but age is an inadequate criterion to distinguish these two conditions. Sometimes more than one abnormality contributes to the dysphagia. Dental disease, oral masses, foreign bodies, trauma, stomatitis, cleft palate, hypoplastic palate, and other congenital and skeletal abnormalities should also be considered. Esophageal hypomotility and megaesophagus may also be associated with pharyngeal dysphagias. Other considerations include functional abnormalities resulting from rabies, central nervous system disease, peripheral neuropathies, neuromuscular disease, myopathies, and myositis.

MEDICAL TREATMENT

Medical management may be attempted with intralesional injection of botulinum toxin. This therapy has only recently been performed on dogs; its efficacy is uncertain at this time.

SURGICAL TREATMENT

Cricopharyngeal myectomy is often curative for congenital cricopharyngeal achalasia. Surgery is not necessarily recommended for acquired cricopharyngeal achalasia. Some surgeons also resect a portion of the thyropharyngeus muscle. Cricopharyngeal myectomy for patients with other pharyngeal dysphagias can be disastrous because it allows food retained in the proximal esophagus to more easily reenter the pharynx and be aspirated.

Preoperative Management

Supportive care is important; patients should be well hydrated and nourished before surgery. Preoperative nutritional support should be provided with a gastrostomy tube if necessary (see p. 97). Oral feeding should include feeding food of a consistency (dry vs. canned vs. gruel) most successfully retained by the animal. Aspiration pneumonia should be treated with fluids, appropriate antibiotics, and expectorants. Perioperative antibiotics are recommended for debilitated patients.

Anesthesia

Anesthetic recommendations for esophageal surgery are provided on p. 367 and Table 18.3. Hypothermia and hypoglycemia are serious problems in young patients and should be prevented during anesthesia and surgery.

Surgical Anatomy

The cranial esophagus is located dorsal to the larynx and slightly to the left of midline. The cricopharyngeal muscle lies on the larynx and pharynx immediately caudal to the thyropharyngeal muscle (Fig. 18.62). It arises from the lateral surface of the cricoid cartilage and passes dorsally to insert on the median dorsal raphe. The cricopharyngeal muscle can be identified as a bundle of transverse muscle fibers converging on the dorsal midline and blending into the longitudinal muscle fibers of the cranial esophagus. The thyropharyngeal muscle can be difficult to differentiate from the cricopharyngeal muscle because their muscle fibers are both oriented transversely. The thyropharyngeal muscle lies cranial to the cricopharyngeal muscle and is separated from it by a thin septum of connective tissue. The separation is found dorsal to the attachment of the sternothyroid muscle. The cricopharyngeal muscle controls most of the upper esophageal sphincter function. Branches of the glossopharyngeal and vagus nerves innervate it. Blood supply to the cricopharyngeal muscle is primarily from branches of the cranial thyroid arteries.

Positioning

The animal is positioned in dorsal recumbency with the legs positioned lateral to the thorax. The ventral neck (from the angle of the mandible to the manubrium) should be prepared for aseptic surgery. Alternatively, the animal is positioned in lateral recumbency and a lateral incision is made.

SURGICAL TECHNIQUE

Make a ventral midline cervical incision beginning cranial to the larynx and extending caudally to the midcervical area. Separate and retract the sternohyoid muscles laterally to expose the trachea. Rotate the larynx and trachea laterally by using traction on the sternothyroid muscle to expose the cricopharyngeal musculature (Fig. 18.63A). Place a suture through the lamina of the thyroid cartilage to maintain laryngeal rotation and exposure of the cricopharyngeal muscle and dorsal esophagus. Pass a gastric tube into the esophagus to aid identification of the esophageal wall. Identify

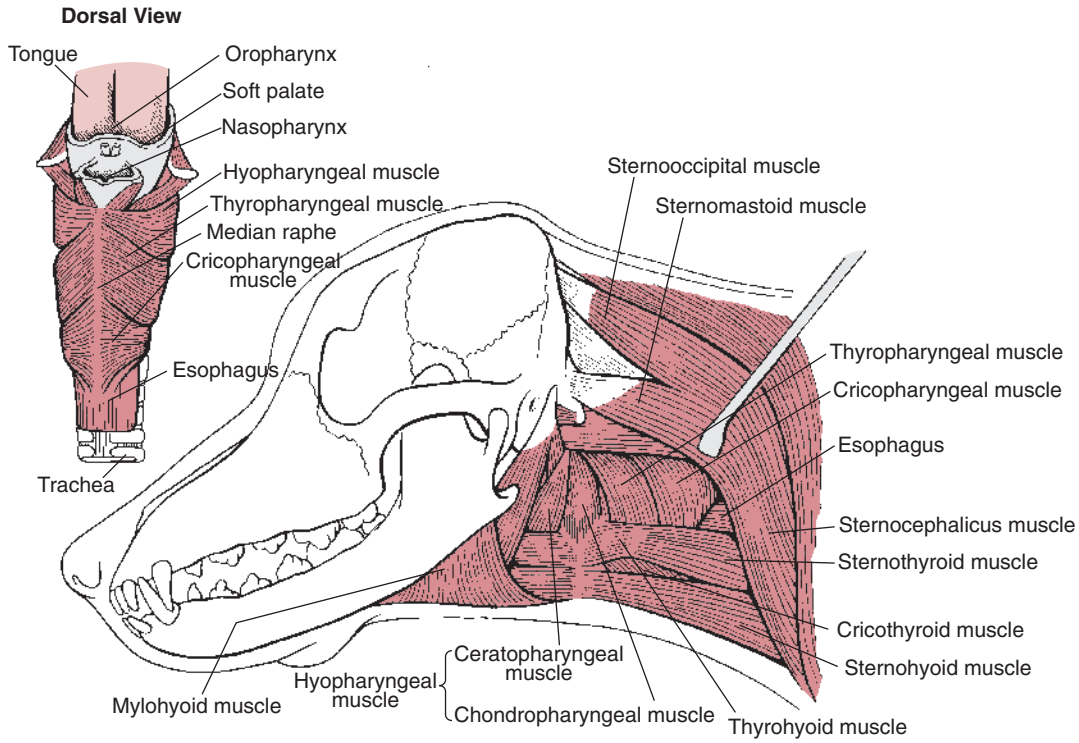

FIG. 18.62 Surgical anatomy of the cranial esophagus and neck.

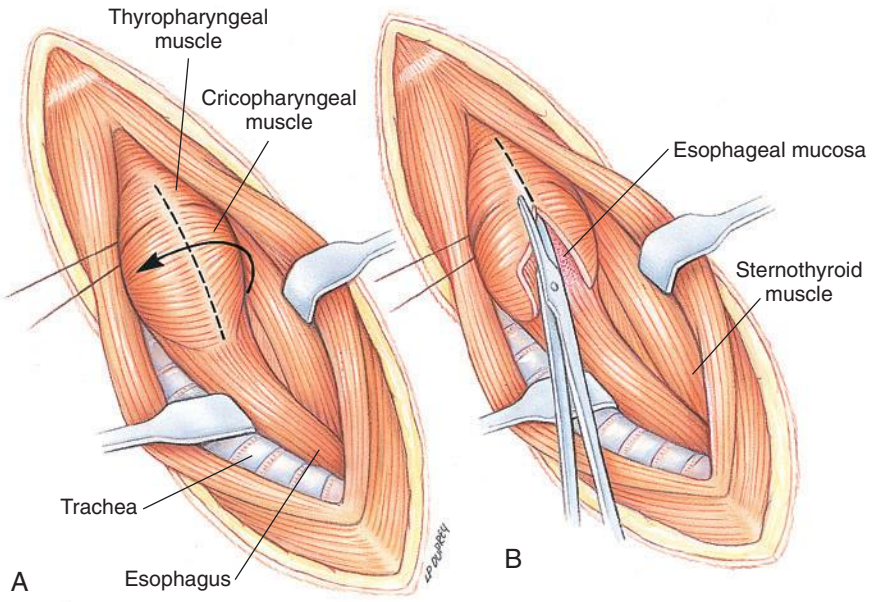

FIG. 18.63 Cricopharyngeal myectomy. (A) Expose the cranial esophagus through a ventral midline cervical incision. Place a stay suture through the thyroid lamina and rotate the cricopharyngeal muscle into view. (B) Resect the lateral portion of each cricopharyngeal muscle.

the cricopharyngeal muscles. Incise the cricopharyngeus (and, if needed, the thyropharyngeus) muscle on its midline (see Fig. 18.63B). Elevate the muscle fibers from the underlying esophageal submucosa with care to avoid perforating the esophageal wall. Resect the lateral portion of each cricopharyngeus (and the thyropharyngeus) muscle. Inspect the esophageal wall for damage and lavage the area. Allow the larynx and trachea to return to their normal position. Appose the sternohyoid muscles with a continuous suture pattern. Close subcutaneous tissues and skin routinely.

POSTOPERATIVE CARE AND ASSESSMENT

Provide analgesia and treat aspiration pneumonia as needed. Immediately after surgery, improvement in swallowing function is expected. When fully recovered from anesthesia, evaluate swallowing function by giving a small amount of soft food. A gruel or canned food should be fed for the first 1 to 2 days after surgery, then the food should gradually be returned to normal consistency over the next 3 to 4 days. If necessary, IV fluids should be continued to maintain hydration. Continue feeding through a gastrostomy tube if necessary to improve body condition. Antibiotics should be continued if aspiration pneumonia is present. Inadequate or unilateral myectomy may not relieve signs of cricopharyngeal achalasia.

COMPLICATIONS

Recurrence of dysphagia because of fibrosis and constriction at the myectomy site can be prevented by adequate removal of muscle. If pharyngeal dysphagias or proximal esophageal dysfunction are present, then cricopharyngeal myectomy will worsen the patient's dysphagia and pneumonia. Aspiration pneumonia may continue to be a problem if esophageal hypomotility exists. Other potential complications include laryngeal paralysis, esophageal perforation, and pharyngocutaneous fistula.

PROGNOSIS

The prognosis is good if the only abnormality present is cricopharyngeal achalasia and guarded if other dysphagias or related conditions are present. Although complete resolution of signs is expected, some have only partial resolution and others have recurrence of clinical signs within 2 to 36 weeks. Persistent regurgitation may result in aspiration pneumonia. The prognosis without surgery is guarded because it is difficult to effectively nourish the patient and control pneumonia.

VASCULAR RING ANOMALIES

DEFINITION

Vascular ring anomalies are congenital malformations of the great vessels and their branches that cause constriction of the esophagus and signs of esophageal obstruction. PRAA, the most common type of vascular ring anomaly, is also known as *persistent fourth right aortic arch.*

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

The most common type of vascular ring anomalies are a persistent fourth right aortic arch, right dorsal aortic root, and rudimentary left ligamentum arteriosum (left sixth arch). The left pulmonary artery and the descending aorta are connected by the ligamentum arteriosum. The esophagus is encircled by the ligamentum arteriosum (or patent ductus arteriosus) on the left, the base of the heart and pulmonary artery ventrally, and the aortic arch on the right. The esophagus is constricted by this vascular "ring" and begins to dilate cranially as food accumulates. Food that does not pass beyond the constriction is intermittently regurgitated. Chronic regurgitation predisposes the animal to aspiration

BOX 18.20 Vascular Ring Anomalies: Key Points

- Regurgitation classically begins at weaning with introduction of solid food
- Some patients are years old before they are diagnosed
- Aspiration pneumonia is a concurrent risk
- 95% are persistent right aortic arch ± other aberrant vessels
- Mostly diagnosed in German shepherds
- Radiographic signs: esophageal dilatation cranial to heart base and tracheal deviation to the left
- Advanced imaging (contrast computed tomography) is recommended to be certain of the diagnosis
- Perform surgery early to prevent irreversible changes
- Treat pneumonia and improve body condition before surgery
- Identify, isolate, occlude, and divide offending vessels
- Dissect constricting fibrous bands from around esophagus
- Feed gruel while standing erect on hind legs; gradually increase food consistency
- Most regurgitate less following surgery; some are clinically normal

pneumonia. Approximately 95% of animals diagnosed with vascular ring anomalies have a PRAA (Box 18.20).

Abnormal location of the great vessels mechanically interferes with functioning of the esophagus and sometimes the trachea and other adjacent structures. The severity of clinical signs and the degree of esophageal stricture depend on the vascular structures involved. Approximately 44% of animals with PRAA have coexisting compressive arterial anomalies. Other types of vascular ring anomalies include (1) PRAA with persistent left subclavian artery, (2) PRAA with persistent left ligamentum arteriosum and left subclavian artery, (3) double aortic arch, (4) normal left aortic arch with persistent right ligamentum arteriosum, (5) normal left aortic arch with persistent right subclavian artery, and (6) normal left aortic arch with persistent right ligamentum arteriosum and right subclavian artery. A patent ductus arteriosus rather than the ligamentum arteriosum persists in approximately 15% of those with vascular ring anomalies. Additionally, persistent left vena cava occurs in conjunction with PRAA in 12% to 40% and a left hemiazygos vein in approximately 6% of the cases.

Six pairs of aortic arches surround the esophagus and trachea during early fetal life. Normal maturation and selective regression of these arches form the adult vasculature. All vascular ring anomalies have resulted from abnormal development of arches three, four, and six. The mechanism of inheritance is complex and polygenic, probably involving multiple recessive genes. In the embryo the first and second aortic arches disappear, and the fifth arches are incomplete and inconsistent. The third arch joins the dorsal aortic arch and continues anteriorly as the right and left internal carotid arteries. The third arch also forms the brachiocephalic trunk. The dorsal aortas disappear between the third and fourth arches. Normally the left fourth aortic arch and the dorsal aortic root persist to form the permanent aortic arch. The left sixth arch becomes the ductus arteriosus, and the right fourth arch contributes to the right subclavian artery.

DIAGNOSIS

Clinical Presentation

Signalment

Vascular ring anomalies occur in both dogs and cats but are more common in dogs. German shepherds, Irish setters, and Boston terriers are the most commonly affected breeds. PRAA may be a hereditary condition in greyhounds. Siamese and Persian cats have been diagnosed more often than other cat breeds. Males and females are equally affected. The condition may affect several animals in a litter. Vascular ring anomalies are present at birth. Clinical signs are usually evident at the time of weaning, most being diagnosed between 2 and 6 months of age; however, the condition may not be recognized until later in life if obstruction is partial and signs are mild or intermittent. Early diagnosis and treatment of PRAA may improve the prognosis.

History

The classic history is acute onset of regurgitation when solid or semisolid food is first fed. Regurgitation of undigested food occurs soon after eating early in the disease; later it may occur at variable times (minutes to hours). Affected animals may grow more slowly than litter mates and appear malnourished. They often have a voracious appetite; some immediately re-eat the regurgitated food. Coughing with respiratory distress may be a result of aspiration pneumonia or tracheal stenosis that occurs secondary to a double aortic arch.

Physical Examination Findings

Affected animals are often thin and small. An enlarged esophagus may sometimes be palpated at the thoracic inlet and neck. The thoracic inlet and caudal neck area may bulge when the chest is compressed. Murmurs are rare; an occasional animal may have a continuous murmur associated with concurrent patent ductus arteriosus. Fever and pulmonary crackles suggest pneumonia.

Diagnostic Imaging

Thoracic radiographs may reveal a dilated esophagus cranial to the heart containing air, water, or food. Focal leftward deviation of the trachea near the cranial border of the heart on dorsoventral or ventrodorsal radiographs strongly suggests PRAA in symptomatic young dogs. The trachea may be displaced ventrally and the esophagus may overlap it. Signs of pneumonia may be identified. Incidental axial skeletal abnormalities of the vertebrae, ribs, or sternebrae have been reported in cats.[17] Positive contrast radiography using a barium sulfate liquid mixed with food demonstrates esophageal constriction at the base of the heart with varying degrees of esophageal dilatation extending cranially (Fig. 18.64). However, other esophageal conditions can sometimes mimic vascular ring anomalies; therefore the contrast study needs to be critically evaluated. The ratio of the area of maximal esophageal dilatation after liquid barium sulfate (8 mL/kg body weight) to the narrowest height of the fifth thoracic vertebrae in normal dogs and cats is ≤1. The animal is considered to have mild dilatation if the ratio is ≤2.5, moderate with a ratio ≤4, and severe with a ratio >4. The caudal esophagus is usually normal in size, although it is sometimes dilated. Fluoroscopy is beneficial in evaluating esophageal motility. The dilated esophagus does not usually demonstrate normal peristaltic contractions. Contrast CT evaluation is more helpful in identifying abnormal vasculature than angiography and is recommended. Echocardiography may also be beneficial. Endoscopic examination of the esophagus helps rule out other causes of esophageal stricture or obstruction and may reveal esophageal ulceration. Sometimes, a dilated esophagus proximal to the heart is due to focal esophageal weakness, but radiographically mimics PRAA. Esophagoscopy can determine if there is a stricture caused by a vascular ring or

FIG. 18.64 Contrast esophagram of a dog with a persistent right aortic arch. Note the esophageal narrowing at the base of the heart. The cranial esophagus is dilated.

if there is no stricture (and therefore the dilated area is due to esophageal weakness). Tracheoscopy is not routinely performed but may document narrowing of the tracheal lumen caused by external compression.

Laboratory Findings

Laboratory findings are expected to be normal (for the animal's age) unless debilitation is severe or pneumonia is present. In animals with pneumonia, neutrophilia may be present and debilitated animals may be hypoproteinemic.

DIFFERENTIAL DIAGNOSIS

The primary differential diagnoses are generalized megaesophagus and obstruction caused by a foreign body, stricture, mass, or hiatal hernia. It can be difficult to radiographically differentiate between esophageal dilatation caused by a vascular ring anomaly and a large outpouching cranial to the heart associated with megaesophagus.

MEDICAL MANAGEMENT

Patients with vascular ring anomalies are treated both medically and surgically. Surgery should be performed as soon after the onset of clinical signs as possible to hopefully prevent progressive damage to the esophageal muscles and nerves. Clients should be informed that medical treatment without surgery is palliative at best and is not recommended. Medical management includes treating aspiration pneumonia (see p. 367) and improving the animal's nutritional status. An affected animal should be fed gruel while vertical (e.g., using a Bailey chair). The animal should be maintained in an upright position (standing on hind legs) for 5 to 10 minutes after eating to allow gravity to assist in emptying the dilated esophagus. Placement of a gastrostomy feeding tube may be beneficial for severely debilitated patients, if aspiration is present, or in cases of longstanding megaesophagus with delayed presentation for surgery.

SURGICAL TREATMENT

The surgical treatment of PRAA is described later. Other types of vascular ring anomalies can be managed in a similar fashion. A persistent left vena cava often covers the left ventral area of the vascular ring. A persistent right ligamentum arteriosum and some aberrant right subclavians should be approached from the right side. Angiograms are helpful in patients with double aortic arches to determine which arch is dominant and if adequate circulation can be maintained after transection of the other arch. It may not be possible to relieve constrictions caused by a double aortic arch. If the animal is severely debilitated, a gastric feeding tube should be placed for several days before surgery.

Some surgeons attempt to reduce the size of the esophageal lumen if the esophagus is severely dilated and not expected to return to normal size. Placing a series of nonpenetrating "plication" or "gathering" sutures in the accessible lateral esophageal wall accomplishes this goal. As an alternative, a portion of the esophagus may be resected. These techniques are not recommended routinely because they increase the risk of complications.

Preoperative Management

Hydration, electrolyte, and acid-base abnormalities should be corrected before surgery if possible. If pneumonia is present or if the animal is severely debilitated, nutrition should be provided via a gastrostomy feeding tube (see p. 97) for several days to a week. Antibiotics are indicated for debilitated animals and those with pneumonia (see p. 367).

Anesthesia

Anesthetic recommendations for animals undergoing thoracotomies are presented on p. 884, Table 29.1, and Table 30.3. Anesthetic recommendations for animals with esophageal disease are found on p. 367 and Table 18.3. In addition, refer to the general anesthesia section in Chapter 26 on p. 722 for anesthetic concerns with the pediatric patient. Animals younger than 6 months of age should be anesthetized with care. Because hepatic glycogen stores are rapidly depleted during fasting in puppies and kittens, fasting longer than 4 to 6 hours is not generally recommended. If you are unable to monitor the blood glucose level, IV fluids containing balanced electrolytes in a 2.5% dextrose solution should be given for surgeries lasting longer than 1 hour or if anesthetic recovery is delayed. Hypothermia commonly develops in puppies and kittens during surgery because they have a higher surface area to body weight ratio, which causes greater heat loss by radiation and evaporation. Hypothermia may cause bradycardia, low cardiac output, and hypotension, which may prolong drug elimination and anesthetic recovery. Drugs that normally redistribute to muscle or fat have prolonged effects in puppies and kittens after repeated administration. Reduced hepatorenal function may also prolong drug effects. Phenothiazine tranquilizers should be used with care in animals younger than 3 months of age, because the drugs may cause prolonged central nervous system depression. If used, phenothiazines should be given at one-fourth to one-half the adult dose. Opioids can be used in young animals but should be started by using half the adult dose and titrated to effect. Chapter 26 contains additional information on handling and caring for pediatric patients.

Surgical Anatomy

The anatomy of the esophagus is discussed on p. 369 and the anatomy of the heart on p. 794. See also the discussion under General Considerations and Clinically Relevant Pathophysiology on p. 394.

Positioning

Most patients with vascular ring anomalies should be positioned in right lateral recumbency for a left lateral thoracotomy (see p. 889); however, those with persistent right ligamentum arteriosum are positioned in left lateral recumbency. Positioning of animals with double aortic arches varies, depending on the dominant arch.

SURGICAL TECHNIQUE

Surgical transection of the constricting structure or structures is recommended before esophageal dilatation becomes severe. Transection is feasible with most vascular ring anomalies, with the exception of some double aortic arches. Staples may be used rather than suture to occlude vascular structures. Thoracoscopic-assisted division of PRAA is an alternative approach.

Perform a lateral thoracotomy at the left fourth (fifth) intercostal space for patients with PRAA. Pack the cranial lung caudally to expose the mediastinum dorsal to the heart. Identify the aorta, pulmonary artery, ligamentum arteriosum, and vagal and phrenic nerves (see Figs. 27.3 and 18.43). Identify the anomalous structure or structures. If a persistent left cranial cava is present, dissect and retract the vena cava to improve visualization. If a prominent hemiazygos vein is also present, dissect, ligate, and divide it. If a constricting subclavian artery is identified, isolate, ligate, and transect it. If an atretic left aortic arch is present isolate, ligate and transect it. Incise the mediastinum and dissect and elevate the ligamentum arteriosum. Double ligate the ligamentum arteriosum and then transect it. If a large-diameter patent ductus arteriosus is present rather than a ligamentum arteriosum, oversew both ends after transection. Pass a balloon catheter or large orogastric tube through the constricted esophagus to aid identification of constricting fibrous bands and to dilate the site. Dissect and transect these fibrous bands from the esophageal wall. Lavage the area, reposition the lung lobes, place a thoracostomy tube, and close the thorax routinely.

Thoracoscopic Ligation and Division of the Ligamentum Arteriosum

Division of the ligamentum arteriosum via thoracoscopy has been described for the treatment of PRAA in dogs. *Establish an endoscopic port in the left seventh intercostal space at the costochondral junction. Place three other ports at the same level in the third and fifth intercostal spaces for operating equipment. Place a fourth port in the dorsal aspect of the fifth intercostal space and pass a lung retractor to manipulate the left cranial lung caudally for exposure of the ligamentum. Use a palpation probe to identify the ligamentum if it is not visible at the junction of the dilated and more normal esophagus (Fig. 18.65A). Pass an endoscope or balloon catheter to assist identification if necessary. Bluntly elevate the ligamentum and place hemoclips dorsally and ventrally prior to transection with Metzenbaum scissors (see Fig. 18.65B). Dissect away remaining connective tissue from the surface of the esophagus taking care to avoid its muscular layer; dilation with a balloon may be done if necessary.*

An alternative, caudal approach to the ligamentum can be done with an endoscope port placed in the middle of the 10th intercostal space with instrument ports in the dorsal and ventral aspects of the ninth intercostal space and a port in the ventral aspect of the sixth intercostal space for lung retraction. Visualization and dissection proceed from caudal to cranial, similar to the preceding lateral approach.

POSTOPERATIVE CARE AND ASSESSMENT

Postoperative analgesics should be provided as described on p. 886. The patient should be closely monitored for dyspnea and the chest tapped if necessary. Nasal oxygen may benefit dyspneic patients. If a thoracostomy tube has been placed, the thorax should be aspirated at regular intervals (initially every 15–30 minutes) and the volume of air and fluid collected at each interval noted. Thoracostomy tubes can generally be removed the day of surgery or by the next morning in these patients. Antibiotics should be continued in debilitated patients if thoracic contamination occurred or if pneumonia exists.

Pediatric patients should be closely monitored for hypoglycemia in the postoperative period. Oral intake can be resumed within 12 to 24 hours of surgery. Initially, a canned food gruel should be fed with the animal in an upright posture. This stance should be maintained for 5 to 10 minutes after eating to help prevent distention of the dilated esophagus and help reestablish esophageal

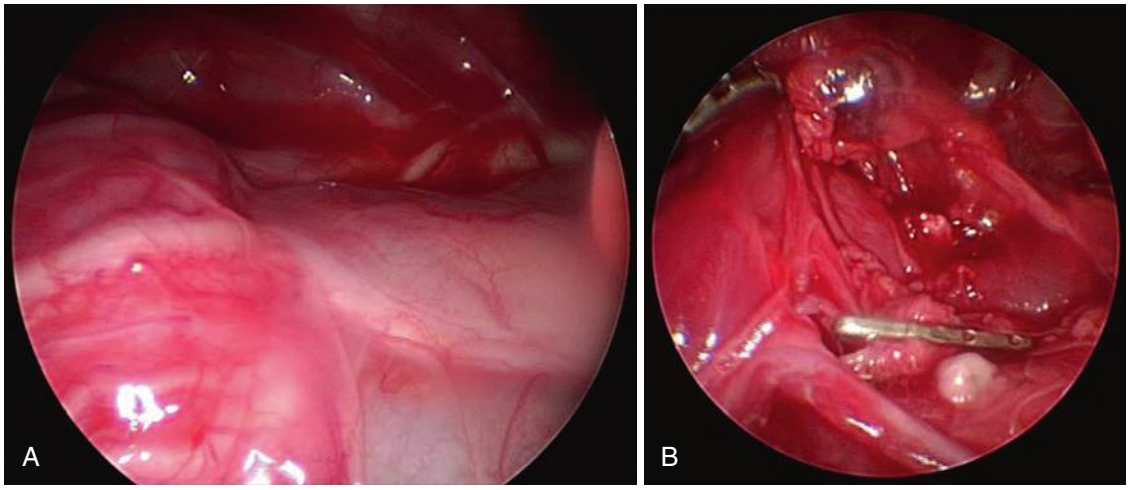

FIG. 18.65 (A) Thoracoscopic view of a dog with a persistent right aortic arch. The dilated esophagus cranial to the ligamentum arteriosum is to the left in the image. The vagus nerve is visible on the ventrolateral surface of the esophagus. (B) Dissection of the ligamentum arteriosum after vascular clip application.

muscle tone and size. Owners may gradually reduce the amount of water in the food 2 to 4 weeks after surgery if minimal regurgitation has occurred with gruel feeding. Hopefully, the addition of water can ultimately be eliminated without increased regurgitation. Animals that can eat solid food without regurgitation should be allowed to eat with the bowl on the floor while standing normally. This feeding practice is continued unless regurgitation recurs. Some animals can eventually be fed any type of food from a normal stance, whereas others must continue eating gruel from an elevated stand.

If the patient is still having trouble, the esophagus should be reevaluated with an esophagram 1 to 2 months after surgery to assess persistent dilatation and motility. Sometimes the esophagus returns to a normal size and function. Other times the esophagus remains severely dilated because of poor motility. If esophageal stricture occurs at the surgery site, balloon dilatation (see p. 382) may be beneficial, but care must be taken to avoid rupturing the esophagus. Owners should be advised against breeding affected animals because the condition is genetic.

COMPLICATIONS

Surgical complications are common because of the initial malnourished and debilitated condition of affected animals and concurrent aspiration pneumonia. Persistent regurgitation is the most common postoperative problem. Preoperative client education must emphasize the high incidence of continued regurgitation and the need for prolonged dietary management. Aspiration pneumonia and death may occur if regurgitation persists. Esophageal resection or imbrication increases the risk of contamination and infection secondary to esophageal leakage or dehiscence.

PROGNOSIS

Most animals that survive surgery improve; however, perioperative mortality can be as high as 8%.[18] Animals with severe esophageal dilatation (esophageal to fifth thoracic vertebrae ratio >4) prior to surgery may have a worse long-term outcome than those with mild or moderate dilatation. Persistence of esophageal dilation, however, may not be associated with either continued regurgitation or an adverse long-term prognosis. They may not have completely normal esophageal function, but they generally regurgitate less and their body condition improves. If surgery is performed soon after signs appear, normal esophageal tone and function might return. The longer the delay before surgical correction, the more cautious the prognosis; some patients show little or no improvement. Megaesophagus often persists with mild to moderate improvement in motility, although most patients no longer have regurgitation. The prognosis is poor with esophageal dilatation caudal to the constriction because this area is often hypomotile and frequently does not regain normal size. Without surgery, regurgitation usually continues and worsens as the esophagus continues to dilate. Aspiration pneumonia is a continuous threat, and the animal may have difficulty maintaining adequate body condition. Short-term causes of death include cardiopulmonary arrest, aspiration pneumonia, and euthanasia due to failure to improve. Good to excellent outcome can be expected in 87%. Poor outcomes relate to the need for specialized or elevated feeding and recurrent regurgitation.[18]

Surgery of the Stomach

GENERAL PRINCIPLES AND TECHNIQUES

DEFINITIONS

Gastrotomy is an incision through the stomach wall into the lumen. **Partial gastrectomy** is a resection of a portion of the stomach, and **gastrostomy** is the creation of an artificial opening into the gastric lumen. **Gastropexy** permanently adheres the stomach to the body wall. Removal of the pylorus (**pylorectomy**) and attachment of the stomach to the duodenum (**gastroduodenostomy**) is a **Billroth I** procedure. Attachment of the jejunum to the stomach (**gastrojejunostomy**) after a partial gastrectomy (including pylorectomy) is a **Billroth II** procedure. In a **pyloromyotomy,** an incision is made through the serosa and muscularis layers of the pylorus only. For a **pyloroplasty,** a full-thickness incision and tissue reorientation are performed to increase the diameter of the gastric outflow tract.

PREOPERATIVE CONCERNS

Gastric surgery is commonly performed to remove foreign bodies (see p. 413) and to correct gastric dilatation-volvulus (GDV; see p. 419). Gastric ulceration or erosion (see p. 427), neoplasia (see p. 430), and benign gastric outflow obstruction (see p. 425) are less common indications. Gastric disease may cause vomiting (intermittent or profuse and continuous) or just anorexia. Dehydration and hypokalemia are common in vomiting animals and should be corrected before induction of anesthesia. Alkalosis may occur secondary to gastric fluid loss; however, metabolic acidosis may also be seen. Hematemesis may indicate gastric erosion or ulceration or coagulation abnormalities. Peritonitis arising from perforation of the stomach caused by necrosis or ulceration is often lethal if not treated promptly and aggressively (see p. 527). Aspiration pneumonia or esophagitis may also occur in vomiting animals. If possible, severe aspiration pneumonia (see p. 367) should be treated before induction of anesthesia for gastric surgery.

Mild esophagitis generally can be treated by withholding food for 24 to 48 hours (see p. 367) and treating with proton pump inhibitors. However, severe esophagitis may necessitate a gastrostomy tube (see p. 97). If continued vomiting is likely, an enteral feeding tube is preferred (see p. 101). Treatment with proton pump inhibitors (i.e., omeprazole, esomeprazole, pantoprazole; see Box 18.13) is important. Orally administered sucralfate slurries may help alleviate pain, but they should be given 1 hour after other medications (see p. 429). Administration of prokinetics (e.g., cisapride, erythromycin, metoclopramide, ranitidine) will improve gastric emptying and help minimize reflux.

When possible, food should be withheld for at least 8 to 12 hours before surgery to ensure that the stomach is empty. If gastroscopy will be performed, it is best to fast the patient for at least 18 and preferably 24 hours before the procedure. However, fasting for only 4 to 6 hours may help prevent hypoglycemia in pediatric patients (see the discussion on anesthetic and surgical management of pediatric patients, which follows). Surgery for gastric obstruction, distention, malpositioning, or ulceration should be performed as soon as possible after the animal's condition has been stabilized.

ANESTHETIC CONSIDERATIONS

Numerous anesthetic protocols have been used in stable animals undergoing abdominal surgery (see Table 19.1). See Table 18.4 for anesthetic recommendations for the acute abdomen.

ANTIBIOTICS

Perioperative antibiotics may be used if the gastric lumen will be entered; however, animals with normal immune function undergoing simple gastrotomy (i.e., proper aseptic technique and no spillage of gastric contents) rarely require them. If antibiotics are used (e.g., cefazolin; 22 mg/kg given intravenously at induction; repeat once or twice at 90-minute to 2-hour intervals), they should be given intravenously before induction of anesthesia and continued for up to 12 hours postoperatively. Except for *Helicobacter* organisms, bacteria are scarce in the stomach compared with other parts of the GI tract because of the low gastric pH.

SURGICAL ANATOMY

The stomach can be divided into the cardia, fundus, body, pyloric antrum, pyloric canal, and pyloric ostium. The esophagus enters

TABLE 18.4 Anesthetic Considerations for the Patient With an Acute Abdomen

Preoperative Considerations	
Associated conditions	• Dehydration • Electrolyte abnormalities • Hypotension • Anemia • Arrhythmias
Bloodwork	• HCT • Electrolytes • BUN • Cr • TP • Lactate • Urinalysis • Blood gas if available
Physical exam	• Often a younger patient that was previously healthy • May be dehydrated, tachycardic or bradycardic, hypotensive, retching, vomiting, or hypothermic • Painful or distended abdomen may be present
Other diagnostics	• Blood pressure • ECG • Radiograph (abdominal)

Premedications	• Rehydrate over 4–6 h if possible; if emergent, may have to give more rapid boluses to expedite time to surgery.
	• Correct electrolyte and metabolic abnormalities if time permits
	• Avoid sedatives in depressed or cardiovascularly compromised patients.
	• Avoid alpha-2 agonists and acepromazine.
	• If patient is stable and anxious, give:
	  • Midazolam (0.2 mg/kg IV, IM) *or*
	  • Diazepam (0.2 mg/kg IV)
	• If patient is not depressed, then give:
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM in dogs; 0.05–0.1 mg/kg IV, IM in cats), *or*
	  • Morphine[b] (0.1–0.2 mg/kg IV or 0.2–0.4 mg/kg IM), *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM)

Intraoperative Considerations	

Induction	• If dehydrated or unstable, give the following:
	  • Etomidate (0.5–1.5 mg/kg IV), *or*
	  • Ketamine (5.5 mg/kg IV) and diazepam (0.28 mg/kg IV)
	• If hydrated and stable, give the following:
	  • Propofol (2–6 mg/kg IV), *or*
	  • Alfaxalone (2–3 mg/kg IV)

Maintenance	• Isoflurane or sevoflurane, *plus*
	  • Fentanyl (2–10 µg/kg IV PRN in dogs; 1–4 µg/kg IV PRN in cats) for short-term pain relief, *plus*
	  • Fentanyl CRI (1–5 µg/kg IV loading dose, then 2–30 µg/kg/h IV), *or*
	  • Hydromorphone[a] (0.05–0.2 mg/kg IV PRN in dogs; 0.05–0.1 mg/kg IV PRN in cats), *or*
	  • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or*
	  • Buprenorphine[c] (0.005–0.02 mg/kg IV PRN), *plus*
	  • Ketamine (low dose) (0.5–1 mg/kg IV)
	• For hypotension (to keep MAP 60–80 mm Hg) give phenylephrine, ephedrine, norepinephrine, or dopamine as needed

Fluid needs	• Two large IV cephalic or jugular catheters • 10–20 mL/kg/h if open abdomen with higher evaporative losses, plus 3 × EBL; higher rates of fluids are necessary if dehydration not corrected preoperatively and animal is hypotensive • Consider colloids if persistent hypotension

Continued

TABLE 18.4 Anesthetic Considerations for the Patient With an Acute Abdomen—cont'd

Monitoring	• Blood pressure • ECG • Respiratory rate • SpO_2 • $EtCO_2$ • Temperature • U/O
Blocks	Epidural: • Morphine (0.1 mg/kg preservative free) *or* • Buprenorphine (0.003–0.005 mg/kg diluted in saline) • Avoid local anesthetics for spinal or epidural Incisional: • Lidocaine (<5 mg/kg in dogs; 2–4 mg/kg in cats), *or* • Bupivacaine (<2 mg/kg)
Postoperative Considerations	
Analgesia	• Fentanyl CRI (1–10 µg/kg IV loading dose, then 2–20 µg/kg/h IV), *or* • Morphine[b] (0.1–1 mg/kg IV or 0.1–2 mg/kg IM q1–4h in dogs; 0.05–0.2 mg/kg IV or 0.1–0.5 mg/kg IM q1–4h in cats) if no hypotension, *or* • Hydromorphone[a] (0.05–0.2 mg/kg IV, IM q3–4h in dogs; 0.05–0.1 mg/kg IV, IM q3–4h in cats), *or* • Hydromorphone CRI (0.025–0.1 mg/kg/h IV in dogs), *or* • Oxymorphone (0.05–0.2 mg/kg IV PRN), *or* • Buprenorphine[c] (0.005–0.02 mg/kg IV, IM q4–8h or 0.01–0.02 mg/kg OTM q6–12h in cats), *plus* • ± Ketamine CRI (2 µg/kg/min IV; if no previous loading dose, give 0.5 mg/kg IV prior to CRI) • Avoid NSAIDs in patients with hypotension
Monitoring	• SpO_2 • Blood pressure • HR • Respiratory rate • Temperature • U/O • ECG
Bloodwork	• HCT if significant blood loss • Repeat abnormal preoperative bloodwork • Serial blood glucose checks if necessary • Blood gas if available
Estimated pain score	• Moderate to moderately severe

[a]Monitor for hyperthermia in cats.
[b]Give slowly to prevent histamine release.
[c]Buprenorphine is a better analgesic than morphine in cats.
BUN, Blood urea nitrogen; *Cr,* creatinine; *CRI,* constant-rate infusion; *EBL,* estimated blood loss; ECG, electrocardiogram; *$EtCO_2$,* end-tidal CO_2; *HCT,* hematocrit; *HR,* heart rate; *IM,* intramuscular; *IV,* intravenous; *MAP,* mean arterial pressure; *NSAID,* nonsteroidal antiinflammatory drug; *PRN,* as needed; *SpO_2,* hemoglobin saturation with oxygen; *TP,* total protein; *U/O,* urine output.

the stomach at the cardiac ostium. The fundus is dorsal to the cardiac ostium, and although relatively small in carnivores, it is easy to identify on radiographs because it is typically filled with gas. The body of the stomach (the middle one-third) lies against the left lobes of the liver. The pyloric antrum is funnel shaped and opens into the pyloric canal. The pyloric ostium is the end of the pyloric canal that empties into the duodenum.

NOTE The gastric mucosa accounts for half of the stomach's weight. You can easily separate the mucosa from the submucosa and serosa when raising flaps or making partial-thickness incisions during a gastropexy or pyloromyotomy.

The gastric (lesser curvature) and gastroepiploic (greater curvature) arteries supply the stomach and are derived from the celiac artery. The short gastric arteries arise from the splenic artery and supply the greater curvature. The portion of the lesser omentum that passes from the stomach to the liver is the hepatogastric ligament. The stomach of the beagle holds more than 500 mL of fluid when distended (a mature cat's stomach may hold 300–350 mL). When the stomach is highly distended, it can be palpated beyond the costal arch.

NOTE The short gastric vessels are often avulsed in animals with GDV, which typically accounts for the intraabdominal hemorrhage seen in these cases (see also the discussion of GDV on p. 423).

SURGICAL TECHNIQUES

Gastric surgery is often performed in small animals. Generally, performing a gastrotomy is safer than performing an esophagotomy or enterotomy. Peritonitis is uncommon after gastrotomy if proper techniques are used. Stricture or obstruction is also rare. Billroth procedures are more difficult and may be associated with severe complications.

Gastroscopy

Endoscopic removal of foreign bodies is preferred over surgical removal but requires appropriate endoscopic snares. Likewise,

endoscopy is more sensitive than gastrotomy when looking for erosions, ulcers, *Physaloptera,* and other small lesions. However, it is imperative that the entire gastric mucosa be systematically examined, including the fundus and lower esophageal mucosa. Similarly, endoscopy is the preferred method for gastric mucosal biopsy because it allows one to obtain more tissue samples than surgery, which is important because gastric mucosal lesions can be very spotty. Scirrhous carcinomas, pythiosis, and submucosal lesions are important gastric lesions but cannot always be diagnosed with endoscopic biopsy. Rarely, intraoperative gastroscopy can be performed to help the surgeon find a mucosal lesion (e.g., ulcer) that is not obvious from the serosal surface. Endoscopic polypectomy using electrosurgery can performed when polyps are causing outflow obstruction or are inflamed.

Gastrotomy

The most common indication for gastrotomy in dogs and cats is removal of a foreign body (see p. 416). *Make a ventral midline abdominal incision from the xiphoid to the pubis. Use Balfour retractors to retract the abdominal wall and provide adequate exposure of the GI tract. Inspect the entire abdominal contents before incising the stomach. To reduce contamination, isolate the stomach from remaining abdominal contents with moistened laparotomy sponges. Place stay sutures to assist in manipulation of the stomach and help prevent spillage of gastric contents. Make the gastric incision in a hypovascular area of the ventral aspect of the stomach, between the greater and lesser curvatures (Fig. 18.66). Make sure the incision is not near the pylorus, or closure of the incision may cause excessive tissue to be enfolded into the gastric lumen, resulting in outflow obstruction. Make a stab incision into the gastric lumen with a scalpel (Fig. 18.67A) and enlarge the incision with Metzenbaum scissors (see Fig. 18.67B). Use suction to aspirate gastric contents and reduce spillage. Close the stomach with 2-0 or 3-0 absorbable suture material (e.g., polydioxanone, polyglyconate) in a two-layer inverting seromuscular pattern (see Fig. 18.67C). Include serosa, muscularis, and submucosa in the first layer, using a Cushing or simple continuous pattern, then follow it with a Lembert or Cushing pattern that incorporates the serosal and muscularis layers (see Fig. 18.67D). As an alternative, close the mucosa in a simple continuous suture pattern as a separate layer to reduce postoperative bleeding. Before closing the abdominal incision, substitute sterile instruments and gloves for those contaminated by gastric contents. Whenever you remove a gastric foreign body, be sure to check the entire intestinal tract for additional material that could cause an intestinal obstruction.*

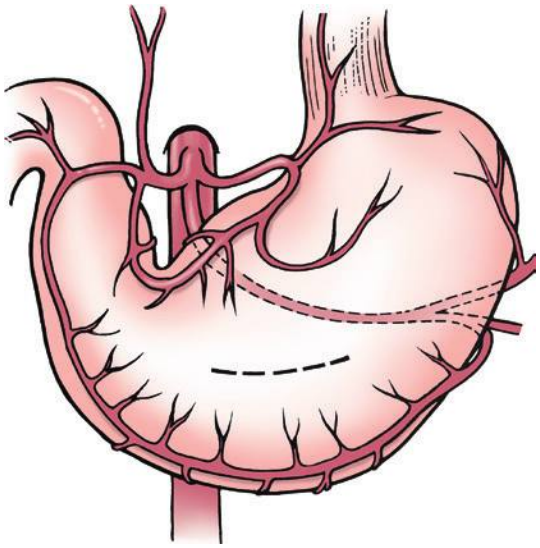

FIG. 18.66 Preferred location of gastrotomy incisions.

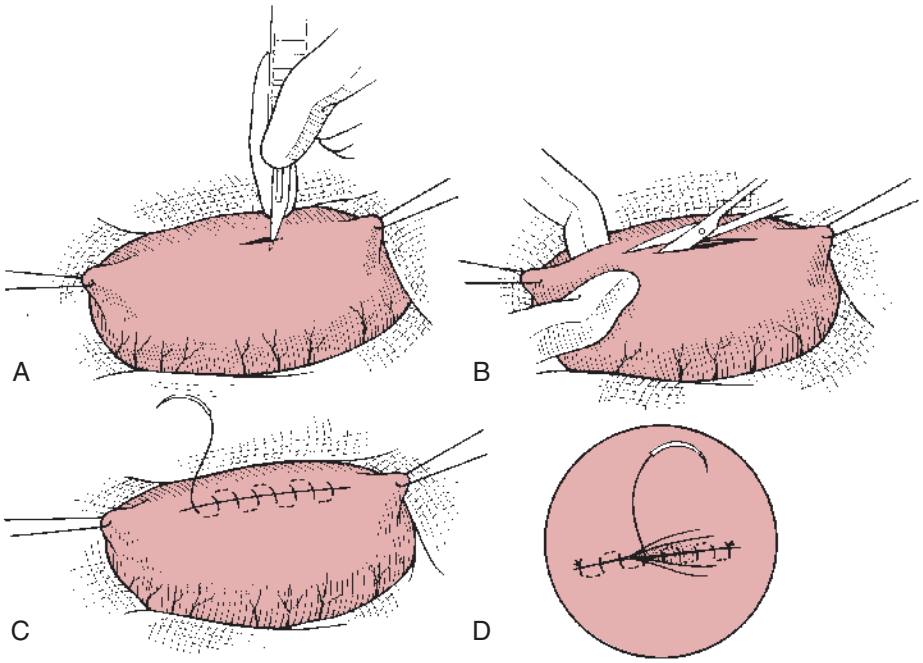

FIG. 18.67 Gastrotomy. (A) Make a stab incision into the gastric lumen with a scalpel. (B) Enlarge the incision with Metzenbaum scissors. (C–D) Close the stomach with a two-layer inverting seromuscular suture pattern.

Partial Gastrectomy and Invagination of Gastric Tissue

Partial gastrectomy is indicated when necrosis, ulceration, or neoplasia involves the greater curvature, or middle portion, of the stomach. Necrosis of the greater curvature is primarily associated with GDV and may be treated by resection or invagination. Invagination does not require opening of the gastric lumen (Fig. 18.68); however, obstruction from excessive intraluminal tissue and excessive bleeding is possible. Assess the extent of necrosis by observing the serosal color, gastric wall texture, vascular patency, and bleeding on incision; however, in many cases it is difficult to determine tissue viability with these techniques (see p. 436 for a discussion of methods for determining tissue viability). Necrotic tissue may range in color from gray-green to black and often feels thin. A full-thickness incision can be made into the suspected necrotic tissue to assess arterial bleeding. IV fluorescein dye has not proved to be an accurate method of determining gastric viability in dogs with GDV. Generally, if you question the viability of the gastric tissue, remove it or invaginate it. Failure to remove or invaginate necrotic tissue may result in perforation, peritonitis, and death. Melena is commonly observed for a few days after gastric invagination.

NOTE Do not use mucosal color to predict gastric viability; the mucosa is commonly black in dogs with GDV because of vascular obstruction. Damage to the mucosa may predispose these animals to gastric ulceration.

To remove the greater curvature of the stomach, ligate branches of the left gastroepiploic vessels or short gastric vessels (or both) along the section of the stomach to be removed (Fig. 18.69). Excise the necrotic tissue, leaving a margin of normal, actively bleeding tissue to suture. Close the stomach in a two-layer inverting pattern using 2-0 or 3-0 absorbable suture (e.g., polydioxanone, polyglyconate). Incorporate the submucosa, muscularis, and serosal layers in a Cushing or simple continuous pattern in the first layer. Then use a Cushing or Lembert pattern to invert the serosa and muscularis over the first layer. As an alternative, you may use a TA stapling device to close the incision. To invaginate necrotic

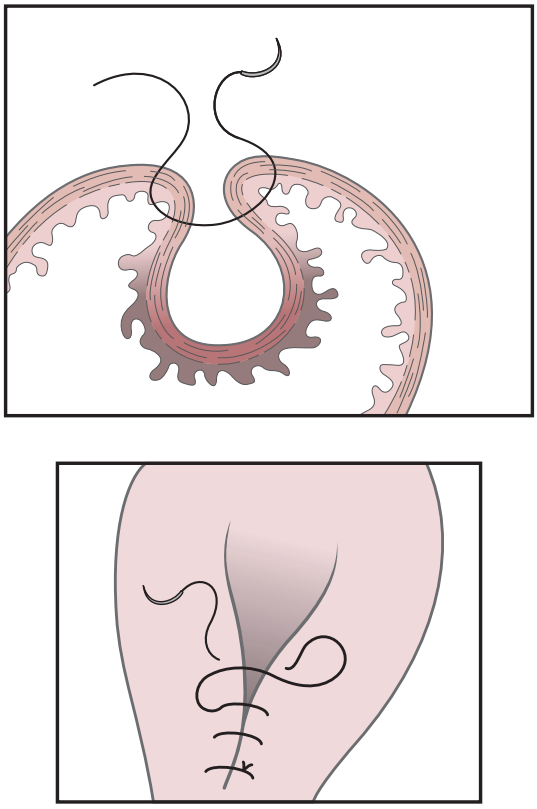

FIG. 18.68 Invagination of necrotic gastric tissue.

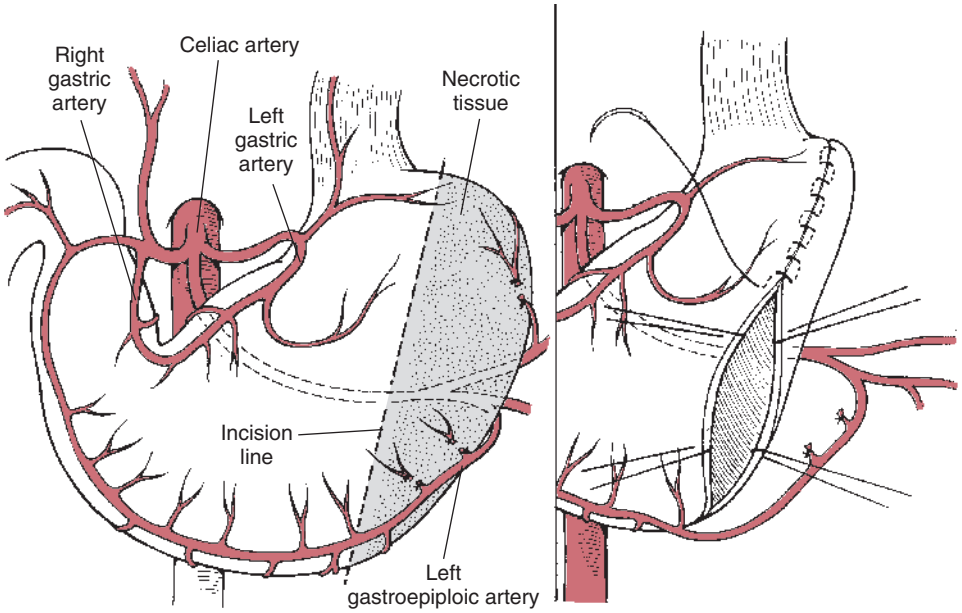

FIG. 18.69 To remove the greater curvature of the stomach, ligate branches of the left gastroepiploic vessels or short gastric vessels (or both) and excise the necrotic tissue. Close the stomach with a two-layer inverting suture pattern.

tissue, use a simple continuous suture pattern followed by an inverting pattern. Place sutures in healthy gastric tissue on both sides of the tissue that is to be invaginated, bringing the healthy tissue over the top of the necrotic tissue. Make sure the sutures are placed in healthy tissues to prevent dehiscence.

Removal of neoplasia (see p. 430) or ulceration (see p. 427) of the greater or lesser curvature is similar to that described for necrotic tissue. Most neoplasms in the gastric body, except for leiomyomas and leiomyosarcomas, have metastasized by the time they are diagnosed. If the abnormal tissue involves the dorsal or ventral aspect of the stomach, an elliptic incision encompassing the lesion and some adjacent normal tissue is used. Closure is as for a simple gastrotomy. Occasionally the extent of the lesion requires resection of both the dorsal and ventral walls of the stomach. *In such cases, ligate branches of the right and left gastric artery and vein (lesser curvature) and left gastroepiploic artery and vein (greater curvature) and remove the omental attachments. After removal of the suspect tissues, perform a two-layer end-to-end anastomosis of the stomach. If the luminal circumferences are of disparate size, the larger circumference can be partly closed using a two-layer suture pattern (Fig. 18.70B). Close the mucosa and submucosa of the dorsal surface of the stomach in a simple continuous pattern using 2-0 or 3-0 absorbable suture (e.g., polydioxanone, polyglyconate), then with the same suture close the ventral aspect. Suture the serosa and muscularis layers in an inverting pattern (e.g., Cushing or Lembert).*

Temporary Gastrostomy

Temporary gastrostomy is used to decompress the stomach and is occasionally indicated in dogs with GDV until more definitive surgery can be performed but is rarely done.

Pylorectomy With Gastroduodenostomy (Billroth I)

AP Removal of the pylorus and gastroduodenostomy is indicated for neoplasia (see p. 430), outflow obstruction caused by pyloric muscular hypertrophy (see p. 425), or ulceration of the gastric outflow tract (see p. 427). If neoplasia is present, at least 1- to 2-cm margins of normal tissue should be removed with the abnormal tissue. The margins of the resected tissue should be evaluated histologically for evidence of neoplasia. If the common bile duct has been damaged, a cholecystoduodenostomy or cholecystojejunostomy may be required (see p. 574). If the pancreatic ducts are inadvertently ligated, supplementation with pancreatic enzymes may be necessary postoperatively.

NOTE Use extreme care when incising in the pyloric area to avoid damaging the common bile duct where it traverses the lesser omentum.

Identify the common bile duct and pancreatic ducts, then place stay sutures in the proximal duodenum and pyloric antrum. If increased caudoventral retraction of the pylorus is desired, identify and transect a portion of the hepatogastric ligament. Ligate branches of the right gastric and right gastroepiploic artery and vein to the affected tissues, and remove the omental and mesenteric attachments (see Fig. 18.70A). Alternatively, use a vessel sealer divider to transect branches along the segment to be excised. Use noncrushing (Doyen) forceps or fingers to occlude the stomach and duodenum proximal and distal to the area to be resected. With Metzenbaum scissors or a scalpel blade, excise the area of pylorus to be removed and inspect the remaining edges to ensure that all abnormal tissue has been excised. If the gastric and duodenal lumens are markedly different in size, incise the duodenum at an angle or partly close the antrum (see Fig. 18.70B). Perform a one- or two-layer end-to-end anastomosis of the pyloric antrum to the duodenum using 2-0 or 3-0 absorbable suture material (polydioxanone, polyglyconate, or poliglecaprone 25) in a simple continuous, crushing, or simple interrupted pattern. There does not appear to be a difference in the prevalence of postoperative leakage and incisional dehiscence between one- and two-layer closures. *Close the far (dorsal) aspect of the incision first (see Fig. 18.70C), followed by the near (ventral) aspect (see Fig. 18.70D). Avoid inverting excessive tissue, which might reduce the diameter of the gastric outflow tract.*

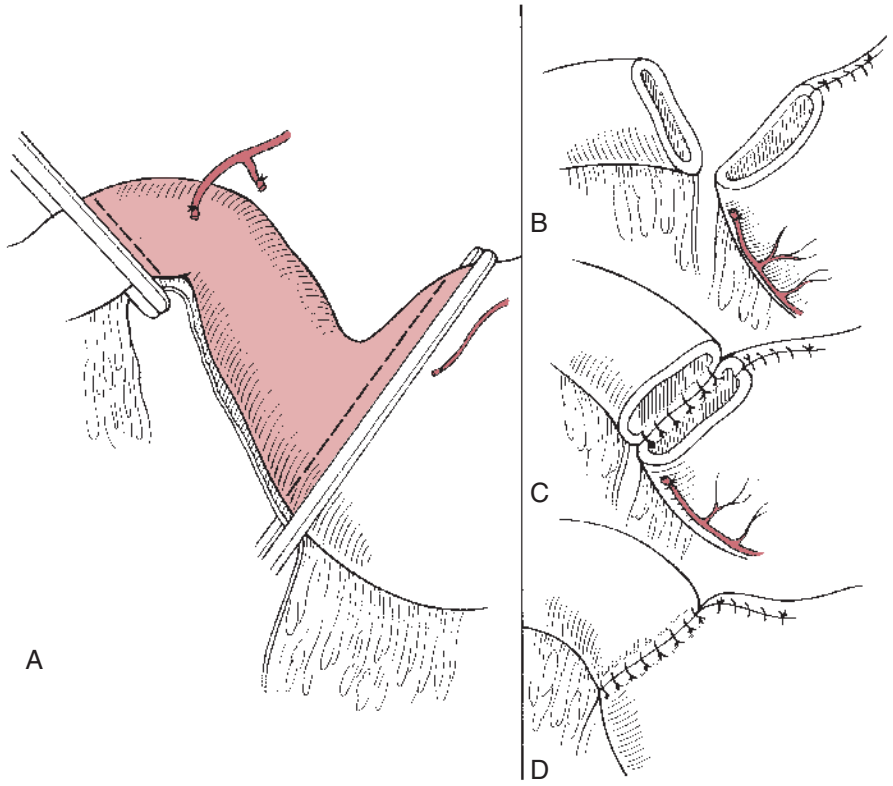
Partial Gastrectomy With Gastrojejunostomy (Billroth II)

AP If the extent of the lesion precludes end-to-end anastomosis of the pyloric antrum to the duodenum, consider a Billroth II procedure. If only mucosal hypertrophy is present, a Y-U pyloroplasty (discussed later) is easier to perform and is effective. Before undertaking this procedure, make sure that there is no gross evidence of metastasis (see p. 430 for information regarding gastric neoplasia). In most cases a cholecystojejunostomy or cholecystoduodenostomy is required in addition to the gastrojejunostomy (see p. 574). Exocrine insufficiency may occur if the pancreatic ducts are damaged. Exocrine plus endocrine pancreatic insufficiency (i.e., diabetes mellitus) may occur as a result of pancreatic resection or severe damage to the pancreatic blood supply.

The procedure is similar to a Billroth I except that the distal stomach and proximal duodenum are closed after pylorectomy, and the jejunum is attached with a side-to-side anastomosis to the diaphragmatic surface of the stomach. *Resect the pylorus, antrum, and proximal duodenum as described earlier, ligating appropriate branches of the right and left gastric and gastroepiploic vessels (Fig. 18.71A). Close the duodenal and pyloric antral stumps in a two-layer pattern. For the first layer, incorporate the mucosa and submucosa in a simple interrupted or simple continuous pattern using 2-0 or 3-0 absorbable suture (see Fig. 18.71B). Then use an inverting suture pattern (e.g., Lembert) in the seromuscular layer. Identify an avascular area between the gastric incision and greater curvature. Bring a loop of proximal jejunum to the selected site and attach it to the stomach with stay sutures. Suture the seromuscular layers of the stomach and intestine together using a simple continuous pattern with 2-0 or 3-0 absorbable suture (see Fig. 18.71C). Make full-thickness, longitudinal incisions into the stomach and intestinal lumens near the suture line (see Fig. 18.71D). Suture the mucosa and submucosa of the stomach to the intestine in a continuous pattern using 3-0 or 4-0 absorbable suture (see Fig. 18.71E). Next, place a continuous suture pattern in the serosa and muscularis.* Use of stapling devices has also been described for stump closure and creation of the gastrojejunostomy.

Pyloromyotomy and Pyloroplasty

Pyloromyotomy and pyloroplasty increase the diameter of the pylorus and are used to correct gastric outflow obstruction (i.e., chronic antral mucosal hypertrophy or pyloric stenosis). These procedures must be done with care as errors can be difficult or impossible to revise. They should not be performed routinely in dogs without evidence of pyloric dysfunction (e.g., most dogs with GDV) because they can slow gastric emptying. Gastric outflow procedures that increase the diameter of the pyloric



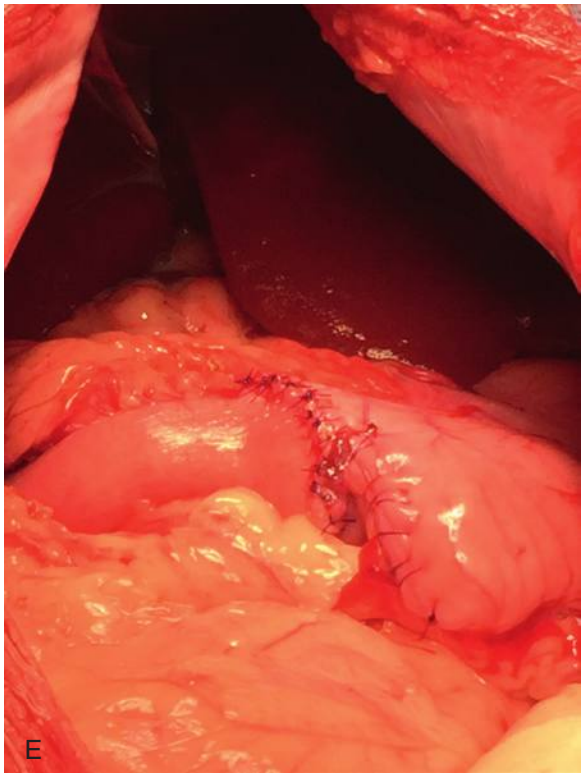


FIG. 18.70 Billroth I procedure. (A) Ligate the vasculature, remove the omental and mesenteric attachments, and excise the area of the pylorus to be removed. (D) Close the near (ventral) aspect. (E) Appearance of the stomach following a Billroth I procedure.

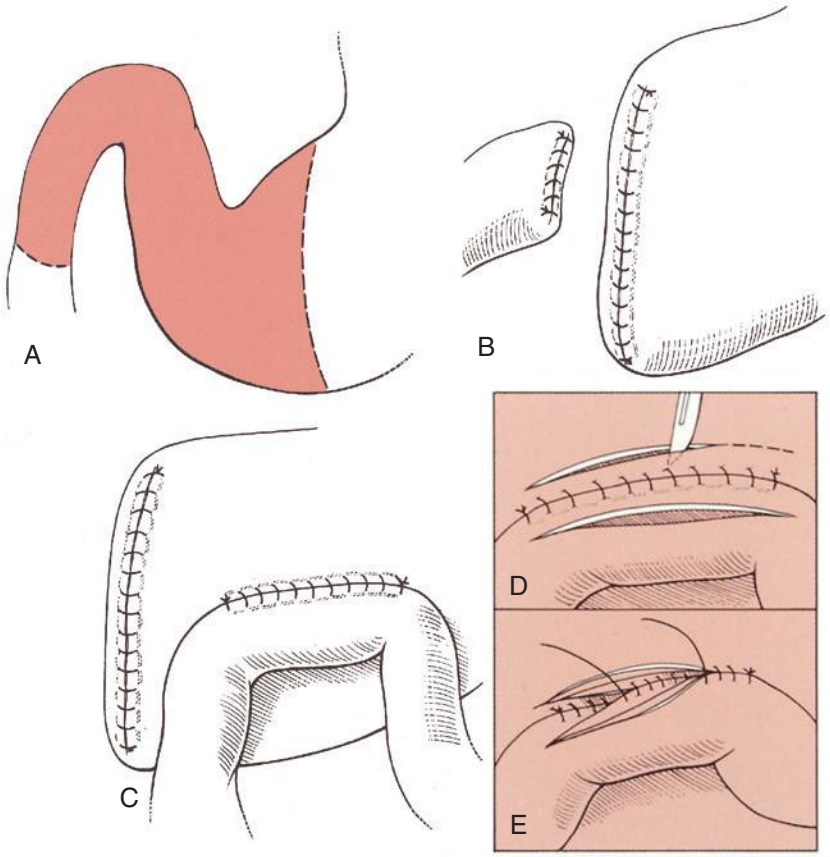

FIG. 18.71 Billroth II procedure. (A) Resect the pylorus, antrum, and proximal duodenum. (B) Close the duodenal and pyloric antral stumps with a two-layer suture pattern. (C) Bring a loop of proximal jejunum to the stomach and suture the seromuscular layers of the stomach and intestine together. (D) Make full-thickness, longitudinal incisions into the stomach and intestinal lumens. (E) Suture the mucosa and submucosa of the stomach to the intestine with a continuous suture pattern.

BOX 18.21 Prokinetic Drugs

Cisapride (Pharmacy Compounded)
Dogs: 0.1–0.5 mg/kg PO q8–24h
Cats: 2.5–5 mg/cat PO q8–12h

Ranitidine
Dogs: 2 mg/kg IV, PO q8–12h
Cats: 2.5 mg/kg IV q12h or 3.5 mg/kg PO q12h

Erythromycin
0.5–1 mg/kg PO or IV q8–12h

Metoclopramide (Reglan)
0.25–0.5 mg/kg PO, IV or SC q6–24h

IV, Intravenous; *PO,* orally; *SC,* subcutaneous.

lumen seem to favor early passage of viscous, nonhomogeneous, and hyperosmolar gastric contents into the duodenum. This early passage may overstimulate the enterogastric reflex, prematurely inhibiting antral motor activity and delaying gastric emptying. In addition, gastroduodenal reflux may occur if pyloric function is altered by surgery. Metoclopramide, cisapride, ranitidine, or low-dose erythromycin (Box 18.21) may stimulate gastric emptying.

Fredet-Ramstedt Pyloromyotomy

Fredet-Ramstedt pyloromyotomy is the simplest and easiest of these procedures. It does not allow inspection or biopsy of the pyloric mucosa and probably provides only temporary benefit because healing may reduce the size of the lumen.

Hold the pylorus between the index finger and thumb in the nondominant hand. Select a hypovascular area of the ventral pylorus and make a longitudinal incision through the serosa and muscularis but not through the mucosa (Fig. 18.72). Make sure the muscularis layer is completely incised to allow the mucosa to bulge into the incision site. If the mucosa is inadvertently penetrated, close it with interrupted sutures of 2-0 or 3-0 absorbable suture material.

Heineke-Mikulicz Pyloroplasty

Heineke-Mikulicz pyloroplasty allows limited exposure of the pyloric mucosa for biopsy and is easy to perform. *Make a full-thickness, longitudinal incision in the ventral surface of the pylorus (Fig. 18.73). Place traction sutures at the center of the incision, and orient the incision transversely. Suture the transverse incision in a one-layer pattern (simple interrupted or crushing) using 2-0 or 3-0 absorbable suture. Place the sutures carefully so that the incision edges are properly aligned and tissue inversion is avoided.*

Y-U Pyloroplasty

The Y-U pyloroplasty allows greater accessibility for resection of the pyloric mucosa in dogs with mucosal hypertrophy while

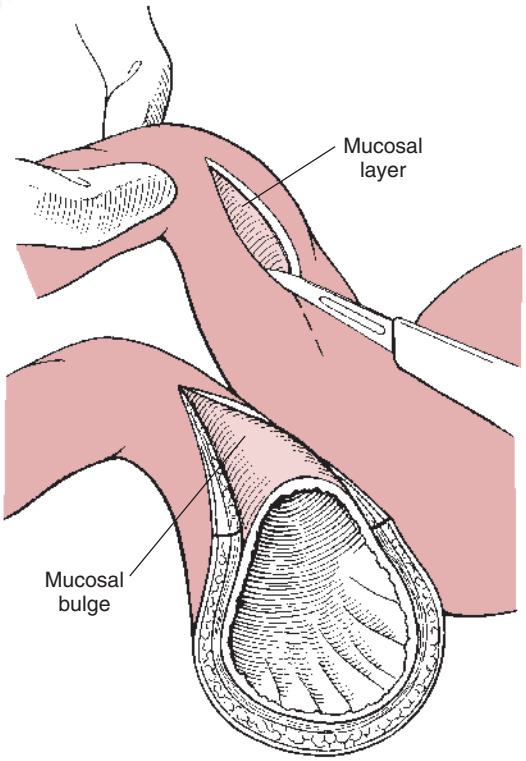

FIG. 18.72 Fredet-Ramstedt pyloromyotomy.

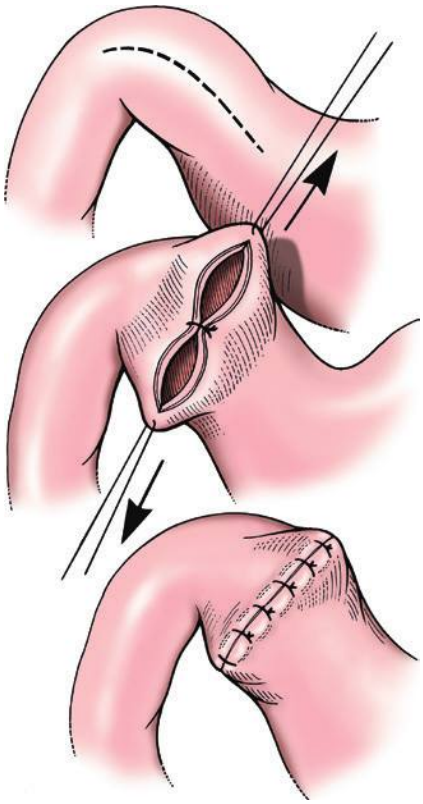

FIG. 18.73 Heineke-Mikulicz pyloroplasty.

simultaneously increasing the luminal diameter of the outflow tract. *Make a longitudinal incision (limb) in the serosa overlying the ventral pylorus and extend it into the stomach by making two incisions (arms) that run parallel to the lesser and greater curvature of the stomach (creating a Y-shaped incision) (Fig. 18.74A). Make sure the angle of the Y is not overly narrow, or necrosis may result. The limbs and arms of the Y-shaped incision should be approximately the same length. Make a full-thickness incision. Inspect the mucosa and resect it if necessary. If the mucosa is resected, appose the remaining mucosal edges in a continuous pattern using absorbable 3-0 to 4-0 suture before closing the Y incision. Suture the base of the antral flap to the distal end of the duodenal incision in a simple interrupted pattern using absorbable 2-0 or 3-0 suture, creating a U-shaped closure (see Fig. 18.74B). Close the remainder of the incision (the limbs) with simple interrupted sutures (see Fig. 18.74C). Make sure that tissue approximation is adequate to prevent leakage and that minimal tissue has been enfolded into the pyloric lumen.*

NOTE To reduce necrosis of the pointed tip of the gastric tissue flap, you may wish to excise the point of the Y before suturing it.

Gastropexy

Gastropexy techniques are designed to permanently adhere the stomach to the body wall. The most common indications are GDV (pyloric antrum to right body wall) and hiatal herniation (fundus to left body wall). Numerous gastropexy techniques have been described. Although the strength and extent of adhesions created by these techniques differ, all of them (when properly performed) prevent movement of the stomach. Careful attention to the normal anatomy and orientation of the stomach and descending duodenum is important to avoid postoperative gastric outflow abnormalities due to gastric malpositioning.[19]

NOTE To create a permanent adhesion, the gastric muscle must be in contact with the muscle of the body wall; intact gastric serosa does not form permanent adhesions to an intact peritoneal surface.

A technique for gastropexy has been described in which the stomach is incorporated into the abdominal incision during closure (ventral midline gastropexy). The recurrence rate after this procedure seems to be similar to other gastropexy techniques and the concern that the adherence of the stomach to the midline abdominal incision would interfere with subsequent celiotomy has not been borne out.

Tube Gastropexy

Tube gastropexy (gastrostomy) is quick and relatively simple (Fig. 18.75). In addition, it allows postoperative gastric decompression and placement of medications directly into the stomach in inappetent animals. The tube should be left in place for 7 to 10 days to form a permanent adhesion. Although this may lengthen the postoperative hospitalization period compared with other techniques, the tube can be capped and secured against the trunk and the patient sent home on oral feeding. The risk of leakage is minimal if proper technique is used; however, improper placement may result in peritonitis.

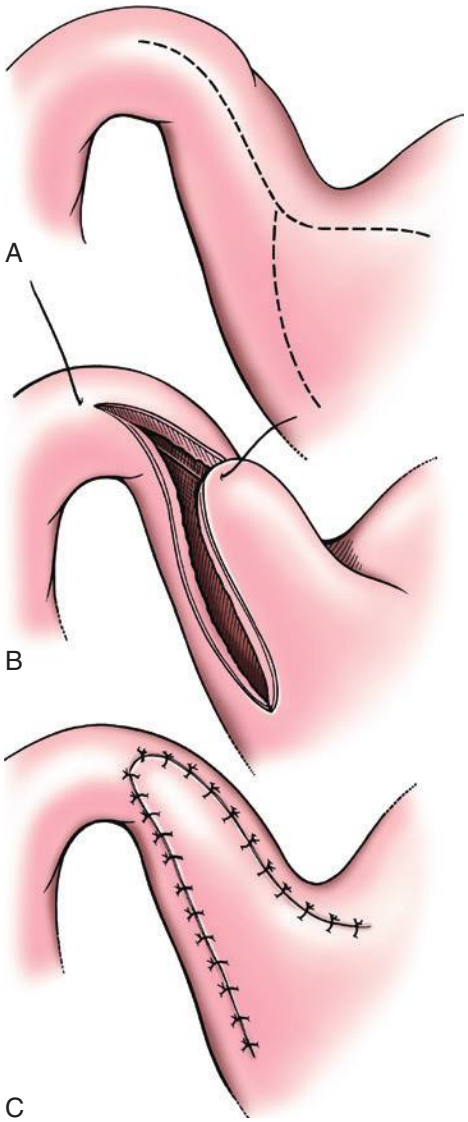

FIG. 18.74 Y-U pyloroplasty. (A) Make a Y-shaped incision in the pylorus and pyloric antrum. (B) Begin by suturing the base of the antral flap to the distal point of the duodenal incision. (C) Close the remainder of the incision in a U-shape.

Make a stab incision into the right abdominal wall caudal to the last rib and 4 to 10 cm lateral to the midline. Place a Foley catheter (18–30 Fr) or a mushroom-tipped silicone catheter through the stab incision. Select a site in a hypovascular region of the seromuscular layer of the ventral surface of the pyloric antrum where the balloon of the catheter will not obstruct gastric outflow. Place a purse-string suture of 2-0 absorbable suture (e.g., polydioxanone, polyglyconate) at this site. Make a stab incision through the purse-string suture and insert the catheter tip into the gastric lumen (Fig. 18.76A). (Note: the catheter can be placed through the omentum before entry into the stomach so that the omentum is secured between the stomach and body wall, or the omentum can be wrapped around the site after the stomach has been secured to the body wall.) *If using a Foley catheter, inflate the bulb with saline (not air), and secure the purse-string suture around the tube. Preplace three or four absorbable sutures between the pyloric antrum and the body wall where the tube exits (see Fig. 18.76B). Avoid penetrating the catheter or balloon when placing the sutures. Draw the stomach to the body wall by placing traction on the catheter, and tie the preplaced sutures (see Fig. 18.76C). Secure the tube to the skin with a Roman sandal suture pattern (see Fig. 30.10), but avoid penetrating it with a suture. Place a bandage around the dog's abdomen and over the tube to prevent premature removal (use an Elizabethan collar if necessary). Leave the tube in place for 7 to 10 days, then deflate the balloon and remove it. Leave the skin incision open to facilitate drainage. Place a light bandage over the open wound if desired.*

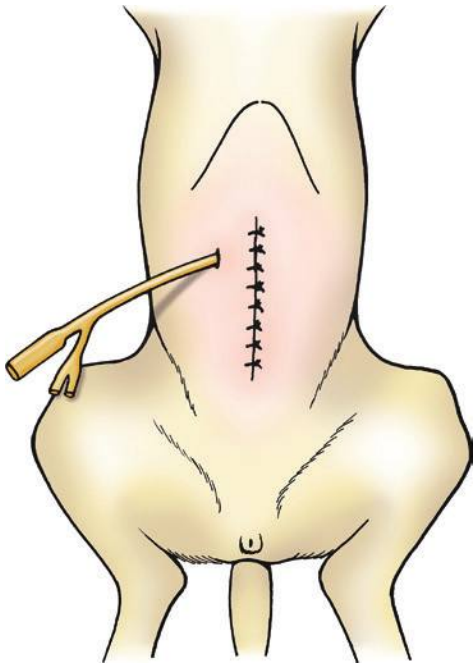

FIG. 18.75 Tube gastropexy using a Foley catheter.

The Roman sandal suture pattern is preferred over friction sutures tied to the skin along the course of the tube, as the Roman sandal pattern requires more force to failure and it is the suture that tends to fail, rather than tube slippage. Silicone tubing has a higher force to failure than latex for gastrostomy tubes.

NOTE Cut the tip off the end of the Foley catheter if food or viscous fluids are to be injected through it. Inflate the balloon with saline, not air.

Circumcostal Gastropexy

Circumcostal gastropexy forms a stronger adhesion than most other techniques but is technically more challenging (Box 18.22). Because the lumen of the stomach is not entered, the risk of gastric leakage and abdominal contamination is diminished compared with tube gastropexy. Possible complications associated with circumcostal gastropexy include pneumothorax and rib fracture.

Make either a one- or two-layer hinged flap (approximately 5–6 cm long in large dogs) by incising through the seromuscular layer of the pyloric antrum (Fig. 18.77A). Do not incise the gastric mucosa or enter the lumen (if this occurs, suture the mucosa with

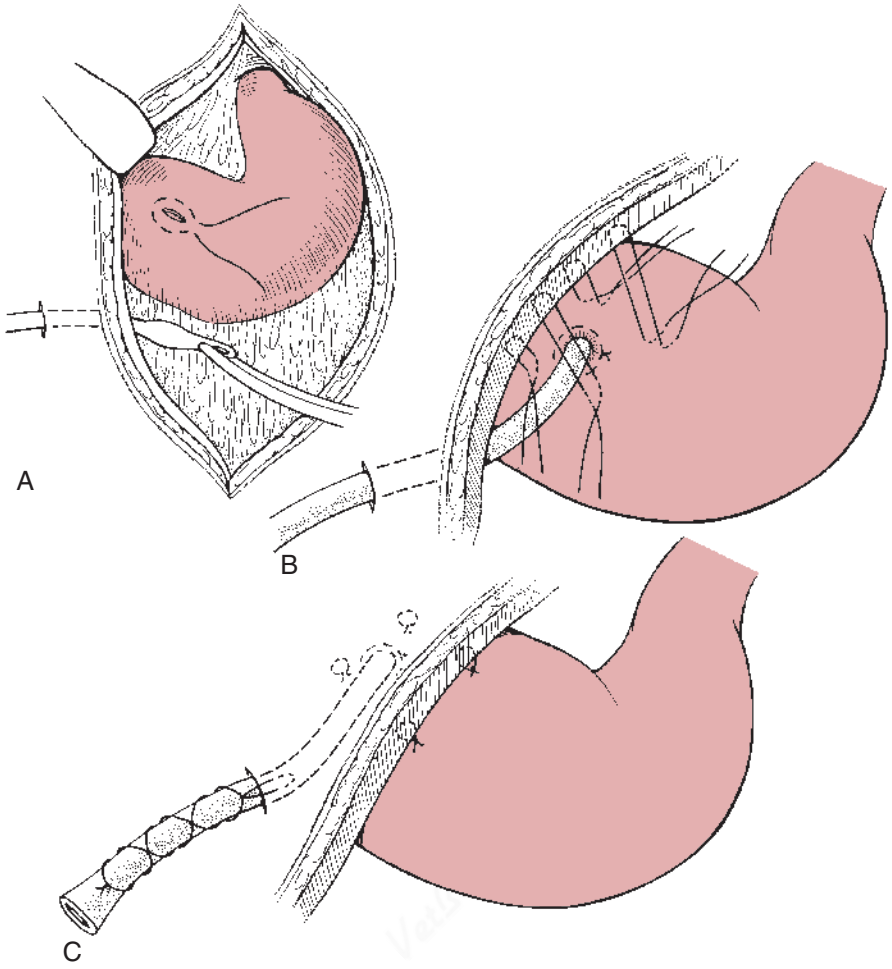

FIG. 18.76 Tube gastropexy using a Foley catheter. (A) Insert the tip of the catheter into the gastric lumen through a purse-string suture. (B) Preplace three or four absorbable sutures between the pyloric antrum and the body wall where the tube exits. (C) Draw the stomach to the body wall and tie the preplaced sutures. Secure the tube to the skin with a Roman sandal suture pattern.

BOX 18.22 Advantages and Disadvantages of Circumcostal Gastropexy

Advantages
- Strong adhesion to body wall
- Gastric lumen not opened

Disadvantages
- More difficult to perform
- Risk of pneumothorax
- Possibility of rib fractures
- Does not provide direct access to gastric lumen if postoperative decompression is necessary

3-0 absorbable suture). Elevate the flap by dissecting under the muscularis. If a one-hinged flap is made, place the hinge toward the lesser curvature. Make a 5- to 6-cm incision over the 11th or 12th rib at the level of the costochondral junction (see Fig. 18.77B). Make sure the incision does not penetrate the diaphragmatic attachments to the body wall, causing pneumothorax. Form a tunnel under the rib using a Carmalt clamp or hemostat (see Fig. 18.77C). Place stay sutures on the flap (if using a two-flap technique, place the sutures on the flap nearest the lesser curvature). Pass the gastric antral flap craniodorsal under the rib (see Fig. 18.77D), and suture it with 2-0 absorbable suture to the original gastric margin (one-flap technique; Fig. 18.78A) or the other flap (two-flap technique; see Fig. 18.78B).

Muscular Flap (Incisional) Gastropexy

Muscular flap (incisional) gastropexy is easier than circumcostal gastropexy and avoids the possible complications associated with tube gastropexy (Box 18.23). *Make an incision in the seromuscular layer of the gastric antrum. Then make an incision in the right ventrolateral abdominal wall by incising the peritoneum and internal fascia of the rectus abdominis or transverse abdominis muscles (Fig. 18.79A). Suture the edges of the incisions in a simple continuous pattern using 2-0 absorbable or nonabsorbable suture (see Fig. 18.79B). Make sure the muscularis layer of the stomach is in contact with the abdominal wall muscle (see Fig. 18.79C). Suture the cranial margin first, then the caudal margin.* As an alternative, you may raise flaps in the stomach and body wall to increase the extent of muscle contact between these tissues.

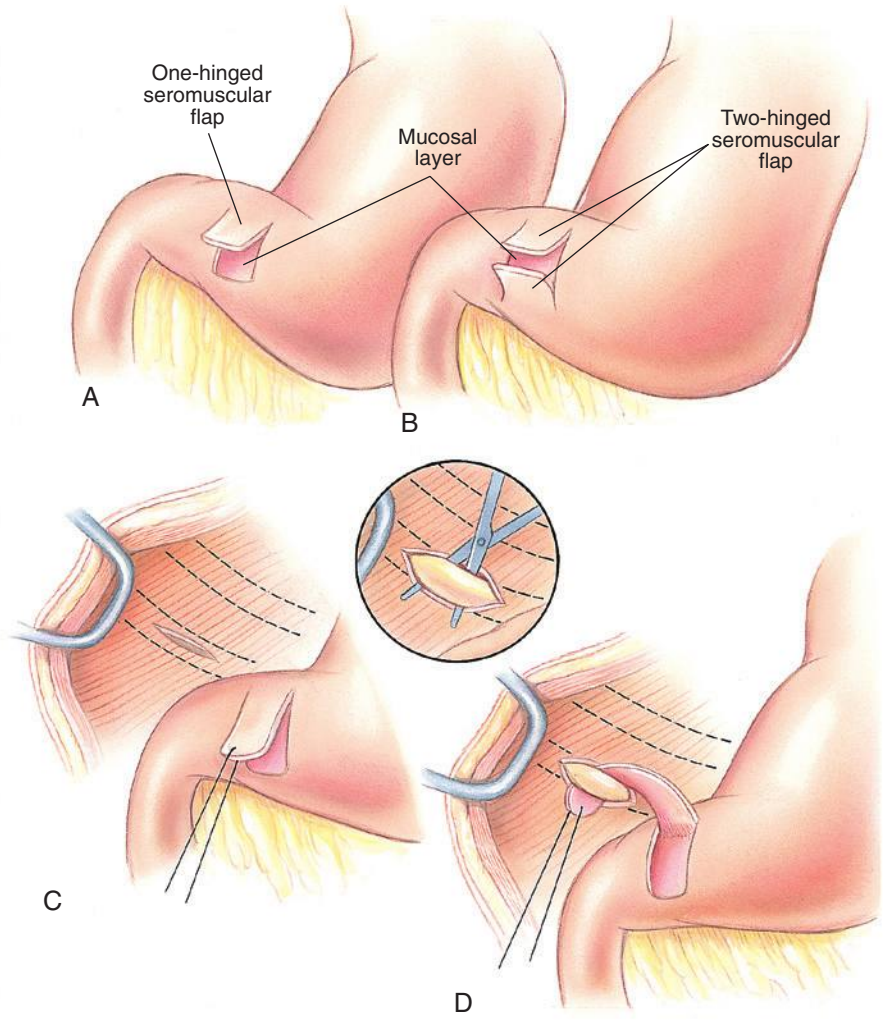

FIG. 18.77 Circumcostal gastropexy. (A) Make a single- or double-layer hinged seromuscular flap in the pyloric antrum. (B) Make an incision over the 11th or 12th rib at the level of the costochondral junction. (C) Form a tunnel under the rib using a Carmalt clamp or hemostat. (D) Pass the gastric antral flap craniodorsal under the rib and suture it to the original gastric margin or to the other flap (see Fig. 18.78).

BOX 18.23 Advantages and Disadvantages of Muscular Flap and Belt-Loop Gastropexy

Advantages
- Easy and quick to perform
- Gastric lumen not opened

Disadvantages
- Less strong than circumcostal gastropexy
- Does not provide direct access to gastric lumen if postoperative decompression is necessary

Alternatively, a horizontal incision may be made in the pyloric antrum (Fig. 18.80A), sutured to an incision crossing the fibers of the transversus abdominus (see Fig. 18.80B). The transverse orientation of the incisions may lessen the difficulty of the procedure for a surgeon without an assistant. Suture the dorsal, or aborad, aspect of the antral incision to the transversus muscle first (see Fig. 18.80C) followed by the ventral, or orad, aspect of the incision (see Fig. 18.80D).

Two studies have shown that incisional gastropexy is adequate for the prevention of recurrent GDV or the prevention of GDV in normal dogs; however, it will not prevent gastric dilatation.[20,21]

Belt-Loop Gastropexy

A belt-loop gastropexy is similar to a muscle flap gastropexy except that a single flap is elevated and passed beneath a tunnel created in the abdominal wall. It is technically simple and seems to result in adequate adhesions. *Elevate a seromuscular flap in the gastric antrum. Make two transverse incisions in the ventrolateral abdominal wall by incising the peritoneum and abdominal musculature (Fig. 18.81A). The incisions should be 2.5 to 4 cm apart and 3 to 5 cm long. Create a tunnel under the abdominal musculature with forceps. Place stay sutures in the edge of the antral flap and use them to pass the flap from cranial to caudal under the*

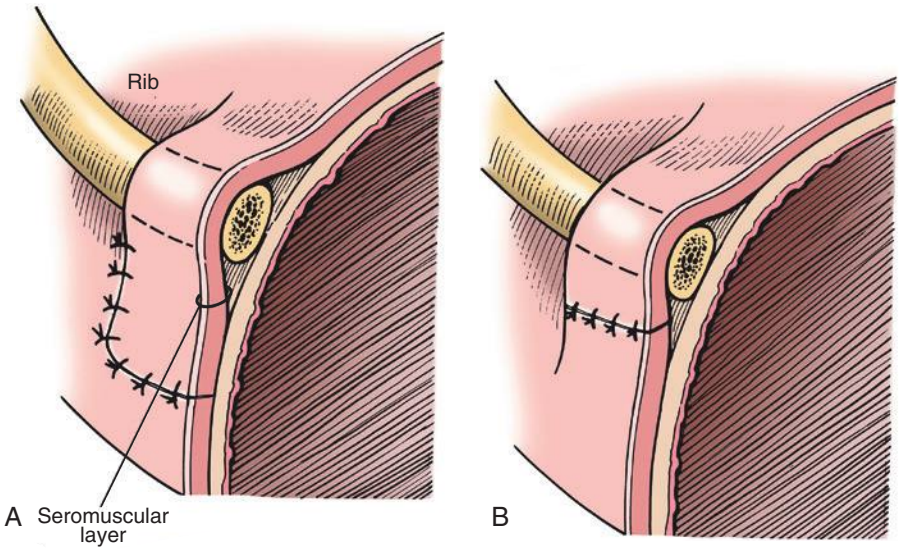

FIG. 18.78 (A) For a single-flap technique, suture the circumcostal flap to the original gastric margin. (B) For a double-flap technique, pass the seromuscular flap under the rib and suture it to the second flap.

muscular flap (see Fig. 18.81B). Suture the flap to its original gastric margin in a simple continuous pattern using 2-0 absorbable or nonabsorbable suture (see Fig. 18.81C) or skin staples. You may wish to place additional sutures between the body wall and the stomach to reduce tension on the gastropexy.

Gastrocolopexy

Gastrocolopexy has also been described as a method of preventing recurrence of GDV. In this technique, the greater curvature of the stomach is sutured to the transverse colon. This technique may result in a recurrence rate as high as 20%.

Laparoscopic-Assisted Prophylactic Gastropexy

This minimally invasive technique allows a rapid gastropexy. *With the dog in dorsal recumbency, place the first cannula just caudal to the umbilicus and place the second 10-mm cannula just right of midline, approximately 2 to 4 cm behind the last rib (make this incision parallel to the rib (Fig. 18.82A). Use Babcock forceps to grasp the antrum, midway between the greater and lesser curvatures and 6 to 8 cm back from the pylorus. Pull this portion of the stomach up to the end of the cannula, and then pull the cannula, Babcock forceps, and stomach out of the abdomen as one unit until the stomach wall can be seen protruding from the peritoneal cavity (see Fig. 18.82B). Enlarge the incision through which the cannula was placed to 4 to 5 cm. Grasp the gastric wall with Allis tissue forceps or Babcock forceps, and place stay sutures between it and the body wall (see Fig. 18.82C). Release the endoscopic Babcock forceps. Perform the gastropexy as described previously under Muscular Flap Gastropexy. Take care to not twist the antrum as it is brought up to and out of the incision.* It is best to reexamine the stomach laparoscopically before final closure to ensure that malpositioning did not take place.

Endoscopically Assisted Gastropexy

Endoscopically assisted gastropexy may be performed in dogs. *Place the dog in a 30-degree, left oblique recumbency. With the surgeon standing toward the dog's spine and the endoscopist positioned at the dog's ventrum (Fig. 18.83), pass the flexible endoscope into the stomach, and insufflate until rugal folds are minimized.* An assistant may be required to manually occlude the cervical esophagus during insufflation. *Palpate and indent the body wall caudal to the 13th rib and stomach at the proposed gastropexy site at the pyloric antrum. Pass polypropylene suture (0 or 2-0; see Fig. 18.83) percutaneously in a mattress suture fashion through the skin, body wall, pyloric antrum, and back through the body wall and skin. Temporarily tighten the suture with hemostatic forceps and place another suture in the same manner 4 to 5 cm aborad to the first suture.* These stay sutures guide the paracostal approach for the gastropexy, which is approached as for the laparoscopic-assisted gastropexy. *Incise the seromuscular layer of the pyloric antrum and suture it to the transversus abdominis muscle in two simple continuous patterns, avoiding the stay sutures. Remove the stay sutures and close the external abdominal oblique muscle in a simple continuous pattern using 2-0 PDS and routinely close the skin and subcutis. Decompress the stomach and remove the endoscope.*

Laparoscopic Sutured Gastropexy

Position the dog in dorsal recumbency, and establish an endoscope portal in the umbilical position and two operating ports 6 to 7 cm cranial to the umbilical port to the left and right of midline. Introduce and grasp the pyloric antrum with a 5-mm bowl grasper and retract the stomach to the right ventral abdominal wall. Use a coagulation hook probe to create four coagulated spots (0.5 seconds, 8 W power) on the peritoneal surface oriented cranial to caudal, separating each by 0.5 to 1 cm. Incise the skin approximately 4 cm over the coagulated region of the body wall under endoscopic guidance. Pass four metric PDS (1 USP) sutures on a 36-mm, half-circle needle through the body wall and seromuscular layer of the stomach in a mattress pattern, exiting the body wall through the skin incision. Coagulate the serosal surface of the stomach incorporated by the horizontal mattress suture. Place three more horizontal mattress sutures through the body wall and coagulated region of the stomach, separating each by 2 to 2.5 cm. Reduce abdominal insufflation and secure the sutures to form a gastropexy. Close the portal sites routinely.

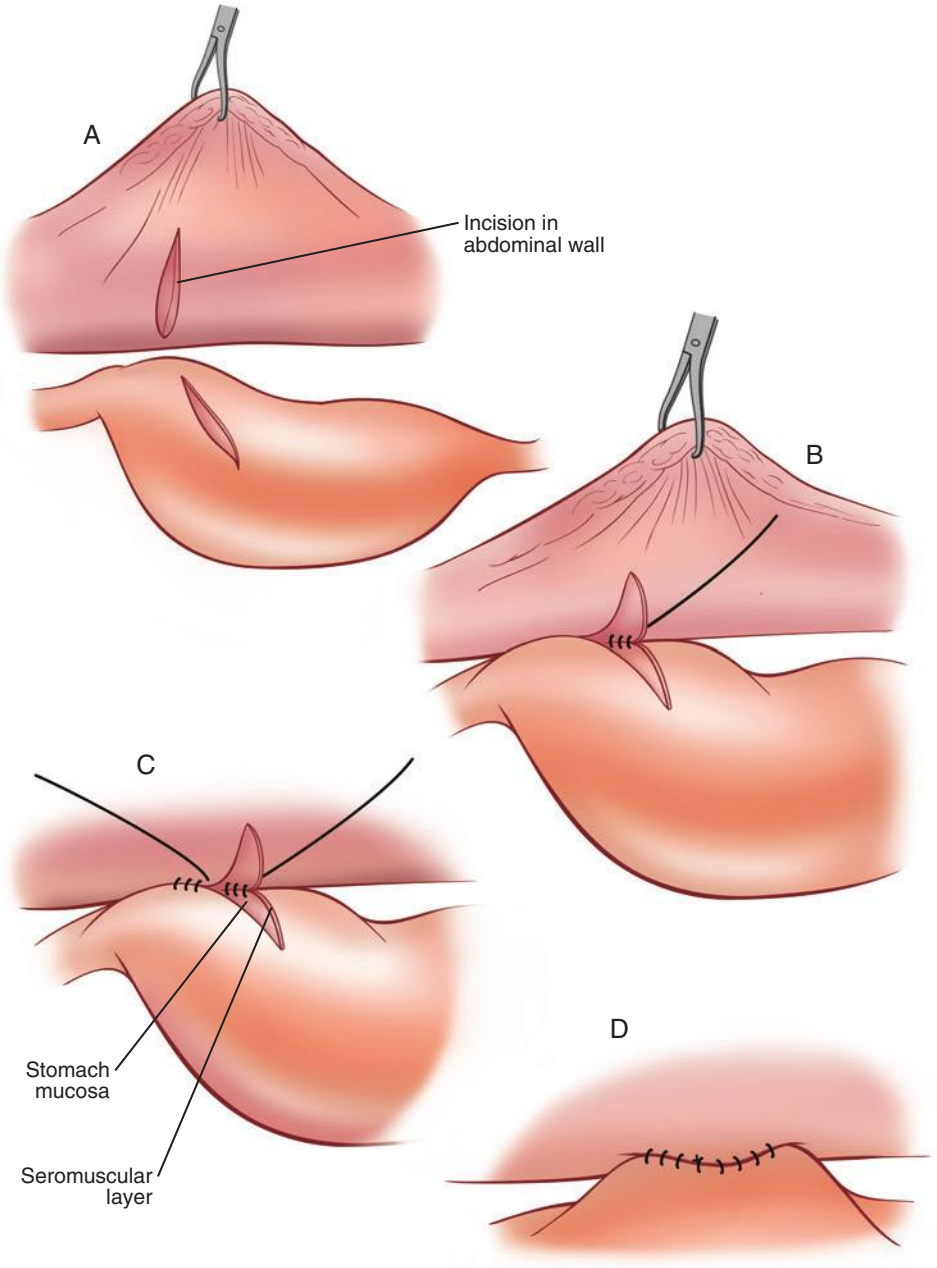

FIG. 18.79 Incisional gastropexy. (A) Incise the seromuscular layer of the pyloric antrum midway between the greater and lesser curvatures longitudinally. Incise the transversus muscle parallel to its fibers. (B) Suture the dorsal half of the cranial transversus and seromuscular layers in a simple continuous pattern. (C) Suture the dorsal half of the caudal transversus and seromuscular layers in a simple continuous pattern. (D) Appearance of the gastropexy following closure of the cranial then caudal ventral portions of the gastropexy.

Intracorporeally Sutured Laparoscopic Gastropexy

Intracorporeally sutured laparoscopic gastropexy may be performed. *Place an initial endoscope port in the infraumbilical site. Establish two instrument ports on the ventral midline with one 3 to 4 cm caudal to the xiphoid process and the second midway between the established ports on midline. Move the endoscope to the middle port. Place a mattress suture (2-0 nonabsorbable monofilament) through the body wall 2 to 3 cm caudal to the last rib and 5 to 8 cm lateral to the linea alba on the right side of the abdomen. Take a full-thickness bite of the pyloric antrum and exit through the body wall adjacent to the entry site. Incise the transversus abdominis and seromuscular layer of the stomach at the gastropexy site. Orient the incision parallel to the linea alba to facilitate visualization during suturing of the aborad then orad sides of the gastropexy.* The gastropexy may be done by hand with intracorporeal knot tying or using an automatic suture assist device (e.g., Endostitch).

Development of barbed suture has led to the knotless endoscopic gastropexy.[22,23] The technique is similar to that described previously; however, the suture is passed through a loop in the

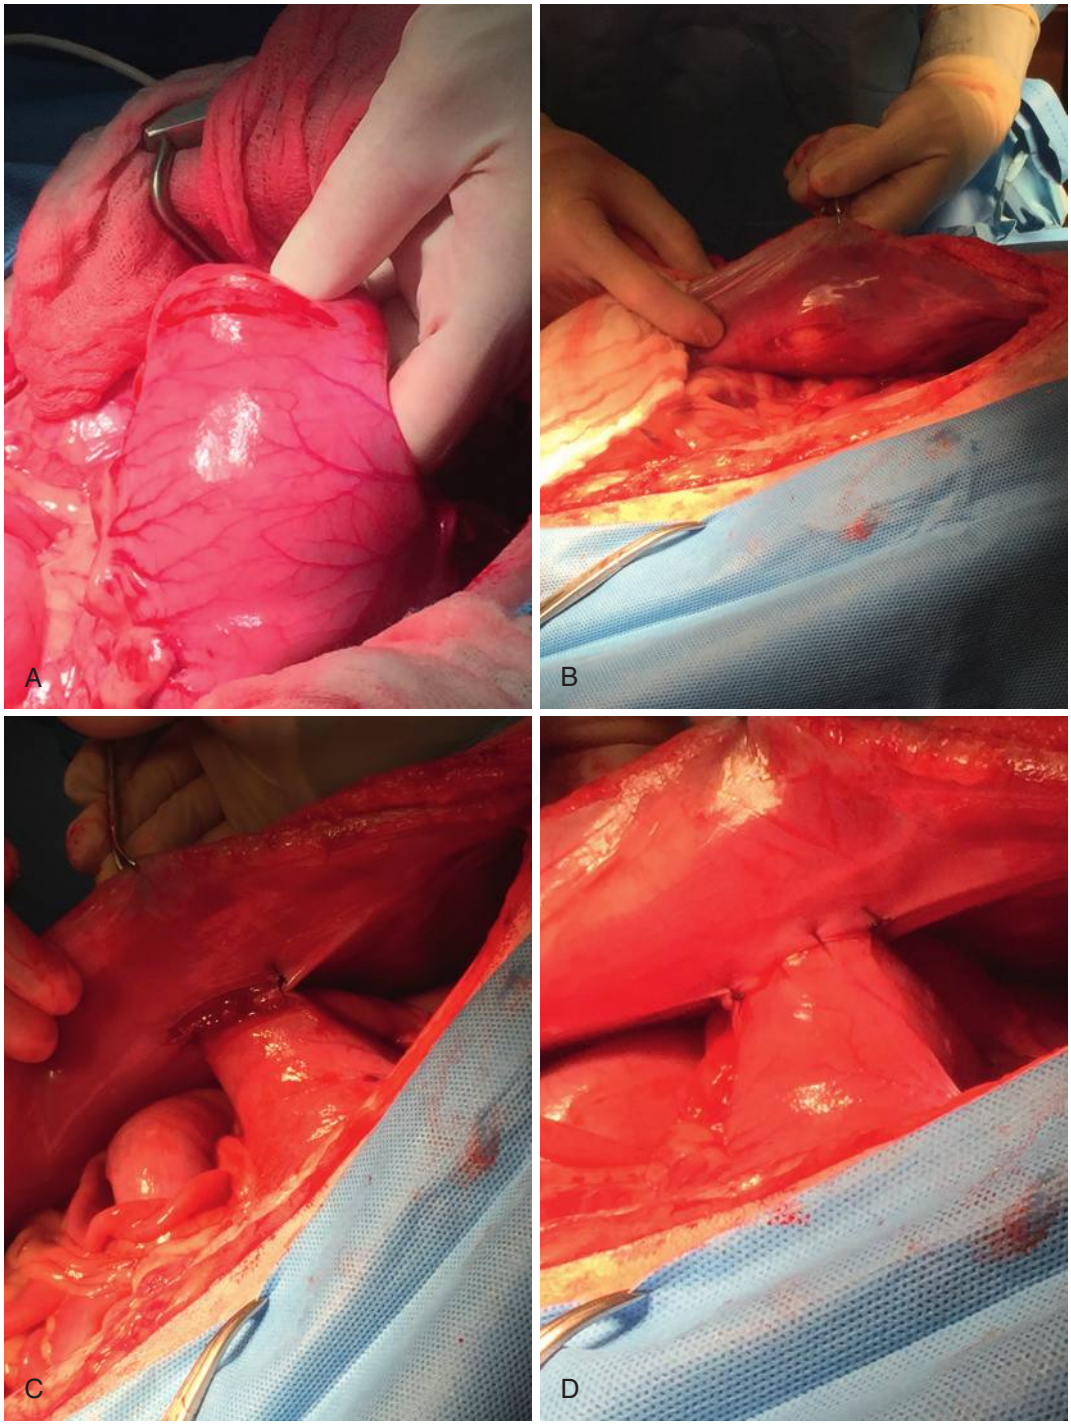

FIG. 18.80 Transverse incisional gastropexy. (A) Make a transverse incision through the seromuscular layer of the pyloric antrum. (B) Make a transverse incision in the adjacent transversus abdominus muscle. (C) Suture the dorsal aspect of the transversus muscle and gastric incisions with a simple continuous pattern. (D) Complete the gastropexy by suturing the ventral aspect of the incisions.

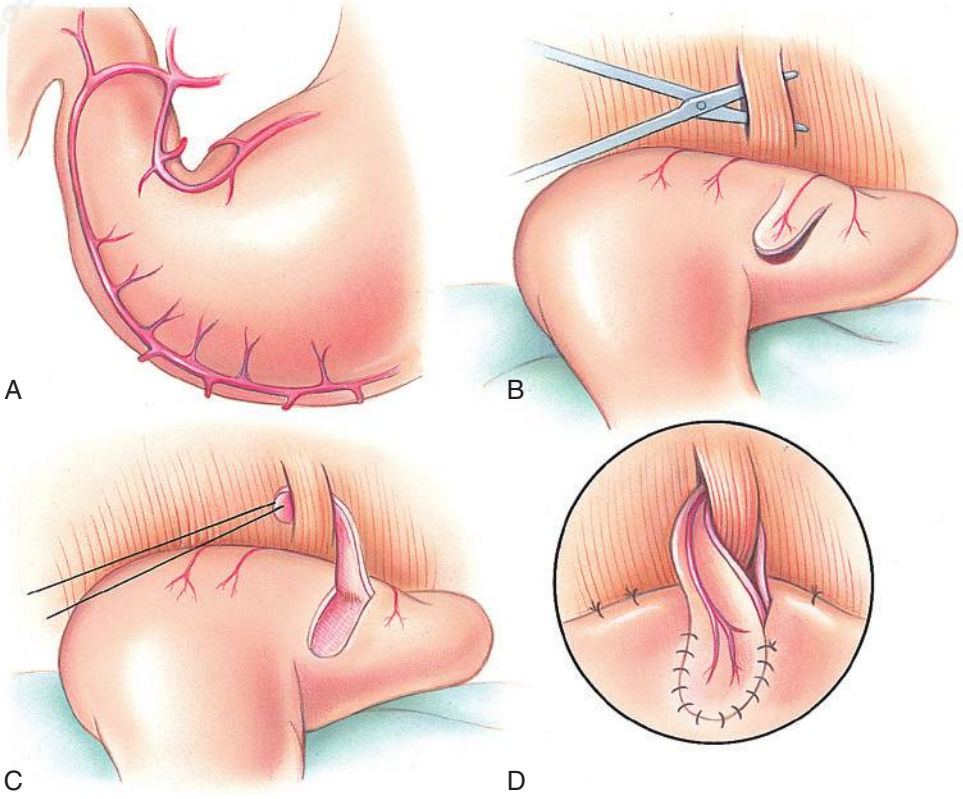

FIG. 18.81 Belt-loop gastropexy. (A) Elevate a seromuscular flap in the gastric antrum. (B) Make two transverse incisions in the ventrolateral abdominal wall and create a tunnel under the abdominal musculature with forceps. Pass the flap from cranial to caudal under the muscular flap. (C–D) Suture the flap to its original gastric margin.

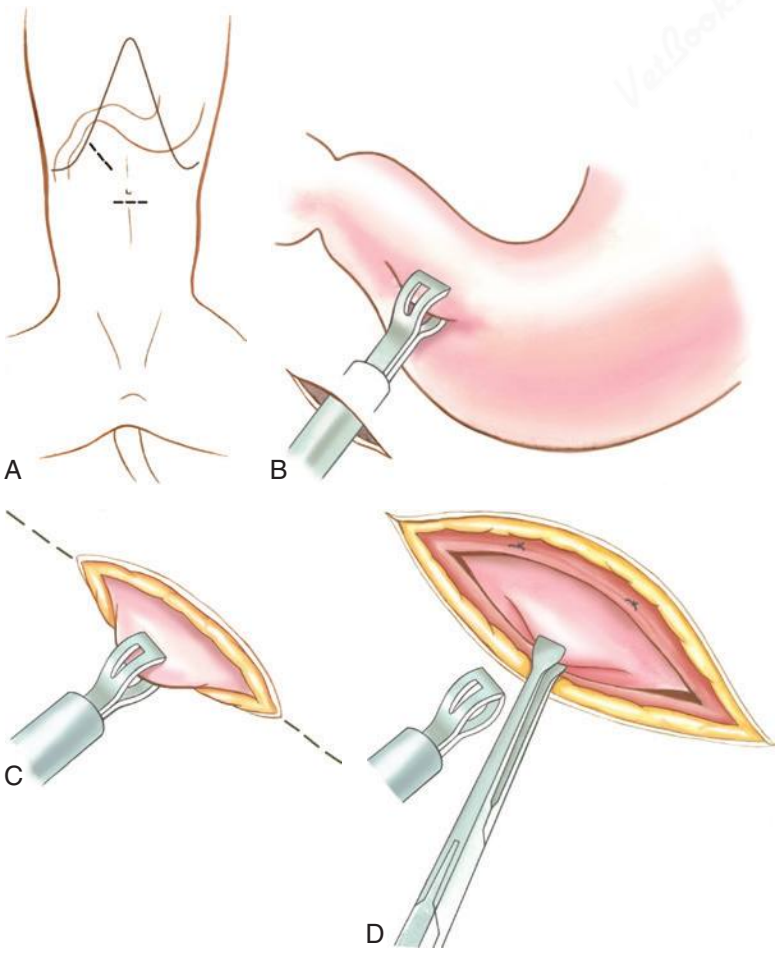

FIG. 18.82 For a laparoscopic assisted gastropexy, (A) place the first cannula just caudal to the umbilicus and place the second cannula just right of midline, approximately 2 to 4 cm behind the last rib (make this incision parallel to the rib). (B) Pull the stomach out through the incision. (C) Place stay sutures between it and the body wall. (D) Perform a gastropexy as described in Fig. 18.79.

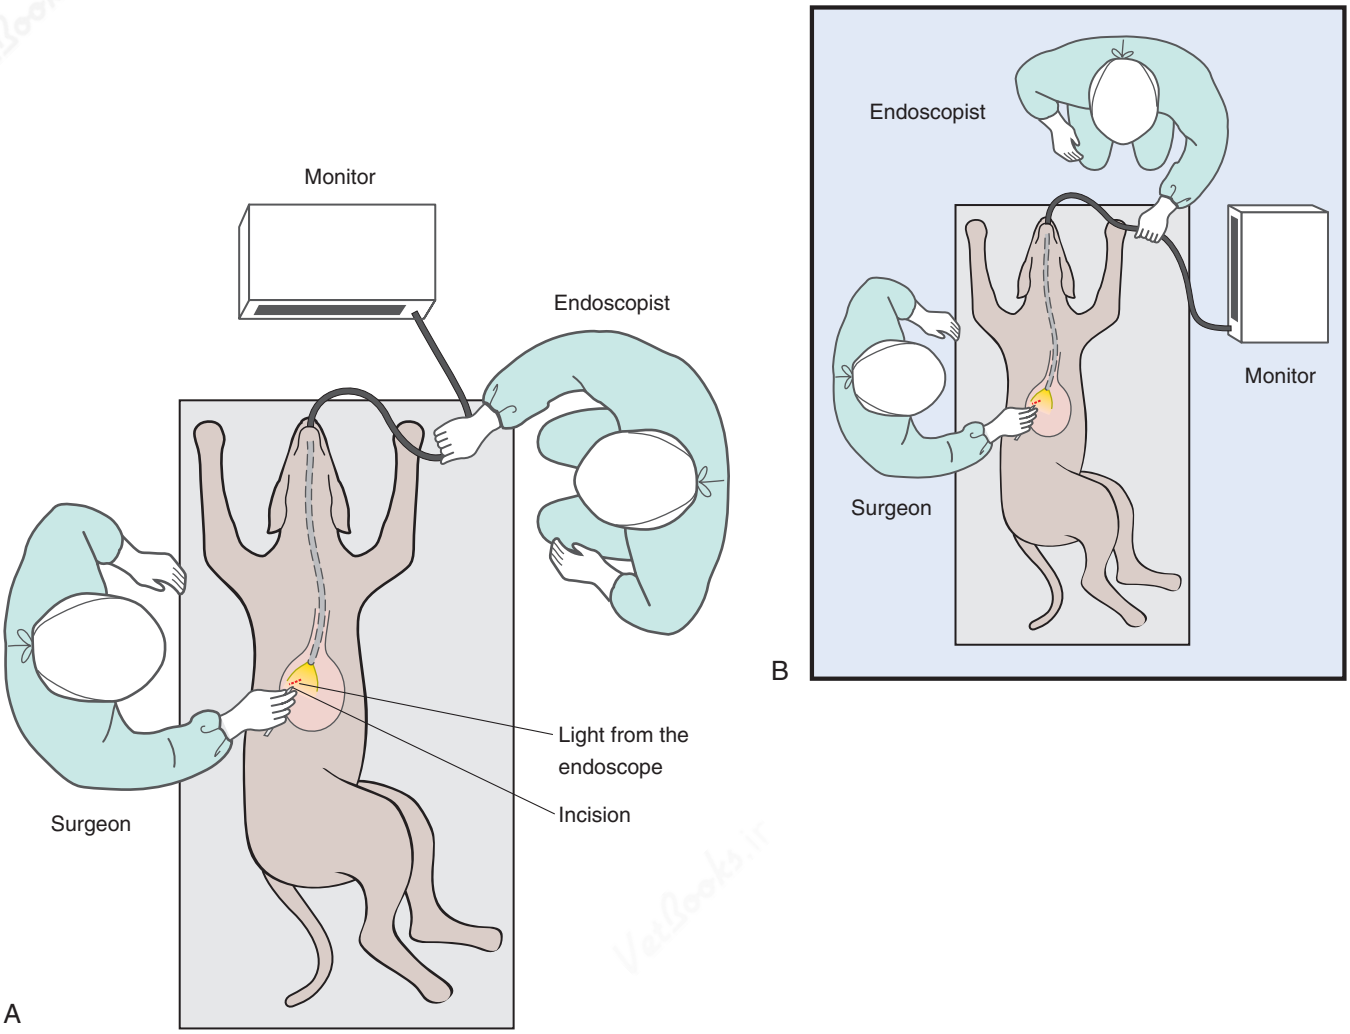

FIG. 18.83 (A) Positioning for endoscopically assisted gastropexy as described in the literature with the endoscopist positioned to the patient's left and the surgeon at the patient's dorsum. (B) Alternatively, the endoscopist may be at the patient's head and the monitor to the patient's left. Strict adherence to asepsis must be maintained with the monitor positioned adjacent to the surgery site.

tail or backstitched to finish the line of closure without knotting. *Pass the barbed suture into the abdomen as described prior to apposing the antrum to transversus muscle.* Two types of barbed suture are the Quill suture, which has bidirectional barbs and two needles, and the V-Loc suture, which has a loop wielded at one end. *For the Quill suture, start the suture centrally and suture in two directions; for the V-Loc suture, start at one end and pass it through the loop prior to suturing the antrum to transversus abdominus.*

Single-Port Laparoscopic Gastropexy

A specialized endoscopic port that allows insertion of the endoscope and multiple laparoscopic instruments may also be used for incisional gastropexy in dogs.[24–26] The multitrochar port is placed in the same position as the endoscopic port for laparoscopic-assisted gastropexy. Elective intraabdominal procedures, usually ovariectomy, are generally done with straight or reticulating instruments, while the port is used to grasp the pyloric antrum and exteriorize it for laparoscopic-assisted gastropexy. *To use the SILS Port (Covidien, Inc.) make a 2 to 3 cm incision in the body wall and place a multiple-trocar port through it while maintaining external traction using stay sutures at either end. Lubricate, then grasp the port with two Rochester Carmalt forceps, staggered on the port for insertion through the incision. To use the ENDOCONE (Karl Storz), which is a reusable metal multiple-trochar port, place the port in the location described for laparoscopic-assisted gastropexy. Make a 30-mm incision extending through the oblique muscles. Retract the oblique muscles with a self-retaining retractor and incise the transversus muscle. Use stay sutures for external traction prior to incising the transversus muscle. Digitally evaluate for adhesions prior to insertion of the flange on the port and clockwise rotating the port. Use the port to identify and grasp the pyloric antrum for performing laparoscopic-assisted gastropexy (see previous description).*

Mini-Laparotomy Prophylactic Gastropexy

This procedure may be considered for prophylactic gastropexy. *Place the dog in left lateral recumbency. Make a 6-cm vertical skin incision*

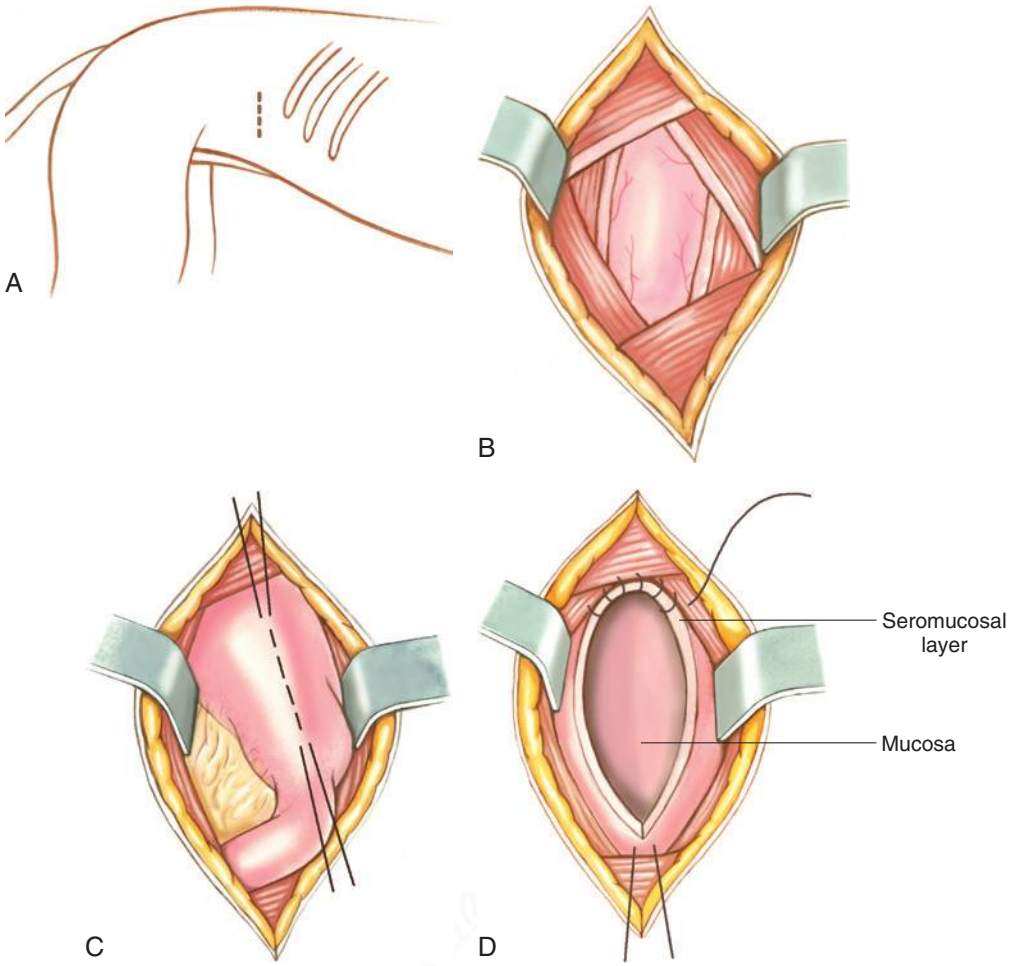

FIG. 18.84 For a mini-laparotomy, (A) make a 6-cm vertical skin incision just caudal and ventral to the right 13th rib. Bluntly dissect through the muscles. (B) Enter the abdomen and visualize the stomach. Grasp the stomach with Babcock intestinal forceps and retract the gastric antrum into the surgical field. (C) Place stay sutures at each end of the intended gastric incision to hold the stomach in the surgical field. Allow the gastric antrum to fall back into the abdomen. Palpate the pylorus to ensure proper placement of the gastric incision. (C–D) Make a 3-cm longitudinal incision through the serosa and muscularis layers of the gastric antrum, approximately 5 cm orad to the pylorus. Beginning at the dorsal edge, suture the edges of the incision to the abdominal muscles using a simple continuous suture pattern.

just caudal and ventral to the 13th rib (Fig. 18.84A). Bluntly dissect through the external and internal abdominal oblique and transversus abdominis muscles. Enter the abdomen via blunt dissection and visualize the stomach (see Fig. 18.84B). If the stomach cannot be visualized, palpate the duodenum and pylorus with two fingers and locate the antrum of the stomach. Grasp the stomach with Babcock intestinal forceps and retract the gastric antrum into the surgical field. Identify the stomach by palpating the pylorus and visualizing the omental attachments, right gastric vessels, and right gastroepiploic vessels. Place stay sutures at each end of the intended gastric incision to hold the stomach in the surgical field. Allow the gastric antrum to fall back into the abdomen (see Fig. 18.84C). Palpate the pylorus to ensure proper placement of the gastric incision. Make a 3-cm longitudinal incision through the serosa and muscularis layers of the gastric antrum approximately 5 cm orad to the pylorus (see Fig. 18.84C). Beginning at the dorsal edge, suture the edges of the incision to the abdominal muscles using a simple continuous suture pattern (see Fig. 18.84D). Close the muscles, subcutaneous tissues, and skin routinely.

HEALING OF THE STOMACH

The extraordinarily rich blood supply, reduced bacterial numbers (caused by gastric acidity), rapidly regenerating epithelium, and defense mechanisms provided by the omentum allow gastric incisions to heal quickly. Because the stomach has a thicker wall than the bowel, it can be difficult to find and stop bleeding vessels. Gentle pressure applied to the bleeding tissues usually is effective; crushing clamps or forceps and electrocautery should be avoided.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Monofilament absorbable suture material (i.e., polydioxanone [PDS], polyglyconate [Maxon], or poliglecaprone 25 [Monocryl]) is preferred for GI surgery. These sutures are strong, have minimal tissue drag, and maintain tensile strength for longer than 10 days. Chromic gut suture is rapidly removed by digestion and phagocytosis and should be avoided. Nonabsorbable suture

material that penetrates the lumen may cause gastric ulcers to form along the suture line if a continuous suture pattern is used; therefore nonabsorbable suture material should be avoided in the stomach. Small-diameter, swaged-on, taper point needles are generally preferred for GI surgery. However, cutting needles are sometimes used because they more readily penetrate submucosa and require less stabilization of tissue, which might result in less crushing.

Noncrushing forceps (e.g., Doyen forceps or some vascular clamps) are useful for occluding the gastric and duodenal stumps during gastroduodenostomy or gastrojejunostomy procedures (see p. 403). Pediatric Doyen forceps are the appropriate size for occluding the duodenal lumen. If noncrushing forceps are not available, the straight portion of an Allis tissue forceps can be wrapped with a moistened sponge. Crushing forceps, such as Carmalt or Allen forceps, are useful for occluding the portion of the GI tract to be removed but should not be placed on tissues that are not to be excised.

Endoscopic gastropexy requires specialized barbed suture for knotless surgery, and multitrochar laparoscopic ports for single incisional laparoscopic surgery may be more efficiently done with reticulating instrumentation.

POSTOPERATIVE CARE AND ASSESSMENT

Electrolytes, especially potassium, should be monitored postoperatively. Analgesics should be provided as needed. IV fluids are continued until the patient is drinking adequate amounts to maintain hydration. If prolonged vomiting or anorexia is anticipated, enteral hyperalimentation should be provided by means of a gastrostomy or enterostomy tube (see Chapter 10). With planning, feeding tubes can be placed during the initial surgery so as to avoid a second procedure. Food can be offered 12 hours postoperatively if there is no vomiting. ECGs should be monitored if arrhythmias were present before surgery or are anticipated postoperatively.

COMPLICATIONS

Complications associated with gastric surgery may include vomiting, anorexia, peritonitis secondary to intraoperative or postoperative leakage, ulceration at anastomotic sites, gastric outlet obstruction, and pancreatitis. Malpositioning of the stomach following gastropexy can result in gastric outflow obstruction and chronic vomiting or gastric dilation. Potential complications of endoscopically-assisted gastropexy include needle breakage and loss, and organ entrapment or damage during passage of the stay sutures. Use of No. 2 polypropylene on a 76-mm-long cutting needle is recommended for stay suture placement. Postoperatively, some dogs may develop short-term (<7 days) intermittent vomiting or diarrhea. With intracorporeally sutured gastropexy, technical difficulties associated with the automated suture assist device (among other complications) may result in the need for supplemental suture placement in some dogs. Although laparoscopic-assisted gastropexy may be faster, activity levels are often greater in the postoperative period with the intracorporeally sutured gastropexy.

SPECIAL AGE CONSIDERATIONS

Young animals and those that are severely emaciated and have little or no body reserve should not have food withheld for longer than 4 to 6 hours before surgery and should be fed as soon as they are fully recovered from the anesthesia. If they cannot be fed, blood glucose concentrations should be monitored and, if necessary, maintained by adding glucose to the IV fluids (see the discussion of anesthesia on p. 399). Polydioxanone suture may cause calcinosis circumscripta in young dogs. Because the skin of puppies and kittens is delicate and elastic, skin sutures should be placed loosely. Geriatric animals may have delayed wound healing and may be immunosuppressed as a result of concurrent disease (e.g., diabetes mellitus, Cushing's disease). Strong absorbable or nonabsorbable suture material should be used in these patients and prophylactic antibiotic therapy initiated at induction of anesthesia.

PROGNOSIS

Evaluation of 24 dogs undergoing Billroth I showed that 88% survived to discharge; death or euthanasia at less than 3 months after surgery is generally related to progression of neoplastic disease. Postoperatively, hypoalbuminemia and anemia are common, and approximately one-third may require blood products postoperatively. Preoperative weight loss and malignant neoplasia may be associated with a decrease in median survival time. Complications included hypotension, aspiration pneumonia, pancreatitis, and septic peritonitis resulting from anastomotic leakage.

SPECIFIC DISEASES

GASTRIC FOREIGN BODIES

DEFINITIONS

A gastric foreign body is anything ingested by an animal that cannot be digested (i.e., rocks, plastic) or that is slowly digested (bones). **Linear foreign bodies** are usually pieces of string, yarn, thread, cloth, or dental floss.

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Gastric foreign bodies usually cause vomiting because of outflow obstruction, gastric distention, and/or mucosal irritation (Box 18.24). Occasionally, however, gastric foreign bodies are asymptomatic,

BOX 18.24 Important Considerations for Gastric Foreign Bodies

- Initial clinical signs may not alert the owner to seriousness of condition.
- Linear foreign objects must be removed as soon as possible to avoid intestinal perforation and peritonitis.
- Not all animals with gastric foreign objects vomit.
- Finding a foreign object in the stomach does not guarantee that it is the cause of vomiting.
- Linear foreign bodies are more common in cats; always check under the tongue (this often requires sedation).
- Most gastric foreign objects can be removed endoscopically.
- Complete exploration of the entire intestinal tract is mandatory in surgical patients.
- Always repeat the radiographs immediately before surgery to make sure that the object has not moved.

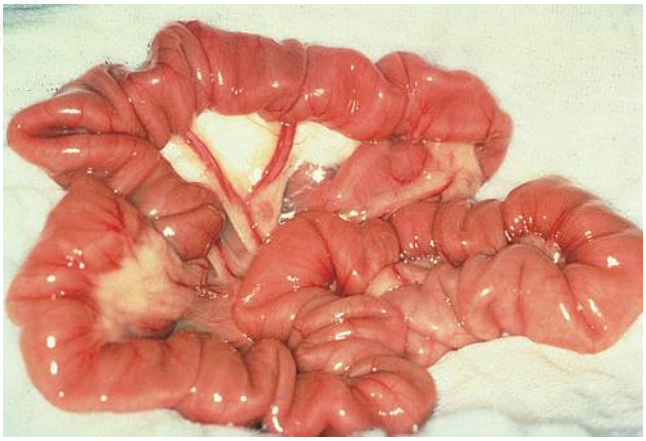

FIG. 18.85 Plication in the intestines of a cat caused by a string foreign body. (Courtesy Dr. J. Hauptman, Michigan State University.)

incidental findings on abdominal radiographs. Dogs are indiscriminate eaters and often ingest rocks, plastic toys, cooking bags, and other objects. Cats more commonly ingest linear material (e.g., yarn or sewing thread attached to a needle). In cats, linear foreign bodies are frequently anchored under the tongue or at the pylorus and often cause intestinal plication (Fig. 18.85). Noxious stimuli or distention of the duodenum or pyloric antrum stimulates vomiting, whereas similar stimulation of the gastric body often does not. Therefore vomiting is often intermittent, occurring when the object is forced into the pyloric antrum.

NOTE Foreign bodies may occur in the stomach and small intestine concurrently; therefore the entire intestinal tract should be explored thoroughly whenever surgery is done to remove a gastric foreign body.

If endoscopic removal is performed, examine the small intestine as far as possible and consider radiographing the patient before waking it up; the gas that has been insufflated will act as a negative contrast. Small, blunt foreign bodies may pass through the digestive system without causing harm; however, most should be removed when they are diagnosed because of the risk of distal obstruction and perforation. Repeat radiographs are indicated immediately before surgery, even if only a few hours have elapsed since the initial radiographs; the object may exit the stomach and be located in either the small intestine or the colon. Foreign objects in the colon are usually eliminated without difficulty unless they have sharp edges that catch in the anus. Opening the colon is seldom justified; if a colonic foreign body must be removed, endoscopy is the preferred technique.

DIAGNOSIS

Clinical Presentation

Signalment

Young animals more commonly ingest foreign bodies than older animals, and gastric or intestinal foreign bodies should be suspected in any puppy or kitten presented for treatment of acute or persistent vomiting.

History

Most animals with gastric foreign bodies have vomiting, anorexia, and/or depression. One study showed 89% of patients with sewing needle foreign bodies exhibited clinical signs and the remainder had no clinical signs associated with extragastrointestinally located needles.[27] Vomiting may be intermittent, and some animals may continue to eat and remain active. Vomiting is often absent if the foreign body is in the gastric fundus and does not obstruct the pylorus. Occasionally abdominal pain is noted. Be sure to consider parvoviral enteritis in young animals that acutely vomit and feel bad.

Physical Examination Findings

Physical examination often is unremarkable. The patient may be dehydrated; however, many animals with gastric foreign bodies continue to drink water. The object usually cannot be palpated because of the stomach's proximal location in the abdomen. Plicated intestines may be felt if a linear foreign object is present, and pain may be evident if gastric perforation has caused peritonitis or if the intestines are bunched together. A thorough examination of the mouth, especially the area ventral to the tongue, is mandatory in all cats suspected of having a linear foreign object. General anesthesia or sedation may be necessary to properly evaluate the base of the tongue.

NOTE Don't forget to check under the tongue in cats that may have a linear foreign object.

Diagnostic Imaging

Radio-opaque foreign bodies may be diagnosed with survey radiographs, but many foreign bodies are radiolucent. Some radiolucent foreign bodies can be identified ultrasonographically if the stomach is fluid filled and an appropriate acoustic window is obtained. A positive contrast or double-contrast gastrogram can be utilized to delineate radiolucent foreign bodies, although these studies have largely been replaced with endoscopy. If contrast studies are performed, remember that barium sulfate should not be utilized if GI perforation is suspected (i.e., pneumoperitoneum, abdominal effusion); an iodinated, water-soluble contrast agent should be used in such cases. Any effusion should be cytologically examined; evidence of sepsis is adequate to recommend surgery, and contrast radiographs are unnecessary. Likewise, spontaneous pneumoperitoneum is automatically assumed to indicate perforation and justifies exploratory surgery. Double-contrast studies using both air and a positive contrast agent (i.e., barium sulfate) are more sensitive than positive contrast procedures but are more difficult to perform. Contrast procedures are especially useful if the foreign object absorbs or is coated by the contrast material. Radiographic findings in cats with linear foreign bodies include plication of the small bowel, increased intraluminal gas bubbles, and peritonitis secondary to bowel perforation (see p. 528).

Currently, radiographic contrast procedures are seldom performed to look for foreign objects. Gastroduodenoscopy is more sensitive than radiographs in finding foreign objects (unless the stomach if filled with food) and may afford the chance to remove it at the same time. In addition, one can find other gastric lesions and biopsy them (see Chapter 14).

NOTE Do not do an upper gastrointestinal series using barium sulfate if you will perform endoscopy within 24 hours, and don't use barium sulfate if perforation is likely!

Gastroduodenoscopy

If a foreign body is located, the endoscopist should first examine and study it to determine the best retrieval device to use and whether any special equipment (e.g., an overtube) is needed. If there are sharp edges or points, then consideration must be given to which end of the foreign body will be grasped. Endoscopic removal of linear foreign bodies should probably only be attempted when the linear foreign body has been present for a relatively short time (e.g., <3–4 days) and the orad-most aspect is lodged at the pylorus. One may try to gently pull the foreign object out of the pylorus, but if it does not readily come out, this tactic must be quickly abandoned. A better technique is as follows: *Insert the endoscope between the foreign object and the pylorus, and then advance the tip of the endoscope to as close to the end of the foreign object as possible.* This can be tedious, so be patient! *Then grasp the linear foreign object as close to the distal end as possible and retrieve the foreign object by pulling the distal end out first. Take a plain abdominal radiograph afterward to check for spontaneous pneumoperitoneum, a sign of perforation.*

In rare cases, when the orad end of the linear foreign object is lodged at the pylorus, one may use the endoscope to push the orad end into the duodenum, thus relieving the point of fixation. This approach is similar to cutting a linear foreign body off the base of the tongue and seeing if it will then pass without incident. This may allow the entire foreign object to pass in the feces. In these cases, if the patient does not clearly feel better within 6 hours, surgery is indicated to remove the foreign object.

Laboratory Findings

The laboratory findings depend on the severity and duration of the obstruction; they cannot be predicted. Laboratory parameters may be normal or may show only changes caused by dehydration (hemoconcentrations, increased serum albumin, prerenal azotemia). If vomiting causes loss of gastric secretions, a hypochloremic, hypokalemic metabolic alkalosis with paradoxical aciduria may occur. Sometimes a metabolic acidosis occurs because of dehydration and subsequent lactic acidosis.

DIFFERENTIAL DIAGNOSIS

Gastric neoplasms sometimes cause filling defects in the gastric lumen that could be confused with a foreign object. However, such lesions should remain in the same location when the animal is positioned for different radiographic views. Radiographs and endoscopy distinguish animals with gastric foreign objects from those with other causes of pyloric obstruction (e.g., chronic antral mucosal hypertrophy or pyloric stenosis; see p. 425) or gastric ulceration (see p. 427).

MEDICAL MANAGEMENT

If the object is small with rounded edges or is cloth, one can attempt to expel it by inducing vomiting with apomorphine (dogs) or xylazine (cats) (Box 18.25). However, this should be attempted only when the clinician is relatively certain the object will be expelled without causing harm. Factors that must be considered include whether the esophagus is apt to be lacerated, the likelihood of the object lodging in the esophagus, and whether the object or gastric contents might be aspirated. Esophageal surgery carries more risk than gastric surgery because the esophagus does not heal as readily as the stomach (see p. 374). Indiscriminate use of antibiotics may mask clinical signs of peritonitis or pyothorax and delay treatment.

BOX 18.25 Induction of Vomition

Dogs
Apomorphine
0.02–0.04 mg/kg IV or IM; 0.1 mg/kg SC

Cats
Xylazine (Rompun)
0.4–0.5 mg/kg IV

IM, Intramuscular; *IV,* intravenous; *SC,* subcutaneous.

SURGICAL TREATMENT

Preoperative Management

If possible, metabolic and acid-base abnormalities should be identified and corrected, and food should be withheld for 12 hours. Radiographs should be taken immediately before surgery (especially before endoscopy) to verify the position of the object in the digestive tract. Perioperative antibiotics may be given at induction of anesthesia and continued for up to 12 hours postoperatively (see p. 399).

Anesthesia

See p. 399 for suggested anesthetic protocols in dogs with gastric disorders.

Surgical Anatomy

See p. 399 for the surgical anatomy of the stomach.

Positioning

The animal is placed in dorsal recumbency and the abdomen is prepared for a ventral midline incision. The prepped area should extend from midthorax to the pubis to allow the entire digestive system to be explored for foreign objects.

SURGICAL TECHNIQUE

Most gastric foreign bodies can be easily removed via a gastrotomy incision (see p. 401). *Inspect the entire digestive system for material that could cause obstruction or perforation. If a linear foreign body is found in the pylorus and extends into the intestinal tract, do not try to pull it into the stomach unless it moves easily. Instead, make several incisions into the stomach and intestines to avoid causing further damage to the intestinal tract. Inspect the stomach for perforation or necrosis and, depending on the location, remove or patch abnormal tissue (see p. 447 for a description of a serosal patch). Close the gastric incision as described on p. 401.*

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Absorbable suture material (2-0 or 3-0) should be used to close the gastrotomy incision (see p. 415). Instruments helpful in performing gastric surgery are listed on p. 415.

BOX 18.26 Treatment of Vomiting[a]

Maropitant (Cerenia)
1 mg/kg IV or 2 mg/kg PO q24h for 5 days if <7 months old; otherwise, can use as long as desired

Ondansetron (Zofran)
0.1–0.2 mg/kg IV or SC, q6–8h; 0.5–1.0 mg/kg given 30 min before administration of chemotherapeutic drugs

[a]Metoclopramide (see Box 18.21), although a poor antiemetic, may be useful in conjunction with these drugs if single-drug therapy fails.
IM, Intramuscular; *PO,* orally; *SC,* subcutaneous.

POSTOPERATIVE CARE AND ASSESSMENT

The patient's fluid status should be monitored and hydration maintained with IV fluids postoperatively until the animal is drinking. Electrolyte abnormalities should be corrected. Hypokalemia is likely if the animal has been vomiting, especially if it was also anorexic. A bland diet should be fed starting 12 to 24 hours after surgery if the patient is not vomiting. If vomiting continues, centrally acting antiemetics such as maropitant or ondansetron (Box 18.26) may be administered, and oral food and water should be withheld. See p. 429 for treatment of ulcers that may occur secondary to foreign bodies.

PROGNOSIS

The prognosis is good if the stomach has not been perforated and the foreign body is removed. If perforation has occurred, the prognosis is guarded (see the discussion of peritonitis on pp. 449 and 527).

GASTRIC DILATATION-VOLVULUS

DEFINITIONS

Enlargement of the stomach associated with rotation on its mesenteric axis is referred to as **gastric dilatation-volvulus (GDV)**. The term **simple dilatation** refers to a stomach that is engorged with air or froth but not malpositioned. **Dilatation** refers to a condition in which an organ or structure is stretched beyond its normal dimensions; **dilation** is the act of stretching a cavity or orifice. GDV is also called *gastric torsion* or *bloat.*

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Classically, GDV syndrome is an acute condition with a mortality rate of 20% to 45% in treated animals. The gastric enlargement is thought to be associated with a functional or mechanical gastric outflow obstruction. The initiating cause of the outflow obstruction is unknown; however, once the stomach dilates, normal physiologic means of removing air (i.e., eructation, vomiting, and pyloric emptying) are hindered because the esophageal and pyloric portals are obstructed.

The stomach becomes enlarged as gas, fluid, or both accumulate in the lumen. The gas probably comes from aerophagia, although bacterial fermentation of carbohydrates, diffusion from the bloodstream, and metabolic reactions may contribute. Normal gastric secretion and transudation of fluids into the gastric lumen secondary to venous congestion contribute to fluid accumulation.

BOX 18.27 Recommendations for Dogs at High Risk for Gastric Dilatation Volvulus

- Feed several small meals a day rather than one large meal.
- Avoid stress during feeding (if necessary, separate dogs in multiple-dog households during feeding).
- Restrict exercise before and after meals (of questionable benefit).
- Do not use an elevated feed bowl.
- Do not breed dogs with a first-degree relative that has a history of gastric dilatation-volvulus.
- For high-risk dogs, consider prophylactic gastropexy.
- Seek veterinary care as soon as signs of bloat are noted.

The cause of GDV is unknown, but exercise after ingestion of large meals of highly processed food or water has been suggested to contribute to it (this is largely unsupported by clinical data). Epidemiologic studies have also not supported a causal relationship between feeding soy-based or cereal-based dry dog food and GDV. However, Irish setters fed a single feed type appear to have an increased risk of GDV compared with those fed a mixture of feed types. Likewise, adding table food or canned food to the diet of large- and giant-breed dogs is associated with a decreased incidence of GDV. Dogs fed a larger volume of food per meal may be at increased risk of GDV, regardless of the number of meals fed daily; however, the risk of GDV is highest in dogs fed a larger volume of food once daily. Feeding dry dog foods in which one of the first four ingredients is an oil or a fat may also increase the risk of GDV. Other contributing causes include an anatomic predisposition, ileus, trauma, primary gastric motility disorders, vomiting, and stress. Recommendations for clients of animals at high risk are provided in Box 18.27. Male sex, increasing age, being underweight, being fed a large volume of food per meal, eating one meal (especially a large volume meal) per day, eating rapidly, having a raised feeding bowl, and having a fearful temperament are predisposing factors that may increase a dog's risk of GDV. Having a deeper and narrower thorax may change the anatomic relationship between the stomach and esophagus such that the dog's ability to eruct is impaired. Feeding dogs from a raised feed bowl may increase the risk of GDV because it may promote aerophagia. Some authors have recommended gastropexy to prevent GDV following splenectomy because of the possible loss of gastric stabilization by the gastrosplenic ligament, but this has not been proved necessary. Finally, military working dogs appear to be more likely to develop a GDV in November, December, and January, but the reasons for this are uncertain. Atmospheric data have been related to the occurrence of GDV; minimum and maximum atmospheric pressure and the maximum atmospheric pressure the day prior were positively associated with GDV.

NOTE Having a first-degree relative with a history of gastric dilatation-volvulus (GDV) is significantly associated with an increased risk of GDV. Thus it may be wise to suggest that dogs with a first-degree relative that has had GDV not be used for breeding.

Generally, with GDV the stomach rotates in a clockwise direction when viewed from the surgeon's perspective (with the dog on its back and the clinician standing at the dog's side, facing cranially; Fig. 18.86). The rotation may be 90 to 360 degrees but is usually 220 to 270 degrees. The duodenum and pylorus move

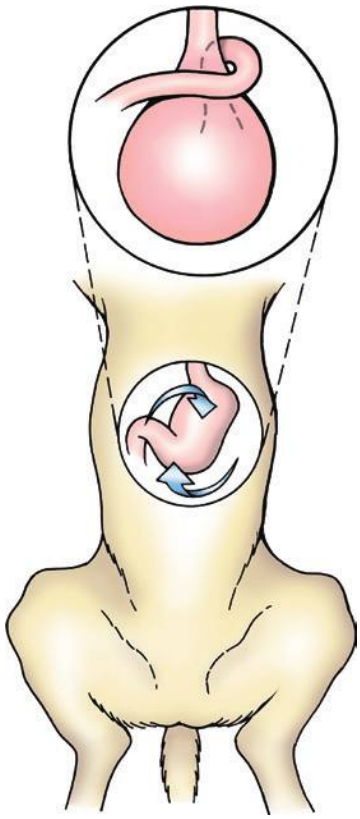

FIG. 18.86 Direction of gastric rotation in most dogs with gastric dilatation-volvulus.

ventrally and to the left of the midline and become displaced between the esophagus and stomach. The spleen is usually displaced to the right ventral side of the abdomen.

Caudal vena cava and portal vein compression by the distended stomach reduces venous return and cardiac output, causing myocardial ischemia. Central venous pressure, stroke volume, mean arterial pressures, and cardiac output are reduced. Obstructive shock and inadequate tissue perfusion affect multiple organs, including the kidneys, heart, pancreas, stomach, and small intestine. Cardiac arrhythmias occur in many dogs with GDV, particularly those with gastric necrosis. Arrhythmias may contribute to mortality and require appropriate monitoring and treatment (see discussion under Postoperative Care and Assessment on p. 423). Myocardial depressant factor has also been recognized in affected dogs, and cardiac damage is common, as seen by increased serum concentrations of troponin. Reperfusion injury has been implicated as causing much of the tissue damage that ultimately results in death after correction of GDV. Early treatment with IV lidocaine (2 mg/kg IV bolus) before decompression followed by CRI of lidocaine (0.05 mg/kg per min) for 24 hours appears to decrease the occurrence of cardiac arrhythmias, acute kidney injury, and hospitalization in dogs with GDV, possibly by mitigating reperfusion injury.

Partial or chronic GDV may occur in dogs, can last weeks to months, and is usually a progressive but non–life-threatening syndrome that may be associated with vomiting, anorexia, and/or weight loss. These dogs may have chronic, intermittent signs and appear normal between episodes. Gastric malpositioning may be intermittent or chronic but without dilatation. Plain or contrast radiographs are diagnostic, but repeat radiographs may be necessary if the stomach is intermittently malpositioned. Endoscopic evaluation has been reported as helpful in the diagnosis of chronic GDV, but the intermittent nature of the condition makes diagnosis somewhat difficult.

DIAGNOSIS

Clinical Presentation

Signalment

GDV primarily occurs in large, deep-chested breeds (e.g., Great Dane, Weimaraner, Saint Bernard, German shepherd, Irish and Gordon setters, Doberman pinscher) but has been reported in cats and small-breed dogs. Shar peis may have an increased incidence compared with other medium-sized breeds and basset hounds may have a higher risk of GDV, despite their not being a large-breed dog. GDV may occur in dogs of any age but is most common in middle-aged or older animals. The thoracic depth to width ratio appears to be highly correlated with the risk of bloat. In one study, intact female dogs had the highest risk of GDV.[28]

History

A dog with GDV may have a history of a progressively distending and tympanic abdomen, or the owner may simply find the animal recumbent and depressed with a distended abdomen. The dog may appear to be in pain and may have an arched back. Nonproductive retching, hypersalivation, and restlessness are common.

Dogs that are fed dry kibble, are anxious, are a family pet, and those that spend 5 hours or more with the owner appear to be at an increased risk of GDV. A decreased risk may be associated with playing with other dogs, being fed egg supplements, and spending equal time indoors and outdoors. Splenectomy has been purported as a risk factor for GDV; however, whether this is true is uncertain. In one study, approximately 8% of dogs undergoing splenectomy and 6.4% of controls undergoing enterotomy developed GDV after initial surgery.[29] In another study of 453 cases the odds of GDV in dogs with a history of previous splenectomy was 5.3 times that of dogs without such a history.[29a] Interestingly, in a retrospective study, large- or giant-breed dogs with gastric foreign body were five times as likely to develop GDV compared with those with no foreign body; however, a causal relationship could not be established.[30]

Physical Examination Findings

Abdominal palpation often reveals various degrees of abdominal tympany or enlargement; however, it may be difficult to feel gastric distention in heavily muscled large-breed or very obese dogs. Splenomegaly is occasionally palpated. Clinical signs associated with shock may be present, including weak peripheral pulses, tachycardia, prolonged capillary refill time, pale mucous membranes, and/or dyspnea.

Diagnostic Imaging

Radiographs are necessary to differentiate simple dilatation from dilatation plus volvulus. Affected animals should be decompressed before radiographs are taken. Right lateral and dorsoventral radiographic views are preferred to facilitate filling the abnormally displaced pylorus with air so that it can be easily identified. The pylorus is normally located ventral to the fundus on the lateral view and on the right side of the abdomen on the dorsoventral

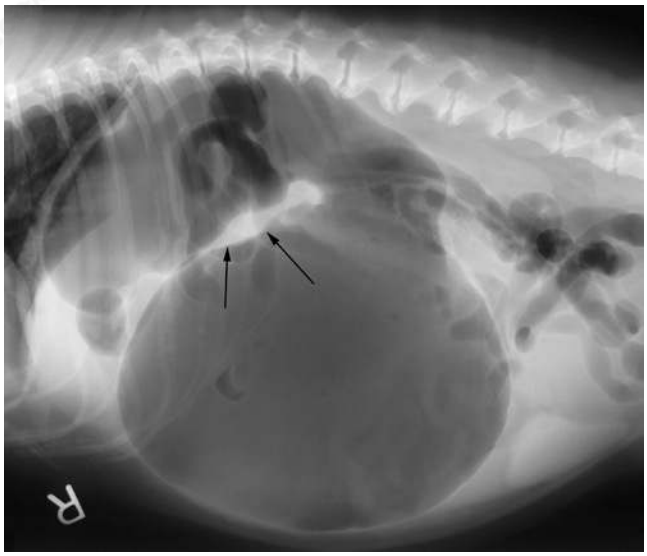

FIG. 18.87 Right lateral abdominal radiograph of a dog with gastric dilatation-volvulus showing a distended, gas-filled stomach. Note the reverse C sign or "double bubble" caused by the shelf of soft tissue *(arrows)*. The pylorus is located dorsal to the shelf of tissue.

view. On a right lateral view of a dog with GDV, the pylorus lies cranial to the body of the stomach and is separated from the rest of the stomach by soft tissue (reverse C sign or "double bubble") (Fig. 18.87). On the dorsoventral view, the pylorus appears as a gas-filled structure to the left of midline (Fig. 18.88). Free abdominal air suggests gastric rupture and air within the wall of the stomach indicates necrosis, both of which warrant immediate surgery.

NOTE Caution! Positioning these animals for a ventrodorsal view may lead to aspiration. Remember that the right lateral and dorsoventral views are preferred when attempting to diagnose GDV.

Laboratory Findings

The CBC is seldom informative unless disseminated intravascular coagulation (DIC) causes thrombocytopenia. Potassium concentrations may be normal or elevated, but hypokalemia is more common. Vascular stasis may cause increased lactic acid and metabolic acidosis. However, metabolic alkalosis caused by sequestration of hydrogen ions in the gastric lumen can offset the metabolic acidosis, causing the blood pH to be normal (i.e., a mixed acid-base disorder). Respiratory acidosis may be caused by hypoventilation secondary to gastric impingement on the diaphragm and diminished ventilatory compliance. Therefore routine administration of sodium bicarbonate is inappropriate. Plasma lactate concentrations are prognostic; higher values (7.4 mmol/L) have been associated with gastric necrosis and a poor prognosis, and were 88% accurate for prediction of necrosis. Its sensitivity, however, was 50%.[31]

DIFFERENTIAL DIAGNOSIS

Simple gastric dilatation occurs commonly in young puppies from overeating and seldom requires specific treatment. The stomach, although greatly enlarged with ingesta and gas, is not malpositioned. Small intestinal volvulus is a differential diagnosis

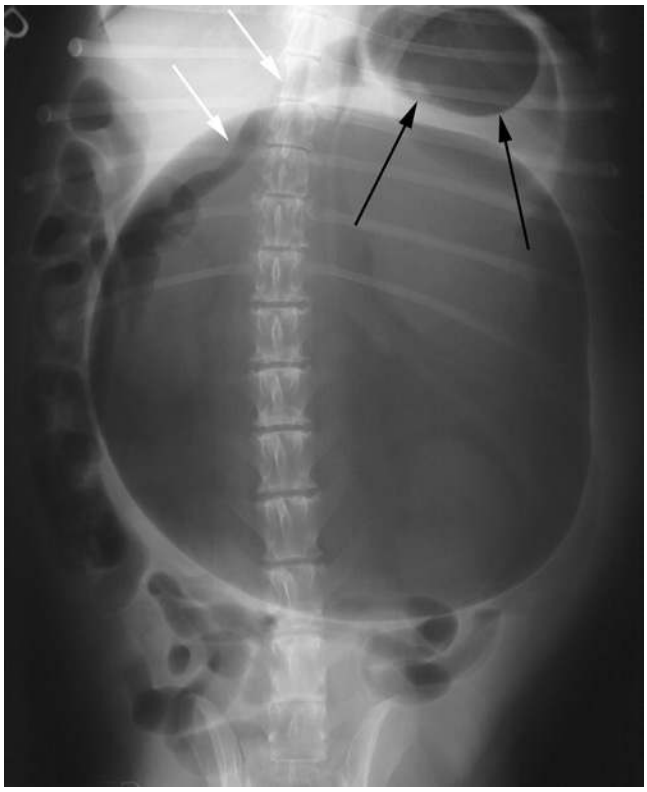

FIG. 18.88 Dorsoventral radiograph of a dog with gastric dilatation-volvulus. The pylorus appears as a gas-filled structure to the left of the midline *(black arrows)*. Notice the duodenum coursing from the pylorus toward the right abdomen *(white arrows)*.

BOX 18.28 Medical Management of Gastric Dilatation-Volvulus

- Fluids (see text)
- Antibiotics such as cefazolin (22 mg/kg IV) or a combination of enrofloxacin (Baytril), 7–15 mg/kg IV (give diluted and slowly, over 30 minutes) plus ampicillin at 22 mg/kg IV

IV, Intravenous.

because it results in a tympanic and enlarged abdomen (see p. 464); however, dilatation of the intestinal tract is apparent on radiographs. Primary splenic torsion (see p. 643) often causes acute abdominal pain; however, abdominal distention is absent to mild. Diaphragmatic herniation may produce clinical signs similar to GDV, particularly if the stomach is herniated and outflow is obstructed (see p. 926). Ascites can cause abdominal distention, but a fluid wave should be felt during ballottement, which distinguishes it from the tympanic abdomen found in GDV.

NOTE You cannot differentiate gastric dilatation-volvulus from gastric dilatation without volvulus simply because you are able to pass a stomach tube. Stomach tubes can frequently be passed in dogs with twisted stomachs.

MEDICAL MANAGEMENT

Stabilizing the patient's condition is the initial objective (Box 18.28). One or more large-bore IV catheters should be

placed in either a jugular or both cephalic veins. Either isotonic fluids (given at 90+ mL/kg per hour to effect), hypertonic 7% saline (4–5 mL/kg over 5–15 minutes), hetastarch (5–10 mL/kg over 10–15 minutes), or a mixture of 7.5% saline and hetastarch (dilute 23.4% saline with 6% hetastarch for a 7.5% solution; administer at 4 mL/kg over 5 minutes) is administered. If hypertonic saline or hetastarch is given, the rate of subsequent crystalloid administration must be adjusted. Blood should be drawn for blood gas analyses, a CBC, and a biochemical panel. Broad-spectrum antibiotics (e.g., cefazolin, ampicillin plus enrofloxacin) should be administered. If the animal is dyspneic, oxygen therapy may be given by nasal insufflation (see p. 31) or mask.

Gastric decompression should be performed while shock therapy is initiated. The stomach may be decompressed percutaneously with several large-bore IV catheters or a small trocar, or (preferably) a stomach tube may be passed. The stomach tube should be measured from the point of the nose to the xiphoid process and a piece of tape applied to the tube to mark the correct length. A roll of tape can be placed between the incisors and the tube passed through the center hole. Attempts should be made to pass the tube to the measured point. Placing the animal in different positions (i.e., sitting, reclining on a tilt-table) may help if it is difficult to advance the tube into the stomach. Do not perforate the esophagus with overly vigorous attempts to pass the tube. If these attempts fail, percutaneous decompression of the stomach should be attempted (Fig. 18.89). This may relieve pressure on the cardia and allow the tube to enter the stomach. Once the air has been removed, the stomach should be flushed with warm water. Failure to lavage the stomach usually results in rapid redilatation after the tube is withdrawn. If blood is seen in the fluid from the stomach, prompt surgical intervention is warranted because this may indicate gastric necrosis. If the stomach tube still cannot be passed and immediate surgical correction is not possible, temporary decompression may be achieved by performing a temporary gastrostomy, but this technique is not recommended. A Foley catheter should not be placed in the stomach percutaneously unless the stomach is simultaneously tacked to the body wall (see p. 406) because of the high risk of peritonitis if the stomach pulls away from the tube. The disadvantages of a temporary gastrostomy are that the stomach must be closed when the permanent gastropexy is performed and there is a high risk of peritoneal contamination. Keeping the stomach from redilating is important; however, this may not reduce gastric necrosis since the latter appears to be associated with malpositioning of the stomach rather than dilatation.

SURGICAL TREATMENT

Surgery should be performed as soon as the animal's condition has been stabilized, even if the stomach has been decompressed. Rotation of an undistended stomach interferes with gastric blood flow and may potentiate gastric necrosis.

Preoperative Management

The animal should be given IV fluids and antibiotics before surgery (see the discussion of Medical Management). Significant electrolyte and acid-base abnormalities should be corrected. A greatly enlarged stomach may hinder respiration and make it difficult for the animal to ventilate during induction of anesthesia. An ECG should be monitored to detect cardiac arrhythmias, which should be treated with lidocaine before surgery if they are significant (i.e., long runs of ventricular tachycardia, which can decrease cardiac output).

Anesthesia

Numerous anesthetic protocols have been described for dogs with GDV. If the animal has been decompressed and its condition is stable without significant cardiac arrhythmias, then hydromorphone and diazepam may be given intravenously and the patient induced with etomidate, thiobarbiturates, propofol, or alfaxalone (see Table 18.4). Refer to the surgery of the small intestine preoperative concerns (p. 433) and anesthesia (p. 435) sections for a more complete discussion of management of the patient with an acute abdomen. If the animal is depressed, premedication is probably not needed. Preoxygenation followed by a rapid induction with either ketamine plus a benzodiazepine (e.g., midazolam, diazepam) or etomidate should be done. Etomidate is a good choice for induction if the animal's condition has not been well stabilized because it maintains cardiac output and is not arrhythmogenic. Lidocaine and thiobarbiturate (e.g., thiopental) may be used if arrhythmias are present; 9 mg/kg of each is drawn up, and half is given initially intravenously. Additional drug is given to effect to allow the dog to be intubated. Generally, no more than 6 mg/kg of lidocaine is given intravenously to prevent toxicity. If bradycardia occurs, anticholinergics (e.g., atropine or glycopyrrolate) may

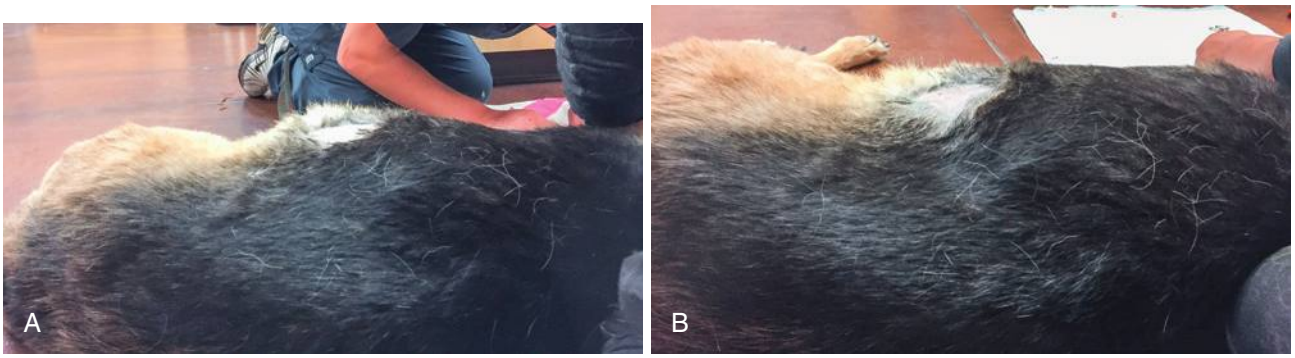

FIG. 18.89 Abdominal contour in a dog with gastric dilatation-volvulus. (A) Significant abdominal distension due to gastric dilatation-volvulus. (B) Appearance of the abdomen following trocharization.

be given. Nitrous oxide should not be used in dogs with GDV (see p. 435). Isoflurane or sevoflurane are the inhalation agents of choice.

Surgical Anatomy

Normally, when viewed from the surgeon's perspective (i.e., with the animal in dorsal recumbency), the pylorus is located on the dog's right side, and the greater omentum arises from the greater curvature of the stomach and covers the intestines. The gastric (lesser curvature) and gastroepiploic (greater curvature) arteries supply the stomach and are derived from the celiac artery. The short gastric arteries arise from the splenic artery and supply the greater curvature. Rupture of the short gastric arteries in dogs with GDV is common and may contribute to blood loss and gastric infarction or necrosis. Eighty percent of the arterial flow is to the mucosa, and the remainder is to the muscularis and serosa; therefore observation of mucosal color is not a reliable indicator of gastric wall viability. The mucosa often appears darkened because of vascular compromise, even when full-thickness necrosis is not present.

Positioning

The dog is placed in dorsal recumbency, and the abdomen is prepared for a midline abdominal incision. The prepped area should extend from midthorax to the pubis. If a tube gastropexy is to be performed, the prepped area should be extended cranially and dorsally to allow the tube to be exteriorized behind the caudal right rib.

SURGICAL TECHNIQUE

The goals of surgical treatment are threefold: (1) to inspect the stomach and spleen so as to identify and remove damaged or necrotic tissues, (2) to decompress the stomach and correct any malpositioning, and (3) to adhere the stomach to the body wall to prevent subsequent malpositioning. Upon entering the abdominal cavity of a dog with GDV, the first structure noted is the greater omentum, which usually covers the dilated stomach.

Decompress the stomach before repositioning by using a large-bore needle (i.e., 14 or 16 gauge) attached to suction. If the needle becomes occluded with ingesta, have an assistant pass an orogastric stomach tube and perform gastric lavage. Intraoperative manipulation of the cardia usually allows the tube to be passed into the stomach without difficulty. If adequate decompression is still not achieved or an assistant is not available, a small gastrotomy incision can be performed to remove the gastric contents. A right-sided gastrotomy can be incorporated into an incisional gastropexy.

For a clockwise rotation, once the stomach has been decompressed, rotate it counterclockwise by grasping the pylorus (usually found below the esophagus) with the right hand and the greater curvature with the left. Push the greater curvature, or fundus, of the stomach toward the table while simultaneously elevating the pylorus toward the incision. Check to make sure the spleen is normally positioned in the left abdominal quadrant. If there is splenic necrosis or significant infarction, perform a partial or complete splenectomy (see pp. 641–642). Remove or invaginate (see Fig. 18.68) necrotic gastric tissues (Fig. 18.90). If you are uncertain whether gastric tissue will remain viable, invaginate or resect the abnormal tissue (see p. 402). Verify that the gastrosplenic ligament is not torsed, and before closure palpate the intraabdominal esophagus to ensure that the stomach is derotated.

Perform a permanent gastropexy (see pp. 406–414). Gastropexy is usually curative for dogs with partial or chronic GDV.

> **NOTE** To prevent recurrence of GDV, the stomach must be permanently adhered to the body wall. However, gastropexy does not guarantee that dilatation or volvulus will not recur; it simply makes it less likely. Gastropexy should always be performed in conjunction with abdominal exploration and derotation of the stomach.

SUTURE MATERIALS AND SPECIAL INSTRUMENTS

Absorbable (polydioxanone or polyglyconate) or nonabsorbable (polypropylene) suture material may be used for the gastropexy (0 or 2-0). A Foley catheter or a mushroom-tipped silicone catheter is needed for a tube gastropexy. Balfour retractors, handheld retractors (i.e., Army-Navy retractors or malleable retractors), and extra towel clamps (for placement on the rib when doing a circumcostal gastropexy) are helpful.

POSTOPERATIVE CARE AND ASSESSMENT

Electrolyte, fluid, and acid-base status should be monitored closely postoperatively. Many dogs with GDV are hypokalemic postoperatively and require potassium supplementation (see Table 4.6). Small amounts of water and soft, low-fat food should be offered 12 to 24 hours after surgery and the patient observed for vomiting. Gastritis that occurs secondary to mucosal ischemia is common and may be associated with gastric hemorrhage or vomiting. If vomiting is severe or continuous, a centrally acting antiemetic may be given (see p. 419). Secondary gastric ulcers may occur and require treatment (see p. 429). Proton pump inhibitors (omeprazole, pantoprazole; see Box 18.13) are the recommended drugs to reduce gastric acidity if ulceration is present. IV fluid therapy should be continued until the patient's oral fluid intake is adequate to maintain hydration. Patients should be monitored for hypoalbuminemia and anemia in the early postoperative period.

> **NOTE** Lidocaine toxicity may be enhanced in patients given cimetidine concurrently.

Ventricular arrhythmias are common in dogs with GDV and usually begin 12 to 36 hours after surgery. Their cause is unknown, but myocardial depressant factor, reduced cardiac output, and myocardial ischemia may contribute. Treatment of cardiac arrhythmias includes maintenance of normal hydration and correction of electrolyte imbalances. Sometimes the arrhythmia can be corrected simply by correcting hypokalemia. Some antiarrhythmic drugs (i.e., lidocaine) are ineffective when the animal is hypokalemic (see Table 4.6). If the arrhythmias interfere with cardiac output (as noted by poor peripheral pulses), are multiform, have subsequent premature beats inscribed on the wave of the previous complex (R on T), or have a sustained ventricular rate above 160 beats per minute, the animal should be treated with IV drugs. A test bolus of lidocaine given intravenously (2 mg/kg bolus, up to 8 mg/kg total dose) can be used to determine responsiveness to this drug. If the arrhythmias diminish or stop, lidocaine should be given by a continuous IV infusion of 50 to 75 µg/kg per minute (Box 18.29). Low doses should be used initially and increased only if necessary. Signs of lidocaine toxicity include

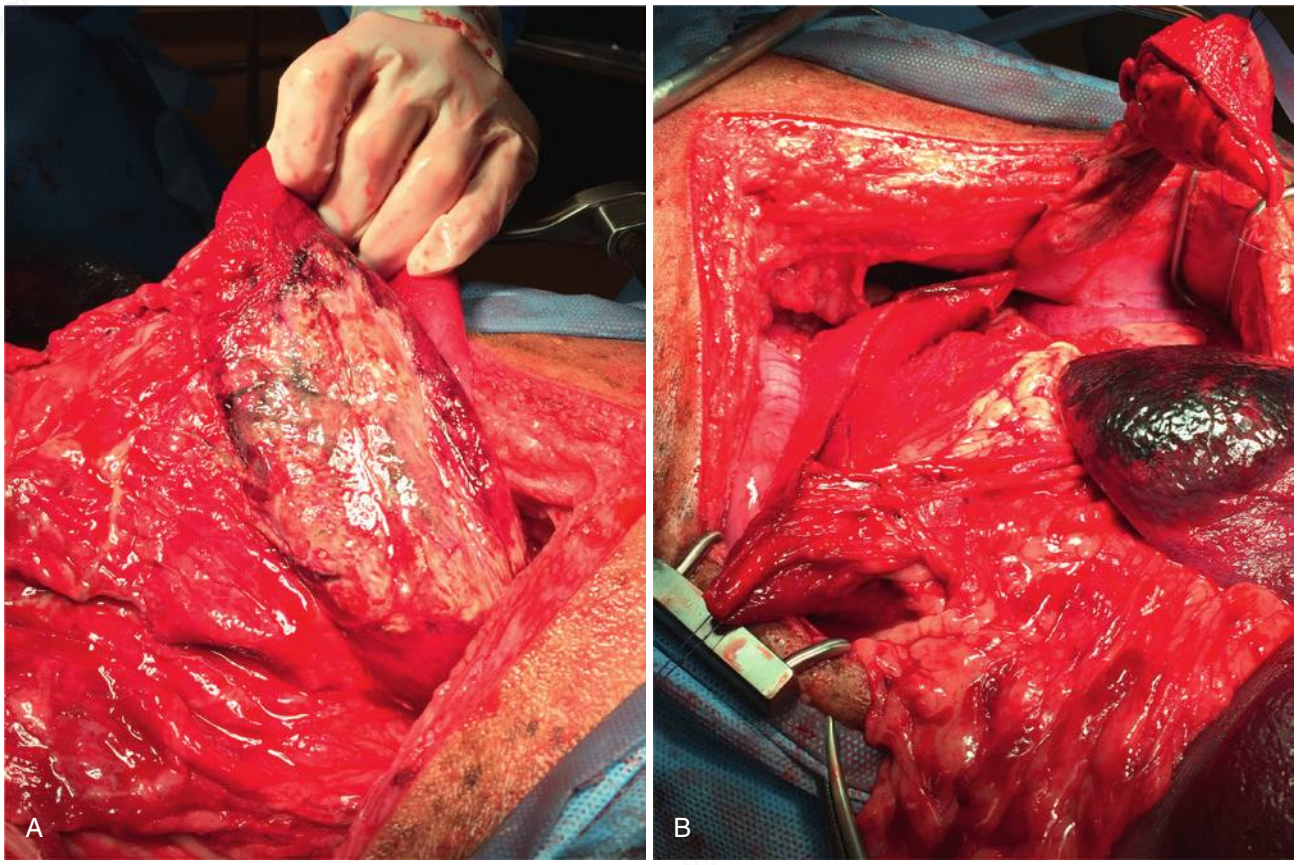

FIG. 18.90 Intraoperative appearance of the stomach of a dog with gastric dilatation-volvulus. (A) Gastric compromise due to gastric dilatation-volvulus. (B) Appearance of the stomach following resection of the compromised portion.

muscle tremors, vomiting, and seizures; lidocaine therapy should be discontinued if these signs occur. Other possibly effective antiarrhythmic drugs are procainamide and sotalol. Procainamide may be given as an IV bolus, by continuous infusion, intramuscularly, or orally (see Box 18.29). Sotalol may be effective in animals that have not responded to lidocaine or procainamide.

COMPLICATIONS

Sepsis and peritonitis may be caused by gastric necrosis or perforation if devitalized tissue is not adequately removed. Diagnostic peritoneal lavage (see p. 534) may help diagnose peritonitis. Peritonitis requires immediate surgical intervention. DIC occurs in approximately one-fifth of dogs with GDV. These dogs are more likely to die than those that do not have DIC; therefore assessment of clotting parameters and appropriate treatment with plasma, fluids, and heparin (see Box 22.7) is important to improve survival. Cardiac arrhythmias are common in dogs with GDV (~45.5% are affected), but arrhythmias do not appear to be associated with an increased risk of death in these dogs.

PROGNOSIS

Mortality rates of 45% and higher have been reported; however, mortality rates as low as 10% are more common with timely, aggressive, rapid therapy. Gastric dilatation without volvulus has a better prognosis than GDV; however, the degree of rotation is not associated with survival in dogs with GDV. Breeds at greatest risk for mortality may be the bloodhound, German longhaired pointer, and Neapolitan mastiff. The prognosis is poor if gastric necrosis or perforation occurs or if surgery is delayed. Preoperative measurement of plasma lactate may be a good predictor of gastric necrosis and outcome for dogs with GDV. Plasma lactate concentrations under 7.4 mmol/L suggest that gastric necrosis is not present, and thus a fair prognosis is warranted. Dogs with gastric necrosis are approximately 10 times more likely to die than those that do not have gastric necrosis. Recurrence rates for GDV differ, depending on techniques used, but most have reported rates of less than 10%. Tube gastropexy has the highest reported recurrence rate, varying from 5% to 29%.

Some dogs with GDV respond to tube decompression and medical stabilization alone. Occasionally the stomach becomes normally positioned after the air is removed, or if it was only partly rotated (less than 180 degrees), or merely dilated. However, these dogs still have a high likelihood of recurrence, and gastropexy should be recommended even when conservative management successfully alleviates the gastric malpositioning. The reported recurrence rates in dogs operated on for GDV in which the stomach was repositioned but gastropexy was not performed approaches 80%.

BOX 18.29 Antiarrhythmic Therapy in Dogs

Intravenous Antiarrhythmic Drugs—Ventricular

Lidocaine

IV bolus (2 mg/kg increments up to total dose of 8 mg/kg) then IV drip at 50 µg/kg/min (500 mg in 500 mL of fluid, administered at maintenance rate [66 mL/kg per day]). CRI can be increased to 75–100 µg/kg/min if indicated clinically.

NOTE: If seizures occur, stop the drug and consider using another antiarrhythmic agent.

Procainamide (Pronestyl)

5–25 mg/kg slow IV bolus then 25–50 µg/kg/min as CRI

Amiodarone[a]

1 mg/kg IV repeated up to a total cumulative dose of 3 mg/kg; alternatively 150 µg/kg/min as a CRI.

Intravenous Antiarrhythmic Drugs—Supraventricular

Diltiazem (Cardizem)

1–8 µg/kg/min CRI for acute SVT

Oral Antiarrhythmic Drugs—Ventricular

Amiodarone[a]

10–20 mg/kg PO q24h for 5–7 days, then 5–10 mg/kg PO q24h (may be able to reduce to q48h)

Mexiletine (Mexitil)

4–8 mg/kg PO q8h

Sotalol (Betapace)

1–3 mg/kg PO q12h

Oral Antiarrhythmic Drugs—Supraventricular

Extended-Release Diltiazem (Dilacor XR; Cardizem CD)

2–4 mg/kg PO q12h

Sotalol (Betapace)

1–3 mg/kg PO q12h

Amiodarone[a]

10–20 mg/kg PO q24h for 5–7 days, then 5–10 mg/kg PO q24h (may be able to reduce to q48h)

Digoxin (Lanoxin)

0.005–0.01 mg/kg PO q12h

Atenolol (Tenormin)

0.1–2.0 mg/kg PO q12–24h (gradually uptitrate the dose)

[a]Solvents used in the commercial intravenous formulations can result in acute anaphylactic reactions.

CRI, Constant-rate infusion; *IV,* intravenous; *PO,* orally; *SVT,* supraventricular tachycardia.

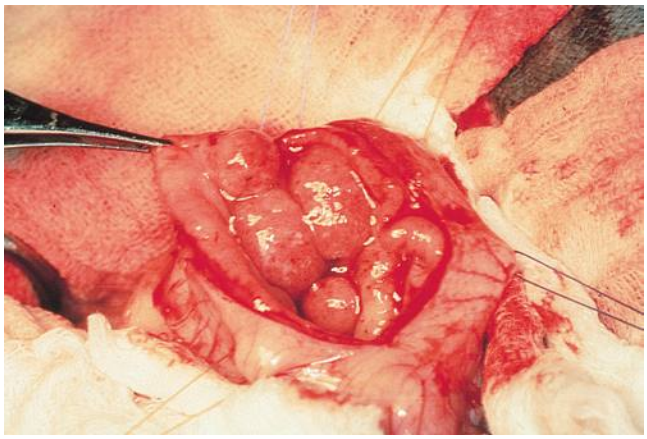

FIG. 18.91 Intraoperative image showing mucosal hypertrophy in a dog with chronic hypertrophic pyloric gastropathy.

BOX 18.30 Important Considerations for Gastric Outlet Obstruction

- Not all older patients with proliferative masses causing outlet obstruction have malignancies.
- Not all obstructed patients have hypokalemic, hypochloremic, metabolic alkalosis.
- Not all animals with hypokalemic, hypochloremic, metabolic alkalosis have gastric outlet obstruction.
- Benign gastric outflow obstruction usually has a good prognosis with appropriate therapy.
- Gastroduodenoscopy is usually more appropriate than contrast radiographs; with endoscopy, you can biopsy and often determine if malignancy is present, as well as remove foreign objects.

BENIGN GASTRIC OUTFLOW OBSTRUCTION

DEFINITIONS

Pyloric stenosis refers to benign muscular hypertrophy of the pylorus. **Chronic antral mucosal hypertrophy** refers to benign hypertrophy of the pyloric mucosa causing outflow obstruction (Fig. 18.91). **Chronic hypertrophic pyloric gastropathy (CHPG)** is a term that denotes pyloric hypertrophy without specifying whether the mucosa or the muscularis is involved. CHPG has been used specifically to refer to acquired mucosal hypertrophy by some authors and to either muscular (type I) or mucosal (types II and III) hypertrophy by others. **Polyps** are benign, adenomatous proliferations that can be single or multiple. Pyloric stenosis is also known as *benign antral muscular hypertrophy, congenital hypertrophic stenosis*, and *congenital pyloric muscle hypertrophy*. Chronic antral mucosal hypertrophy is also called *pyloric* or *gastric mucosal hypertrophy, chronic hypertrophic gastritis, multiple polyps of the gastric mucosa,* and *acquired hypertrophy.*

GENERAL CONSIDERATIONS AND CLINICALLY RELEVANT PATHOPHYSIOLOGY

Gastric outlet obstruction may be caused by pyloric abnormalities, disorders of gastric motility, or extrinsic lesions compressing the outflow tract (e.g., pancreatic, duodenal, or hepatic neoplasia; Box 18.30). Hypertrophy of the pyloric mucosa or muscle may be isolated or may occur in conjunction with other abnormalities. A syndrome of polycystic kidneys, hepatic disease, polyneuropathy, and hypertrophic gastropathy has been described in the Drentse Patrijshond breed. Hyperplastic pyloric polyps have been reported in French bulldogs with a history of chronic vomiting since weaning.

The cause of pyloric stenosis is unknown, but excessive production of gastrin has been suggested. Gastrin is the major regulator

of gastric acid secretion and is trophic for gastric smooth muscle and mucosa. Congenital pyloric stenosis has been produced in puppies by administering gastrin to pregnant bitches. Neurogenic dysfunction may also play a role. Acute stress, inflammatory disease, or trauma might stimulate the sympathetic nervous system, reducing gastric motility and causing retention. Prolonged gastric distention may then lead to increased gastrin secretion and subsequent hypertrophy.
