Preface

The sixth edition of *Small Animal Clinical Oncology* continues to chronicle significant advancement in the field of comparative clinical oncology. Since the first edition in 1989, this text has expanded all segments of the book to keep current with the profound changes in cancer biology and technology; in fact, each edition could be considered a milestone in the development of this specialty. The intent of this text continues to be production of a relevant summary of the field of comparative cancer biology and management for those engaged in all aspects of the veterinary profession. Approximately 20% of this edition has been substantially changed, with new authors and additions and deletions of entire chapters to reflect an appropriate emphasis on the current state of the profession.

This text, in all its editions, parallels the expansion and maturity of comparative oncology during the past 30 years. The Specialty of Oncology was formalized under the American College of Veterinary Internal Medicine (ACVIM) in 1989 and has grown steadily, particularly in the past 10 to 15 years. Likewise, the European College of Veterinary Internal Medicine (ECVIM)–Oncology Specialty is now a robust and dynamic organization providing important resources to students and practitioners in Europe. The American College of Veterinary Surgeons (ACVS) has formally authorized the Fellowship Training Programs in Veterinary Surgical Oncology, which will promote the expansion of new centers of surgical excellence in this field. Equally important has been the growth of the Veterinary Cancer Society (VCS) and the European Society of Veterinary Oncology (ESVONC), as well as other like-minded associations in Japan (JVCS), Brazil (ABROVET), and others to develop soon. The globalization of the interest and desire for high-quality cancer care for companion species is a remarkable and welcome occurrence.

During the past decade, the formalization of clinical trials in companion animals for investigation of animal and human health has matured significantly. The Comparative Oncology Program at the National Cancer Institute (NCI) continues to lead the effort to promote the benefits of companion animals in human cancer control and has currently completed or initiated more than 25 multicenter trials through the Comparative Oncology Trials Consortium. Other clinical trial organizations and centers, within both the public and private sector, have emerged and have established a more formal infrastructure for cooperative clinical research. No better evidence of this exists than the U.S. Food and Drug Administration (FDA) and U.S. Department of Agriculture (USDA) approvals for products licensed for use specifically in canine cancer that occurred due to a clinician–animal health industry partnership.

Examples of marked advances in the field of cancer biology, etiology, and staging reflected in this text include a complete rewrite of the role of genetics in cancer development (Chapter 1, Section A), cancer epidemiology (Chapter 4), tumor imaging technology (Chapter 6), and the reliance on more sophisticated molecular diagnostics (Chapter 8). All chapters devoted to specific cancer types have been updated, along with significant additions in sections on therapeutic options. Although consensus standards-of-care do not exist for most malignancies in veterinary species, available therapeutic options and published outcomes are presented that should allow the reader to choose the option best suited for his or her particular patient and client population.

There is still much to be done and future advances should continue to be a focus for expansion in subsequent editions of this text. Advancing the use and application of evidence-based medicine still remains a challenge in veterinary oncology. The desire to increase evidence-based decision-making in clinical practice is being considered throughout the veterinary profession as a whole, and appropriate reporting guidelines for manuscript submission have been implemented in the leading veterinary journals. Such guidelines permit sorting of levels of evidence and an opportunity to engage in formal post-publication data analysis for systematic reviews. We look forward to the next edition of the text that includes therapeutic recommendations based on strong evidence and consensus opinion from leading veterinary collaborative scientific organizations. We also continue to hope that the next edition will see a quantum leap in satisfying several critical needs in the field. We urgently need improved durable outcomes for canine lymphoma, hemangiosarcoma, and osteosarcoma, and validated biomarkers to assist with prognostic and predictive estimates for all cancers—but in particular, those highly lethal disease processes mentioned previously that have frustrated all of us for decades. Furthermore, advancements in supportive measures that can ensure the maintenance of quality of life and abrogation of adverse events are similarly in need of further development.

It is also important to consider potential operational effects and solutions to the continued development of comparative oncology. The inconsistent availability of certain chemotherapy drugs often now rises to levels of serious concern for continuity of care and will require innovative business solutions to ensure robust coverage of the expanding market need. It is obvious that the cost of care for companion animals will continue to rise, and the role that companion animal healthcare insurance will play in this dynamic could have far-reaching effects on the profession in the next decade. Likewise, the potential changes in the profession from increasing liability issues related to emotional pain and suffering litigation could create new operating paradigms.

The authors and editors have created the following text, which both describes the phenomenal strides made during the past 5 to 6 years and sets the standard to measure future growth and understanding of comparative oncology. We hope that it will be a useful resource for those engaged in animal and human oncology and for the ultimate improvement of the quality and length of life for our patients.

VetBooks.ir

We dedicate this edition to these fine men, each of whom pioneered his particular branch of veterinary oncology:

Dr. E. Gregory MacEwen
1943–2001
The father of veterinary medical oncology, Greg was personally responsible for educating and inspiring the current generation of medical oncologists, both as clinicians and clinician scientists.

Dr. Robert S. Brodey
1927–1979
The father of veterinary surgical oncology, Bob will be remembered for his tireless effort to advance the field of oncology, to teach principles of surgery, and, most importantly, to preserve nature.

Dr. Edward L. Gillette
1932–2006
The father of veterinary radiation oncology, Ed was a leader in comparative oncology. His vision and leadership have created a new and contemporary breed of oncologists in all disciplines.

Part I: The Biology and Pathogenesis of Cancer

1 The Etiology of Cancer, 1
- A The Genetic Basis of Cancer, 1
- B Chemical, Physical, and Hormonal Factors, 13
- C Cancer-Causing Viruses, 19

2 Tumor Biology and Metastasis, 36

3 The Pathology of Neoplasia, 61

4 Epidemiology and the Evidence-Based Medicine Approach, 81

5 Paraneoplastic Syndromes, 98

Part II: Diagnostic Procedures for the Cancer Patient

6 Diagnostic Imaging in Oncology, 113

7 Diagnostic Cytopathology in Clinical Oncology, 126

8 Molecular Diagnostics, 146

9 Biopsy and Sentinel Lymph Node Mapping Principles, 158

Part III: Therapeutic Modalities for the Cancer Patient

10 Surgical Oncology, 164

11 Interventional Oncology, 174

12 Cancer Chemotherapy, 182

13 Radiation Oncology, 209

14 Cancer Immunotherapy, 231

15 Molecular/Targeted Therapy of Cancer, 251
- A Gene Therapy for Cancer, 251
- B Signal Transduction and Cancer, 257
- C Antiangiogenic and Metronomic Therapy, 263
- D Novel and Emerging Therapeutic Agents, 268

16 Supportive Care for the Cancer Patient, 286
- A Management of Chronic Cancer Pain, 286
- B Nutritional Management of the Cancer Patient, 300
- C Relationship-Centered Approach to Cancer Communication, 310

17 Integrative Oncology, 330

18 Clinical Trials and Developmental Therapeutics, 340

Part IV: Specific Malignancies in the Small Animal Patient

19 Tumors of the Skin and Subcutaneous Tissues, 352

20 Melanoma, 367

21 Mast Cell Tumors, 382

22 Soft Tissue Sarcomas, 404

23 Cancer of the Gastrointestinal Tract, 432
- A Oral Tumors, 432

Introduction

Why Worry About Cancer in Companion Animals?

Why should health care professionals in general, and veterinarians in particular, be concerned about cancer in companion animals? Several compelling motivations and opportunities exist for the profession as a whole to continue, and indeed expand on, the significant role we play in the understanding, prevention, and elimination or control of this devastating constellation of disease processes. Although, as veterinarians, our prime directive is to ensure the health and quality of life of the companions under our care, the needs of our client caregivers during the difficult times of cancer diagnosis, treatment, and outcome (whether optimistic or pessimistic) should be of nearly equal importance. Because cancer is a disease that knows no species boundaries, our profession has considerable opportunity to play a key role in comparative oncologic investigations, with the ultimate goal of effecting cure or, in the absence of cure, transforming cancer from an acute life-threatening disorder into a manageable chronic condition (much like diabetes) in all species; essentially the basis of the "One Medicine" approach to disease investigation.

The sheer numbers involved highlight the magnitude of the problem of cancer in companion species. The prevalence of cancer in companion animals continues to rise for a variety of reasons, not the least of which is related to animals living longer thanks to the increasing care offered by caregivers and the advanced veterinary care they seek. There are more than 165 million dogs and cats at risk in the United States,[1] and cancer remains a major cause of companion animal morbidity and mortality (see Chapter 4), with at least 4 million dogs and 4 million cats developing cancer each year.[2–6] Although the true incidence or prevalence of companion animal cancer is currently not known, based on necropsy surveys describing proportional mortality, 45% of dogs that live to 10 years or older die of cancer.[4] With no age adjustment, 23% of patients presenting for necropsy died of cancer. In a 1998 Morris Animal Foundation (MAF) Animal Health Survey, more than 2000 respondents stated that cancer was the leading cause of disease-related death in both dogs (47%) and cats (32%).[3] Another MAF survey performed in 2005 revealed that cancer was by far the largest health concern among dog owners (41%), with heart disease the number two concern at 7%. Regardless of the exact numbers, both the reality and the perception support the clients' point of view that cancer remains the number one concern in their minds with respect to the health and quality of life of their companions—the so called "emperor of all maladies".[7] Furthermore, breakthroughs in the management of human cancers have received a great deal of exposure through the Internet, news media, and popular press, which further serves to educate companion caregivers and raise the level of expectations as to therapeutic possibilities and promote an atmosphere of optimism and a demand for similar care for their animals. Increased longevity of companion animals, the increasing prevalence of cancer, and enhanced caregiver expectations require that the veterinary profession be prepared to meet these challenges and opportunities.

Because cancer is a common and serious disease for human beings, many owners have had or will have a personal experience with cancer in themselves, a family member, or a close friend. Realizing the importance of companion animals to our clients, it must be appreciated that they value the veterinarian's ability to care as much as his or her ability to cure. Keeping this in mind, the veterinarian should approach the patient with cancer in a positive, compassionate, and knowledgeable manner. Frequently, the veterinary profession has taken a pessimistic approach to cancer. This attitude is not only a detriment to the companion but may also negatively reinforce unfounded fears in the client about the disease in humans. We owe it to our companion animal patients and their caregivers to be well informed and up-to-date on current treatment methods to prevent imparting unnecessary feelings of hopelessness.

Perhaps the greatest opportunity presented to our profession, beyond the immediate care of our patients' and clients' needs, is the more global role (and responsibility) we play in advancing the understanding of cancer biology, prevention, and treatment from a comparative oncology standpoint. Companion animals with spontaneously developing cancer provide an excellent opportunity to investigate many aspects of cancer, from etiology to treatment. Indeed, the role of comparative oncology was highlighted at a National Cancer Policy Forum hosted by the National Academy of Sciences in 2015 entitled "The Role of Clinical Studies for Pets with Naturally Occurring Tumors in Translational Cancer Research".[8] One of the most exciting achievements in veterinary oncology over the past 15 years has been the development of successful and collaborative consortia groups that are purposed to perform multicenter clinical trials and prospective tumor biospecimen repository collections. These include the Comparative Oncology Trials Consortium (COTC; https://ccrod.cancer.gov/confluence/display/CCRCOPWeb/Comparative+Oncology+Trials+Consortium) and the Canine Comparative Oncology and Genomics Consortium (CCOGC, www.ccogc.net) centrally managed by the National Institutes of Health (NIH)-National Cancer Institute's Comparative Oncology Program (NCI-COP) and discussed in Chapter 18. Their infrastructure allows larger scale clinical trials and provides the voice for collective advocacy in veterinary and comparative oncology. Their success is an example of the growing importance of the study of comparative tumor biology and clinical investigations. Access to novel drugs and biologics will speed clinical applications for both veterinary species and humans. Ultimately, including companion animal populations in clinical trials assessing novel drugs and biologics of interest to the National Cancer Institute, the U.S. Food and Drug Administration, and the pharmaceutical industry will both

VetBooks.ir

advance veterinary-based practice and inform future human clinical trials that may follow. Some of the aspects of companion animal cancer that enable attractive comparative models include the following:

1. Companion dogs and cats are genetically outbred (like humans), as opposed to many experimental models of rodents and other animals.
2. The cancers seen in practice are spontaneously developing as opposed to experimentally induced and better recapitulate the natural human and veterinary condition.
3. Companion species share the same environment as their caregivers and may serve as epidemiologic or etiologic sentinels for the changing patterns of cancer development seen in humans.
4. Companion species have a higher incidence of some cancers (e.g., osteosarcoma, non-Hodgkin lymphoma) than humans.
5. Most animal cancers will progress at a more rapid rate than will the human counterparts. This permits more rapid and less costly outcome determinations such as time to metastasis, local recurrence, and survival.
6. Because fewer established "gold standard" treatments exist in veterinary medicine compared with human medicine, it is ethically acceptable to attempt new forms of therapy on an untreated cancer rather than wait to initiate new treatments until all "known" treatments have failed, as is common in the human condition. It is important to recognize that this latitude in clinical trials can be misused to permit diverse and poorly characterized or even unethical treatments to be attempted as well. We have an obligation to ensure that our patients are not denied known effective treatment while at the same time planning well-designed prospective clinical trials of newer, scientifically sound treatment methods.
7. Companion species' cancers are more akin to human cancers than are rodent tumors in terms of patient size and cell kinetics. Dogs and cats also share similar characteristics of physiology and metabolism for most organ systems and drugs. Such correspondence allows better and safer comparison of treatment modalities such as surgery, radiation, and chemotherapy between animals and humans to be made.
8. Dogs and cats have intact immune systems as opposed to many rodent model systems, which allows immunologic assays and treatment approaches to be explored. Furthermore, their cancers develop in a syngeneic tumor microenvironment and tumor–tumor microenvironment interactions are equally important to understand basic tumor biology and the development of novel therapeutic targets.
9. Companion animal trials are generally more economical to perform than human trials.
10. Companion animals live long enough to determine the potential late effects of treatment.
11. Regional referral centers exist to concentrate case accrual and facilitate clinical trials.
12. Clients are often willing to allow a necropsy, which is a crucial end point for not only tumor control but also treatment-related toxicity.
13. Dogs and cats are large enough for high-resolution imaging studies and multiple sampling opportunities, as well as for surgical interventions.
14. The elucidation of the canine genome and its resemblance and relevance to the human genome open unique and unparalleled opportunities to study comparative oncology from a genetic perspective.[9]

Clients who seek treatment for their companion animals with cancer are a devoted and compassionate subset of the population. Working with these caregivers can be a very satisfying aspect of a frequently frustrating specialty. Clients are almost always satisfied with an honest and aggressive attempt to cure, control, or palliate the disease of their companion, making the experience satisfying for the veterinarian, for the client, and, most important, for the companion.

Oncology also offers the inquisitive veterinarian a complex and challenging area for both clinical and basic research. The challenges and accomplishments in oncology have been and continue to be very impressive. Oncology offers unlimited opportunity for the pursuit of knowledge for the benefit of animals and humankind. "Cancer, unlike politics and religion, is not a topic of controversy. No one is for it. Cancer is not another word for death. Neither is it a single disease for which there is one cure. Instead, it takes many forms, and each form responds differently to treatment".[10]

Clinical and comparative oncology continues to be a rapidly advancing field of study. More training programs are developed each year that allow a wider distribution of experienced veterinarians into practice, research, industry, government, and the academic setting. Through the continued investigation of tumor biology and treatment and the inclusion of veterinary species in well-designed, rigorous, and humane clinical trials, the veterinary profession will play a key role in advancing the diagnosis, treatment, and prevention of cancer for all species.

1 The Etiology of Cancer

SECTION A: THE GENETIC BASIS OF CANCER

JAIME F. MODIANO AND JONG HYUK KIM

Cancer is a powerful and fearsome word describing a group of diseases that have recently surpassed cardiovascular disease as the most common cause of death for humans in 12 European countries[1] and in 22 states in the United States.[2] Cancer is also believed to be the most common cause of disease-related death in companion and working dogs in the developed world.[3–6] The fear of cancer, however, is rooted in misunderstanding, misconception, and mysticism. Thus the goals of this chapter are to clarify why cancer happens and highlight advances have been made that allow many human and animal cancer patients to lead full and productive lives after diagnosis.

The seminal work of Nowell and Hungerford in the early 1960s describing the nonrandom translocation between two chromosomes in chronic myelogenous leukemia represents the first time a genetic event (the translocation) could be linked to a specific cancer.[7,8] These observations can be considered the start of the modern era of cancer genetics, and they still pose one of the best arguments for why a strong foundation in contemporary genetics is necessary to understand the etiology of cancer. This chapter provides context for the genetic basis of cancer, updating recent data from domestic animals, especially dogs, that highlights how the judicious application of comparative oncology studies can improve our understanding of cancer risk, progression, and therapy.

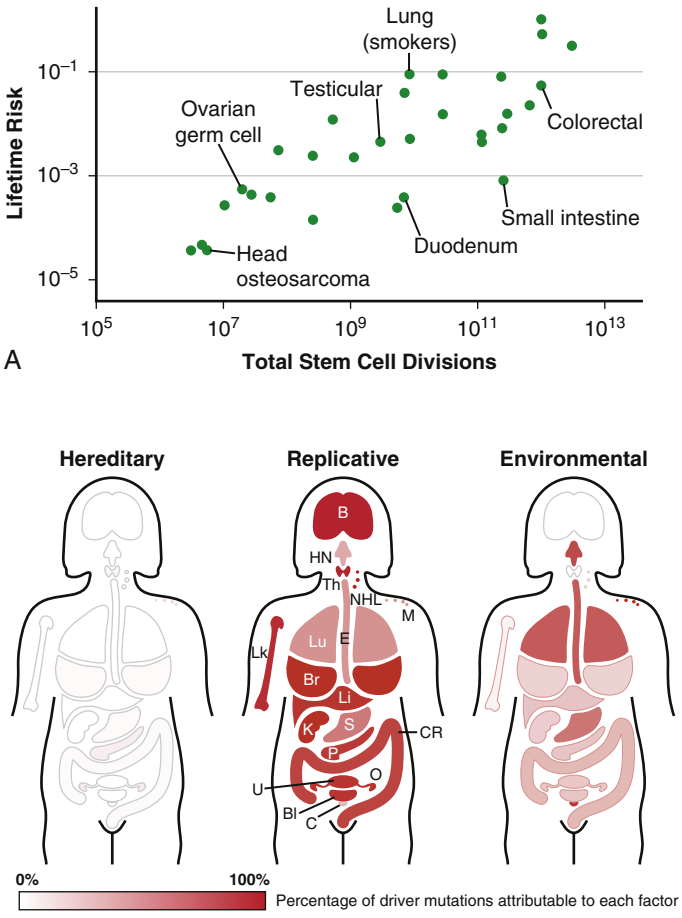
Cancer Risk

Cancer is neither a single nor simple disease. Rather, the term *cancer* describes a large number of diseases for which the only common feature is uncontrolled cell growth and proliferation. These only critical requirement for the manifestation of cancer is multicellularity, and neoplastic diseases have been described in representative species from every group in the animal kingdom and also in plants.[9]

An important concept that is now universally accepted is that cancer is a genetic disease, although it is not always heritable. Tumors arise from the accumulation of mutations that eliminate normal constraints of proliferation and genetic integrity in a somatic cell, promoting immortalization and the capacity to modify and maintain a supportive niche for survival and expansion. Among other causes, mutations can arise after exposure to environmental mutagens, such as cigarette smoke and ultraviolet irradiation. Changes in the cancer incidence in humans over the course of the 20th century underscore the significant influence the environment can exert on the genetic makeup of individuals. Some environmental effects reflect behavior patterns (e.g., lung cancer in smokers), infectious diseases (e.g., stomach cancer in people infected with *Helicobacter pylori*), or exposure to cultural factors, such as urbanization or changes in diet (e.g., increasing breast cancer rates in the second and subsequent generations of Asian American women). Nevertheless, it would be incorrect to assume that the environment is wholly responsible for most tumors, especially because the increased risk of cancer upon exposure to potential environmental carcinogens is relatively small, except for tobacco products, ultraviolet or gamma irradiation, and a small group of chemical mutagens.

Another important intrinsic "mutagen" is the inherent error rate of enzymes that control DNA replication, which introduces 1 in 10 million to 1 in 1 million mutations for each base that is replicated during each round of cell division. Mammalian genomes comprise approximately 2 billion to 3 billion (10^9) base pairs; therefore every time a cell divides, each daughter cell is likely to carry a few hundred to a few thousand mutations in its DNA. Most mutations, whether caused by extrinsic or intrinsic factors, are silent and do not hinder the cell's ability to function; however, others can disable tumor suppressor genes or activate proto-oncogenes, which respectively inhibit or promote cell division and survival. Thus it can be said that simply being alive is the single largest risk factor for cancer.

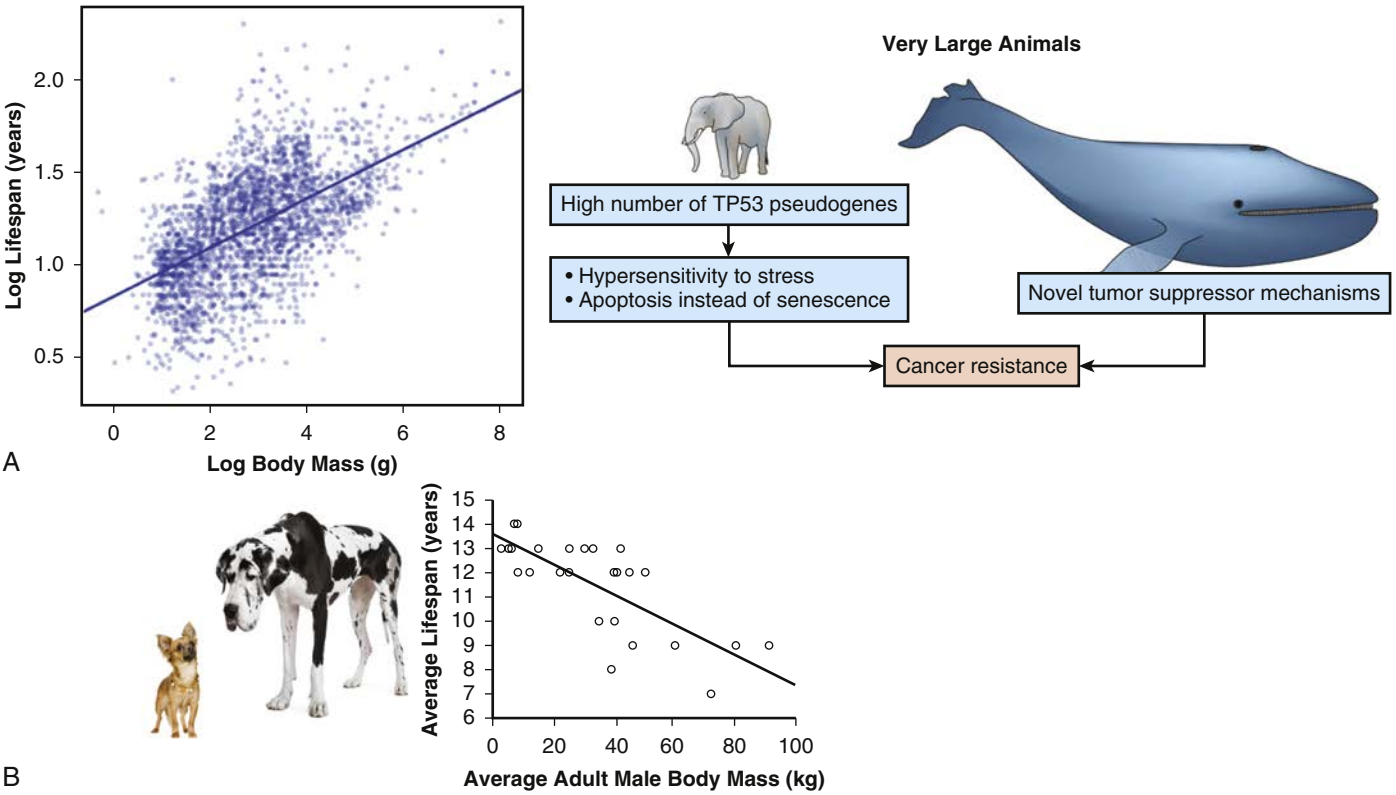
The concept of intrinsic mutagenicity describes cancer risk as a function of the number of stem cell divisions required to maintain structure and function for a given tissue; it also suggests that more than two-thirds of human cancers originate from mutations caused by errors in DNA replication and are stochastic (random) in nature.[10–12] Furthermore, this concept suggests that more than half of the mutational load present in cancer cells occurs before tumors ever form. This is actually a "good news" scenario, in that it makes it possible to envision the development of strategies for early cancer detection using genomic tools.



Normal tissues and organs contain different numbers of stem cells that maintain homeostasis. These stem cells self-renew and live longer than other tissue resident cells, which are replaced to

maintain normal organ structure and function. Recent studies by Tomasetti and Vogelstein identified a strong correlation (r = 0.81) between the total number of stem cell divisions and the lifetime risk of cancer arising from 31 distinct tissues (Fig. 1.1A).[11] In contrast, no significant correlations were seen between the risk for these cancers and heritable or environmental and geographic factors.[10]

The take-home message from this work is that DNA replication (R) represents a major risk factor for cancer, joining heritable risk (H) and environmental risk (E) as the major causes of mutations that can lead to cancer (see Fig. 1.1B). Heritable risk arises from mutations in the germline, such as those in the genes *BRCA1* and *BRCA2, TP53,* and *CDKN2A* that are associated, respectively, with breast cancer risk, with Li-Fraumeni syndrome and susceptibility to many cancers, and with susceptibility to melanoma and pancreatic carcinoma. Only one heritable cancer syndrome has been identified in domestic dogs. A germline mutation of the *BHD* gene encoding folliculin was identified in a family of German shepherd dogs that showed susceptibility to a syndrome of renal cystadenoma and nodular dermatobibrosis[13]; however, controlled breeding practices make it difficult for heritable cancers associated with single gene mutations to be perpetuated in domestic animals outside a laboratory environment.



In animals, and specifically in dogs, in which the lifetime risk of cancer seems to be approximately equivalent to that of humans, the apparent increased prevalence of certain tumor types in certain breeds (closed gene pools) suggests that incompletely penetrant, heritable factors might contribute to cancer causation. Indeed, even relatively minor traits that do not considerably alter the phenotypic appearance have been found to be associated with risk. Perhaps this is most easily appreciated in greyhounds; registered racing greyhounds are at higher risk of developing osteosarcoma (OSA) than American Kennel Club (AKC) "show" greyhounds.[14] This suggests that different components of risk could have become established in the founders of the racing and show greyhound lineages. In the racing greyhounds, however, part of the risk could be due to concussive forces during training and performance racing, which have the potential to create microfractures and activate chronic repair processes.

Environmental risk factors include chronic exposures to genotoxic agents, including habitual use of tobacco products; high-energy radiation from the sun or from occupational hazards, such as uranium mining; workplace chemicals, such as vinyl chloride; and agents that promote chronic inflammation and activate tissue repair processes unremittingly, such as asbestos. Tobacco use and sun exposure account for a large portion of human cancers worldwide. The risk of cancer from these exposures has been compounded in the past century by the increased longevity of human populations, which allows more time for mutations to accumulate.[10] In animals, strong associations have been established between exposure to ultraviolet radiation from the sun and some skin cancers in dogs, cats, cows, and horses; however, these account for a small proportion of cancer in these populations. Likewise, exposure to environmental tobacco smoke seems to increase the risk for a small proportion of cancers of dogs (nasal carcinoma) and cats (possibly lymphoma). The association between risk for cancer and exposure to other chemicals in dogs, cats, and other domestic animals is a topic of controversy; such exposure is likely to account for a small fraction of cancers seen in these species, although, as in humans, their effects might be compounded by the increased life span provided by modern veterinary care.

• **Fig. 1.1** (A) The relationship between the number of stem cell divisions in the lifetime of a given tissue and the lifetime risk of cancer in that tissue. (B) Etiology of driver gene mutations in women with cancer. For each of 18 representative cancer types, the schematic depicts the proportion of mutations that are inherited due to environmental factors or due to errors in DNA replication (i.e., not attributable either to heredity or to environment). The sum of these three proportions is 100%. The color codes for hereditary, replicative, and environmental factors are identical and span white (0%) to brightest red (100%). *B,* brain; *Bl,* bladder; *Br,* breast; *C,* cervical; *CR,* colorectal; *E,* esophagus; *HN,* head and neck; *K,* kidney; *Li,* liver; *Lk,* leukemia; *Lu,* lung; *M,* melanoma; *NHL,* non–Hodgkin lymphoma; *O,* ovarian; *P,* pancreas; *S,* stomach; *Th,* thyroid; *U,* uterus. (Reproduced with permission. (A) From Couzin-Frankel J. Biomedicine: the bad luck of cancer. *Science*. 2015 Jan 2;347(6217):12. doi: 10.1126/science.347.6217.12.; Tomasetti C, Vogelstein B. Variation in cancer risk among tissues can be explained by the number of stem cell divisions. *Science*. 2015 Jan 2;347(6217):78-81. https://doi.org/10.1126/science.1260825. Fig. 1.1. (B) Illustration by Corinne Sandone © 2017 Johns Hopkins University. Used with permission.)

Replicative risk of cancer is ever present, and it increases inexorably with age. The stochastic nature of replicative risk is reflected in the molecular heterogeneity observed in histologically similar tumors, and the strong correlation between cancer and advanced age in dogs suggests that the replication-associated R factor likely is responsible for an even greater proportion of cancers in this species than it is in humans.

• **Fig. 1.2** Body size and life span. (A) Relationship between body mass (g) and life span (years) among 2556 vertebrates. In the left panel, the *blue line* shows the linear regression between log (body mass) and log (life span), R2 = 0.32. The right panel illustrates potential anticancer mechanisms in the largest mammals: elephants and whales. Elephants have evolved multiple copies of the *TP53* gene (pseudogenes) that are associated with an increased apoptotic response. Anticancer mechanisms in the largest mammals, whales, are not yet known, but they do not involve *TP53* duplications. (B) The relationship between body mass and life span across 32 different dog breeds. The diversity of size and life span among dog breeds is remarkable, but it is also well known that larger breeds tend to be short-lived relative to small breeds. (Reproduced with permission. (A) Redrawn from Sulak M, Fong L, Mika K, et al. *TP53* copy number expansion is associated with the evolution of increased body size and an enhanced DNA damage response in elephants. *eLife*. 2016 Sep 19;5:pii:e11994. https://doi.org/10.7554/eLife.11994. Photo of dogs © iStockphoto.com.

It should be noted that infectious agents can also be causally linked to cancer, by acting as direct mutagens or by increasing inflammation, replication, and repair, and consequently cancer risk.

Body Size and Cancer

The notion that mutations that accumulate stochastically during normal cell replication drive malignant transformation raises an important question: Why aren't bigger animals that have more cells more vulnerable to cancer? This question, originally posed by Sir Richard Peto,[15] is commonly referred to as Peto's paradox (at the species level, the incidence of cancer does not appear to correlate with the number of cells in an organism). The answer involves evolution and natural selection. Several cancer-protective mechanisms have been identified in mammals at the extremes of size. Elephants are the largest living land mammals; in the elephant lineage, cancer protection seems to be associated with enhanced activity of the *TP53* tumor suppressor gene, which underwent multiple duplication events after the split from a common ancestor that gave rise to hyraxes and manatees but that preceded diversification into mastodons, mammoths, and modern elephants.[16,17] Whales include the largest living animals, and in the bowhead whale lineage, for example, variants or alterations of multiple genes seem to confer protection from cancer and aging.[18] However, in the common minke whale, an alternative adaptation has evolved that resulted in fewer microsatellites in genomic regions near proto-oncogenes and tumor suppressor genes, where cumulative mutations could lead to an increased cancer risk.[19] As these examples illustrate, adaptive solutions that enable large size and longevity likely are unique and specific to the evolutionary history of each species (Fig. 1.2A).

The norm for mammalian evolution is that large size is correlated with longevity. This is consistent with selective pressures that otherwise would disfavor the energy expenditure required to achieve large size. However, this trend is reversed in domestic dogs,[20] in which large body size is associated with shorter life spans and possibly with a higher rate of certain diseases, including cancer (see Fig. 1.2B). The precise reasons for this remain unclear, but dogs present a unique natural model to study

VetBooks.ir

associations between age, body mass, and disease risk under conditions in which artificial selection has superseded natural selection. Specifically, natural selective pressures in dogs were replaced by artificial selection since the initial domestication events approximately 10,000 to 25,000 years ago.[21] Changes in demand for form, instead of function, drove the creation of more than 400 breeds in the past 300 to 400 years. This artificial selection, usually for a single or a few phenotypic traits, gives little chance for adaptation across the rest of the genome. Consequently, the risks of mutation associated with normal processes of cell replication during development, growth, and maintenance into adulthood are enhanced in large dogs (more cells), making it possible to explain the disproportionate risk of certain cancers, such as appendicular OSA, by manipulation of their genomic plasticity with extreme selection for size. This is also consistent with the fact that the overall risk for axial OSA in dogs is similar to that observed in other species, accounting for the effects of size and functional/mechanical stresses on bone. The greater risk for large and giant dogs to develop appendicular OSA can be explained, at least in part, by the fact that more cell divisions are needed to create and maintain large bones, especially as bone tissues undergo continuous remodeling. Each round of replication for an osteoblast, in turn, contributes to its mutational burden and potential transformation. The late age of onset in dogs is consistent with chronic selection for cells that accumulate a critical complement of mutations. In humans, OSA is among the cancers in which the R factor can explain virtually all of the risk; also, an association has been recognized that shows OSA is more common in children in the higher percentiles of size for their age.[22–24]

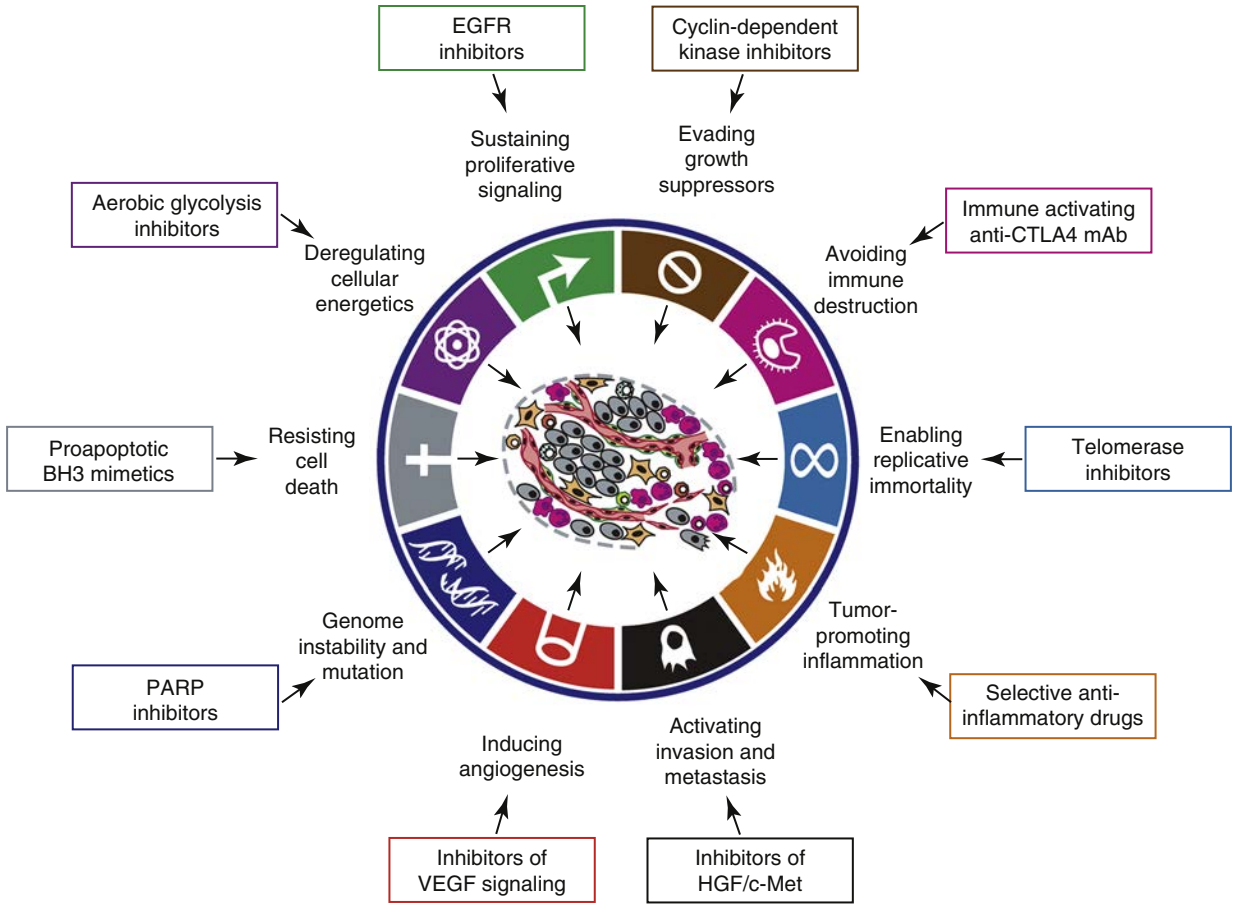
Accounting for the risk of appendicular OSA (or other cancer types) stochastically as a function of replication risk leaves another important question unanswered: Why does the risk for some dog breeds seem to be higher (or lower) than expected based on their overall size? Partial answers to this question are available, and again, solid data is available for OSA. In terms of breed-specific risk, multiple heritable factors seem to influence the risk for OSA. Data from a genome-wide association study (GWAS) in three high-risk dog breeds indicates that the patterns of heritable risk for OSA are complex and incompletely penetrant.[14] However, selective breeding, especially for large size, seems to have enriched risk alleles that are now fixed in certain populations.[14,25,26] Fixed alleles associated with risk are not unique to OSA; they have also been associated with breed-specific risk for canine mammary cancer,[27] canine digital squamous cell carcinoma,[28] and other cancer types (discussed later in the chapter).

In humans a GWAS identified two loci associated with the presence of OSA[29] and a single, distinct locus in the *NFIB* gene associated with the presence of metastasis at diagnosis.[30] The risk alleles for humans and dogs are not located in orthologous regions of the genome. It appears, then, that achieving a large size relatively rapidly, and not breed-specific (or individual) traits in the germline, is the overwhelming contributor to OSA risk. It is thus reasonable to conclude that Peto's paradox arises as a result of barriers of natural selection, and that when such barriers are removed and the natural life span of an organism is extended, as is the case for dogs, the paradox disappears, revealing the overwhelming influence of DNA replication errors on individual cancer risk.

The examples provided underscore that cancer risk and progression have both shared and unique traits across species in the animal kingdom. This creates opportunities to study the natural history of cancer in a spontaneous setting. However, it is important to avoid the significant pitfalls that arise from assumptions of equivalence where none exists. The next section of this chapter reviews the hallmarks of cancer that are shared by virtually every cancer from every species. The final section of the chapter focuses on recent studies that elevate companion dogs as models for understanding the complex genetics of cancer through the use of contemporary technology and cautious, deliberate interpretation of data.

The Hallmarks of Cancer

Forty years of research culminated in an insightful and a thorough review paper by Douglas Hanahan and Robert Weinberg in 2011 that synthesized knowledge about cancer into 10 essential, acquired characteristics.[31]



In 2000 the same authors had described six characteristics necessary for cellular transformation, which comprised the abilities to (1) sustain proliferative signaling, (2) evade growth suppressors, (3) resist cell death, (4) enable replicative immortality, (5) induce angiogenesis, and (6) activate invasion and metastasis.[32] In this initial paper describing the hallmarks of cancer, Hanahan and Weinberg created a paradigm shift by providing the first ever comprehensive synthesis of the molecular events leading to cancer. The important concepts that were clarified included these: no single gene is universally responsible for transformation; five or six critical (driver) mutations are the minimum theoretical number required to endow the cancer phenotype (an observation that has since been confirmed experimentally)[33]; each step in the path toward transformation and cancer progression is regulated by multiple interactive biochemical pathways,[34] and thus, mutations of different genes along a pathway can result in equivalent phenotypes and, conversely, mutations of the same gene can result in different cancers with distinct biology; tumors behave as tissues; and the interactions between the tumor and its microenvironment are major drivers of cancer behavior.

The updated hallmarks of cancer added two "enabling" characteristics, (7) genome instability and mutation and (8) tumor-promoting inflammation, and two "emerging" hallmarks, (9) deregulating cellular energetics and (10) avoiding immune destruction.

The effect of this unifying conceptualization of cancer genetics and this level of understanding are clearly evident when one considers how they have influenced the design, development, implementation, and success of new cancer therapies (Fig. 1.3). A summary of the information with added refinements is provided later in the chapter.

Sustaining Proliferative Signaling

Arguably the most important event in neoplastic transformation is the capability of cells to proliferate in perpetuity. Under normal conditions, cells communicate with each other and integrate environmental signals by sensing cues and gradients. For example, migration, metabolism, and proliferation of mature hematopoietic cells are regulated in autocrine and paracrine fashions by locally secreted cytokines. The same cytokines may act systemically in an endocrine fashion. With the notable exception of steroid hormones that bind to intracellular receptors, growth-promoting cytokines work by binding transmembrane receptors, which in turn initiate signaling cascades that culminate in transcriptional changes. These transcriptional responses, in turn, allow cells to adapt their behavior to match

• **Fig. 1.3** Therapeutic targeting of the hallmarks of cancer. Drugs that interfere with each of the acquired capabilities necessary for tumor growth and progression have been developed and are in clinical trials, or in some cases have been approved for clinical use in treating certain forms of human cancer. Additionally, the investigational drugs are being developed to target each of the enabling characteristics and emerging hallmarks, which also hold promise as cancer therapeutics. The drugs listed are examples; a deep pipeline of candidate drugs with different molecular targets and modes of action is in development for most of these hallmarks. (Reproduced with permission from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. *Cell*. 2011 Mar 4;144(5):646-674. https://doi.org/10.1016/j.cell.2011.02.013. Fig. 1.6.)

the environmental signals. The activity of cytokines, their receptors, and the corresponding signaling molecules are finely tuned. The system can be shut down when the concentration of the cytokine falls below a threshold that can stably bind the receptor, when the receptor ceases to be expressed, or when signaling molecules are downregulated or otherwise inactivated; however, mutations in even one of the molecules involved in regulating these pathways can provide sustained growth signals in the absence of the initiating cytokine. Among many examples is a translocation between chromosome 2 and chromosome 5 (t(2;5)) that is present in almost half of human anaplastic lymphomas. The translocation creates a fusion protein between the nucleophosmin gene *(NPM1)* and the anaplastic lymphoma kinase gene *(ALK);* this aberrantly activates the Jak2/STAT5 signaling pathway,[35] which normally is responsive to various interleukins (IL), including IL-2, IL-3, and IL-6. The genes that encode the normal growth-promoting proteins (e.g., ALK, Jak2, and STAT5) are called *proto-oncogenes;* the mutated versions that allow cells to gain self-sufficiency from the environmental signals are called *oncogenes*. It is important to note that not all growth-promoting genes have the capacity to become oncogenes and that the outcomes of oncogenic activation are most commonly senescence or apoptosis, unless additional events promote stable transformation and survival.

Evading Growth Suppressors

In addition to the hallmark capability of inducing and sustaining positively acting growth-stimulatory signals, cancer cells must also circumvent powerful programs that negatively regulate cell proliferation; many of these programs depend on the actions of tumor suppressor genes. To maintain homeostasis, cells also must integrate antigrowth signals from the environment. Quiescence in nonhematopoietic cells is enforced by signals delivered by contact inhibition.[36] Hematopoietic cells, on the other hand, use cell-cell contacts to maintain interactions within the niche and to regulate the timing and intensity of hematopoiesis, inflammation, and immunity.[37]

"Stop" signals usually are delivered and integrated by the products of tumor suppressor genes, which derive their name largely from the observation that their inactivation facilitates tumor formation. Tumor suppressor genes balance the activity of

VetBooks.ir

growth-promoting proto-oncogenes and tend to act in tandem with these in most biochemical pathways. Loss of function of one or more tumor suppressor genes occurs in virtually every cancer; inactivation of *TP53, RB1, PTEN,* or *CDKN2A* is seen in more than 50% of all tumors. Inactivation of these pathways seems to contribute to the pathogenesis of companion animal tumors, and their dysfunction also may be predictive for outcomes in some of them (see for example refs.[38–42]).

Resisting Cell Death

Apoptosis, or programmed cell death, is the imprinted outcome for every cell in multicellular organisms. Survival requires support from extrinsic (environmental) factors, in addition to a precise balance of cellular energetics and metabolism. Bone marrow–derived cells (BMDCs) normally undergo apoptosis when concentrations of survival factors (e.g., stem cell factor, IL-3, IL-7) or nutrients are limiting or when cellular bioenergetics is severely disrupted.[43]

Evasion of apoptosis is an essential acquired feature of all cancers, and it can result from loss of proapoptotic tumor suppressor genes, such as *TP53* or *PTEN,* or by gain of function of antiapoptotic genes, such as *BCL2.* Gain of function of *BCL2* in humans generally is associated with indolent, follicular lymphomas that carry t(14:18) translocations that juxtapose *BCL2* and the immunoglobulin heavy enhancer locus *(IGH).* These tumors rarely are seen in domestic animals, but evasion of apoptosis may be an important mechanism in the pathogenesis of other indolent tumors seen more commonly in these species.

A more recent concept in the cell death field is autophagy—a process that tumor cells have efficiently co-opted as a means to survive under adverse conditions.[44] As part of the autophagy program, intracellular vesicles called *autophagosomes* surround intracellular organelles and fuse with lysosomes. There, the organelles are broken down and then channeled to form new molecules that support the energy-producing machinery of the cell, allowing it to survive in the stressed, nutrient-limited environment that defines most cancers.

Tumor cells also must avoid death by anoikis, or loss of integral cell-to-cell or cell-to-matrix contacts.[36] Absent these physiologic death pathways, the body often reacts to the anatomic and physiologic disruptions caused by cancer cells by targeting these cells for destruction through inflammatory pathways, leading to necrosis. The process of necrosis might also be regulated genetically, providing another mechanism that favors survival of the whole (organism or tumor) over survival of the one. New findings that lend further nuance to the perception of how evasion (or incitation) of these cell death mechanisms contributes to neoplastic transformation and tumor progression continue to be published almost daily, and readers are encouraged not to limit their investigation to this summary, but rather to seek recent updates to the literature in this field.

Enabling Replicative Immortality

Immortalization is another essential feature of cancer. The genetic program limits the number of times a cell is able to replicate (the so-called Hayflick limit), and when this limit is reached, replicative senescence is induced. Induction of replicative senescence does not induce death; cells maintain energetic homeostasis and remain functional, but they undergo significant genetic changes characterized by telomere erosion. Cells that are able to replicate must maintain the integrity of telomeres, which are "caps" made of repetitive DNA sequence that protect chromosomes from destruction. Solid tumors acquire immortalization predominantly by activation of the telomerase enzyme system and the consequent maintenance of telomere integrity. In hematopoietic cells, telomerase activity seems to be retained longer than in other somatic cells, so this may facilitate immortalization in lymphoma and leukemia.[45] The role of immortalization and the importance of telomerase (both to maintain telomere length and to maintain other biochemical functions that are essential for cell survival) are well established; however, the role of replicative senescence has been questioned recently because improved technology has allowed researchers to circumvent this process in normal cells.[31] Mouse models complicate the story because of significant differences in telomere length between rodents and humans; therefore this is an area in which other models, such as companion animals, might provide clarity in the future.[46]

Inducing Angiogenesis

Folkman proposed a role for angiogenesis in cancer more than 30 years ago,[47,48] but this idea took time to gain traction in the scientific community. It is now apparent that angiogenesis not only is an important pathogenetic mechanism during tumor progression, but also a potential target for therapeutic intervention.

Angiogenesis is a complex, tightly regulated process that requires the coordinated action of a variety of growth factors and cell adhesion molecules in endothelial and stromal cells. So far, vascular endothelial growth factor (VEGF-A) and its receptors comprise the best-characterized signaling pathway in tumor angiogenesis.[49] VEGF binds several receptor tyrosine kinases, including VEGF receptor-1 (VEGFR-1 [also known as Flt-1]) and VEGFR-2 (KDR or Flk-1). Genetic polymorphisms of *VEGF* or of *FLT1* or *KDR* genes are associated with increased angiogenesis, and mutations of *KDR* are reported in human vascular tumors.[50,51] VEGF expression also is upregulated by hypoxia and inflammation. The transcription factor hypoxia-inducible factor-1α (HIF), which is part of a pathway that also includes regulation by the von Hippel-Lindau (VHL) tumor suppressor gene, is a major regulator of VEGF expression. Under conditions of normal oxygen tension, the VHL protein targets HIF for degradation; under low oxygen conditions, HIF increases as VHL-mediated degradation is reduced, allowing for upregulation of VEGF.

Other signaling molecules also contribute to angiogenesis, including platelet-derived growth factor-β (PDGF-β) and its receptor (PDGFR), and the angiopoietins Ang-1 and Ang-2 and their receptors Tie-1 and Tie-2. PDGF-β is required for recruitment of pericytes and maturation of new capillaries. Recent studies also document the importance of tumor-derived PDGF in the recruitment of stroma that produces VEGF and other angiogenic factors.

Tumors use multiple mechanisms to resist antiangiogenic therapy. For example, tumor cells cooperate with niche cells, such as endothelial cells, BMDCs, cancer-associated fibroblasts (CAFs), and pericytes, to create a microenvironment that abolishes the therapeutic benefits of VEGF blockade.[52] But overall, it is apparent that antiangiogenic therapies can benefit cancer patients by promoting vascular normalization, at least partially restoring the balance among blood vessel–forming and stromal cells, including pericytes, myeloid-derived cells, endothelial progenitors, and fibroblasts. This, in turn, can reverse the anatomic and hemodynamic dysfunction created by the tumor microenvironment,

VetBooks.ir

disabling some of the intrinsic advantages this dysfunction provides for cancer cells and allowing better penetration of drugs. (Chapter 15, Section C, provides additional information about antiangiogenic therapies.)

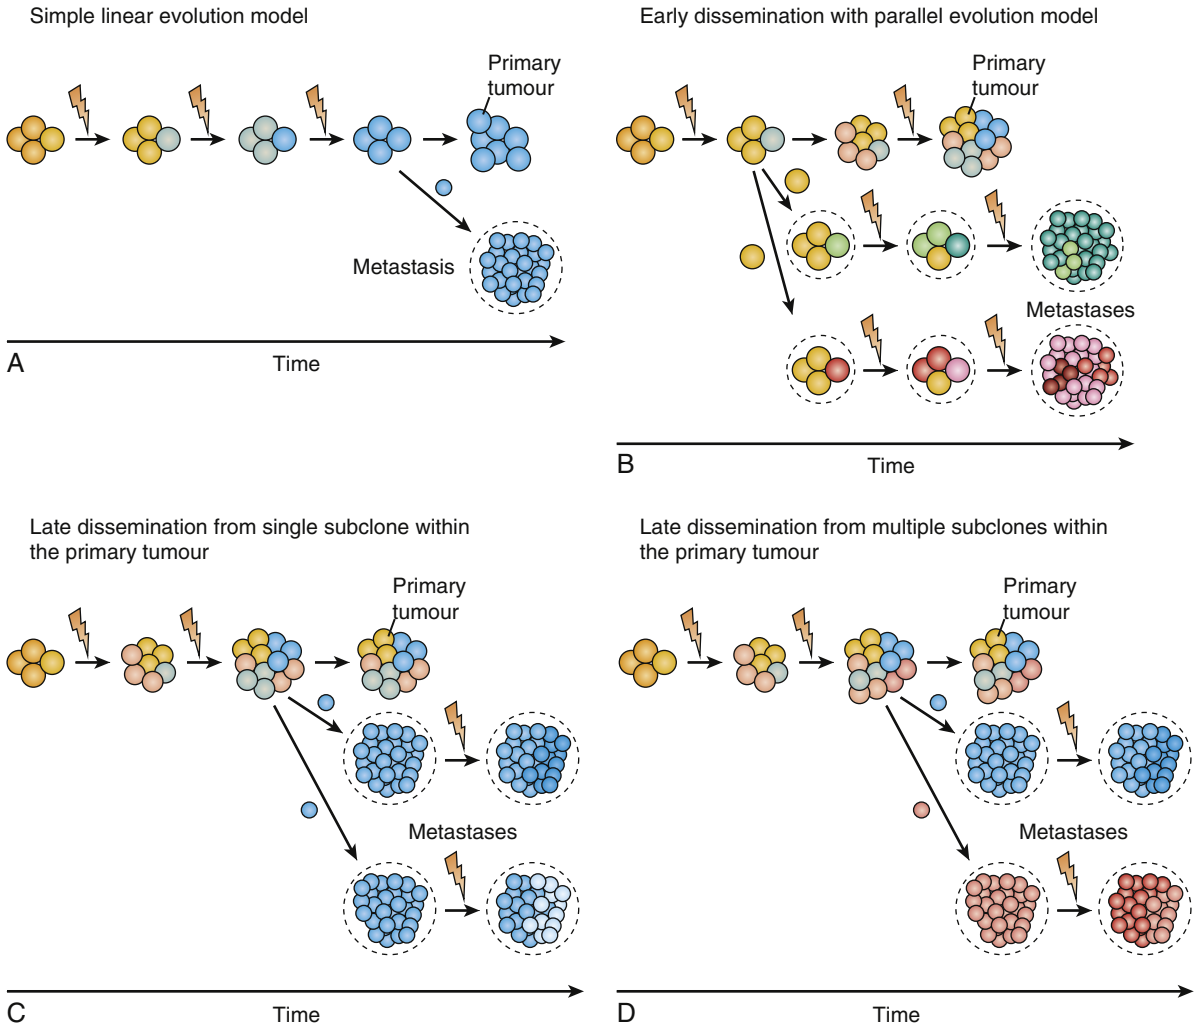
Angiogenesis takes center stage in malignant vascular tumors such as hemangiosarcoma (HSA), which occurs commonly in dogs.[53] Malformed, disorganized vascular structures composed of a mixture of malignant and nonmalignant cells are the defining feature of canine HSA and human angiosarcomas. Among other proangiogenic drivers, canine HSAs show elevated production of VEGF,[54–56] IL-8,[57] and sphingosine-1 phosphate (S1P) and its receptor, S1P1[58]. Furthermore, the magnitude of the angiogenic drive is associated with somatic mutations of angiopoietin, VEGF, and PI3K signaling pathways, in addition to the biologic behavior of the tumors.[42,59] This data suggests that canine HSA may provide a powerful, spontaneous model for unraveling critical events that control tumor angiogenesis.

Activating Invasion and Metastasis

The role of genetic events in invasion and metastasis is still incompletely understood. The classic model of metastasis proposed by Fidler suggests a stepwise acquisition of assets that enables cells to leave the primary tumor site, travel through the blood or lymph, invade stroma in favorable locations, and thus become reestablished at distant sites.[60] Other research suggests that most tumors have the ability to dislodge cells that travel to distant sites, and the ability of such cells to survive in capillary beds may be the most important step in the metastatic process.[61–65] A systematic assessment of metastasis reveals that it is a complicated process partly controlled by tumor heterogeneity and in which genetically distinct cells contribute to the dissemination of tumor cells from primary sites to metastatic sites (Fig. 1.4).[66]

BMDCs have intrinsic properties that allow them to travel throughout the body, traffic through all major organs, and home to areas of inflammation. Thus bone marrow–derived tumors are inherently metastatic. Nevertheless, hematopoietic tumors that are cytologically indistinguishable can have distinct and preferential tissue distribution. The events that make leukemic cells stay in the peripheral circulation are not yet fully understood, even though cells from corresponding lymphomas or myeloid sarcomas, with virtually identical molecular signatures, stay confined to lymphoid or visceral organs.

In epithelial neoplasms that account for most tumors in humans, the epithelial-to-mesenchymal transition (EMT) has received increasing attention for its role in metastasis. It remains unclear whether EMT is equally important in the sarcomas more commonly seen in domestic animals, in which the cells of origin seem to retain EMT capabilities to a greater extent. Increasing evidence indicates that interactions between cancer cells, including both the "initiating" population in the tumor (colloquially referred to as cancer stem cells, or CSCs), and the remainder (bulk) of tumor cells and other cells in the tumor microenvironment, including mesenchymal stem cells (MSCs), CAFs, inflammatory cells, and angiogenic cells, may be responsible for cancers' invasive behaviors and for their ability to survive in hostile environments at distant (metastatic) sites. One example is signaling through the CXCR4-CXCL12 axis, which contributes to the metastatic process through interactions between tumor cells and the tumor-permissive niche.[67] CXCR4 is upregulated recurrently in canine HSA and OSA,[68–70] where it is presumed to promote invasion and migration upon binding CXCL12. Thus dogs with HSA and OSA provide an opportunity to test therapeutic inhibition of the CXCR4-CXCL12 axis as a means to delay or prevent metastasis. (Chapter 2 presents additional information about basic mechanisms and treatments to manage cancer metastasis.)



Genomic Instability and Mutation

The concept of genomic instability is not new, but it was incorporated as an "enabling hallmark" into the updated Hanahan and Weinberg model.[31] Traditionally, stepwise clonal evolution provided a satisfactory explanation of tumor progression because it could be correlated with discrete pathologic changes. This is especially true for epithelial tumors, in which such progression can be appreciated in lesions that go through stages of hyperplasia, atypical hyperplasia (dysplasia), adenoma, carcinoma in situ, invasive carcinoma, and metastatic carcinoma. However, analysis of tumor genomes, even in early stages, usually shows aneuploidy (an abnormal DNA copy number), in addition to chaotic changes indicative of multiple numeric and structural DNA abnormalities. Similar abnormalities, first noticed by Boveri more than 100 years ago in studies of sea urchin cells, led him to formulate the "aneuploidy theory" of cancer.[71] Aneuploidy now is known to be especially evident in solid tumors; based on this, Loeb proposed the existence of the "mutator phenotype," in which cells are predisposed to undergo multiple mutations, some of which inevitably lead to cancer.[72] Some tenets of his hypothesis appear to be correct, although perhaps through different mechanisms than those envisioned by Loeb, as they might relate to increased activity of polymerases with low fidelity under conditions in which the rate of DNA damage (and consequently mutations) is higher than the expected background from normal DNA replication (e.g., in lung epithelial cells from heavy smokers). However, direct measurements of mutation rates of sporadic tumors are much lower than those predicted if a "mutator phenotype" was operative in these tumors.[73] Indeed, the minimum number of "critical" or driver mutations required for the clinical onset of cancer in solid tumors, based on sequencing of solid tumor genomes, probably is on the order of 15 to 25.[74] However, this may apply mainly to tumors with chaotic karyotypes, because the number of mutations identified in a cytogenetically stable leukemia was significantly smaller.[33]

Still, genetic instability is a hallmark of most tumors, and although it can be partly explained by increased errors in DNA replication and chromosomal segregation in cells that are rapidly dividing, other mechanisms are clearly operative, involving telomeres and telomerase.[73,75–79] Although many of these changes are not "recurrent" and appear to be random products of instability, some may in fact contribute to a proliferative crisis.[80] This is consistent with Tomasetti and Vogelstein's observation that initiation events for many tumors occur early in life, during highly proliferative stages of tissue growth and remodeling, but they become evident later in life when one or a few critical mutations allow the transformed cell to reach this crisis stage.

Tumor-Promoting Inflammation

The role of inflammation in cancer has received considerable attention in the past 20 years. Although our understanding of this phenomenon remains incomplete, it clearly met the criteria for inclusion as an "enabling hallmark" in the updated Hanahan and Weinberg model.[31] The importance of inflammation was

• **Fig. 1.4** Models of metastasis evolution and implications of genetic heterogeneity. (A) The classic simple linear model, in which clones sequentially arise that dominate the primary tumor owing to survival and proliferative advantages. (B) The early dissemination and parallel evolution model, in which tumor cells begin to disseminate early in the primary tumor life span and continue to evolve somatically in parallel with the primary tumor during clinical dormancy until they acquire metastatic capacity and proliferate into a clinically relevant lesion. (C) The late dissemination model, in which tumors evolve over time until a late-arising subclone is able to seed multiple metastases successfully. (D) Late dissemination from multiple metastatically competent subclones within the primary tumor. Metastases seeded by this mechanism share all the somatic events acquired by the tumor preceding the divergence of the different metastatically competent primary tumor subclones. The blizzard symbol indicates somatic genetic alterations. (Reproduced with permission from Hunter KW, Amin R, Deasy S, et al. Genetic insights into the morass of metastatic heterogeneity. *Nat Rev Cancer*. 2018 April;18(4):211-223. https://doi.org/10.1038/nrc.2017.126. Fig. 1.1.)

inferred from the earliest microscopic studies of cancer, but it was a seminal paper by Dvorak in 1986, in which he described tumors as "wounds that never heal,"[81] that provided synthesis for the recurrent observation that tumors often were infiltrated by inflammatory cells of the innate immune system (granulocytes, histiocytes, and macrophages) and the adaptive immune system (lymphocytes). Mechanistic distinctions between inflammation that favors tumor growth and inflammation that retards growth or eliminates the tumor remain to be defined[82–84]; however, it can be concluded confidently that inflammation contributes to tumor growth and survival by supplying factors that sustain proliferation; factors that limit cell death; proangiogenic factors; extracellular matrix-modifying enzymes that facilitate angiogenesis, invasion, and metastasis; and other signals that lead to activation of EMT and other hallmark-facilitating programs.[31] Inflammatory cells also release reactive oxygen species that are actively mutagenic for nearby cancer cells, accelerating their genetic evolution toward states of heightened malignancy.[85]

Deregulating Cellular Energetics

In the early years of the 20th century, Otto Warburg observed that cancer cells preferentially used glycolytic (anaerobic) rather than oxidative (aerobic) pathways to generate, energy even under conditions of normal or high oxygen. This metabolic peculiarity of cancer cells, called the *Warburg effect*, seems to be driven by

VetBooks.ir

activated oncogenes and/or by loss of tumor suppressor genes, providing cancer cells with selective growth and survival advantages by conferring the hallmark capabilities of cell proliferation, avoidance of cytostatic controls, and attenuation of apoptosis. The reliance of cancer cells on glycolysis can be further accentuated under hypoxic conditions. In fact, Warburg-like metabolism seems to be present in rapidly dividing embryonic tissues, suggesting a role in supporting large-scale biosynthetic programs that are required for active cell proliferation.

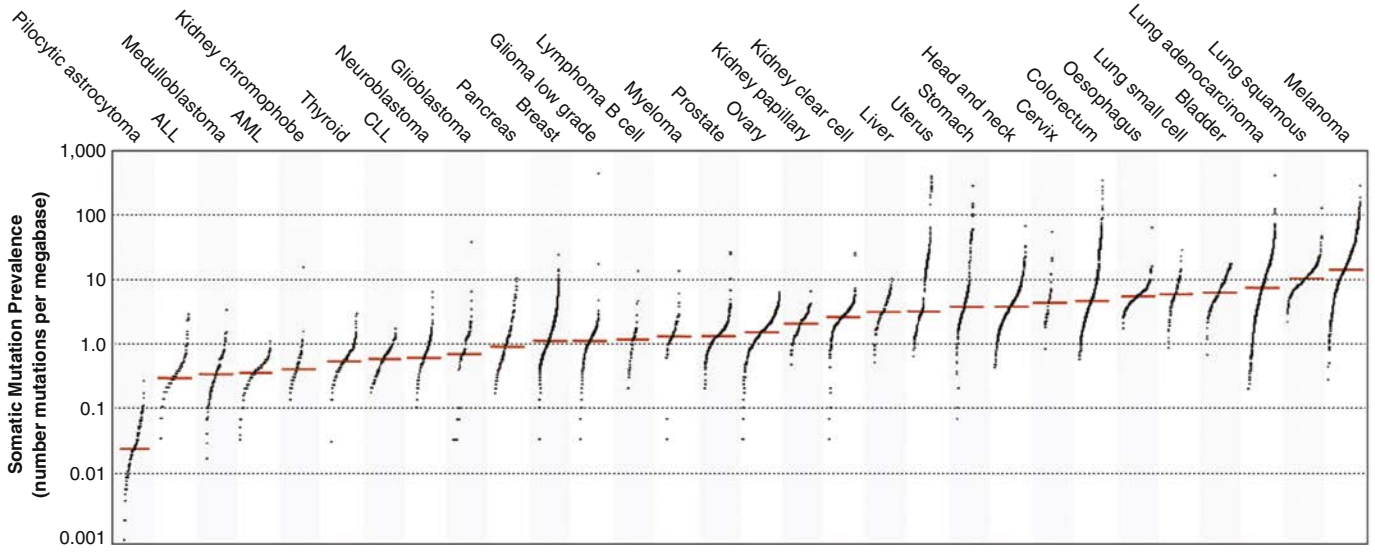
Cancer cells do not seem to enable the Warburg effect universally. Rather, much like other cells with high energetic demands, they seem to sort out into lactate-secreting (Warburg) and lactate-consuming cells, providing an efficient, albeit homeostatically disturbed, energy environment. Furthermore, it seems that oxygenation is not static in tumors, but instead fluctuates temporally and regionally as a result of the instability and chaotic organization of tumor-associated neovasculature. Altered energy metabolism is proving to be as widespread in cancer cells as in many of the other cancer-associated traits that have been accepted as hallmarks of cancer. This realization raises the question of whether deregulating cellular energy metabolism is a core hallmark capability of cancer cells that is as fundamental as the six well-established core hallmarks. In fact, the redirection of energy metabolism is largely orchestrated by proteins that are involved in one way or another in programming the core hallmarks of cancer. When viewed in this way, aerobic glycolysis is simply another phenotype that is programmed by proliferation-inducing oncogenes, and the designation of reprogrammed energy metabolism as an emerging hallmark seems most appropriate.

It is worth noting that this characteristic of tumor cells provides at least one important diagnostic advantage. Upregulation of the major glucose transporter, GLUT-1, is seen in virtually all tumors, making the cells efficient glucose scavengers. This can be exploited to image tumor cells precisely and noninvasively by visualizing glucose uptake using positron emission tomography (PET) with a radiolabeled analog of glucose (^{18}F-fluorodeoxyglucose, or ^{18}F-FDG) as a reporter. The combination of PET with computed tomography (PET-CT) now is one of the most robust means to evaluate composition of tumors, minimal residual disease, and tumor-specific objective responses in patients receiving conventional and experimental therapies, and it increasingly is being applied to improve the diagnosis and staging of dogs with cancer.[86–88]

In addition, evidence is accumulating that deregulated cellular energetics contribute to tumor progression through immunomodulation. Our group has proposed a model in which cancer cells' self-renewal is causally related to reprogramming of fatty acid metabolism and immune signaling[89]; this supports the notion that fate decisions of tumor-initiating or stem cells rely on cellular metabolism and immunomodulation in the tumor microenvironment.

Avoiding Immune Destruction

Burnet and Thomas proposed the concept that the immune system can recognize and destroy incipient tumors (cancer immunosurveillance) in the 1950s.[90] Their hypothesis was far ahead of its time, and technologic obstacles impeded proof, so the theory fell into disfavor. In recent years the immunosurveillance theory has gained traction anew because data strongly suggest that the immune system helps to keep tumors at bay, and thus tumors must evade the immune response to survive. In its recent incarnation, the theory has been refined to incorporate the concept of immunoediting, in which the immune system destroys strongly antigenic tumor cells, providing weakly antigenic cells a survival advantage.[90] Experimental evidence for this concept includes differences between tumors grown in immunocompetent mice (only weakly antigenic tumors survive) and immunocompromised mice (no selection against strongly antigenic tumors is observed), but evidence only now is emerging that will allow us to understand the importance of immunoediting in spontaneous cancers.



That the tumor microenvironment forms and maintains an immunosuppressive barrier provides more compelling evidence for the role of the immune system in limiting tumor growth and metastasis.[91,92] This immunosuppressive barrier includes cellular factors, such as regulatory T cells (T_{regs}), myeloid-derived suppressor cells (MDSCs), and MSCs. Soluble factors, including transforming growth factor-β (TGF-β) and immunoglobulins, also contribute to the immunosuppressive barrier directly and indirectly.[93] This is an active area of basic and clinical research in which companion animal oncology has been at the forefront; for example, through the generation and approval of the first active gene-based therapeutic cancer vaccine for canine melanoma.[94]

A transformational advance in cancer therapy has been the ability to block immune checkpoints that are engaged by a number of tumors—particularly those that have unstable genomes and tend to generate greater numbers of neoantigens (Fig. 1.5).[95,96] Antibodies against cytotoxic T lymphocyte-associated protein 4 (CTLA-4), and against programmed cell death protein 1 (PD-1) and its corresponding ligand, programmed death-ligand 1 (PD-L1), aim to reactivate tumor-specific T cells and cause a robust antitumor immune response.[97,98] The remarkable responses observed in patients receiving immune checkpoint blockade as adjunctive or first-line therapy have made this class of compounds part of the standard of care for several types of lung cancer, malignant melanoma, renal cell carcinoma, Hodgkin lymphoma, head and neck squamous cell carcinoma, urothelial carcinoma, certain colon cancers, and certain liver cancers.

Checkpoint inhibitors currently are being tested in canine clinical trials[99]; expression of canine PD-L1 has been detected in a number of canine tumor types, including mastocytoma, melanoma, renal cell carcinoma, and several others.[100] Canine CTLA-4 has been identified and cloned,[101] and although canine anti–CTLA-4 has not yet been developed, an agonistic recombinant canine CTLA-4 molecule has been successfully used to induce tolerance in a transplant model.[102] (Chapter 14 presents additional information about cancer immunotherapy.)

Adaptive Evolution and the Tumor Microenvironment

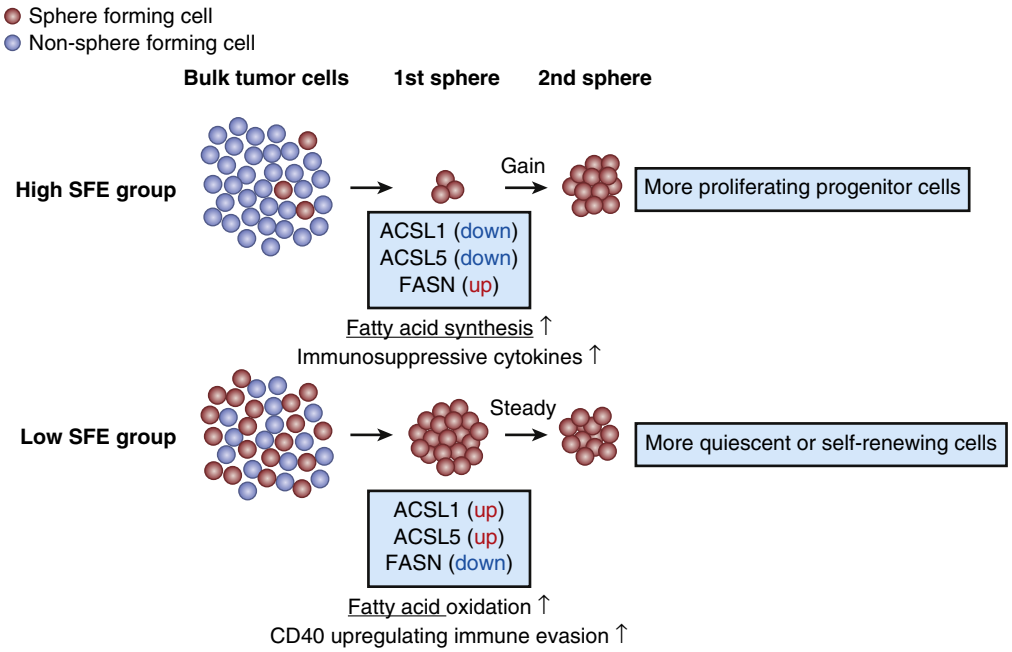
A bidirectional flow of information occurs between the tumor and the microenvironment, with each helping to mold the other into functional growing tissue that can evade or withstand attack by the host.[103] The previous reference to a "selective growth advantage" that is reminiscent of darwinian selection is not accidental. The clonal evolution theory[104] addresses the significance of sequential genetic changes providing growth and survival advantages; however, to this must be added the fact that, in addition to these self-sufficient events that influence growth and survival, tumor cells must also evade "predators" (e.g., inflammation and the immune system).[90,105] In essence, the interaction of the tumor

• **Fig. 1.5** The prevalence of somatic mutations across human cancer types. Signatures of mutational processes in human cancer. *Nature*. 2013 Aug 22;500(7463):415-421. https://doi.org/10.1038/nature12477. Fig. 1.1.)

with its microenvironment and ultimately with the host is in fact subject to darwinian laws of evolution, albeit in an accelerated time scale.[75] This is evident in the ability of tumors to modulate stromal cells to support their own growth by providing a suitable matrix and an abundance of nutrients while keeping antitumor responses at bay.

As is true for other selective environments, tumors that outgrow the capability of their immediate surroundings to support their growth must alter that environment to suit their needs or identify other favorable locations where they can become established. The tumor microenvironment recently was shown to exert a significant effect on the complement of genes expressed by incipient tumor cells.[106] Incipient sarcoma cells, in turn, can reside as quiescent inhabitants of distant microenvironments, themselves modulating growth, morphology, and behavior of microenvironment constituents in the process of metastatic dissemination.[53,57]

Epigenetic Events



Events leading to cancer need not necessarily be caused by mutational events, but instead can be caused by epigenetic changes, which can alter the phenotype without changing the genotype. Two well-characterized epigenetic mechanisms regulate gene expression; methylation of 5'—C—phosphate—G—3' (CpG) residues in promoter regions and histone deacetylation both result in gene silencing by interfering with the transcriptional machinery. The effects of global changes in methylation or deacetylation (e.g., by inactivation of DNA methylases or histone deacetylases) remain incompletely understood, but silencing of specific genes by methylation is implicated in numerous cancers of humans and animals.[107–110] One important observation is that most (or all) genes subject to silencing by methylation in specific cancers are inactivated by mutation or deletion in other cancers, and it is apparent that developmental programs that control chromatin structure play a role in defining susceptibility to mutations[111] and thus presumably cancer risk. This area of research is likely to create the next giant leap in our understanding of cancer etiology.

As is true for mutations, gene regulation by epigenetic methylation can occur sporadically or it can be heritable. Silencing of some tumor suppressor genes in sporadic cancers occurs more frequently by epigenetic methylation than by mutation or deletion. These different mechanisms of gene silencing are not equivalent, because they each result in specific tumor phenotypes. For example, data from our laboratories indicates that loss of canine chromosome 11, with resultant deletion of the *INK4* tumor suppressor locus containing the *CDKN2A, CDKN2B,* and *ARF* genes, and methylation of *CDKN2A* are each associated with morphologically distinct types of T-cell lymphoma that have a different clinical presentation and prognosis.[39,40]

Genomic imprinting presents a unique example in which heritable epigenetic changes influence cancer predisposition. Genomic imprinting refers to a pattern of gene expression that is determined by the parental origin of the gene; in other words, unlike most genes in which both parental alleles are expressed, only one allele (specifically derived from the mother or from the father, depending on the gene) of an imprinted gene is expressed and the other one is permanently repressed. Epigenetic changes in Wilms tumor and in heritable colon cancer (among others) alter the expression of the imprinted allele, leading to loss of imprinting that causes overexpression of the insulin growth factor-2 *(IGF2)* gene.[107,112]

Cancer Stem Cells

The paradoxical nature of some cancers gave rise to the notion of a "cancer progenitor" or a CSC, as far back as the 1960s. The best illustration of this concept is chronic myelogenous leukemia (CML), in which the bulk of the tumor consists of terminally differentiated neutrophils incapable of recreating the malignancy.

• **Fig. 1.6** A proposed model of cancer cells showing their distinct capacity to form and maintain spheres. (Reproduced with permission from Kim JH, Frantz AM, Sarver AL, et al. Modulation of fatty acid metabolism and immune suppression are features of in vitro tumor sphere formation in ontogenetically distinct dog cancers. *SFE*, sphere-forming efficiency. *Vet Comp Oncol*. 2018 March;16(1):E176-E184. https://doi.org/10.1111/vco.12368. Fig. 1.5.)

However, it was apparent that multipotent stem cells were present in this tumor population. In 1994 Dick's group proved conclusively that another type of leukemia, acute myelogenous leukemia (AML), was a hierarchically organized disease in which a small number of cells undetectable by conventional methods could be isolated from patients and made to recapitulate the full spectrum of the disease in an animal model.[113] This gave rise to the CSC, or "tumor-initiating cell," hypothesis, which is based on the concept that tumors are hierarchically organized into a subpopulation of cells that retain or acquire the capacity for self-renewal and are capable and responsible for initiating and maintaining the tumor.[114] Another subpopulation of cells that consists of the CSC progeny undergo partial to complete differentiation and lose the capability to support the tumor, albeit still contributing to the morbidity of cancer. This hypothesis fundamentally altered the way cancer is understood, but it also gave rise to a debate about how widely this model applies. In the competing hypothesis, commonly referred to as the stochastic model, all the cells in a tumor have an equal capacity for self-renewal. According to this model, the process of cancer is driven entirely (or almost entirely) by environmental selection of favorable mutations; this model necessarily would predict that cancer is an inevitable outcome for multicellular organisms, and few, if any, long-lived animals would reach reproductive age.[115] Thus, by necessity, this model must invoke the existence of protective mechanisms independent of the cancer risk (e.g., efficient DNA repair mechanisms and immune surveillance).

The two models may represent a continuum dependent on the extent to which CSCs undergo asymmetric versus symmetric divisions. Under conditions in which CSC divisions are primarily asymmetric, few CSCs would be apparent and the population would achieve a hierarchical organization; under conditions in which CSCs underwent symmetric divisions, virtually every cell in the tumor would have CSC-like properties and the organization would be more consistent with a stochastic model. The prevailing opinion is that CSCs exist and are characterized both by peculiar phenotypes and defined sets of mutations of a small number of genes.[116–118] Other mutations then endow their progeny with a limited or an extensive capacity to undergo programmed differentiation, thus resulting in the distinct clinical phenotypes that characterize acute and chronic leukemias or high-grade and low-grade solid tumors.

In companion animals, progenitor cells with putative CSC or tumor-propagating properties have been identified in HSA, OSA, brain tumors, and possibly lymphoma.[119–122] These cells appear to rely on metabolic and immune reprogramming to regulate their self-renewal and differentiation programs (Fig. 1.6).[89]

As is true for the rest of cancer genetics, information in this field is rapidly evolving. Large-scale bioinformatics and conceptual advances are integrating the CSC theory into the mainstream of cancer research and biology, and also into the design for new diagnostic and therapeutic strategies. For example, it appears that much like hematopoietic stem cells, the CSC niche favors oligoclonality and some genetic diversity. Thus clonal competition can ensue, giving rise to heterogeneous tumors and maintaining a reservoir of cells that can reestablish the tumor when a therapy effectively kills the predominant CSC clone and its progeny. Similarly, clonal competition can facilitate distant spread by selection of cells with different capabilities. An extreme example may be the potential for a single tumor cell (or a small population of oligoclonal cells in a tumor) to give rise to histologically distinct tumors—an event that has been observed in xenotransplanted sarcomas.

Recent Advances in Canine Cancer Genetics

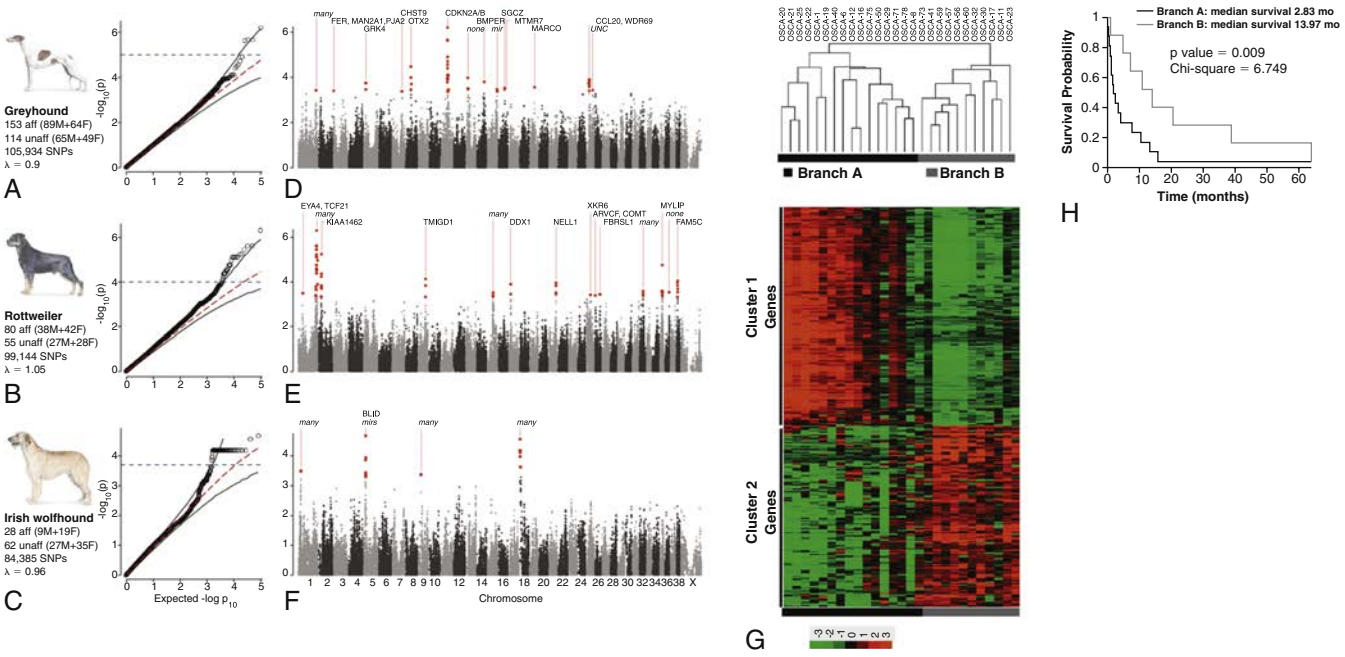
An important conceptual advance in canine cancer genetics was the identification of conserved (homologous) aberrations in spontaneous dog tumors that had been previously characterized in

VetBooks.ir

human tumors. The prototypical example was a structural aberration resulting from a balanced chromosomal translocation that creates a fusion gene composed of most of the *BCR* gene (located on chromosome 22 in humans and on chromosome 26 in dogs) and a truncated form of the *ABL* gene (coincidentally located on chromosome 9 in both humans and dogs) in CML.[123] Both translocations give rise to a derivative chromosome, the Philadelphia (Ph) chromosome in humans and the "Raleigh" chromosome in dogs. Certain numeric aberrations (changes in DNA copy number) are similarly conserved in both species in a variety of cancers, including lymphoma, soft tissue sarcomas, OSA, and brain tumors.[124–129]

The development of specific tumors from cells harboring such shared mutations is not surprising, but why would homologous, highly conserved pathologic rearrangements, deletions, or amplifications occur in cells from distinct organisms? One possibility is selection for phenotype; in other words, the genetic change "freezes" development at a particular stage for that cell lineage and enhances growth and survival compared with normal cells in the niche. But it is also possible that these mutations are evolutionarily related on a mechanistic basis. For example, rearrangements of the immunoglobulin heavy chain locus and the *MYC* locus are thought to be due to recognition of *MYC* flanking sequences by the recombinase enzyme system.[123] No such mechanism is known to be operative for other defined sites, so these other mutational events could occur stochastically, with their recurrent characterization across multiple species being the result of the selective advantage provided by the acquired gene to a cell of a highly specific lineage under highly specific conditions. Another possibility is that they are related to the nuclear anatomy of the cell and specifically caused by proximity of chromosomal regions, cellular stress, inappropriate DNA repair (or, as mentioned previously, recombination), and DNA sequence and chromatin features, such as reuse breakpoints.[130] A third intriguing possibility is that cellular genomes are reverting to a conformation that was found in a common ancestor (thus the high affinity and specificity between the rearranged chromosomal segments lead to the same recurrent event in many patients) but lost during the process of chromosomal reorganization in evolution, or that these sites represent targets for gene deletions or duplications that have been repeatedly advantageous to species under conditions of natural selection and so have become embedded in their contemporary descendants.

In dogs and other domestic animals, the coexistence of genetic isolates in closed populations we call "breeds," along with animals of mixed breeding, lends itself to the study of how a relatively homogeneous background influences cancer in outbred populations. Dogs were the first species in which genetic background was shown to mold tumor genomes and tumor gene expression profiles, highlighting the utility of comparative approaches to understanding cancer genetics.[55,128,131] Over the past decade, technologic advances in next-generation sequencing and bioinformatics have improved our understanding of these relationships; GWASs have identified disease-specific risk alleles in histiocytic sarcoma,[132] squamous cell carcinoma of the digit,[28] OSA,[14] canine mammary tumors,[27] B-cell lymphomas and HSA,[133,134] mast cell tumors,[135] and brain tumors[136] in susceptible dog breeds. In the case of OSA, the GWAS revealed 33 unique risk loci in three breeds, and although none obviously overlapped, the existence of shared risk alleles might have been masked because they reside within fixed regions in some breeds (Fig. 1.7).[14] Convergent data from the GWAS suggested a role for *CDKN2* and the associated cycle regulatory processes in OSA risk; the significance of these pathways was independently confirmed as a key indicator of the prognosis in canine OSA using gene expression studies.[41,137,138] In the case of HSA and B-cell lymphomas, two histologically different tumors that occur commonly in golden retrievers, the GWAS identified two shared risk loci on chromosome 5.[133] This observation suggests that HSAs and B-cell lymphomas might originate from a common lineage of hematopoietic progenitor cells.[119,139] Such meticulous work has improved our understanding of how distinct heritable traits segregate with cancer phenotypes in dogs, although it remains to be seen if these traits will be shared between closely related breeds or whether they contribute to risk independently among different breeds.[127]



Next-generation sequencing of tumor and normal exomes has been completed for canine lymphoma (Fig. 1.8), HSA, and OSA.[41,59,140–142] In the case of B-cell lymphomas, 64 exomes were sequenced from golden retrievers and cocker spaniels. The tumors had an average of 500 somatic mutations each, of which about 20 were nonsilent coding mutations. The most common recurrently mutated genes were *TRAF3, FBXW7,* and *POT1,* which regulate signaling pathways of telomerase and autoimmunity. *FBXW7* mutations, in particular, were found in 15 of 54 (28%) golden retriever samples and in 1 in 10 (10%) cocker spaniel samples. The two most common, nonsilent mutations in *FBXW7* were mutually exclusive and created arginine to leucine amino acid substitution at positions 470 and 484, respectively. These residues are also hotspots of *FBXW7* mutation in human cancers.

The exomes in T-cell lymphomas were more heterogeneous; still, 7 of 16 peripheral T-cell lymphomas from boxers harbored mutations in the *PTEN*-mTOR pathways. The data, however, is not sufficient to distinguish whether this is due to a genetic propensity for mutations of *PTEN* and other functionally related genes in boxers, or to an association in which such mutations favor selection for ontogenetically related tumors. Because genes in the *PTEN*-mTOR axis are also common targets of mutation in human cancers, studies of canine T-cell lymphoma might help to unravel their contribution to the origin and progression of cancer in a vulnerable breed and provide a discovery platform to test the safety and efficacy of drugs that target these pathways.

In the case of HSA, independent reports by two groups documented recurrent somatic mutations of *TP53* and *PIK3CA* in more than 50% of tumors within a background of many "private" mutations (i.e., unique to individual tumors). And in the case of OSA, two independent reports identified somatic mutations of *TP53* as the most common genetic abnormality in this tumor. Exome sequencing also confirmed that chaotic OSA and HSA genomes had extensive, albeit minimally overlapping, copy number aberrations, which were far in excess of those found in lymphomas[124,125,128]; predictably, translocations resulting in de novo fusion genes also were more frequent in HSA and OSA than they were in lymphoma.[42]

Most of the coding mutations identified by exome sequencing were confirmed in RNAseq data sets from the same cases, allowing us to extend the observations to additional dogs and other breeds and then to conclude that common somatic mutations in lymphoma, HSA, and OSA are not associated with breed, age, sex, or hormonal status (intact or neutered).

Genomic studies, including GWAS, comparative genomic hybridization, and next-generation sequencing, are expected to proceed in cats with the advent of the feline genome sequence.[143,144]

• **Fig. 1.7** Mixed model genome-wide association study corrects for population structure and identifies 33 osteosarcoma-associated loci, explaining a large fraction of phenotype variance. In each breed the QQ plots show no evidence of stratification relative to the expected distribution, identifying nominal significance at –log10p of 3.5 and the 95% empirically determined confidence intervals *(dashed gray line)* at –log10p of (A) 5 in greyhounds, (B) 4 in Rottweilers, and (C) 3.7 in Irish wolfhounds (IWHs). In IWHs a plateau of SNPs at P = 6.6 × 10 to 5 corresponds to a 1.65 Mb haplotype on chromosome 18, peaking at the gene *GRB10*. (D) In greyhounds 14 loci have p > 0.0005, with 1 locus, on chromosome 11, exceeding 95% confidence intervals *(dashed lines).* (E) In Rottweilers 15 and 6 loci are identified, (F) whereas only 4 and 2 loci are identified in IWHs. (G) Unsupervised hierarchical clustering defines two osteosarcoma subtypes (Branch A and Branch B), characterized by two reciprocal gene clusters (Gene Cluster 1 and Gene Cluster 2). Heat map showing 282 differentially expressed transcripts (p ≤ 0.0068, mean average fold-change > 3). Heat map colors represent median-centered fold change expression after log2 transformation (a quantitative representation of the colors is provided in the scale at the bottom). Upregulated genes are shown in red, and down regulated genes are shown in green. (H) Kaplan-Meier survival (KM) and log rank analysis of 21 dogs in the cohort with known survival outcomes show two clinically significant groups in canine osteosarcoma. The toe bar defines groups for the KM analysis. The median survival time for dogs in Branch A was ~2.8 months, and the median survival time for dogs in Branch B was ~14 months. Conclusion

The genetic basis of cancer is now beyond question. It is estimated that at least five to seven mutational events are required for overt malignant transformation. These events can occur through multiple mechanisms, including heritable factors, environmental elements, and/or stochastic DNA damage during cell replication. Genomic instability seems to be necessary to establish a pathogenic molecular program of convergent regulatory signaling pathways that cause clinical disease. Ultimately, a subpopulation endowed with metastatic properties that is drug resistant leads to death of the cancer patient. The rate and the flow of information are such that we predict the coming decade will see additional transformational changes in our perception of how genes interact with the macroenvironment at the organism level and with the microenvironment in tumors. Although it is possible that cancer in higher vertebrates is an inevitable consequence of evolution,[145] improvements in our understanding of fundamental mechanisms that account for malignant transformation and tumor progression will allow the design of strategies to improve quality of life and outcomes for cancer patients.

SECTION B: CHEMICAL, PHYSICAL, AND HORMONAL FACTORS

CAROLYN J. HENRY AND BRIAN K. FLESNER

In 1978 the US Congress ordered the development of the first Report on Carcinogens (RoC), a document designed to educate the public and health professionals on potential cancer hazards. The

• **Fig. 1.8** Next generation sequencing of tumor and normal exomes for canine lymphoma in three breeds. (A) Sample numbers and average mutations per breed and immunophenotype. (B) Overlap of significantly mutated genes between lymphoma types. *Left panel,* The two B-cell lymphoma-predisposed breeds share some of their most significantly mutated genes. *Center panel,* The two T-cell lymphoma-predisposed breeds do not share any top significantly mutated genes. *Right panel,* Some overlap in significantly mutated genes can be seen between all the B-cell lymphomas and all the T-cell lymphomas. Exome sequencing of lymphomas from three dog breeds reveals somatic mutation patterns reflecting genetic background. *Genome Res*. 2015 Nov;25(11):1634-1645. https://doi.org/10.1101/gr.194449.115. Figs. 1.1A and 1.2.)

document is now required by law to be released every 2 years by the Secretary of the Department of Health and Human Services. The fourteenth edition of the RoC, released in 2016, lists 248 potential carcinogens, of which 61 are categorized as known to be human carcinogens, and 186 are categorized as reasonably anticipated to be human carcinogens.[146,147] Five of the seven additional carcinogens were viruses: Epstein-Barr virus, human immunodeficiency virus (HIV) type 1, human T-cell lymphotrophic virus type 1, Kaposi sarcoma–associated herpesvirus, and Merkel cell polyomavirus. Although no such report exists for companion animals, one could reasonably assume that there would be considerable overlap between such a list and the potential carcinogens found in the RoC. Although the list of carcinogens reportedly associated with cancer in companion animals is less extensive, this section addresses chemical, physical, and hormonal factors that have been linked to carcinogenesis in pet animals. Viral carcinogenesis is addressed in a separate section (see Section C later in the chapter). Additionally, more in-depth information regarding the epidemiology of cancer, and the strength of evidence for these factors, is addressed in Chapter 4 (see Tables 4.4 and 4.5, specifically).

Chemical Factors

Environmental Tobacco Smoke

In people tobacco use continues to be one of the leading causes of mortality worldwide; an estimated 1 billion deaths could be possible in the next century.[148] Cancers currently recognized by the US Surgeon General as being caused by smoking include lung, esophagus, bladder, pancreas, and other cancers.[149] Of course, animals are not likely to be primary smokers, but they do share our environment and can commonly be exposed to secondhand smoke. Despite ample evidence that secondhand smoke increases the risk of lung cancer in people,[150,151] the data for this effect in companion animals is less compelling. One case-control study involving dogs with lung cancer from two veterinary hospitals showed only a weak relationship between living with a smoker and the development of lung cancer, and the risk did not increase with an increased smoke exposure index.[152] Additionally, a more recent case-control study found no association between secondhand smoke and primary lung cancer in dogs.[153] However, an association between environmental tobacco smoke (ETS) and nasal cancer in dogs, especially in dolichocephalic breeds, was supported in a case-control study that ran from 1986 to 1990.[154]

Based on human data suggesting that smoking may increase the risk of non–Hodgkin lymphoma,[155,156] Bertone et al examined the relationship between ETS exposure and the development of feline lymphoma.[157] In a case-control study of 80 cats with malignant lymphoma and 114 control cats with renal disease that presented between 1993 and 2000, the relative risk of lymphoma for cats with any household ETS exposure was 2.4. As reported for male smokers,[158] the risk of lymphoma increased with increases in either duration or quantity of exposure. More recently, an Italian study of waste management and cancer in companion animals demonstrated that ETS exposure significantly increased the risk of the development of lymphoma in dogs.[159]

Hypothesizing that inhalation and ingestion of carcinogens in ETS during grooming might predispose cats in smoking households to the development of oral squamous cell carcinoma (SCC), Bertone et al examined ETS and other environmental and lifestyle risk factors in cats with SCC.[160] Exposure to ETS was associated with a twofold, but statistically insignificant, increased risk of oral SCC.[160] In a separate report the investigators found positive associations between ETS and p53 overexpression; however, the findings again were not statistically significant.[161] Loss of wild type p53 and/or gain of mutant p53 function have been shown to be critical to carcinogenesis from tobacco exposure in human lung cancer.[162] The aforementioned suggestion that both ETS and p53 mutations might play a role in the etiology of feline oral SCC is intriguing. The study of other genetic mutations[163] and epigenetic aberrations[164] in tumor-bearing animals with ETS exposure is warranted.

VetBooks.ir

Pesticides, Herbicides, and Insecticides

In 1991, investigators at the National Cancer Institute (NCI) completed a case-control study to examine the relationship between the exposure of dogs to the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D), and the development of lymphoma.[165] Dogs with a histologically confirmed diagnosis of lymphoma during a 4-year period were identified through the computerized medical record information from three veterinary teaching hospitals. Each case animal was age matched with two control animals. The first control group consisted of dogs diagnosed with tumors other than lymphoma during the same time period, and the second control group was a nontumor group, selected from all other dogs presenting for conditions deemed unrelated to chemical exposure. Owners were questioned about household use of and potential pet exposure to commercial lawn care and owner-applied herbicides. A positive association was found between exposure to owner-applied 2,4-D or the use of commercial lawn care services and the development of lymphoma. The risk of lymphoma doubled when owners applied 2,4-D liquid or granules to the lawn four or more times a year. After these findings were reported, an independent review panel was convened to assess the validity of the NCI study.[166] The panel voiced concerns about the original study design, data analysis, and interpretation, concluding that a relationship between 2,4-D exposure and the development of canine lymphoma could not be established based on the reported data. In response, the original investigators reanalyzed their data, addressing many of the concerns raised by the scientific review panel.[167] A more stringent definition of exposure to 2,4-D was used, including only cases in which the owner applied 2,4-D as the sole herbicide and did not use other lawn chemicals or lawn care services. The second report did not show a statistically significant association between exposure to 2,4-D and the development of lymphoma[167]; however, it did indicate a dose-response relationship between disease incidence and the number of yearly 2,4-D applications by dog owners. In a subsequent study conducted by researchers at Michigan State University, the original 1991 data again were reanalyzed, using the more stringent definition of exposure, and a dose-response analysis was completed. The study, which was funded by a chemical industry task force, showed no dose-response relationship between the number of 2,4-D applications and the occurrence of canine lymphoma.[168] Although increased urinary excretion of 2,4-D has been demonstrated in dogs exposed to herbicide-treated lawns, a direct link between such exposure and development of lymphoma has not been shown.[169]

A 2011 case-control study conducted in Italy was designed to assess the effect of residential exposure to environmental pollutants on the risk of developing lymphoma.[170] The investigators were unable to demonstrate an association between exposure to pesticides (which by their definition included herbicides) and the development of lymphoma. However, they did find that living in industrial areas and owner use of chemicals such as paints and solvents were significantly and independently associated with lymphoma. A larger case-control study with more 260 cases of canine lymphoma and 240 and 230 cases of benign tumors and chronic diseases, respectively, was performed at a single veterinary teaching hospital.[171] In this questionnaire-based study, cases of canine lymphoma were more likely to come from a household with professionally applied pesticides (OR = 1.7) or self-applied insect growth regulators (OR = 2.7). Flea and tick control products were not associated with the risk of lymphoma.[171]

Canine transitional cell carcinoma (TCC) of the urinary bladder is another malignancy that has been linked to environmental carcinogens, including insecticides and herbicides. To further elucidate a mechanism for the carcinogenesis of canine urothelium exposed to lawn chemicals, 2,4-D and other herbicides were measured in the urine of dogs within a 50 mile radius of West Lafayette, Indiana.[172] Interestingly, chemicals were found in the urine of dogs from both treated and untreated yards. However, dogs in this study were not followed for the development of TCC.[172] In a case-control study of 59 dogs with TCC and 71 age-matched and breed size–matched control dogs with other neoplasms or chronic disease, investigators compared the two populations to assess the effect of obesity, exposure to sidestream cigarette smoke and chemicals, and the use of topical insecticides, on the risk of TCC.[173] They reported an increased risk of TCC in dogs treated with topical insecticides, with an enhancement of this risk in overweight or obese dogs. Scottish terriers, already at an increased risk of developing urothelial cancer because of a breed predisposition,[174] have been more extensively studied in regard to chemical exposure. Scottish terriers exposed to lawn and garden care products containing phenoxy herbicides, including 2,4-D, 4-chloro-2-methylphenoxy acetic acid (MCPA), and 2-(4-chloro-2-methylphenoxyl) propionic acid (MCPP), have an increased risk of developing TCC.[175] Newer topical spot-on flea and tick products have been evaluated in Scottish terrier populations and were not associated with an increased risk of TCC.[176]

In the aforementioned study of risk factors for oral SCC in cats, a significantly increased risk of oral SCC was seen in cats that wore flea collars.[160]Although links between phenoxy herbicides and the development of cancers such as SCC, lymphoma and TCC have been inconsistent, attempts to limit exposure of pets to these products is advised.

Cyclophosphamide

The cytotoxic alkylating agent cyclophosphamide (CYC) has been implicated in the development of urinary bladder cancer in people and dogs.[177–179] A known potential side effect of CYC therapy is sterile hemorrhagic cystitis, which develops from the generation of its metabolite, acrolein.[180] Acrolein causes a pyroptotic reaction in the urothelium, leading to ulceration; it also upregulates reactive oxygen species and nitric oxide production.[181] A recent review of CYC use for human rheumatic diseases listed several key conclusions. Daily oral CYC was associated with an increased risk of both hemorrhagic cystitis and bladder cancer, and patients who developed hemorrhagic cystitis had an increased risk of bladder cancer years later.[182] In dogs treated with metronomic chemotherapy,[183,184] the occurrence of hemorrhagic cystitis appears to be higher than in dogs receiving maximally tolerated dose CYC.[185,186] Although rare, bladder cancer development after CYC therapy has been reported in dogs.[187] Diligent monitoring of the urogenital tract seems warranted in patients receiving metronomic CYC.

Rural Versus Urban Environment

Several reports have identified differences in the cancer incidence between companion animals living in urban settings and those living in rural settings. The underlying cause for these differences is unclear. An increased incidence of some canine cancers, including lymphoma, tonsillar SCC, and nasal carcinoma,[154,170,173,188] has been reported in urban/industrial settings compared with rural settings. However, the coexistence of multiple environmental

VetBooks.ir

carcinogens in the same setting makes discerning the "smoking gun" a difficult task. Nonetheless, the study of animals as sentinels of environmental health hazards has been recommended and provides supportive evidence for carcinogenic risk assessment across species.[172,189–192] The results of a hospital-based case-control study conducted in Naples, Italy, and nearby cities with known high levels of illegal waste dumping suggest that living in these sites of waste emission increases the risk of cancer development in dogs, but not cats. This may relate to reduced exposure of cats to environmental carcinogens, because they are more often exclusively indoor pets.[159]

Physical Factors

Sunlight

The relationship between sunlight exposure or ultraviolet (UV) irradiation and the subsequent development of skin cancer is one of the better known examples of physical carcinogenesis. Recognized for its role in human SCC induction, sunlight also has been implicated as a cause of SCC in domestic animals and livestock.[193–196] In particular, light skin pigmentation and chronic sun exposure are associated with the development of facial, aural, and nasal planum SCC in white or partially white cats and may play a similar role in some cutaneous SCC lesions in dogs.[197–199] The portion of the UV spectrum most likely to be responsible for nonmelanotic skin lesions in people and animals is UV B (UV-B), which is in the range of 280 to 320 nm. Cumulative long-term exposure to UV-B may induce skin tumors directly through genetic mutations, including mutations in p53, and indirectly by impairing the response of the immune system to tumor antigens.[200–202] Pets are at greatest risk of exposure to UV-B during the midday hours and should be protected from this exposure, especially if they are a lightly pigmented breed.

Trauma/Chronic Inflammation

Tumor-promoting inflammation recently was deemed an enabling characteristic, because it allows cancer the ability to acquire core and emerging hallmarks necessary to continue uncontrolled propagation.[203] In four dogs with chronic pigmentary keratitis, neoplastic lesions of the cornea were reported, including three SCCs and one squamous papilloma.[204] Although the underlying etiology of the keratitis could not be confirmed, the neoplastic transformation likely was related to chronic inflammation. Earlier reports have linked feline eye tumors to ocular trauma that induces secondary uveitis and lens rupture (see Chapter 32).[205] Unlike the corneal tumors reported in dogs with pigmentary keratitis, the ocular lesions in cats were intraocular sarcomas. Despite the varied histology, the underlying etiology in all cases was thought to be related to inflammatory changes. Chronic inflammation also has been suggested as a cause of intraocular sarcoma in the domestic rabbit.[206] Another companion animal malignancy thought to be associated with inflammation is injection site sarcoma in the cat. This tumor type and its etiology are discussed in detail in Chapter 22.

Magnetic Fields

Nearly 40 years ago a potential link was proposed between chronic low-dose exposure to magnetic fields and the development of childhood cancer.[207] Since then multiple studies have been conducted in an attempt to discern links between magnetic fields and a variety of human cancers, ranging from hematopoietic malignancies to breast cancer. The extremely-low-frequency magnetic fields (<60 Hz) in question are ubiquitous in today's society and are generated by household appliances, industrial machinery, and electrical power lines. Because pets share our environment and have similar exposure to magnetic fields, a similar risk of cancer development has been presumed for companion animals. In a 1995 study the risk for the development of lymphoma was found to be highest in dogs from households with the highest measured exposure to magnetic fields.[208] The risk was related both to the duration and the intensity of exposure and was highest for dogs that spent more than 25% of the day outdoors. The next year, at the request of Congress, a report was published by the National Research Council (NRC) that reviewed more than 500 studies on the subject of cancer risk and exposure to electromagnetic fields.[209] The report concluded that, although a weak association has been shown between the development of childhood leukemia and exposure to electromagnetic fields, no clear evidence exists to suggest that exposure to electromagnetic fields is a true threat to human health. To the authors' knowledge, no reports on a possible link between magnetic fields and cancer in companion animals have been published since the 1995 report, although the magnetic field debate continues in the human literature. The NRC report suggested that other factors, including air quality and proximity to high traffic density, may be more likely environmental causes of cancer than low-frequency magnetic fields.

Radiation

The first report of cancer development after therapeutic irradiation in a dog dates back more than 30 years, when orthovoltage radiation was considered state of the art.[210] At that time the term *malignant transformation* was used to describe the development of epithelial malignancies at the site of prior irradiation for acanthomatous epulides in four dogs. After a review of more recent cases involving megavoltage irradiation, the author of the original report has suggested that the concept of malignant transformation should be discarded, because the occurrence of second tumors was not likely due to a true transformation of epulides into carcinomas.[211] Rather, the relatively high rate of carcinomas at previously irradiated sites for epulides is a result of less effective forms of irradiation or misclassification of the tumor type. Radiation carcinogenesis is considered the cause of secondary tumors arising in radiation fields. In human oncology most tumors occurring in heavily irradiated treatment fields are mesenchymal, rather than epithelial, in origin.[212–214] Several reports of sarcomas occurring in sites of prior irradiation also can be found in the veterinary literature.[215–217] A retrospective review of 57 dogs undergoing definitive megavoltage radiation therapy with ^{205}cobalt photons for acanthomatous epulides[211] described the development of a second tumor (one sarcoma and one OSA) in two dogs, occurring 5.2 and 8.7 years after the initial treatment, respectively. The overall incidence of second tumors (3.5%) was lower than in previous reports. The report suggests that the risk of second tumors at sites of radiation therapy is primarily of clinical concern for young dogs expected to enjoy long-term survival. Secondary tumors have been reported in at least 36 people who have undergone stereotactic radiosurgery; thus the risk for a secondary neoplasm is low but not zero.[218] As this radiation technique becomes more commonplace in veterinary medicine, the possibility of second tumors may need to be considered in companion animals undergoing stereotactic radiosurgery.

VetBooks.ir

Surgery and Implanted Devices

The development of sarcomas at the site of metallic implants has been reported in people, dogs, and laboratory animal models[219–221]; however, it often is difficult to discern whether sarcoma development is related to implants or to other factors, including wound healing complications and osteomyelitis. Three large veterinary studies have examined the relationship between surgical implants and tumor development in dogs. The first reported on 222 dogs that developed tumors of any kind after fracture fixation, compared with 1635 dogs that underwent fracture fixation without subsequent tumor development.[220] The authors concluded that the use of metallic implants was not a risk factor for bone tumor development. A second case-control study, using the Veterinary Medical Databases (VMDB), included more than 19,000 dogs with fracture fixation; this study also found no increased risk of a case reappearing in the VMDB a minimum of 2 years later with a diagnosis of OSA.[222] This was compared with dogs undergoing open joint reduction. The second report was a bi-institutional cohort study that evaluated more than 2400 dogs undergoing tibial plateau leveling osteotomies (TPLO), with more than 1 year of follow-up.[223] The authors concluded that the incidence of OSA at TPLO sites is rare and did not find an increased association between infection or fracture and tumor development. The median time to occurrence of OSA after TPLO was approximately 4.5 years, longer than tumors occurring at sites distant to TPLO. The investigators postulate that the pathogenesis for implant-associated tumors was different from that of spontaneously developing tumors.[223]

Newer reports have tried to establish a cause and effect relationship between implants and secondary tumors[224,225]; however, the small number of cases and questionable controls prevent these studies from providing a definitive link. Other types of implants and foreign materials related to surgery sporadically are implicated in carcinogenesis in human and veterinary case reports. Published examples include dogs developing sarcomas associated with pacemakers, and multiple dogs with tumor formation caused by retained surgical swabs or gauze.[226–230] Although a true cause and effect relationship has yet to be determined, neoplasia at the site of a previous surgery should be a differential in animals with new pain or lameness.

Asbestos

Asbestos exposure is a known risk factor for the development of mesothelioma in people.[231] In fact, an estimated 60% to 88% of all cases of human mesothelioma are attributable to asbestos exposure.[231] A similar association has been found for dogs whose owners have an asbestos-related occupation or hobby.[232] This association was further supported by a study in which significantly more asbestos bodies were found in dogs with mesothelioma than in control dogs.[233] Pericardial mesothelioma was reported in five golden retrievers with histories of chronic idiopathic hemorrhagic pericardial effusion, suggesting that other factors, including breed predispositions and chronic inflammation unrelated to asbestos exposure, may be involved in the etiology of mesothelioma affecting the pericardium.[234]

Hormonal Factors

The debate about spaying and neutering pets has increased over the past decade. Although neutering may be protective against some cancers, recent breed-specific reports have shown a potential association between neutering and cancer development (Table 1.1).[235] In the next section, the authors discuss organ-specific relationships between gonad status, potential hormone-related pathogenesis, and tumor development. However, although spaying and neutering may be associated with an increased risk of cancer in some breeds, if we extrapolate that information to the entire pet population, the risk does not outweigh the issue of overpopulation and multiple, life-threatening diseases.

TABLE 1.1 Tumors That May Be Influenced by Spay/Neuter Status

Tumor Types Possibly Influenced	Concerning Breeds
Tumor with Increased Risk After Castration	
Cardiac tumors	All
Osteosarcoma	All, purebred dogs, rottweilers (<1 yr of age at castration)
Prostatic epithelial tumors (including transitional cell)	All
Urinary bladder transitional cell carcinoma	All
Lymphoma	All, golden retrievers (<1 yr of age at castration)
Tumors with Decreased Risk After Castration	
Testicular	All
Tumors with Increased Risk After Spay	
Cardiac tumors (including hemangiosarcoma)	All
Osteosarcoma	All, purebred dogs, rottweilers (<1 yr of age at spay)
Splenic hemangiosarcoma	All, Vizslas, golden retrievers (>1 yr of age at spay)
Mast cell tumors	All, Vizslas, golden retrievers
Lymphoma	All
Tumors with Decreased Risk After Spay	
Ovarian tumors	All
Uterine tumors	All
Canine mammary tumors (spay before third estrus)	All
Feline mammary tumors (spay before third estrus)	All

Reproduced with permission. Smith AN. The role of neutering in cancer development. *Vet Clin North Am Small Anim Pract.* 2014;44:965–975.

Canine Mammary Cancer

Canine mammary cancer is a well-established model of hormonal carcinogenesis in domestic animals (see Chapter 28). The most common neoplasm of female intact dogs,[235] mammary tumors affect approximately 260 in 100,000 dogs in the United States each year.[194,236] Dogs spayed before their first estrus cycle have a greatly reduced risk of developing breast cancer; the risk rises to

VetBooks.ir

26% for dogs spayed after their second estrus.[237,238] Mammary tumors primarily affect late middle-aged (9 to 11 years) female intact dogs, and an increased incidence begins at approximately 6 years of age.[239] Despite the studies describing the protective effect of spaying on mammary tumor development, the highest level of evidence manuscript in veterinary medicine found only weak evidence of an association because of potential bias in almost all studies screened.[240] A systematic review retrieved more than 11,000 references, with only 13 studies published in peer-reviewed English language journals addressing the authors' research question. According to the Scottish Intercollegiate Guidelines Network (SIGN) level of evidence system, 9 of the 13 studies were judged to be at high risk of bias. The remaining four studies had mixed results, with some bias noted in all studies. The authors concluded that some evidence suggested that neutering female dogs before 2.5 years of age resulted in a considerable reduction in the risk of malignant mammary tumors, with further reduction possible if neutering occurred before the first estrus.[240] Randomized controlled clinical trials published after this systematic review have shown a protective effect. In dogs spayed at the time of mammary tumor excision, significantly fewer dogs subsequently developed nonmalignant tumors than if they were not spayed at the same time (hazard ratio 0.47).[241] The same group then looked at dogs with malignant tumors and found a subset of dogs, those with intermediate-grade and estrogen receptor–positive tumors, benefited from ovariohysterectomy.[242]

Sexual steroid hormones likely have their primary effect on target cells during the very early stages of mammary carcinogenesis in dogs; thus the protective effect of spaying is lost with time.[243–249] In addition to the influence of ovarian hormones on breast cancer development, the use of medroxyprogesterone acetate products (progestin and estrogen combination) to prevent estrus or to treat pseudopregnancy has been linked to an increased incidence of mammary tumor development in dogs.[250–252]

Progestin-induced growth hormone (GH) excess in dogs originates in the mammary gland. Within the mammary gland the gene encoding GH may act in an autocrine/paracrine fashion, effecting cyclic epithelial changes and, perhaps, carcinogenesis. Research to determine the mechanism of progestin-induced mammary GH expression in dogs has led to the cloning and cellular localization of the canine progesterone receptor (PR).[253] The investigators concluded that within the same mammary gland cell, the activated PR may transactivate GH expression and function as a prerequisite transcription factor; however, this regulation may be lost during malignant transformation. Mammary GH expression also has been reported in people, suggesting that evaluation of links between this hormone and mammary carcinogenesis may have implications for both species.[254,255]

Feline Mammary Cancer

Both estrogen and progesterone are thought to play important roles in feline mammary carcinogenesis, although the underlying mechanisms are less clear than for dogs. Prior studies have shown that intact female cats and cats exposed regularly to progestin are at an increased risk for mammary cancer development. The literature also suggests that, as is the case in dogs, ovariectomy may be protective against mammary tumor development in cats.[194,256–258] In one study, cats ovariectomized at 6 months of age had an approximate sevenfold reduction in risk of mammary tumor development compared with intact cats.[194] What has been lacking in the veterinary literature is an epidemiologic study of cats with age-matched controls for comparison to specifically investigate the effects that spaying and age of spay have on the risk of feline mammary carcinoma development. Overley et al attempted to address these issues in a retrospective study that compared a population of 308 cats with biopsy-proven mammary carcinoma diagnosed between 2000 and 2001 and a control population of 400 female cats not diagnosed with mammary tumors but from the same biopsy service population as the affected cats. Cats from the two groups were frequency matched by age and year of diagnosis.[258] The study reported a 91% reduction in risk for those spayed before 6 months of age and an 86% reduction in risk for those spayed before 1 year of age, compared with intact cats. Although the study was retrospective in nature and relied on questionnaire data from a survey with a 58% response rate, the manuscript is the first published report attempting to age match controls and evaluate age at time of spay as a risk factor for mammary tumor development in cats. Although further epidemiologic evaluation and prospective assessment are needed to confirm these findings, the reported results provide some justification for recommending ovariohysterectomy before 1 year of age in cats.

Lymphoma

The National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) data indicate that non–Hodgkin lymphoma is approximately 50% more common among men than women.[259] Although a similar male predisposition is reported for canine lymphoma, the underlying role of sex in lymphoma etiology remains elusive. The author and others undertook a population-based study using the VMDB to determine the relationship between sex and the development of canine lymphoma.[260] The VMDB included nearly 15,000 lymphoma cases in a population of more than 1.2 million dogs over a span of 20 years. Intact female dogs were about half as likely to develop lymphoma compared with spayed females and with males, whether neutered or intact.[260] In addition, two breed-specific studies have evaluated gonad status and lymphoma development.[261,262] Both studies concluded that spaying increases the risk of lymphoma in golden retrievers[261] and Vizslas.[262] A retrospective, single-institution medical record search involving more than 90,000 dogs evaluated at the University of California–Davis (UCD), assessed odds ratios (OR) and neuter status in multiple disease processes and neoplasms.[263] In this study spayed female dogs had more than double the risk (OR 2.25) of developing lymphoma compared with intact female dogs.[263] Male castrated dogs also were at an increased risk of lymphoma diagnosis compared with intact males. Further examination of the role of estrogen and neuter status in the development or prevention of canine lymphoma is warranted.

Osteosarcoma

Although historically reported to be a disease more common in male dogs, a review of all dogs with OSA presenting to Colorado State University over 27 years found an equal male-to-female relationship (see Chapter 25). A case-control study using the VMDB that evaluated gonad status and the development of OSA found a twofold excess risk of OSA development among neutered dogs.[264] Data collected through questionnaires from owners of 683 rottweiler dogs from North America showed that the age of spay or neuter had a significant influence on bone sarcoma incidence.[265] Both male and female dogs that underwent gonadectomy before 12 months of age were significantly more likely to develop a bone

VetBooks.ir

tumor than intact dogs. For each additional month of being intact, a 1.4% reduction in tumor risk was noted.[265] OSA also was evaluated in the aforementioned Davis study of more than 90,000 dogs.[263] Both spayed female and neutered male dogs had a significantly increased risk of having OSA, OR 2.53 and 1.62, respectively, compared with intact animals. The authors did theorize that this increased risk could be associated with greater longevity in neutered dogs.[263]

Hemangiosarcoma

A highly aggressive and almost uniformly fatal neoplasm, hemangiosarcoma (HSA) is diagnosed more frequently in dogs than in any other species, with breed predilections in retriever breeds (see Chapter 34). The aforementioned breed-specific studies[261,262] reported an increased risk for HSA development in spayed female dogs compared with intact female dogs. Female golden retrievers spayed after 1 year of age were diagnosed with HSA four times more frequently than intact female dogs, or dogs spayed "early."[261] Of note, only overall percentages of disease incidence were reported; statistical analysis of those percentages and subsequent p-values were not available. The authors did not report a difference in neuter status and HSA development in male golden retrievers.[261] Spayed Vizsla dogs were nine times more likely than intact females to develop HSA.[262] As in the golden retriever study, no difference in intact or neutered males was noted. In the large UCD retrospective study, neutered female and male dogs were at increased risk (ORs 3.18 and 1.39, respectively) of developing HSA compared with their intact counterparts.[263] Also at UCD, an association between age of cancer-related mortality and gonadectomy in golden retrievers was explored.[266] Goldens available for a necropsy examination from 1989 to 2016 were included. HSA was the most common cause of cancer-related death in this breed. Although a greater proportion of spayed female dogs died of cancer, their overall life span (9.83 years) was significantly longer than dogs that died of non–cancer-related causes (6.93 years).[266] The authors concluded that age had a larger effect on cancer-related mortality than reproductive status.

Mast Cell Tumors

Breed predilections for mast cell tumor (MCT) development have been reported, but a gender predilection in this neoplasm appears to be lacking (see Chapter 21). Again, in the retrospective study of 90,000 dogs at UCD, spayed female and neutered male dogs were at an increased risk for MCT development compared with intact dogs.[263] Mirroring the findings for previously described cancers, spayed female dogs seemed to have the highest risk of MCT development. This phenomenon is reflected in golden retrievers and Vizslas.[261,262] In a case-control study of 252 dogs with MCTs, an increased risk for development was found in spayed female dogs (OR 4.1).[267] Despite the repeatable finding of increased risk in spayed female dogs, the influence of hormones in canine MCTs remains unclear. Conflicting evidence exists on the presence of estrogen receptors in canine MCTs.[268,269]

Perianal Adenoma

Perianal adenoma is androgen dependent and occurs primarily in intact male dogs, whereas perianal adenocarcinoma occurs in both intact and castrated males. Perianal adenomas also may develop in female dogs secondary to androgenic hormone secretion from the adrenal gland.[270] Most of these tumors in male dogs resolve after castration, a fact that lends further support to the assertion that androgens are involved in the etiology of this tumor (see Chapter 23).[271]

Prostate Cancer

Although a well-established link exists between the presence of testosterone and the development of benign prostatic hyperplasia (BPH) in dogs and man, prostatic cancer risk is not higher in intact dogs compared with those that are castrated.[272] To the contrary, neutered dogs have been shown to be at increased risk. Castration is likely not an initiating event, but it is thought to favor tumor progression.[273–276] A clear relationship between age at castration and the risk of prostate cancer development has yet to be determined (see Chapter 29).

SECTION C: CANCER-CAUSING VIRUSES

DENNIS W. MACY

Both DNA- and RNA-containing viruses are known to cause cancer. An initial step in malignant transformation of normal cells by most tumor viruses is the integration of all or part of the viral DNA (or DNA copy of retroviral RNA) into the host cell genome. For some viruses specific viral genes (oncogenes) have been identified that lead to malignant transformation when expressed in normal cells. Other viruses, through the process of integration, enhance or repress the expression of normal cellular genes, resulting in cellular transformation or uncontrolled growth.[277]

Tumor-Causing Viruses of Dogs

Papillomaviruses

Papillomaviruses are potentially oncogenic, contagious, and infectious and have been described in wild and domestic animal species.[278] Papillomaviruses are considered relatively species specific, and isolates of humans, cattle, and dogs lack serologic cross-reactivity.[278] However, cross-infection with other species can occur. For example, the coyote can be infected with dog isolates, and bovine papillomaviruses type 1 and type 2 have been reported to infect horses.[279] In addition, bovine papillomaviruses have been isolated from tumors in cats, indicating a unique cross-species infection in a dead-end host.[280]

Sixteen papillomaviruses from three different genera infect dogs and are responsible for a wide spectrum of clinical syndromes—canine papillomavirus (CPV)-1, oral papillomas; CPV-2 and -6, cutaneous papillomas and cutaneous pigmented plaque. CPV-3, -4, -7, -8, -9, -10, -11, -14, -15, -16 are papillomaviruses of the family Papovaviridae; they produce benign, mucocutaneous and cutaneous canine papillomas and in rare cases transform into squamous cell carcinoma.[281,282,403]

The canine papillomaviruses are naked (e.g. non-enveloped) DNA viruses; they are larger than the canine parvoviruses but similar in structure. In vitro propagation methods are not used to identify the virus, but electron microscopy has been used to detect the virus in infected tissues. Other methodologies with varying sensitivity and specificity, such as Southern blot hybridization, dot blot, and reverse hybridization, have been used more recently to identify the virus. Although considered less sensitive,

VetBooks.ir

the polymerase chain reaction (PCR) most often is used to detect the virus in tissues.[403] Detection of the P16 protein in tissues by immunohistochemistry often is used to link papilloma infection to neoplastic transformation.[404,405] As are other papillomaviruses, canine papillomaviruses are resistant, acid stable, and relatively thermostable.[283] Only limited sequence homology exists between the DNA sequences of papillomaviruses of different species, but substantial sequence homology exists between isolates from any given species. Canine isolates have preferential tissue tropisms, but these tropisms have been shown to broaden with glucocorticoids and other immunosuppressive therapies.[403]

Pathogenesis

Papillomaviruses have a tropism for squamous epithelial tissues. After the introduction of the papillomavirus through breaks in the surface of the epithelium, replication of the virus is linked to the growth and differentiation of the cells in the stratified squamous epithelium. After the virus enters the basal layer keratinocytes, the virus undergoes disassembly and early (E) protein enters the nucleus and produces episomal copies of viral DNA. The ability of the papillomavirus to express the E gene forces the infected cell to divide, thus maintaining viral replication.[403] As these cells progress to the surface, they express the late gene (L), which forms the capsids of the virus, which then are released in the sloughing epithelial surfaces. A key feature of papillomaviruses in tumorigenesis is the E proteins, which prevent infected cells from leaving the cell cycle and are classified as oncoproteins. The amount of E protein produced and the interactions of these proteins with cellular regulatory systems, including p53, is believed to be responsible for lesion production and tumor risk.[403]

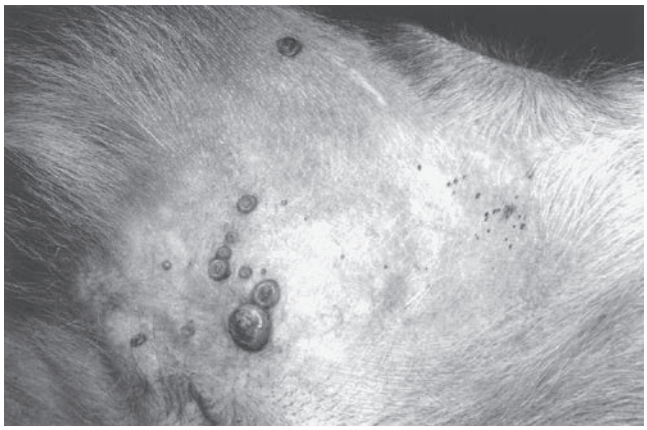
The tissue tropism for papillomaviruses may be expanded in immunosuppressed patients. The type of papillomavirus and the host's immune response after inoculation predict the risk for clinical disease; a good host response provides protection from the development of clinical disease, in which case the infection remains asymptomatic.[404,408] The presence and location of mature complete viruses on the surface of papillomas are believed to aid in their transmission to adjacent epithelial tissues and often are believed to be the cause of surgical treatment failure.[278] In contrast to other oncogenic or transforming DNA viruses, papillomaviruses rarely integrate into the cellular genome and remain episomal.[278]

Infection of epithelial cells results in a marked increase in cellular mitosis and hyperplasia of cells within the stratum spongiosum, with subsequent degeneration and hyperkeratinization.[286] Clinical evidence of hyperplasia and hyperkeratinization usually manifests 4 to 6 weeks after experimental infection.[286] Canine papillomas generally persist for 4 to 6 months in the mouth and 6 months to 1 year on the skin before undergoing spontaneous regression, and multiple papillomas generally regress simultaneously.[286] Although antibodies are produced against the papillomavirus, antibody levels do not appear to correlate with either growth or regression of the papilloma during infection; the mechanism of induction or regression remains unknown. Although vaccination has been shown to protect against infection, it is thought to be associated with induction of cell-mediated immunity.[287] The development of multiple papillomavirus-associated epidermal lesions and SCC in situ in a dog after treatment with prednisone and cyclosporine has been reported.[288,409]

Clinical Features

Papillomas may be referred to as warts, verruca vulgaris, squamous cell papillomas, or cutaneous papillomatosis. Papillomas caused by the papillomavirus usually are multiple and frequently involve young dogs. In the dog multiple papillomatosis most frequently is seen in the oral cavity, involving the labial margins, tongue, pharyngeal mucosa, hard palate, and epiglottis (Fig. 1.9).[287] Four to 8 weeks after infection, small, pale, smooth, elevated lesions appear; these quickly develop a cauliflower-like appearance, with fine, white fronds extending from the surface of the lesions. Multiple sites of susceptible tissue in the oral cavity appear to be affected early in the course of the disease; as many as 50 to 100 tumors may be present at the time of diagnosis.[287] The primary complaints of owners of infected dogs are halitosis, ptyalism, hemorrhage, and dysphagia. Most oral cavity papillomas start regressing after 4 to 8 weeks; however, some oral lesions may show incomplete regression, and some have been known to persist up to 24 months.[287,406]

• **Fig. 1.9** Multiple papillomatosis in the oral cavity of the dog.



• **Fig. 1.10** Solitary ocular papilloma in a dog.

Canine cutaneous (exophytic) papillomas are most commonly found in older dogs. Certain breeds, such as Kerry blue terriers and cocker spaniels, appear to be predisposed. Most lesions appear on the head, eyelids (Fig. 1.10), and feet. Lesions may be single or multiple, pigmented and/or alopecic.

Cutaneous inverted papillomas are found most frequently in young dogs and are located on the ventral abdomen and inguinal regions. The lesions maybe single or multiple and are considered self-limiting (Fig. 1.11).[406]

Multiple pigmented plaques have been described in young miniature schnauzers and pugs. The plaques may progress to scaly, hyperkeratotic flat masses and then may progress to SCC.[289,406]

VetBooks.ir

• **Fig. 1.11** Multiple cutaneous papillomatosis in the inguinal region of a dog.

Canine genital papillomas are considered uncommon but venereal in nature and are characterized by raised papillomatous plaques on the penis or vaginal mucosa.

Canine footpad papilloma was first noted in young greyhounds but now is recognized in adult dogs and other breeds. It may be present on multiple footpads, interdigital spaces, and on multiple limbs.[289,406]

Ocular papillomas, which are less numerous and less common than the oral type, appear on the conjunctiva, cornea, and eyelid margins (see Fig. 1.10).[287] Experimentally, viruses isolated from ocular lesions can produce oral papillomatosis, although whether this occurs in nature is unknown.[284] Ocular papillomatosis most frequently occurs in dogs 6 months to 4 years of age, but it occasionally is reported in older dogs.

Although papillomatosis generally should be considered a benign disease, in rare cases oral and corneal papillomas have transformed into SCC.[281,282]

Treatment

Most clinicians elect not to treat papillomatosis because of the lack of proven efficacy of recommended treatments and the expected spontaneous regression of these tumors; however, if the number of papillomas increases or if the animal has significant dysphagia, owners often request treatment. Surgical excision, cryotherapy, laser surgery, radiation therapy, electrocautery, or surgery for just a few lesions has resulted in regression of the remaining papillomas, presumably through immunologic mechanisms.[287,290,291]

If surgery is performed, seeding of the virus is a possible complication, resulting in lesion recurrence. The exact mechanism by which regression of papillomas occurs is unknown. Serum from dogs in which papillomas have undergone spontaneous regression not only fails to produce tumor regression when administered to infected animals, but may enhance existing tumor growth. This effect may be a result of induction of blocking antigen-antibody factors, which may impede cytotoxic lymphocyte action on target cells. CD4 T cells activate macrophages and have been shown to inhibit the virus in dogs, and administration of immune lymphocytes from dogs in which tumors have regressed has been shown to enhance regression.[283] Interferon-α also has been tried therapeutically, with some success (1–3 million IU/m^2 given subcutaneously three times a week [Monday-Wednesday-Friday]), and chemotherapy of resistant lesions has produced variable results.[292] Azithromycin (5–10 mg/kg PO every 12 to 48 hours) has been reported to be beneficial, as has imiquimod cream (Aldara) applied topically every 24 to 48 hours.[406] A new recombinant canine oral papillomavirus vaccine (COPV) produced by Georgetown University Medical center has been reported effective. The vaccine presents the capsid protein L1 of CPV-1 and was given in six injections; after the initial vaccination, three booster vaccines were given every 2 weeks followed by two more boosters given monthly.[406] Corticosteroids should be avoided because they are thought to contribute to papilloma dissemination.[293,409]

Most systemic chemotherapeutic agents (e.g., bleomycin, vincristine, cyclophosphamide, and doxorubicin) have failed to cause regression of papillomas. However, the retinoid drug etretinate (1 mg/kg PO every 24 hours) has been effective in some dogs with persistent papillomas.[294] Topical or intralesional compounds containing 5-fluorouracil (5-FU) have been used in both humans and dogs to treat papillomas.[406] In the past, autologous wart vaccines have been recommended, but they have proved of little value in the treatment of resistant papillomatosis in the dog.[287] In at least one study papillomavirus vaccines have been shown to prevent the development of oral papillomas in the dog; however, cutaneous neoplasms at the injection sites have been attributed to administration of the vaccines.[285,295,296]

Tumor-Causing Viruses of the Cat

Papillomaviruses

Feline viral papillomatosis is a less commonly recognized clinical condition caused by a papillomavirus specific to the cat.[409] The virus is widespread in the cat population, and most infections are asymptomatic.[408] At least three papilloma viruses FcaPV-1, -2, -3, have been recently sequenced for the domestic cat and are responsible for cutaneous plaques, bowenoid in situ carcinoma (Bowen disease), and cutaneous SCC.[403] These viruses are thought to be genomically similar to the canine isolates but are considered species specific.[297] Bovine papillomavirus BPV-14 is thought to be responsible for feline sarcoid.[403] Papillomavirus-associated lesions have been reported in six species of felids besides the domestic cat: the mountain lion, Florida panther, bobcat, Asian lion, snow leopard, and clouded leopard.[298,299] Unlike in the domestic cat, in which the lesions commonly affect areas of haired skin, papillomas in exotic species most often are found in the oral cavity, similar to those in the dog.[298,302] Despite the clinical similarities, genetic and antigenic studies indicate that each species of felid is infected by a unique papillomavirus.

Pathogenesis

In cats, as in other species, papillomas are believed to develop after the virus is introduced through lesions or abrasions in the skin. Unlike in the dog most feline case reports involve older cats (6 to 13 years of age), although papillomavirus lesions have been reported in kittens as young as 6 to 7 months old.[300,301] As in other species, impaired T-cell function likely plays a significant role in lesion formation. Papillomas in cats that are receiving immunosuppressive therapy or are infected with the feline immunodeficiency virus (FIV) support this hypothesis.

Although papillomas most frequently are benign lesions, recent studies have associated the papillomavirus with SCCs and other malignant neoplasms in cats[302]; specifically, papillomavirus has been isolated from 30 of 63 SCC in situ skin lesions. Through the use of PCR techniques, papillomaviruses have been found in

VetBooks.ir

17 of 19 and 9 of 12 fibropapillomas in cats.[303,304] Although a cause and effect relationship has yet to be proved for carcinoma in situ, Bowen disease, fibropapillomas, and papillomaviruses, the evidence is compelling.[302–304]

Bovine papillomaviruses may also play a role in the pathogenesis of feline cutaneous fibropapilloma (sarcoid). In a study of 20 cats with fibropapillomas, more than half were known to have exposure to cattle, and all were within an area with dairy farms.[303] In one isolate the nucleotide sequence was similar to that of the bovine papillomavirus. Injection of that isolate back into bovine skin resulted in asymptomatic infection.

Clinical Features

Lesions in the cat differ from those in the dog because they are more like plaques than warts.[406] The plaques are several millimeters in diameter, may be white or pigmented, and are scaly or greasy. Lesions in the cat usually affect haired skin. Thought to be associated with grooming activity, lesions on the ventral tongue surface that are sessile in character also occur.[298,302] Cutaneous viral plaques and bowenoid in situ carcinomas (BISCs) are caused by FcaPV-2; the former are a precursor to BISC. Some of these lesions progress to SCC, with spread to lymph nodes and lungs. Sarcoids occur in young cats and appear on the head, neck and digits.

Diagnosis

Definitive diagnosis depends on histopathologic, immunohistochemical (IHC), or electron microscopic (EM) examination of excised lesions. Histologic features include proliferation of all cell layers with little or no inflammation. Typically, epidermal hyperplasia is accompanied by acanthosis, hypergranulosis, hyperkeratosis, and ballooning degeneration of cells of the stratum spinosum and stratum granulosum. Amphiphilic cytoplasmic inclusion structures may be present in cells of the upper stratum granulosum. EM findings in the lesions include intranuclear particles within keratinized cells in the superficial epithelial strata of the plaques.[403] IHC can be performed on tissue sections using band-reactive, genus-specific antisera. Interestingly, the histologic features of the feline fibropapilloma are very similar to those of equine sarcoids, with characteristic fibroblastic proliferation, hyperplasia of epidermis, and rete ridges.[303] PCR also has demonstrated papillomavirus DNA in 40% of SCCs, but whether it is responsible for these tumors in all cases is unknown.[404]

Treatment

Surgical excision generally is used; however, parenteral human recombinant interferon-α-2a has been suggested as an alternative. Medications containing 5-FU that are used in humans and dogs should **not** be used in cats.[409] Imiquimod 5% cream is a novel immune-response modifier (IRM) that has been used in humans with Bowen disease and recently has been used in cats with the same disease. Although 41% of cats treated with imiquimod developed some level of toxicity, most adverse events were manageable.[305]

Retroviruses

Retroviral infections are considered the number one infectious cause of morbidity and mortality in the domestic cat. Before the vaccine was developed and routine testing and control measures became widespread, the feline leukemia virus (FeLV) was associated with one-third of deaths in cats.[306,307] Since the introduction of the feline leukemia vaccine in 1985, the incidence of lymphoma in cats in the United States and Europe has markedly declined; however, along with the reduction in FeLV-related disease, there has been a rise in FeLV vaccine injection site tumors.[407] The cat is believed to be affected by the largest number of retroviruses of any companion animal, and these viruses produce a wide spectrum of diseases, including cancer.[308–310]

The cat has both endogenous and exogenous retroviruses. The endogenous retroviruses generally are considered nonpathogenic, are present in the host DNA, and are passed from generation to generation genetically, as are other chromosomal genes. The exogenous retroviruses include both pathogenic and nonpathogenic viruses and are passed horizontally and vertically between cats. Pathogenic exogenous retroviruses include FeLV and FIV.[311] The exogenous RNA sequences of FeLV play the most important role in tumorigenesis in the cat.[310] Another pathogenic retrovirus, the feline sarcoma virus (FeSV), arises from the recombination of exogenous FeLV and proto-oncogenes in the cat's genome.[312] Feline syncytium-forming virus (FeSFV), also called the feline foamy virus, is a nonpathogenic exogenous retrovirus.[306]

FeLV is believed to have been contracted from the ancestral rat approximately 10 million years ago.[313] The ancestral source of other retroviruses is unknown.

Feline Leukemia Virus

The retrovirus FeLV belongs to the subfamily Oncornavirinae, or tumor-producing RNA viruses. As do other retroviruses, it has a single strand of RNA and an enzyme, reverse transcriptase (RT), which synthesizes DNA from the virus RNA template. Nondomestic felids, including the cheetah and bobcat, can be infected by FeLV; however, it is considered enzootic in wild felids, and in European wild cats in France and Scotland. It has been reported in mountain lions in the United States.[314,315]

The basic FeLV proteins include the envelope proteins and the core proteins, several of which are important clinically. Two envelope proteins, the P15E and the GP70 glycoproteins, have particular clinical significance.[316–318] P15E is thought to be one of the mediators of immunosuppression in FeLV-infected cats.[319] The glycoprotein of the envelope GP70 may contain three subgroup antigens, A, B, and C.[320–321] An individual cat may have combinations of viruses with these subgroup viral antigens. Considerable antigenic variation exists within subgroups, which can affect the biologic properties of the individual isolates or strains of FeLV.[310,320] These subgroup antigens bind the virion to receptors on the surface of cells. The specific characters of these proteins also predict the pathogenicity, host range, infectivity, and other biologic properties of the virus.[310,320] Antibodies produced against envelope proteins can be neutralizing and thereby can prevent infection. Envelope proteins thus are important components of FeLV vaccines.

Core proteins (capsids) include P15C, P12, P10, and P27. P27 is quite soluble and can be found in large amounts in the cytoplasm of cells and bodily fluids, such as tears and serum.[316–318] P27 is the antigen that is detected in immunofluorescent assay (IFA) tests and enzyme-linked immunosorbent assays (ELISAs), which are commonly used in the diagnosis of FeLV infection.[321]

Transmission

FeLV is an enveloped virus and is considered very fragile. Desiccation rapidly reduces the amount of viable virus in saliva, and inactivation occurs in 1 to 2 hours. In exudates or blood the virus may be viable for only 48 hours (at 37°C) or 1 to 2 weeks (at 22°C).[322]

VetBooks.ir

Like most retroviruses, FeLV is rapidly inactivated by heating and most disinfectants.[317] Given these characteristics, environmental contamination (e.g., examination tables, cages, and waiting rooms) is unlikely to be a potential source of FeLV infection.[310] Although saliva may contain up to 100,000 virus particles per milliliter, prolonged, intimate contact with infected cats usually is required for transmission. The factors most frequently incriminated in the transmission of FeLV are licking, biting, grooming, and sharing of litter pans, food bowls, and water dishes. Intimate contact is enhanced in catteries and multiple-cat households, where infection rates may be very high.[319]

Before vaccines and routine testing became available, the overall prevalence of FeLV infection in the United States was estimated at 1% to 3% of the cat population.[308,309] The prevalence of FeLV infection was less than 1% in single-cat households and as high as 30% in multiple-cat households.[327] The incidence of FeLV-positive test results in sick cats in the United States was approximately 11.5%.[328] Several studies have reported a decline in the prevalence of FeLV by as much as 50% over the past 20 years; this decrease may be attributed partially to the widespread use of FeLV vaccination.[307,329,330]

Although cats may be infected with FeLV subgroups A, B, or C or other recombinants, only subgroup A has been found in cell-free fluids and is thought to be associated with natural transmission of FeLV. Subgroups B and C and other recombinants are more cell associated and are not thought to be transmitted in nature.[323–326]

The FeLV subgroups are characterized by their cross-interference with homologous but not heterologous subgroups of FeLV and by their host range and other factors. All naturally infected FeLV cats have subgroup A, 50% of infected cats have a combination of subgroups A and B, and 1% of infected cats in nature have a mixture of subgroup C, either as AC or ABC.[308,328,331]

The relevance of subgroups in strains is essential to an understanding of the biodiversity of the clinical disease caused by FeLV infection. Although subgroups A, B, and C maintain 85% genomic homology, cats infected with various combinations of these subgroups may manifest vastly different diseases.

Subgroup A has a variety of strains that range from nonpathogenic to very pathogenic.[332] Although most strains of subgroup A have limited pathogenicity, their pathogenicity increases dramatically if they are present with other subgroups.

Subgroup B is created when subgroup A recombines with endogenous FeLV envelopes at sequences already in the feline genome.[333–335] Each recombination is unique, resulting in many strains of FeLV-B. The combination of subgroups A and B is more contagious and pathogenic than subgroup A alone.[328,331,332] Cats infected with subgroups A and B often develop thymic lymphoma and myeloproliferative disease.[333]

Subgroup C arises from the mutation of subgroup A.[336] Cats may be infected with a combination of C and other subgroups, although these combinations are uncommon and are found in only about 1% of naturally infected cats. FeLV-C is antigenically similar to the associated membrane antigen (feline oncornavirus-associated cell membrane antigen [FOCMA]); cats carrying FeLV-C have developed severe erythroid hypoplasia and anemia and usually die within 1 to 2 months.[323] Further complicating the biodiversity of subgroups and strains is the fact that subgroups A and B can recombine with proto-oncogenes, such as MYC or TCR, producing FeLV-MYC or FeLV-TCR.[306] Both of these recombinants are considered more potent tumor producers than their nonrecombinant FeLV parent. Another subgroup, T, is highly cytolytic for T lymphocytes and causes severe immunosuppression.[324–326]

The Rickard strain of FeLV (FeLV-R), although similar to MYC-containing recombinant strains in its ability to rapidly produce mediastinal lymphoma, does not recombine with the MYC gene.[306,337] Instead, it exerts some of the biologic effects by integrating adjacent to the MYC gene, causing its overexpression.[306]

Feline Oncornavirus-Associated Cell Membrane Antigen

FOCMA is a protein found on the surface of FeLV and FeLV-induced neoplasms but not on nonneoplastic feline cells.[338,339] FOCMA is detected serologically when cells expressing it react to immunoglobulins produced in cats that have regressed FeSV-induced fibrosarcoma or FeLV infection. The presence of the FOCMA antibody is determined by the ability of the serum to react with FL74 cells, a transformed infected feline lymphocyte line.[340] Antibodies to FOCMA protect against neoplastic and myeloproliferative disease. Some FeLV vaccines contain FOCMA and elicit an anti-FOCMA response.[341] The relative importance of this in preventing disease in vaccinates is unknown.

Neoplastic Diseases Caused by Feline Leukemia Virus

Much has yet to be learned about the genetic basis for the vast diversity of tumor types produced by FeLV and its recombinants. We now know that FeLV, through one or another of its recombinants, may cause virtually any hematopoietic neoplasm in the cat. The only hematopoietic neoplasms not yet associated with FeLV in nature are mast cell leukemia, eosinophilic leukemia, plasma cell tumors, and polycythemia vera.[306]

Although FeLV infection is considered the most significant infectious cause of morbidity and mortality in cats, only 20% of cats persistently infected with FeLV develop lymphoid cancer.[342,343] The cat has the highest incidence of hematopoietic neoplasms of domestic animals, and the prevalence of lymphoma ranges from 44 to 200 cases per 100,000 cats, six times the rate of this disease in humans.[306] Twenty years ago 70% of lymphomas in cats were believed to be caused by FeLV.

Some cancers are more commonly associated with FeLV infection than others. Large granular lymphoma and globular leukocyte tumors usually test negative for FeLV,[344–345] whereas 70% to 90% of cats with nonlymphoid hematopoietic neoplasia (myeloproliferative disease) test positive for FeLV.[306] The percentage of lymphomas that test positive for FeLV also varies, depending on the anatomic location of the tumor.[346–347] Cats with spinal, mediastinal, ocular, and renal lymphoma frequently tested positive for FeLV before routine vaccination (more than 70%).[349] Extranodal lymphomas, such as those of the nasal cavity and the alimentary tract, frequently test negative for FeLV infection.[306] Over the past 20 years, the multicentric FeLV-positive form has declined in young cats, and the FeLV-negative alimentary form in older cats has increased.[350,351] Although the alimentary form most often is FeLV negative, as assessed by IFA and ELISA testing, some of these lesions have been shown by PCR to be FeLV positive, which suggests that the disease may be related to previous FeLV exposure.

Although not all lymphomas are caused by FeLV, the relative risk of developing lymphoma is 62 times higher in FeLV-positive cats, and cats that are FeLV negative but that have had previous exposure to FeLV have a fortyfold increase in the risk of developing lymphoma.[352] Most spontaneous lymphomas of cats that test positive for FeLV arise from T cells, whereas FeLV-negative lymphoma frequently is of alimentary or B-cell origin.[353,354] The time from infection to tumor development varies and may depend on the age at which the cat is infected or on other factors, such as strain, anatomic location, and viral subgroup.[306] The range from

VetBooks.ir

the time of experimental infection to tumor production is 1 to 23 months (mean, 5.3 months).[355,356] The younger the cat when infected with FeLV, the shorter the time to the development of neoplastic disease. Some cats infected with FeLV die of immunosuppressive disease before tumors have a chance to develop.

Treatment of Feline Leukemia Virus Infections

Although no effective treatment exists to eliminate established FeLV infection in cats, a variety of antiviral drugs and biologic response modifiers (BRMs) have been used to manage retroviral infections in cats and humans. The mainstay of therapy for cats infected with FeLV or other retroviruses is supportive care.[357–359] Maintaining hydration and nutritional status not only prolongs life, but also enhances quality of life. The cat should be kept in a humid environment to reduce the chance of water loss. Appetite stimulants and placement of gastrostomy tubes may facilitate nutritional therapy. The cat's requirement for B vitamins is eight times that of the dog, and dietary concentrations must be maintained to maintain appetite. Semimoist cat foods often contain propylene glycol, which can shorten red blood cell survival. These foods, although often quite palatable, should not be used for the nutritional management of cats infected with FeLV.[358] Many cats with FeLV are anemic, but administering erythropoietin is not helpful because endogenous erythropoietin levels usually are 20 times normal.[360]

Biologic Response Modifiers

A variety of BRMs have been used in cats infected with FeLV,[361–369] but none has shown benefit in controlled trials. A few of the most popular are discussed here.

Human recombinant, bovine, and feline interferons have been studied extensively for the management of FeLV infection, but the results have been mixed. However, some uncontrolled studies have shown improvement in the clinical status of cats treated with oral human recombinant interferon-α,[368] and one study in a limited number of cats using feline interferon subcutaneously showed improvement compared with placebo-treated controls.[410] Larger controlled trials are needed to establish the true efficacy of interferon products. Orally administered interferon probably is inactivated by gastric acid in the stomach. Parenterally administered interferons from other species (i.e., bovine and human) are likely to have only temporary activity because of the production of neutralizing antibodies.

Carrisyn (Acemannan) is a BRM designed to enhance macrophage phagocytosis and cell killing. Viremic cats treated with Carrisyn have been reported to improve clinically; however, the studies reporting these results have not been well controlled, and the observed benefit may be due to the natural waxing and waning of the clinical course commonly observed in FeLV-positive cats.[369]

A lymphocyte T-cell immunomodulator (LTCI) recently has become commercially available for the treatment of cats infected with FeLV and FIV. The true efficacy of this product, if any, awaits the results of controlled trials in cats.[370]

The apparent positive effect of many of the BRMs, which, in fact, may be due to the anabolic effect observed with some of these cytokines, is thought to be based on endorphin release rather than a direct effect on the viral infection.

Reverse Transcriptase Inhibitors

Drugs that inhibit RT and retrovirus integration into the host cell have been evaluated for their potential use in the treatment of FeLV-positive cats. The drugs evaluated include suramin (a polyionic dye used to treat filariasis in humans), nucleoside analogs (AZT, DDC, DDA, and PNEA), glucose homopolymers, dextran sulfate, phosphonate, and others.[371–374] More detailed descriptions of these therapies are provided elsewhere.[371,374] In general, most of these agents have shown efficacy *in vitro* against FeLV, the human immunodeficiency virus (HIV), and in some cases, FIV. Most of these drugs result in some reduction in viremia *in vivo*, but none are capable of reversing established viremia, although some may prevent viremia if administered prophylactically. Most of these drugs cause significant adverse effects at the dosages needed to produce antiviral effects and therefore have not gained popularity in clinical practice. Azidothymidine (AZT, zidovudine) is the most widely studied RT inhibitor.[375] AZT inhibits FeLV reverse transcriptase when administered at a dosage of 10 to 20 mg/kg in daily divided doses. AZT prevents viremia if given within 72 hours of exposure to FeLV. The antiviral effects of AZT appear to be synergistic with human recombinant interferon-α-2a.[376,377] Reversal of established experimental FeLV viremia through adoptive transfer of lectin/IL-2–activated lymphocytes, interferon-α, and AZT has been reported.

Prevention and Control

The most effective means of preventing FeLV infection is to eliminate contact with viremic cats. The "test and removal" program is the most effective means of controlling FeLV in multiple-cat households.[378] The program consists of closing the household or cattery to new cats, testing the remaining cats every 3 months, and removing all animals that test positive. When all cats test negative for two consecutive sessions, the facility is determined to be FeLV free. New cats may enter the household or facility only after a 3-month quarantine and two negative FeLV tests. The test and removal system has been shown to reduce the incidence of FeLV in a variety of settings and geographic locations.[378]

Prevention by Vaccination

Vaccinations help control or eliminate many infectious diseases in veterinary medicine. The first commercial FeLV vaccine was introduced in 1985. Since then many FeLV vaccine products have been licensed for sale to veterinarians in the United States. Despite the fact that FeLV vaccines have been available for decades, they come with the risk of injection site tumors. The frequency of use of FeLV vaccines continues to be debated, especially in adult cats, most of which develop age-acquired immunity. In addition to age-acquired immunity and the risk of injection site tumors, most currently available FeLV vaccines, although effective in preventing persistent viremia, fail to prevent latent infections of the bone marrow after challenge. Some studies of available vaccines have reported efficacies ranging from 0% to 100%.[379,380]

FeLV vaccination issues are discussed elsewhere.[341] However, several comments about FeLV vaccines should help practitioners decide whether to use FeLV vaccines in their practice. FeLV vaccines may contain two or three subgroup antigens. Because only subgroup A is transmitted contagiously between cats, vaccines need only to contain subgroup A. Their primary means of protecting against tumor development is preventing persistent viremia. If a vaccine protects against persistent FeLV infection, it need not contain FOCMA. The value of FOCMA in FeLV vaccines has yet to be proven. Vaccines should protect against a variety of strains of subgroup A, and none of the available vaccines contain more than one strain of subgroup A. Differences in published comparative studies of vaccine efficacy probably are related to differences in vaccine strains and to the challenge

VetBooks.ir

strains used. Vaccines that contain adjuvants enhance immunity but at the expense of producing local inflammatory reactions at the injection site.[381] These local reactions may lead to the development of soft tissue sarcomas; however, the development of soft tissue sarcomas after vaccination, either with rabies or FeLV vaccines, is thought to occur in only 1 in 1000 to 1 in 10,000 vaccinates.[380] Nonadjuvanted FeLV vaccines have shown little or no inflammatory reaction 21 days after administration.[381] A canarypox-vectored FeLV nonadjuvanted vaccine is available that stimulates both cellular and humoral immunity without significant injection site inflammation. Clinical discretion, considering the potential risk and benefit, should be used when recommending FeLV vaccines. The reader is advised to consider the current recommendations of the American Association of Feline Practitioners (AAFP) (www.catvets.com).

Feline Sarcoma Virus

FeSVs are true hybrids that result from the rare recombination of FeLV DNA provirus with cat proto-oncogenes. Cats have at least 30 proto-oncogenes.[306,382,383] Proto-oncogenes have many biologic functions; when they are altered and activated inappropriately, they are called *oncogenes*, which can play a key role in the development of cancerous phenotypes. Proto-oncogenes can be activated by mutations that produce chromosomal translocations, such as those that may be associated with inflammation and vaccine-associated sarcomas, or by incorporation into a retrovirus, such as FeLV.[382–384] When FeLV-derived DNA inserts near a proto-oncogene and takes up the proto-oncogene into the FeLV provirus, formation of FeSV results. In the process, part of the FeLV *GAG* gene, most of the FeLV envelope gene, and all of the pol genes are lost.[383] The loss of these vital components makes FeSV dependent on FeLV as a helper virus for replication. Cats that have FeSV always test FeLV positive. Because several different recombinations may recur with several different proto-oncogenes, each recombination is a unique event, and each isolate is distinct.[384] Despite this phenotypic heterogeneity, the recombinations transform fibroblasts, and all produce fibrosarcomas.

Natural transmission of FeSV between cats has not been described, and as with other FeLV recombinants (e.g., FeLV-B), transmission of the recombinant product is not thought to occur in nature. Some cats are capable of rejecting transformed cells and producing FOCMA antibody.[359,360] FOCMA is important in the experimental response of cats to FeSV because it has been associated with tumor regression and failure to develop tumors.[385] Cats that fail to develop antibodies against FOCMA die quickly of fast-growing sarcomas.[386]

Clinical Features of Feline Sarcoma Virus–Induced Fibrosarcomas

Only 2% of fibrosarcomas of cats are virally induced.[312] In contrast to the solitary, slow-growing, nonvirally induced sarcomas seen in older cats, FeSV-induced tumors are multicentric and are found most frequently in young cats.[387] They are characterized by rapid growth, including doubling times as short as 12 to 72 hours.[306] This rapid growth often is accompanied by superficial ulceration. Lesions frequently occur at sites of previous bite wounds.[306] Metastasis to the lungs or other organs occurs with approximately 30% of virally induced fibrosarcomas in cats. Hypercalcemia was observed in association with multicentric fibrosarcomas in one cat with FeSV.[306] Virally induced fibrosarcomas are always FeLV positive; this helps differentiate them from vaccine-associated sarcomas, which may have growth characteristics similar to those of virally induced tumors. Cats with multicentric FeSV-induced tumors have a very poor prognosis.

Feline Immunodeficiency Virus

FIV, which is classified as a retrovirus in the subfamily Lentivirinae, is distinct from other retroviruses that infect cats. As are other retroviruses, FIV is an enveloped, single-stranded RNA virus in which the RNA is copied into the DNA in the infected host by RT in the virus.

The nucleotide sequence of several FIV isolates has been determined, and genetic homology falls between 36% and 97%. Despite this homology, significant differences in pathogenicity and infectivity exist between FIV strains.[389,390] Although lentiviruses are known to infect wild felids, they are antigenically distinct from domestic cat isolates; they also are well adapted to their host and seldom cause clinical disease.

Transmission

FIV is present in all bodily fluids of infected cats, similar to FeLV, but at much lower concentrations. FIV is mainly cell associated and is present in relatively low concentrations in the blood, although high amounts can be found in the saliva.[391,392] FIV is not thought to be highly infectious and is mainly transmitted through biting during cat fights.[393,394]

Feline Immunodeficiency Virus–Associated Neoplasms

The prevalence of neoplasms in FIV-positive cats ranges from 1% to 62%.[352,395,396] Lymphomas and myeloid tumors (myelogenous leukemia, myeloproliferative disease) and a few carcinomas and sarcomas are the neoplasms most commonly linked to FIV infection. One study found that cats infected with FIV and FeLV are 5.6 times more likely to develop lymphoma or leukemia than if they had been infected with either virus alone. Cats with combined infections had a 77% greater likelihood of developing lymphoma or leukemia than noninfected cats.[352] In contrast to FeLV-associated lymphomas, FIV-associated lymphomas most often develop in extranodal sites and occur in older cats (mean age, 8.7 years).[352] Myeloproliferative disease also has been observed in cats naturally and in cats experimentally infected with FIV.[352,397,398]

Although lentiviruses such as FIV have not been thought to be oncogenic in themselves, they are markedly immunosuppressive and affect normal immunosurveillance of neoplastic cells. FIV-positive cats with lymphoma have extremely low CD4 lymphocyte counts.[388] SCCs of the skin have been linked to FIV infection in two geographic areas, California and Colorado, but this association is believed to be due to a co-risk behavior (outdoor cats) rather than to any direct viral contribution to tumor development.[399,400] Other reports have linked FIV infection to oral SCC, mammary carcinoma, fibrosarcoma, myeloproliferative disease, Bowen disease and histiocytic mast cell disease.[395,401,402] The nature of these associations awaits further investigation.

Treatment

The same treatment considerations in the management of cats with FeLV can be applied to the treatment of FIV-positive cats. The most widely applied treatments have been the RT inhibitors and human recombinant interferon-α (see the earlier discussion on the treatment of FeLV). As in the treatment of FeLV,

FIV-positive cats remain positive despite these therapies. A single inactivated FIV vaccine has been licensed for use in domestic cats. However, this is an adjuvanted vaccine, and it may be associated with an increased risk of vaccine-associated sarcoma. The primary concern with the vaccine is that it generates antibodies that cross-react with the currently recommended antibody-based diagnostic test for FIV infection. PCR-based tests are not currently considered reliable for diagnosis of FIV, and antibody-based testing remains the gold standard.[409] It is important to note that the AAFP does not recommend the use of an FIV vaccine in domestic cats.

Comparative Aspects

The association between human viruses and certain cancers has been established on the basis of epidemiologic, clinical, and molecular studies.[277] Human T-cell leukemia virus (HTLV-1) has been linked to adult T-cell leukemia. More than 100 papillomaviruses occur in humans; these are believed to be responsible for cervical cancer; for 25% to 60% of SCCs of the oral cavity; and in rare cases some SCCs that occur on the skin surface.[33] The human papillomavirus (HPV) is associated with cervical cancer. The Epstein-Barr virus (EBV) is related to the development of Burkitt lymphoma and nasopharyngeal carcinoma, and the human hepatitis B and hepatitis C viruses are associated with hepatocellular carcinoma. The human herpes virus (HHV) is implicated in the development of Kaposi sarcoma.

Tumor Biology and Metastasis

DAVID J. ARGYLE, CHAND KHANNA, AND NICOLE GIANCRISTOFARO

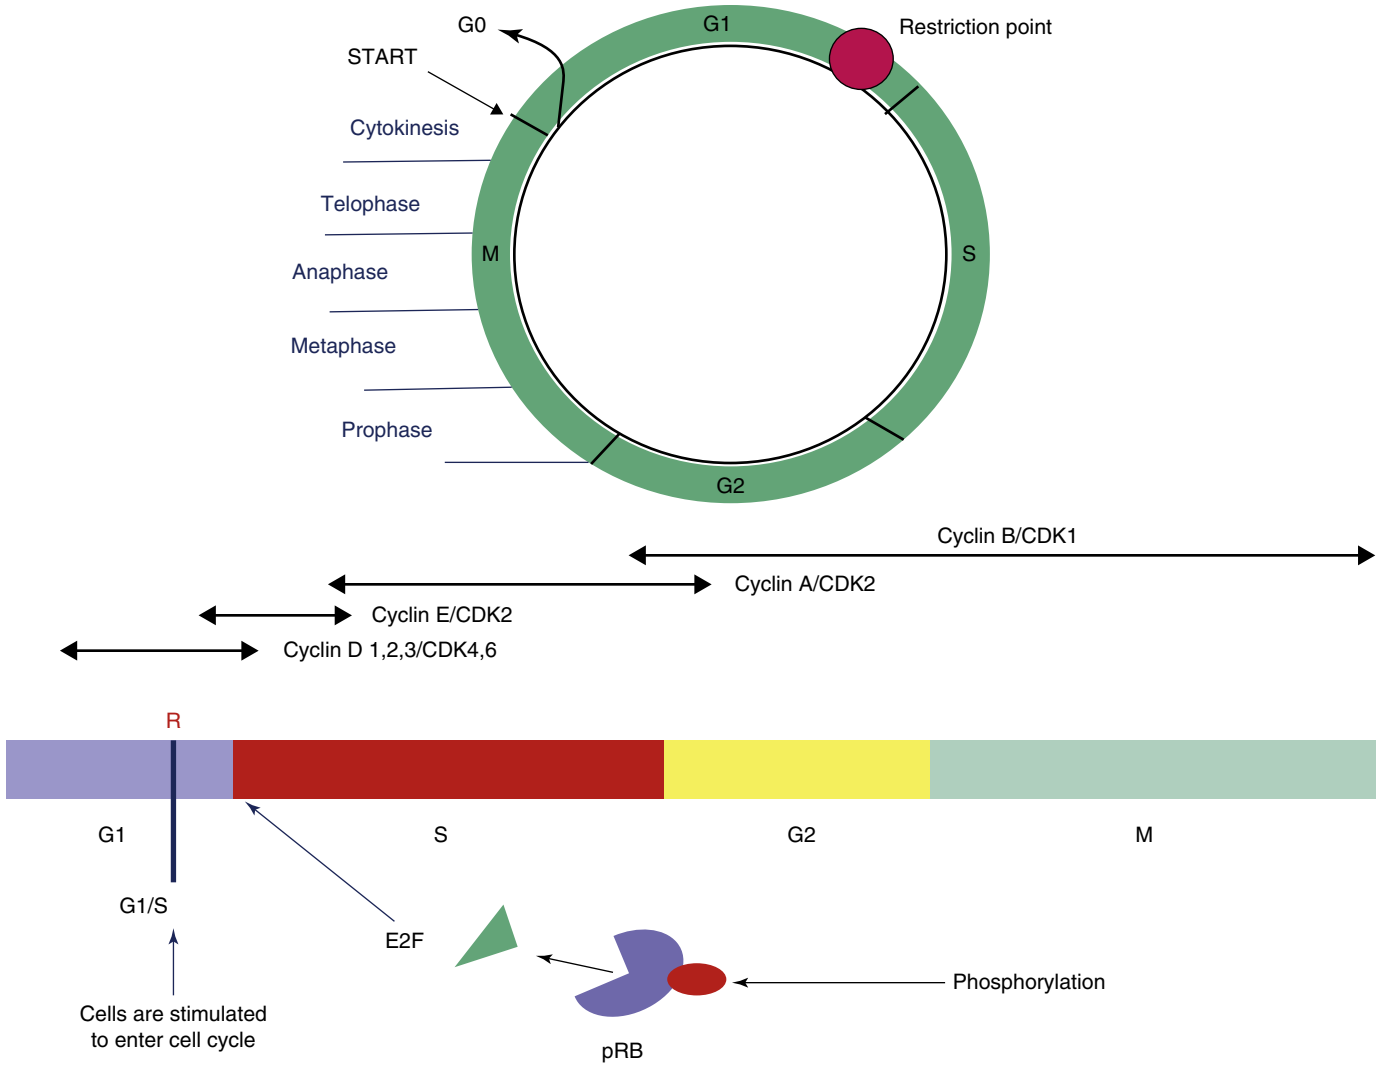
Cells of multicellular organisms form part of a specialized society that cooperate to promote survival of the organism. In this society, cell division, proliferation, and differentiation are strictly controlled, and a balance exists between normal cell birth and the natural cell death rate.[1] Derangement of these normal homeostatic mechanisms can lead to uncontrolled proliferation or loss of the ability to die, which may contribute to a normal cell taking on a malignant phenotype.

Cancer in animals is well documented throughout history but has taken on significance over the past hundred years for a number of reasons. Studies on chicken, feline, and bovine retroviruses have made significant contributions to our overall understanding of carcinogenesis through the discovery of oncogenes and tumor suppressor (TS) genes.[2] Further contributions to the understanding of viral oncogenesis have come from studies of the papillomaviruses in cattle and horses, complementing research into cervical cancer in women.[3–10] This complementary cancer research has paved the way for the development of programs of research in comparative medicine that has benefits for both humans and veterinary species. This chapter summarizes the current understanding of the molecular mechanisms of cancer development and metastasis.

Normal Cell Division

To understand the genesis of cancer, it is important to first understand the basic biology of normal cell division (i.e., normal cellular homeostasis). Within an animal all cells are subject to wear and tear, making cellular reproduction a necessity for maintenance of the individual. Reproduction of the gametes occurs by the process of meiosis, whereas reproduction of somatic cells involves two sequential phases known as *mitosis* and *cytokinesis.* Mitosis is nuclear division (karyokinesis), and cytokinesis involves the division of the cytoplasm, the two occurring in close succession. Nuclear division is preceded by a doubling of the genetic material of the cell during a period known as *interphase*. In addition to copying of the chromosomes, this period is characterized by marked cellular activity in terms of RNA, protein, and lipid synthesis. The alternation between mitosis and interphase in all tissues is often referred to as the *cell cycle.*

The Cell Cycle



The cell cycle comprises four phases (M phase, G1, S phase, and G2) (Fig. 2.1). Nonproliferating cells are usually arrested between the M (mitosis) and S (DNA synthesis) phases and are referred to as *G0 (quiescent) cells*. Most cells in normal tissues are in G0. Cells are stimulated to enter the cell cycle in response to external factors, including growth factors and cell adhesion. During the G1 phase of the cell cycle, cells are responsive to mitogenic signals. Once the cell cycle has traversed the restriction point (R) in the G1 phase, cell cycle transitions become autonomous.

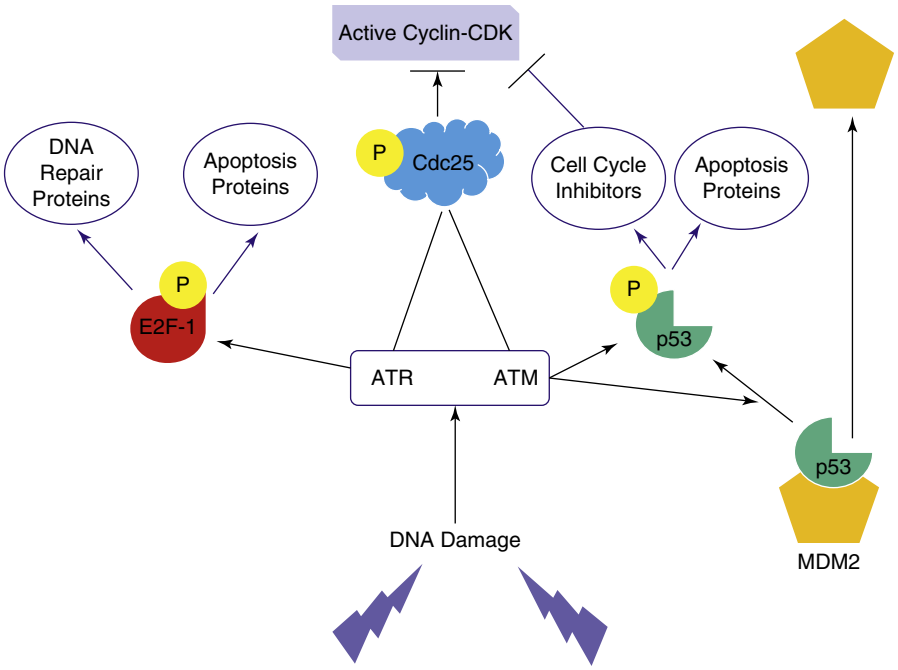
Interphase (G1, S, and G2 phases) is the longest phase of the cell cycle. During interphase the chromatin is very long and slender; however, it shortens and thickens as interphase progresses. The M phase is further subdivided into four phases. The first phase is referred to as *prophase* and sees the first appearance of the chromosomes. As the phase progresses, the chromosomes appear as two identical sister chromatids joined at the *centromere.* As the nuclear membrane disappears, spindle fibers form and radiate from the two *centrioles,* each located at opposite poles of the cell. The spindle fibers serve to pull the chromosomes to opposite sides of the cell.

During *metaphase* the spindle fibers pull the centromeres of the chromosomes, which become aligned to the middle of the spindle, often referred to as the *equatorial plate.* During *anaphase* the centromeres split and the sister chromatids are pulled apart by the contraction of the spindle fibers. The final stage of cell division is *telophase,* characterized by the formation of a nuclear membrane around each group of chromosomes, followed by cytokinesis or separation of the cytoplasm to produce two identical diploid cells. Progression through the cell cycle lasts approximately 12 to 24 hours.

Control of the Cell Cycle

Progression through the cell cycle is mediated by the sequential activation and inactivation of a class of proteins called *cyclin-dependent kinases* (CDKs).[11–16] CDKs are enzymes that catalyze the addition of phosphate groups onto target substrates involved in the processes of DNA replication, protein synthesis, and cell division. CDKs act as "fine tuning" for cell cycle control and so must themselves be controlled in a strict and temporal fashion. CDK activity is controlled by regulatory subunits known as *cyclins.*[11,13] Although the levels of CDKs remain constant throughout the cell cycle, the concentration of cyclins varies in a phase-specific manner during the cell cycle. The periodic synthesis and destruction of cyclins provides the primary level of cell cycle control (see Fig. 2.1). The activity of cyclin/CDK complexes is also regulated by phosphorylation. Activation of CDK/cyclin complexes

• **Fig. 2.1** The cell cycle and its control. The cell cycle is divided into four phases (G1, S, G2, and M) and G0, which represents cycle-arrested cells. Cells are stimulated to enter the cell cycle in response to external factors, including growth factors and cell adhesion molecules. During G1, cells are responsive to mitogenic signals. Once the cell cycle has traversed the restriction point (R) in the G1 phase, the cell cycle transitions become autonomous. Progression through the cell cycle is mediated by the sequential activation and inactivation of the cyclin-dependent kinases (CDKs). Control of CDK activity is through their interaction with specific cyclins (D, E, A, B) and with specific CDK inhibitors. G1-phase cyclin–CDK complexes commit the cell to cell cycle entry at the G1/S transition through phosphorylation of pRb, causing release of the E2F transcriptional factor and therefore an ability to overcome the Restriction point R and move into the S-phase. After completion of S phase, M-phase cyclin–CDK complex activity rises and drives the cell through the G2/M checkpoint by inducing chromosome condensation and creation of the mitotic spindle.



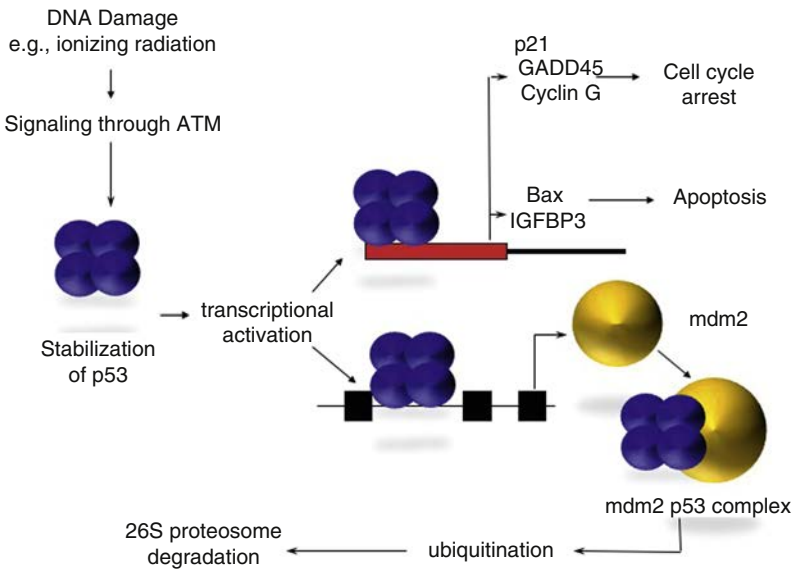
requires phosphorylation by *CDK-activating kinases* (CAKs); meanwhile, the phosphorylation at threonine and serine residues suppresses activity.[11–16] CDKs are also tightly regulated by a class of inhibitory proteins known as *CDK inhibitors* (CDKIs). CDKIs can block G1/S progression by binding CDKs/cyclin complexes and can be classified into two groups:

- INK4A family ($p15^{INK4b}$, $p16^{INK4a}$, $p18^{INK4c}$, and $p19^{INK4d}$).[13] These act primarily on CDK4 and CDK6 complexes and prevent the association with cyclin D.
- CIP/KIP family ($p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$).[13] These are less specific and can inactivate various cyclin/CDK complexes.

G1-phase cyclin–CDK complexes commit the cell to cell cycle entry at the G1/S transition through phosphorylation of Rb, causing release of the E2F transcriptional factor and therefore an ability to overcome the restriction point R and move into the S phase. After completion of S phase, M-phase cyclin–CDK complex activity rises and drives the cell through the G2/M checkpoint by inducing chromosome condensation and creation of the mitotic spindle. The corollary of all of these events is that loss of these control mechanisms can be a driving event in the development of cancer.[11–16]

Cellular Responses to DNA Damage

Cancer in animals and people is a common disease; however, considering the number of environmental stressors (that have the potential to cause DNA damage) to which cells are exposed on



• **Fig. 2.2** ATM and ATR can be considered as "sensor" kinases that are responsive to DNA damage. If DNA is damaged during the cell cycle, there is activation of ATM and ATR and subsequent phosphorylation of downstream targets involved in cell cycle progression, repair, and cell death. These initiate a number of signaling pathways that inhibit cell cycle progression and stimulate the expression of genes involved in DNA repair (e.g., E2F-1 and p53). ATM and ATR can also target the Cdc25 family of phosphatases. These can block the cyclin-CDK activity and thus inhibit cell cycle progression.

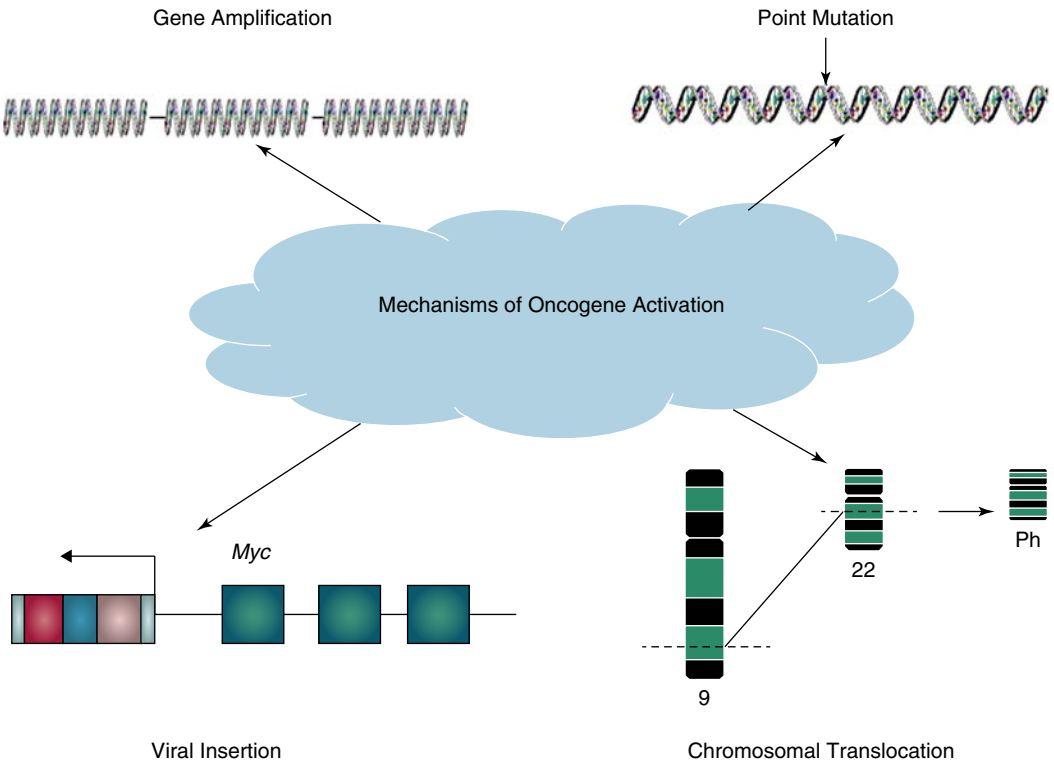
a daily basis and the total number of cells in the body, the formation of cancer actually could be considered a very rare event. This is because the cell has a number of homeostatic mechanisms to protect it from accumulated damage. When normal cells are subjected to stress signals (e.g., radiation, DNA damage, oxygen depletion), most cells have the ability to undergo cell cycle arrest in G1, S, and G2, enter programmed cell death (apoptosis), or both. Within cells, numerous surveillance systems called *checkpoints* function to recognize and respond to DNA damage. Cell cycle checkpoints occur in the G1 phase in response to DNA damage, during S phase to monitor the quality of DNA replication and the occurrence of DNA damage, and during the G2/M phase to examine the status of the spindle. ATM and ATR are two key protein kinases that are involved in DNA damage responses.[17] They can be considered "sensor" kinases that are responsive to DNA damage. If DNA is damaged during the cell cycle, there is activation of ATM and ATR and subsequent phosphorylation of downstream targets involved in cell cycle progression, repair, and cell death. These initiate a number of signaling pathways that inhibit cell cycle progression and stimulate the expression of genes involved in DNA repair (e.g., E2F-1 and p53). ATM and ATR can also target the Cdc25 family of phosphatases. These can block cyclin-CDK activity (described previously) and thus inhibit cell cycle progression. Mutations in DNA damage–responsive elements, such as ATM, ATR, and p53, generally result in an increase in the accumulation of damaged DNA in cells, which leads to an increased risk of developing cancer (Fig. 2.2).

p53 Functions as a Genomic Guardian

p53 is a negative regulator of the cell cycle and is intimately involved is the cell's response to DNA damage or stress.[18] The p53 response to stress is largely mediated through the ATM kinase (see Fig. 2.2) and leads to the phosphorylation of the N terminus of p53. In normal cells p53 is short lived; however, phosphorylated p53 is stabilized and can then function as a transcriptional regulator binding to specific DNA regulatory sequences and transactivating a number of genes, including p21.[19,20] p21 has a high affinity for G1 CDK/cyclin complexes and acts as a CDKI inhibiting kinase activity, thereby arresting cells in G1.[21,22] Holding cells in G1 prevents the replication of damaged DNA, and the cell's own DNA repair machinery has the opportunity to repair damage before the cell reenters the active growth cycle (Fig. 2.3).

Cellular levels of p53 protein are regulated by the product of another gene called mouse double minute 2 oncogene (MDM2).[23] The principal role of MDM2 is to act as a negative regulator of p53 function. One mechanism for MDM2's effect on p53 is targeting p53 for degradation.[20,22] The p53 protein is maintained in normal cells as an unstable protein, and its interaction with MDM2 can target p53 for degradation via a ubiquitin proteosome pathway. MDM2 can also control p53 function by suppressing p53 transcriptional activity. MDM2 is a transcriptional target of p53, and expression is induced by the binding of p53 to an internal promoter within the *mdm2* gene. MDM2 can in turn bind to a domain within the amino terminus of p53, thereby inhibiting the transcriptional activity and G1 arrest function of p53 by masking access to the transcriptional machinery.[21,22,24] This pivotal role for MDM2 in the regulation of p53 checkpoint function has provided the rationale to therapeutically target MDM2 with a number of novel therapeutic inhibitors (i.e., Nutlin). The highly conserved structure of these targets across species and expected activity in many cancers provides a strong rationale for the development of these agents in veterinary patients. The recent discovery that elephants have multiple copies of p53 may explain why this species has a very low incidence of cancer.[25]

• **Fig. 2.3** The mediators of apoptosis. A wide variety of signals can initiate an apoptotic response, including Fas ligand (CD95 or FasL) and its interaction with the Fas receptor, tumor necrosis factor (TNF) and its receptor interaction, and certain oncogenes. The Fas and TNF receptors are members of the death receptor family. These are transmembrane proteins with cysteine-rich extracellular domains and intracellular regions that share a common structure termed the *death domain.* The proapoptotic ligands for these receptors are homotrimeric peptides that are either soluble or expressed at the surface of the adjacent cell. Ligand-induced receptor clustering promotes the binding of a soluble cytosolic adapter protein called *Fas-associated death domain* (FADD), which itself contains a death domain, in addition to a caspase binding site, to the clustered death domains of the receptors. This leads to activation of caspase 8 and downstream activation of effector caspases for apoptosis.



Cell Death

If DNA damage is extensive and the cell cannot repair itself, then the cell may be triggered to die by apoptosis. In contrast to necrosis, apoptosis is a distinct type of cell death most often characterized as the "programmed" self-destruction of cells that occurs in disease states and also as part of normal physiologic cell turnover. Whereas necrosis is characterized by swelling of the cell and lysis, apoptosis is marked by cellular and nuclear shrinkage followed by fragmentation and subsequent phagocytosis. These morphologic features of apoptosis result from a number of apoptosis effectors (i.e., caspases) and regulators (particularly the Bcl-2 protein family). The molecular mechanisms involved in apoptosis are shown in Fig. 2.4.[26] Apoptosis provides a controlled mechanism for eliminating cells that are irreversibly damaged; it involves an adenosine triphosphate (ATP)–dependent activation of cellular pathways, which move calcium from the endoplasmic reticulum to the cytoplasm and activation of endonucleases. As noted previously, some of these pathways are mediated through caspases. However, a wide variety of signals can initiate an apoptotic response, including Fas ligand (CD95 or FasL) and its interaction with the Fas receptor, tumor necrosis factor (TNF) and its receptor interaction, and certain oncogenes. The Fas and TNF receptors are members of the death receptor family. These transmembrane proteins with cysteine-rich extracellular domains and intracellular regions share a common structure termed the "death domain." The proapoptotic ligands for these receptors are homotrimeric peptides that are either soluble or expressed at the surface of the adjacent cell. Ligand-induced receptor clustering promotes the binding of a soluble cytosolic adapter protein called *Fas-associated death domain* (FADD), which itself contains a death domain and a caspase binding site, to the clustered death domains of the receptors. This leads to activation of caspase 8 and downstream activation of effector caspases for apoptosis (Fig. 2.5).

If cells are damaged and unable to repair DNA, p53 expression can upregulate p21 and cause cell cycle arrest or can aid in directing the cell into programmed death or apoptosis through upregulation and expression of Bax (a proapoptotic Bcl-2 family protein) and also through priming of caspases. In this, the expression of p53 can also downregulate expression of the Bcl2 gene itself (a prosurvival, negative regulator of apoptosis).[22]

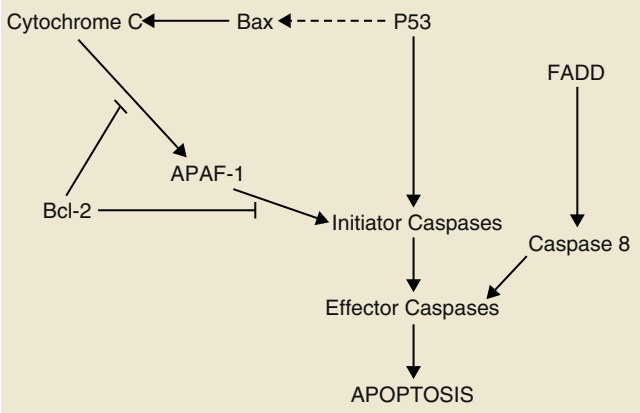
Key Points

- The cell cycle ensures a regulated process so that each cell can complete DNA replication before cell division occurs.
- The cell responds to growth and environmental signals through the cell cycle.
- Cancer is a common disease; however, the formation of cancer is actually a rare event, because of tightly regulated DNA repair mechanisms in the cell.
- Cellular responses to DNA damage are regulated through ATM and ATR, which act as "sensory kinases."
- The cellular response to DNA damage is either to inhibit cell cycle progression (allowing repair) or to facilitate entry into an apoptosis pathway. Failure to do this has the potential to promote the malignant phenotype.
- Components of the cell cycle that have a stimulatory effect include the cyclins and the CDKs. The negative influences come from a series of checkpoints that respond to external stimuli. These include tumor suppressor genes, such as p53 and Rb, and also genes involved in DNA repair.

• **Fig. 2.4** Methods of oncogene activation. Oncogenes can be activated by chromosomal rearrangements (e.g., BCR/ABL–induced leukemia), gene amplification (e.g., amplification of mouse double minute 2 oncogene [MDM2] in some sarcomas), point mutations (e.g., changes in nucleotide sequence that alter protein production), or by viral insertions (e.g., the insertion of feline leukemia virus [FeLV] at the *myc* locus in FeLV-induced lymphomas).

- The process of DNA replication is also subject to the introduction of errors, and this is closely monitored by a class of enzymes called *DNA repair enzymes.* Consequently, a number of safeguards within the cell cycle ensure that normal cells are produced during division and that the DNA is replicated accurately. The next section describes how these systems are overcome to produce a malignant cancer cell.

From Normal Cell to Cancer Cell



It is difficult to define a cancer cell in absolute terms. Tumors are usually phenotypically recognized by the fact that their cells show abnormal growth patterns and are no longer under the control of normal homeostatic growth-controlling mechanisms, including apoptosis. Although the range of mechanisms involved in the development of tumors and the spectrum of tissues from which tumors are derived are diverse, they can be classified into three broad types:

- **Benign tumors:** Broadly speaking, these tumors arise in any of the tissues of the body and grow locally. Their clinical significance is the ability to cause local pressure, cause obstruction, or form a space-occupying lesion, such as a benign brain tumor. Benign tumors do not metastasize.
- **In situ tumors:** These are often small tumors that arise in the epithelium. Histologically, the lesion appears to contain cancer cells, but the tumor remains within the epithelial layer and does not invade the basement membrane or the supporting mesenchyme. A typical example of this is preinvasive squamous cell carcinoma (SCC) affecting the skin of cats, which is often referred to as *Bowen's disease.*
- **Cancer:** This often refers to a malignant tumor, characterized by unchecked cellular division and the capacity for both local invasion and distant metastasis.

Multistep Carcinogenesis

Cancer has been defined as the phenotypic end result of a whole series of changes that may have taken a long period of time to develop. Indeed, recent studies that have sequenced the genome of pancreatic and brain tumors have identified 63 and 60 genetic alterations on average in each cancer, respectively. From this large list of genetic alterations, a small number of commonly mutated genes are "drivers" of the cancer phenotype.[27,28]

The application of a cancer-producing agent (carcinogen) to tissues does not lead to the immediate production of a cancer cell. After an *initiation* step produced by the agent, a period of tumor *promotion* follows. This promotion may be caused by the same initiating agent or by other substances, such as normal growth promoters or hormones. The initiating step is a rapid event and affects the genetic material of the cell. If the cell does not repair this damage, then promoting factors may progress the cell toward a malignant phenotype. In contrast to initiation, progression (the stochastic accumulation of mutations that impose a survival advantage on the daughter cells) may be a very slow process and may not even manifest in the lifetime of the animal. Each stage of multistep carcinogenesis collectively results in an accumulation of genetic changes in the cell that ultimately provide a selection advantage that drives the progression toward a highly malignant cell. The age-dependent incidence of cancer suggests that between four and seven rate-limiting, stochastic events are required to produce the malignant phenotype.[29]

• **Fig. 2.5** p53 is involved in cell cycle control. The p53 response to stress may be mediated by DNA-dependent protein kinase (DNA-PK) or by the ATM kinase and leads to phosphorylation of the N terminus of p53. In normal cells, p53 is short lived; however, phosphorylated p53 is stabilized and can then function as a transcriptional regulator binding to sequences and transactivating a number of genes, including p21 and Bax. Consequently, the cell cycle is arrested or the cell undergoes programmed cell death (apoptosis). The cellular levels of the p53 protein are regulated by the product of another gene mouse double minute 2 oncogene (MDM2). The principal role of MDM2 is to act as a negative regulator of p53 function. One mechanism for MDM2 to downregulate p53 is to target p53 for degradation. The p53 protein is maintained in normal cells as an unstable protein, and its interaction with p53 can target p53 for degradation via a ubiquitin proteosome pathway. MDM2 can also control p53 function by suppressing p53 transcriptional activity. MDM2 is a transcriptional target of p53, and expression is induced by the binding of p53 to an internal promoter within the MDM2 gene. MDM2 can in turn bind to a domain within the amino terminus of p53, thereby inhibiting the transcriptional activity and G1 arrest function of p53 by masking access to the transcriptional machinery.

In 2011 a new phenomenon was described that challenges the slower, stepwise progression of cancer development; this phenomenon suggests that thousands of clustered chromosomal rearrangements could occur in a single event in localized and confined genomic regions in one or a few chromosomes. This event, known as *chromothrypsis,* occurs through one massive genomic rearrangement during a single catastrophic event in the cell's history.[30–32] Although chromothrypsis may occur as an early event in cancer cells, leading to more rapid transformation through loss of TS function or gain of oncogene function, the phenomenon has never been recapitulated in experimental models, but rather remains a cytogenomic observation in several pediatric cancers. Indeed, the lack of mechanistic understanding of chromothrypsis has limited its study in conventional animal models.[30–32]

Irrespective of speed of development, these events in tumor formation are a consequence of changes in genes or the regulation of gene expression. Over the past 30 years cancer research has generated a rich and complex body of information revealing that cancer is a disease involving dynamic changes in the genome. Seminal to our understanding of cancer biology has been the discovery of the so-called *cancer genes* or *oncogenes* and *TS genes.* Mutations that produce oncogenes with dominant gain of function and TS genes with recessive loss of function have been identified through their alterations in human and animal cancer cells and by their elicitation of cancer phenotypes in experimental models. A summary of the differences between oncogenes and TS genes is highlighted in Table 2.1.

TABLE 2.1 Key Differences Between Oncogenes and Tumor Suppressor Genes

Oncogenes	Tumor Suppressor Genes
Altered versions of proto-oncogenes that play a role in promoting cellular proliferation. Considered to be the cellular "gas pedal."	Genes involved in blocking cellular proliferation. Considered to be the cellular "brakes."
Mutation at the cellular level causes a dominant gain of function.	Mutations are recessive and require loss of both alleles for a phenotypic change.
Mutation causes a gain of function.	Mutation causes a loss of function.
Mutations occur in somatic cells.	Mutations can occur in germ cells (inherited cancer predisposition) and/or can arise in somatic cells.

Oncogenes

The RNA tumor viruses (retroviruses) provided the first evidence that genetic factors play a role in the development of cancer. The initial observation came in 1910, when Rous demonstrated that a filterable agent (later classified as a retrovirus and termed *avian leukosis virus*) was capable of producing lymphoid tumors in chickens.[33] Retroviruses have three core genes (*gag, pol,* and *env*) and an additional gene that gives the virus the ability to transform cells. Retroviral sequences responsible for transforming properties are called *viral oncogenes* (v-onc). The names of these genes are derived from the tumors in which they were first described (e.g., *v-ras* from rat sarcoma virus).

Viral oncogenes were subsequently shown to have cellular homologs called *cellular oncogenes* (c-onc). Later, the term *proto-oncogene* was used to describe cellular oncogenes that do not have transforming potential to form tumors in their native state but can be altered to lead to malignancy.[34] Most proto-oncogenes are key genes involved in the control of cell growth and proliferation, and their roles are complex. For simplicity, their sites and modes of action in the normal cell can be divided as follows (Table 2.2):

- Growth factors
- Growth factor receptors
- Protein kinases
- Signal transducers
- Nuclear proteins and transcription factors

Growth Factors

Growth factors (GFs) are molecules that act on the cell via cell surface receptors. Their contribution to carcinogenesis may be through excessive production of the GF or through ectopic expression in a cell type that does not normally express that GF.

Growth Factor Receptors

Several proto-oncogene–derived proteins form a part of cell surface receptors for GFs. The binding of GF ligand to receptor is the initial stage of the delivery of mitogenic signals to cells. Their role in carcinogenesis may be through structural alterations in these proteins, leading to enhanced or constitutive activation.

TABLE 2.2 Functional Classification of Tumor Oncogenes

Oncogene	Name	Abbreviation
Growth factors	Platelet-derived growth factor	PDGF
	Epidermal growth factor	EGF
	Insulin-like growth factor-1	IGF-1
	Vascular endothelial growth factor	VEGF
	Transforming growth factor-β	TGF-β
	Interleukin-2	IL-2
Growth factor receptors	PDGF receptor	PDGFR
	EGF receptor	EGFR, erbB-1
	IGF-1 receptor	IGF-1R
	VEGF receptor	VEGFR
	IL-2 receptor	IL-2R
	Hepatocyte growth factor receptor	C-met
	Heregulin receptor	neu/erbB-2
	Stem cell factor receptor	C-Kit
Protein kinases	Tyrosine kinase	bcr-abl
	Tyrosine kinase	src
	Serine-threonine kinase	raf/mil
	Serine-threonine kinase	mos
G-protein signal transducers	GTPase	H-*ras*
	GTPase	K-*ras*
	GTPase	N-*ras*
Nuclear proteins	Transcription factor	ets
	Transcription factor	fos
	Transcription factor	jun
	Transcription factor	myb
	Transcription factor	myc
	Transcription factor	rel

GTPase, Guanosine triphosphatase.

Protein Kinases

Protein kinases are associated with the inner surface of the plasma membrane and are involved in signal transduction after ligand-receptor binding. Structural changes in these genes and proteins lead to increased kinase activity that can have profound effects on signal transduction pathways.

Signal Transduction

The binding of an extracellular GF to the membrane receptor leads to a series of events by which the mitogenic signal is transduced to the nucleus of the cell. Essential to this signaling is the successive phosphorylation of signaling intermediaries or the second messengers such as guanosine triphosphate (GTP) and proteins that bind GTP (G-proteins). During signal transduction GTP is converted to guanosine diphosphate (GDP) by the guanosine triphosphatase (GTPase) activity of G-proteins. A group of proto-oncogenes called *Ras* encode proteins with GTPase and GTP-binding activity and, in the normal cell, help modulate cellular proliferation. Mutations in the *Ras* proto-oncogene can contribute to uncontrolled cellular proliferation.

Nuclear Proteins and Transcription Factors

Nuclear proteins and transcription factors encode proteins that control gene expression. These proto-oncogenes may have roles in cellular proliferation. Not surprisingly, changes in transcription factor activity may contribute to the development of the malignant genotype.

Mechanisms by which Oncogenes Become Activated

The advent of recombinant DNA technology has allowed scientists to unravel a number of mechanisms by which the normal products of proto-oncogenes can be disrupted to produce uncontrolled cell division. The conversion of a proto-oncogene to an oncogene is a result of somatic events in the genetic material of the target tissue. The activated allele of the oncogene dominates the wild-type allele and results in a *dominant gain of function.* This means that only one allele needs to be affected to obtain phenotypic change; this is in contrast to TS genes, in which both alleles have to be lost for phenotypic change. The mechanisms of oncogene activation are outlined in this list and are shown in Fig. 2.4.[34–41]

- *Chromosomal translocation.* When proto-oncogenes are translocated within the genome (i.e., from one chromosome to another), their function can be greatly altered. The classic example in human medicine is the chromosomal breakpoint that produces the Philadelphia chromosome found in chronic myelogenous leukemia (CML). This involves translocation of the *c-abl* oncogene on chromosome 9 to a gene on chromosome 22 (*bcr*). The point where two genes come together is referred to as a *chromosomal breakpoint* (or *translocation breakpoint*).[42] The BCR/ABL hybrid gene produces a novel transcript whose protein product has elevated tyrosine kinase activity and can contribute to uncontrolled cellular proliferation. Transgenic mice for this chimeric gene develop lymphoblastic leukemia and lymphoma. Because this gene product is linked directly to CML formation, it is a logical target for tyrosine kinase inhibitors in the treatment of CML in humans.
- *Gene amplification.* Quantitation of gene copy number is possible by a number of molecular techniques, including comparative genomic hybridization, genotyping arrays, and Southern hybridization. Amplification of oncogenes can occur in a number of tumor types and has been demonstrated in childhood neuroblastoma, in which the *myc* proto-oncogene (nuclear transcription factor) is amplified up to 300 times.[43] Gene amplification is possibly the most common mechanism of proto-oncogene activation. A further example is the MDM2 proto-oncogene, which has been identified in dogs and horses, and recently was shown to be amplified in a proportion of canine soft tissue sarcomas.[44]
- *Point mutations.* These are single base changes in the DNA sequence of proto-oncogenes, leading to the production of abnormal proteins. Point mutations can arise through the actions of ionizing radiation, chemical carcinogens, or errors in DNA replication and repair. A mutation in a proto-oncogene

VetBooks.ir

or the transcriptional machinery that controls its expression may disrupt homeostasis and result in sustained proliferation signals or failure to respond to negative feedback signals. A classic example is the *Ras* proto-oncogene, in which point mutations are a consistent finding in a number of human tumors. Point mutations have also been identified in a number of canine tumors, suggesting a model for human disease.[45–47]

- *Viral insertions.* The discovery of oncogenes was a direct result of studies on tumor-causing viruses. In some circumstances proto-oncogene function can be damaged by the insertion of viral elements.[48–50] Occasionally, novel retroviruses are isolated from leukemias or sarcomas in animals that have been viremic with a leukemia virus for some time. These viruses induce tumors very rapidly when inoculated into members of the species of origin and are referred to as *acutely transforming oncoviruses.* The prototype of the acutely transforming virus is the Rous sarcoma virus (RSV) isolated from a chicken in 1911.[51] Subsequently, many more have been isolated from animals infected with avian, feline, murine, or simian oncoviruses. These viruses are generated by a rare recombinant event between the leukemia virus, with which the animal was originally infected, and a cellular proto-oncogene. In this, part of the viral genome is deleted and replaced with the cellular oncogene. The virus then becomes acutely transforming because this oncogene is now under the transcriptional control of a very efficient viral promoter. This then allows infection of a cell and insertion of this continuously expressed oncogene into the cellular genome, leading to rapid progression and malignancy. Evidence suggests that these acutely transforming viruses are not transmitted naturally, but all events occur in the individual animal. Because the virus has itself lost some of its own genetic material, it is defective for replication; however, it is spread throughout an animal by the provision of help from the normal leukemia virus, which provides the missing proteins in co-infected cells. In addition to acutely transforming mechanisms, retroviruses can activate cellular oncogenes by integrating adjacent to them. A good example of this is the *myc* gene, which is frequently activated in feline T-cell lymphomas.[52] In one mode, the virus integrates adjacent to the oncogene, and transcription initiation in the viral long terminal repeat (LTR) proceeds into the adjacent oncogene, producing a hybrid mRNA. In a second form, the enhancer of the virus overrides the regulation of the c-*myc* transcription from its normal promoter.

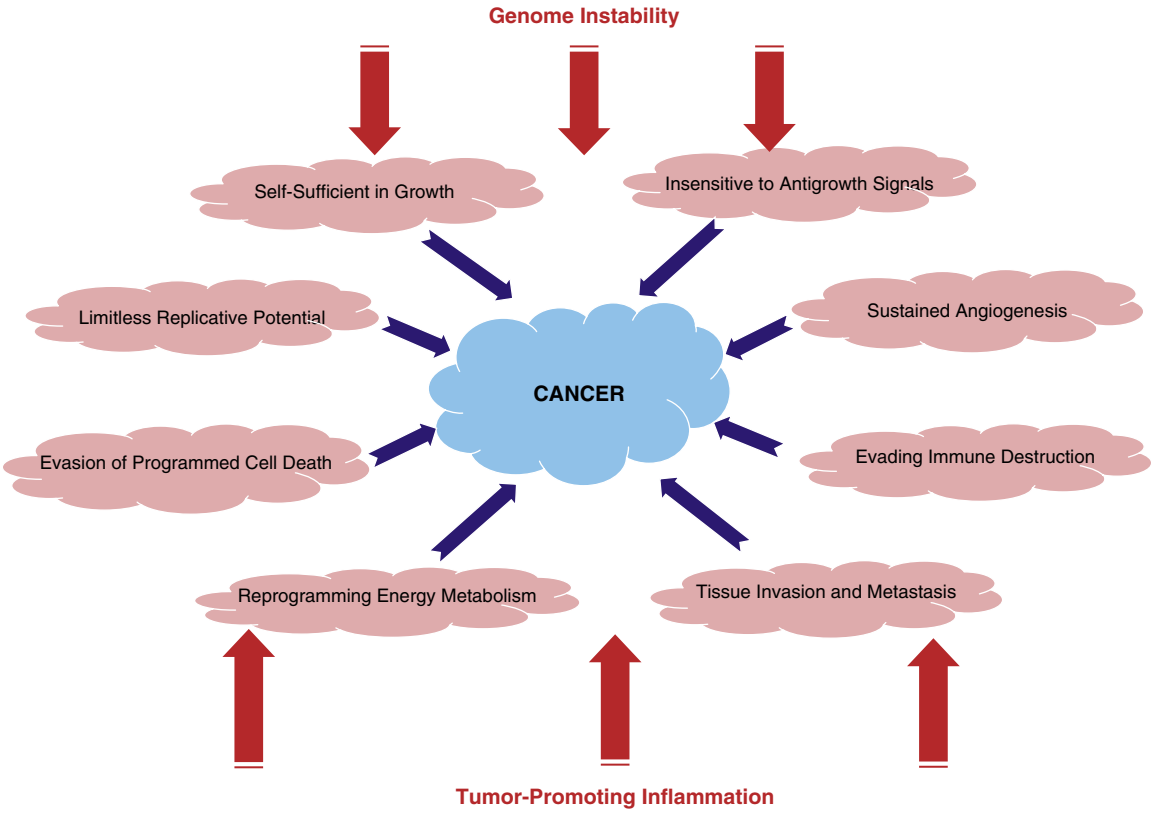
Tumor Suppressor Genes

Changes in genes can lead either to stimulatory or inhibitory effects on cell growth and proliferation. The stimulatory effects are provided by the proto-oncogenes, as described earlier. Mutations or translocations of these genes produce positive signals leading to uncontrolled growth. In contrast, tumor formation can result from a loss of inhibitory functions associated with another class of cellular genes called the *TS genes.* The discovery of these genes began by observations of inherited cancer syndromes in children, in particular studies of retinoblastoma. In the early 1970s epidemiologic studies of both retinoblastoma and Wilms tumor led Knudson to propose his "two hit" theory of tumorigenesis.[53]

Retinoblastoma Provides the First Clues to the Existence of Tumor Suppressor Genes

Retinoblastoma occurs in two forms: a sporadic form and an inherited form (accounting for 40% of cases).[54] In the inherited form the mode of inheritance is autosomal dominant, and about half the children are affected by the condition. Knudson's model required the retinoblastoma tumor cells (in either sporadic or inherited forms) to acquire two separate genetic changes in the DNA before tumor development. The first or predisposing event could be inherited through the germ line (familial retinoblastoma) or it could arise de novo in somatic cells (sporadic form). The second event occurred in somatic cells. Thus in sporadic retinoblastoma both events arose in the retinal cells. However, in familial retinoblastoma, the individual had already inherited one mutant gene and required only a second hit in the remaining normal gene in somatic cells.

The mode of inheritance of retinoblastoma is dominant with incomplete penetrance. However, at the cellular level loss or inactivation of both alleles is required to change the cells' phenotype. The retinoblastoma gene codes for Rb, which was previously described as a normal cellular gene involved in control of the cell cycle (see earlier discussion). Rb is described as a TS and, in a cell with only one normal allele, that allele usually produces enough TS product to remain normal. Generically mutations in TS genes behave very differently from oncogene mutations. Whereas activating oncogene mutations are dominant to wild type (they emit their proliferating signals regardless of the wild-type gene product), suppressor mutations are recessive. Mutation in one gene copy usually has no effect, as long as a reasonable amount of wild-type protein remains. Consequently, some texts refer to TS genes as "recessive oncogenes."



More recently Knudson's hypothesis was confirmed when the Rb gene was cloned and characterized. The TS Rb is the principal member of a family of proteins that also encompass pRb2/p130 and p107. Rb plays a central role in regulating cell cycle progression in G1 to S phase (see Fig. 2.2). Indeed, disruption of Rb function has been found to be a common feature of many human cancers other than retinoblastoma. Rb function can be abrogated by point mutations, deletions, or complex formation with viral oncoproteins, such as SV40 large T antigen and adenoviral E1a protein.[55] The function of additional proteins associated with the Rb pathway is also subjected to deregulation in human cancers, including overexpression of D type cyclins, overexpression of CDK4, and downregulation of the CDKI cell cycle inhibitor p16.[56] Although loss of cell cycle control via the Rb pathway occurs commonly in many human tumors, little is known about the role of Rb, cyclin D, CDK4, and p16 in domesticated animal tumors.

The p53 Tumor Suppressor Gene

As described previously, p53 is a gene whose product is intimately involved as a negative regulator of the cell cycle control. Its discovery by Sir David Lane in 1979 marked a major milestone in cancer research and has allowed greater understanding of molecular mechanisms of cancer and identified potential targets for therapeutic intervention.[57]

The p53 protein has been described as the "guardian of the genome" by virtue of its ability to push cells into arrest or apoptosis, depending on the degree of DNA damage. Thus the p53 TS gene plays an important role in cell cycle progression, regulation of gene expression, and the cellular response mechanisms to DNA damage. Under normal physiologic conditions, wild-type p53 can bind specific DNA sequences and regulate transcription of a number of genes involved in cell cycle progression and apoptotic pathways, including $p21^{waf1/cip1}$ and *Bax* (see Fig. 2.5). The p53-mediated mechanisms are responsible

VetBooks.ir

• **Fig. 2.6** The hallmarks of cancer. Cancer can be considered the end product of acquisition of eight fundamental characteristics. Underpinning these capabilities are the common denominator enabling characteristics of genome instability and tumor-promoting inflammation.

for tumor suppression and prevent accumulation of potentially oncogenic mutations and genomic instability. Failure of p53 to activate such cellular functions may ultimately result in abnormal uncontrolled cell growth, leading to tumorigenic transformation.[58–62]

p53 is the most frequently inactivated gene in human neoplasia, with functional loss commonly occurring through gene mutational events, including nonsense, missense and splice site mutations, allelic loss, rearrangements, and deletions. However, p53 function can also be abrogated by several nonmutational mechanisms, including nuclear exclusion, complex formation with a number of viral proteins, and through overexpression of the cellular oncogene MDM2.[63]

The homologs of p53 and MDM2 have both been identified in domestic animal species, and a number of studies indicate that this gene also has a central role in the progression of veterinary cancers.[64–68]

Key Points

Fig. 2.6; also see Table 2.1.

- Cancer is a genetic disease characterized by aberrant molecular changes in the genetic material of the cell.
- Cancer arises through mutations in DNA and/or changes in gene expression (epigenetic events).
- Cancer is a clonal disease resulting from the accumulation of mutations in oncogenes or tumor suppressor genes. Each successive change leads to a survival advantage for the cell, akin to darwinian natural selection.
- In this process of natural selection, the acquired characteristics that are advantageous to the cancer phenotype are often referred to as the *hallmarks of cancer.*
- Studies on viral carcinogenesis and/or monogenic cancer syndromes have facilitated the dissection of cancer biology and the identification of cancer-causing genes (oncogenes and tumor suppressor genes). However, most cancers encountered in clinical practice are sporadic (occurring as a result of changes in adult somatic cells) and not inherited.
- Proto-oncogenes are normal genes involved in growth and proliferation and can be "activated" to promote malignancy.
- Tumor supressor genes are normal genes expressing proteins that inhibit growth and proliferation.
- If proto-oncogenes are the "accelerator pedal" in a cell, then tumor supressor genes are the "brakes."
- Gain of function in oncogenes and/or loss of function in tumor suppressor genes promotes the malignant phenotype.

Cancer Arises through Multiple Molecular Mechanisms

The advances in understanding of normal cell biology and the processes that lead to malignancy have increased dramatically over the past 30 years. The last decade has shown that transformation of a normal cell into a malignant cell requires very few molecular, biochemical, and cellular changes that can be considered as acquired capabilities.[42,43] Furthermore, despite the wide diversity of cancer types, these acquired capabilities appear to be common to all types of cancer. An optimistic view of increasing simplicity

VetBooks.ir

in cancer biology is further endorsed by the fact that all normal cells, irrespective of origin and phenotype, carry similar molecular machineries that regulate cell proliferation, differentiation, aging, and cell death.

Tumorigenesis is a multistep process, and these steps reflect genetic alterations that drive the progression of a normal cell into a highly malignant cancer cell. This is supported by the finding that genomes of tumor cells are invariably altered at multiple sites. The spectrum of changes ranges from subtle point mutations in growth regulatory genes to obvious changes in chromosomal complement.

Cancer cells have defects in regulatory circuits that govern cellular proliferation, homeostasis, and survival. A model has been proposed that suggests that the vast array of genetic abnormalities associated with cancer is a manifestation of eight alterations in cellular physiology that collectively contribute to malignant growth. First proposed in 2000 and updated in 2011, these "hallmarks" of cancer constitute an organizing principle for rationalizing the complexities of cancer and are underpinned by two overarching themes: *genome instability* and *chronic inflammation*.[69,70] The eight acquired characteristics can be summarized under these headings (see Fig. 2.6):

- Self-sufficient growth
- Insensitivity to antigrowth signals
- Evasion of programmed cell death (apoptosis)
- Limitless replicative potential
- Sustained angiogenesis
- Reprogramming energy metabolism
- Evading immune destruction
- Tissue invasion and metastasis

Cancer exhibits another dimension of complexity in that it contains an array of "normal" cells that contribute to the acquisition and maintenance of the cancer hallmarks by creating the tumor microenvironment (TME). The next section is an overview of these traits and the strategies by which they are acquired in cancer cells. The process of metastasis requires angiogenesis and invasion; therefore the traits of sustained angiogenesis and tissue invasion and metastasis are collectively reviewed under a final section on metastasis.

The Hallmarks of Cancer

In the preceding section we described the normal cell and the role of oncogenes and TS genes in cell cycle control and regulation. Directly or indirectly all components of the cancer phenotype (i.e., hallmarks of cancer) emerge from dysregulation of genes or the regulation of gene expression. Cancer-associated changes in the regulation of gene expression (epigenomics) have increasingly become the focus of cancer research. Amplifying this study of the regulation of gene expression has been a new understanding of therapeutic interventions that target various aspects of gene regulation (e.g., bromodomain inhibitors).[71]

Furthermore, understanding of the targets of the regulation of gene expression has expanded from the conventional view of epigenetic regulation of promoter activity to a new understanding of enhancer epigenomics and the description of "super enhancers." As suggested by the name, super enhancers may be considered to be have a broad control of a transcriptional signature. As such, the alteration in the activity of a single super enhancer may yield a change in many transcriptional components of the cancer phenotype.[72]

As described previously, cancer is a very common disease in animals and humans; however, the development of cancer is, in fact, a rare event. Despite the number of cells in the body, the proliferation and regulation of these cells, and the potential for malignant transformation, the development of a single cancer is rare. This is because of the cell's own natural defenses against progression toward the malignant phenotype. The ability of the cell to effect DNA repair or initiate cell death is a defense mechanism against malignant transformation and serves to maintain cellular homeostasis. Each of the acquired capabilities described previously represents a breach in a cell's homeostatic mechanisms. However, the biology of cancer cannot be understood by simply considering the phenotypic traits of the cancer cell. Rather, the cancer phenotype is defined by the interactions between the cancer cell, the TME, and the enabling effects of fundamental genomic instability and chronic inflammation.

Self-Sufficiency in Growth Signals

Normal cells require mitogenic stimuli for growth and proliferation. These signals are transmitted to the nucleus by the binding of signaling molecules to specific receptors, the diffusion of growth factors into the cell, extracellular matrix (ECM) components, or cell-to-cell adhesions or interactions.[73,74] As previously discussed, many oncogenes act by mimicking normal growth signals. Tumor cells are not dependent on external mitogenic stimuli for proliferation and sustained growth, but rather are self-sufficient. The liberation from dependency on exogenous signals severely disrupts normal cellular homeostasis. Arguably the most fundamental trait of cancer cells is their ability to sustain chronic proliferation. By deregulating these signals, cancer cells become masters of their own destinies, promoting signaling (typically through intracellular kinase domains) to promote progression through the cell cycle, increases in cell size, increases in cell survival, and changes in energy metabolism.

The cancer cell can acquire this capability in a number of ways:

- They may produce growth factor ligands themselves.
- They may induce stromal cells to produce such ligands.
- Receptor concentration on the cell surface may increase, leading to receptor homodimerization or heterodimerization, making the cell hyperresponsive to ligands.
- Structural alterations in the receptor may take place that cause ligand-independent "firing."
- Constitutive activation of the signaling pathway (downstream of the receptor) may occur. A good example of this is the constitutive activation of the PI3K-Akt pathway, through mutations in the catalytic subunit of the PI3 kinase.
- Disruptions in negative feedback mechanisms that attenuate proliferative signaling may occur; for example:
    - Mutations in the *Ras* gene compromise the Ras GTPase activity, which acts as a negative feedback mechanism to ensure the effects of *Ras* are only transitory.
    - *PTEN* is a tumor suppressor protein that counteracts PI3K signaling. *PTEN* loss has an effect similar to constitutive PI3K activation and promotes tumorigenesis.

Although the acquisition of growth signaling autonomy by cancer cells is conceptually satisfying, it is in fact too simplistic. One of the major problems of cancer research has been focusing on the cancer cell in isolation. It is now apparent that we must also consider the contribution of the TME to the survival of cancer cells. Within normal tissues paracrine and endocrine signals contribute greatly to growth and proliferation. Cell-to-cell growth signaling is

VetBooks.ir

also likely to operate in cancer cells and may be as important as some of the autonomous mechanisms of tumor growth. It recently was suggested that growth signals for the proliferation of carcinoma cells are derived from the tumor stromal elements (e.g., cancer- or carcinoma-associated fibroblasts [CAFs]). It is therefore possible that the survival of tumor cells not only relies on the acquisition of growth signal autonomy, but also may require the recruitment or modulation of stromal cells to provide these growth signals.

Insensitivity to Antigrowth Signals or Evading Growth Suppressors

Within the normal cell multiple antiproliferative signals operate to maintain cellular quiescence and homeostasis. These signals include soluble growth inhibitors that act via cell surface receptors and immobilized inhibitors that are embedded in the ECM and on the surface of nearby cells. The signals operate to push the cell either into G0 or into a postmitotic state (usually associated with the acquisition of specific differentiation–associated characteristics) and thus are intimately associated with cell cycle control mechanisms. Cells monitor their external environment during the progression through G1 and, on the basis of external stimuli, decide whether to proliferate, become quiescent, or enter into a postmitotic state.

Most cellular programs that negatively regulate cell growth and proliferation depend on the actions of TS genes. At the basic level most of the antiproliferative signals are funneled through the Rb protein and its close relatives. Disruption of Rb allows cell proliferation and renders the cell insensitive to antiproliferative signals, such as that provided by the well-characterized transforming growth factor-β (TGF-β).[54] The Rb protein integrates signals from diverse extracellular and intracellular sources and can control cell cycle progression. The other major TS is p53, which integrates intracellular signals and can promote either cell cycle arrest or apoptosis (depending on the degree of cellular stress or damage). However, the effects of p53 expression are highly context dependent. Loss of Rb or p53 is associated with the malignant phenotype through the cell's ability to evade antigrowth signals.

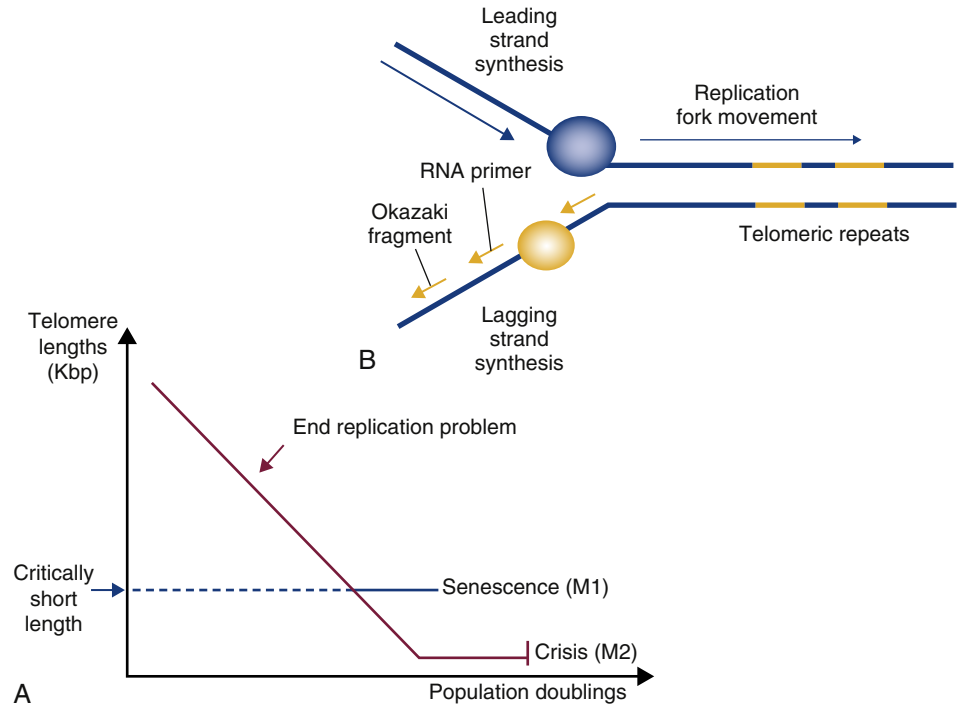
In addition to TS gene loss, cells can evade antigrowth signals by alternative cellular programs:

- Evasion of contact inhibition. Cell-to-cell contact in most normal cells results in an inhibitory signal against further cell proliferation. The role of this mechanism in vivo has been thought to be to maintain tissue homeostasis. In cell culture contact inhibition is abrogated in cancer cell monolayers, leading to their indefinite expansion. NF2 and LKB1 genes are considered tumor suppressor genes that are involved in this process, and loss of these genes in vivo may promote loss of contact inhibition that contributes to the progression of cancers.[75]
- Although TGF-β has antiproliferative effects in cancer, it is now appreciated that the TGF-β pathway can be corrupted in the later stages of malignancy and can contribute to cancer progression.[76]
- In this late effect TGF-β is found to activate a cellular program termed *epithelial-to-mesenchymal transition* (EMT) that promotes invasion and metastasis (see the following discussion).

Evading Cell Death: The Roles of Apoptosis, Autophagy, and Necrosis

The growth of any tumor depends not only on the rate of cell division, but also on the rate of cellular attrition (mainly provided by apoptotic mechanisms). Basic molecular and pathologic studies of tumors have confirmed that acquired resistance toward apoptosis and other types of death is a hallmark of all types of cancer.

Cancer cells, through a variety of strategies, can acquire resistance to cell death and apoptosis. One of the most common ways is through loss of function of the TS protein p53. Removal of normal p53 function leads to failure of the cells' sensor mechanism for DNA damage. When the cell suffers an insult, such as UV radiation, hypoxia, or exposure to DNA-damaging agents, signals are funneled through p53 to cause either cell cycle arrest or apoptosis. Failure of this mechanism can contribute to the progression of the cell toward malignancy and promote the accumulation of additional genetic defects that are not corrected at defined checkpoints in cell cycle progression.[59]



The mechanisms involved in apoptosis are now well established, as are the strategies by which cancer cells evade its actions. However, recently conceptual advances have been made involving other forms of "programmed cell death" as a barrier to cancer development. A notable example is the emerging role that autophagy plays in cancer development. *Autophagy* is a normal cellular response that operates at low basal levels in cells but can be induced in states of cellular stress, such as nutrient deficiency. In autophagy controlled breakdown of cellular organelles yields energy and cellular substrates that can be used for a variety of cellular functions. Recent evidence suggests that autophagy may be involved in both tumor cell survival and, paradoxically, tumor cell death, depending on the cellular state. The link between apoptosis and autophagy suggests that autophagy may represent another barrier for cells to overcome before they can attain malignancy. In contrast, it has also been shown that irradiation or cytotoxic drug treatment in late-stage tumors may promote autophagy, leading to cells attaining a state of reversible dormancy. The situation seems to suggest that autophagy is a barrier to tumor development in early disease, but in late-stage disease may allow cancer cells to survive severe cellular stress.[77,78]

In both autophagy and apoptosis the process does not lead to the release of any "proinflammatory" signals. In contrast, the process of necrosis, observed in larger tumors, causes release of signals that support an influx of inflammatory cells. For many years this has been considered a positive event, helping expose the immune system to tumor antigens and promote immune destruction. However, recent evidence suggests that some phenotypes of inflammatory macrophages can actually support tumor growth through fostering of angiogenesis, cancer cell proliferation, and invasion. Consequently, our understanding of macrophage phenotypes in cancer progression is an area of active research.[79,80]

Limitless Replicative Capacity

More than 30 years ago the pioneering observations of Hayflick established that when normal human or animal cells are grown in culture, they demonstrate a finite replicative life span.[81] That is, they are capable of a finite number of cell divisions, after which they undergo what has been termed *replicative senescence* and are incapable of any further cell division. The mechanism underlying the replicative clock that monitors this process has been the subject of intense research. This process has further evoked considerable interest because it is also one of the mechanisms that must be overcome to establish the "immortal" phenotype that is characteristic of the cancer cell.[69,70]

In mammalian cells DNA is organized into chromosomes within the nucleus, and these are capped by specialized

• **Fig. 2.7** A) Telomeric attrition in cultured cells. In mammalian cells the DNA is organized into chromosomes within the nucleus, and these are capped by specialized DNA-protein structures known as *telomeres.* The major function of these structures is protection, but they are progressively eroded at each cell division because of the inability of DNA to completely replicate itself. This is referred to as the "End Replication Problem", and arises because of the inability of chromosomes to completely replicate their extreme 5′ ends (B). The result is that there is progressive telomeric attrition as cell populations double. After an estimated 50 cell divisions, cells enter an irreversible (and prolonged) state of cellular senescence (sometimes referred to as *mortality stage 1* [M1]). This period is characterized by arrest of proliferation without loss of biochemical function or viability. At the end of this period, cells exhibit altered morphology and chromosomal instability, a state often referred to as *crisis* (mortality stage 2 [M2]).

DNA-protein structures known as *telomeres.*[81] The major function of these structures is protection, but they are progressively eroded at each cell division because of the inability of DNA to completely replicate itself. The result is progressive telomeric attrition as cell populations double. After an estimated 50 cell divisions, cells enter an irreversible (and prolonged) state of cellular senescence (sometimes referred to as *mortality stage 1* [M1]). This period is characterized by arrest of proliferation without loss of biochemical function or viability. At the end of this period cells exhibit altered morphology and chromosomal instability, a state often referred to as *crisis* (mortality stage 2 [M2]) (Fig. 2.7). Thus telomeric attrition is intimately involved with the aging of cells. Cancer cells must overcome replicative senescence and take on an immortal phenotype.

It has now been demonstrated in human tumors, and more recently in tumors of the dog, that telomere maintenance is a feature of virtually all cancer types.[82–89] Tumor cells succeed in telomere maintenance by the expression of the enzyme *telomerase.* From studies on cellular senescence, expression of the enzyme telomerase has emerged as a central unifying mechanism underlying the immortal phenotype of cancer cells and has thus become the most common marker of malignant cells. Telomerase is a ribonucleoprotein enzyme that maintains the protective structures at the ends of eukaryotic chromosomes, at the telomeres. In humans, telomerase expression is repressed in most somatic tissues, and telomeres shorten with each progressive cell division. In contrast, telomerase activity is a common finding in many human malignancies, resulting in stabilized telomere length. The telomerase complex consists of an RNA subunit that contains a domain complementary to the telomeric repeat sequence TTAGGG and a catalytic protein component. The catalytic protein component acts as a reverse transcriptase and can catalyze the addition of telomeric repeats onto the ends of chromosomes, using the RNA subunit as a template (see Fig. 2.7). It is now well documented that the level of telomerase in malignant tissue, compared with normal tissue, is much higher, and this differential is greater than that for classic enzymatic targets, such as thymidylate synthase, dihydrofolate reductase, or topoisomerase II.[90.] Telomerase biology is complex, and the mechanisms by which telomerase becomes reactivated in tumor cells is the subject of intense research. However, this represents an exciting opportunity for further understanding the complex biology of cancer and also the identification of completely novel targets for therapy.

Sustained Angiogenesis

It is now well accepted that the development of new blood vessels from endothelial progenitors (vasculogenesis) or from existing blood vessels (angiogenesis) is required for cancer progression and metastasis.[91,92] Endothelial cells (EC) or endothelial progenitors are activated by tumor-derived growth factors and result in new capillaries at the tumor site.[93] In healthy tissue EC proliferation is controlled by a balance between protein factors that activate EC and those that antagonize activation. Malignant tumors provide

VetBooks.ir

signals that result in EC survival, motility, invasion, differentiation, and organization. These steps are required to create a supportive vasculature for the tumor. In many ways these required endothelial processes share parallel features with the processes required for the success of a metastatic cancer cell itself. The creation of new blood vessels requires the tumors to recruit circulating EC to their site, presumably through the release of growth factors, such as vascular endothelial growth factor (VEGF). Circulating EC must survive at their new site with the help of survival signals and form vascular tubes that then reorganize to sustain blood flow. The resulting vasculature of cancers is typically aberrant with often poorly organized and chaotic vascular structures that are leaky, with limited adventitial development and excessive branching.[94] Once developed, this angiogenic phenotype (the result of the angiogenic switch) is associated with a diverse pattern of ongoing angiogenesis and neovascularization. This ongoing process is likely complex and involves a wide variety of tumor and microenvironmental-derived growth factors and signaling molecules. Adding to this complexity, certain phases of cancer progression likely are associated with and require periods of antiangiogenesis. Indeed, these hypovascularized states may directly contribute to the progression of certain cancers.[95] Regulation of angiogenesis depends on the balance between proangiogenic and antiangiogenic factors. There is controversy as to the exact biologic function of thrombospondin-1 (TSP1) in angiogenesis. Although some studies suggest that TSP1 promotes neovascularization, TSP1 is commonly recognized as an endogenous angiogenesis inhibitor.[96]

Many lines of evidence support the importance of angiogenesis in the biology of metastasis. The vascularity of a primary tumor (measured by microvessel density) has been correlated with metastatic behavior for most human and many veterinary tumors. The expression of angiogenesis-associated growth or survival factors and their receptors (i.e., VEGFR) in serum and in tumors, respectively, has also been correlated with outcome; more recently functional imaging studies using magnetic resonance imaging (MRI) and other means has provided correlates of vascularity with poor outcome.[97,98] The strength of this biologic argument has supported the development of a number of novel therapeutic agents with antiangiogenic activities. These agents have moved through discovery and development and are now approved drugs for cancer. Additional information regarding angiogenesis and antiangiogenic therapy is provided in Chapter 15, Section C.

Reprogramming Energy Metabolism

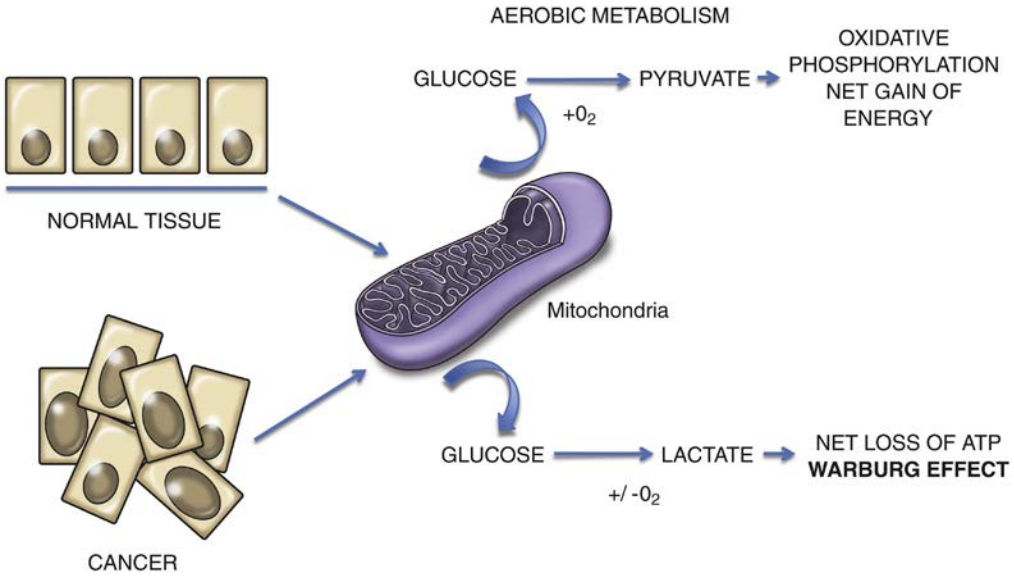
The sustained growth and proliferation of a cancer requires a corresponding adjustment of energy metabolism to ensure this growth can be fueled. Under normal conditions, cells respire aerobically in that they metabolize glucose to pyruvate with a net gain in energy as ATP.[70] Cancer cells can undergo a "metabolic switch" so that glucose is metabolized to lactate, in the presence or absence of oxygen, causing a net energy deficit. A corresponding upregulation of glucose transporters (e.g., GLUT-1) occurs, which increases the uptake of glucose into the cytoplasm. This process is exploited in positron-emission tomography (PET) imaging because tumors preferentially uptake a radiolabeled analog of glucose (^{18}F-fluorodeoxyglucose [FDG]). This metabolic switch is sometimes referred to as the *Warburg effect* (Fig. 2.8).[99]

It is difficult to appreciate the survival advantage of this mechanism. One hypothesis is that the switch allows the diversion of glycolytic intermediates into other biosynthetic pathways that support the production of new cells. This is supported by the observation that the Warburg effect also can be detected in growing cells in the embryo. An expansion of the theory of reprogramming of energy metabolism in cancer suggests that cancer cells have an advantage in a flexibility in their ability to derive ATP. This may come from a number of metabolic pathways that derive ATP from glucose metabolism under aerobic and anaerobic conditions, but it may also include efficiencies in metabolizing amino acids and lipids toward ATP and other biomolecule synthesis. Such metabolic flexibility may be necessary during primary tumor development, but even more so during metastatic progression (see next section).

Evading Immune Destruction

It is well defined that primary tumors and metastatic lesions can elicit both protective and suppressive immune responses.[79–80] B cells serve the host by the production of tumor-reactive antibodies. However, these antibodies may help define tumor-specific antigens (TSA) and aid in diagnosis, but they tend not to be protective for the host. Intense research has proven that the most protective forms of immunity against cancer are provided by the cell-mediated arm of the immune system, and immunocompromised animals are at increased risk of tumor development. (Tumor immunology is covered in detail in Chapter 14.)

The current and long-standing theory suggests that the cellular and tissue environment is constantly sampled and monitored by the immune system.[100] If a tumor is "altered self," then this should lead to eradication by a functioning immune system. Although there is a strong body of evidence to suggest that the immune system plays a major role in creating a barrier to tumor formation and progression, it is clear that when cancer arises, there is a failure of either surveillance or elimination mechanisms or both.[100] Epidemiologic evidence suggests that even the most immunogenic tumors have the ability to evolve mechanisms to subvert an apparently functioning immune system. This may arise through multiple mechanisms, but the best characterized of these include[101]:



- Inhibition of the effects of infiltrating cytotoxic T cells or natural killer (NK) cells
- Recruitment of immunosuppressive inflammatory cells (regulatory T cells [Treg] or myeloid-derived suppressor cells (MDSC) and tumor-promoting macrophages
- Defective antigen presentation; for example, by downregulation of the MHC class-1 machinery in cancer cells
- Failure of cancer cells to express co-stimulatory molecules, creating anergy or tolerance
- Expression of "immune checkpoint molecules," such as CTLA-4, or programmed-death-1 ligand/receptor (PD/PDL-1), which inhibit T-cell function

Tissue Invasion and Metastasis

The process of invasion and metastasis is covered in detail in subsequent sections of this chapter.

The Enabling Characteristics

As previously suggested, the hallmarks of cancer have been defined as functional capabilities that allow cancer cells to survive, proliferate, and disseminate. The fact that these critical hallmarks can be attained within a single cancer is explained by two key enabling characteristics of cancer – genome instability and tumor-promoting inflammation.

• **Fig. 2.8** In normal tissues, cellular respiration in the presence of oxygen allows the production of a net gain in energy through metabolism of glucose to pyruvate. The *Warburg effect* in cancer cells refers to a metabolic switch that causes cancer cells to preferentially metabolize glucose to lactate irrespective of oxygen status, leading to a net loss of energy in the form of adenosine triphosphate (ATP).

Genome Instability

Most acquired hallmarks of cancer require changes in the genome through mutation, amplification, or chromosomal translocation. However, the process of random mutation is inefficient because of the complex and fastidious maintenance mechanisms of the normal cell that monitor DNA damage and regulate repair enzymes. As such, it is actually difficult to explain why cancers arise in animals at all, because the acquisition of all traits would seem an impossible task. To explain this, it may be argued that genomes must attain increased mutability or genome instability to overcome the redundant homeostatic mechanisms that ordinarily prevent the emergence of a cancer cell.[1,2]

A number of mechanisms have been suggested that may support the development of genomic instability.[70]

- Defects that affect various components of the DNA-maintenance machinery (caretakers of the genome), which may involve mutations in caretaker genes
- The loss of telomeric DNA, which may cause karyotypic instability and chromosomal changes (amplification/deletion)
- Inactivation of TS genes through genetic (mutation) or epigenetic (DNA methylation/histone modifications) mechanisms

Tumor-Promoting Inflammation

It has been recognized for decades that tumors contain inflammatory and immune cell infiltrates, which classically have been considered an attempt by the immune system to eradicate the tumor. However, recent evidence suggests that tumor-associated inflammation paradoxically may have a tumor-promoting effect. Inflammation can contribute to neoplastic progression through one of several mechanisms.[70, 80, 102,103]

- The supply of growth factors and growth signals to the TME that promote angiogenesis, cell proliferation, and invasion
- Induction signals that support the process of EMT
- Fostering of the progression of premalignant lesions to overt malignancy
- The production of reactive oxygen species that are mutagenic

Many of the cells that contribute to this are components of the innate immune system, particularly macrophages with a specific, cancer-promoting phenotype. Specifically, they form part of the TME that supports the maintenance of the cancer phenotype.

The Pathways to Cancer

The eight acquired capabilities of cancer cells and the two overarching enabling characteristics of genome instability and tumor inflammation have been outlined. It is important to stress that the pathways by which cells become malignant are highly variable. Mutations in certain oncogenes can occur early in the progression of some tumors and late in others. As a consequence, acquisition of the essential cancer characteristics may appear at different times in the progression of different cancers. Furthermore, in certain tumors a specific genetic event may, on its own, contribute only partially to the acquisition of a single capability, whereas in others it may contribute to the simultaneous acquisition of multiple capabilities. Regardless of the path taken, the hallmark capabilities of cancer remain common for multiple cancer types and help clarify mechanisms, prognosis, and the development of new treatments.

The highly complex signaling circuitry in cells is highly integrated and aligned with function. In the formation of a cancer cell, these circuits are "reprogrammed" to regulate the acquired capabilities of the cancer cell, or hallmarks of malignancy. The change is not simplistic, and considerable cross-talk occurs between circuits to support these hallmarks. This is in addition to a connection and signaling between the cancer cell and the TME

The Role of Tumor Microenvironment and Cancer Stem Cells

Over the past 10 years tumors have been increasingly considered as organ systems similar to the tissues from which they derive. This

VetBooks.ir

is in contrast to a reductionist view of cancer biology, which considers the tumor just a mass of tumor cells. In reality, the tumor is a complex system containing cancer cells and supporting cells, all of which contribute to the maintenance of the malignant population and support ultimate dissemination and metastasis. The major players in the cancer "organ system" are:

- Cancer cells and cancer stem cells (CSCs)
- Endothelial cells
- Pericytes
- Immune cells
- Tumor-associated fibroblasts

Cancer Cells and Cancer Stem Cells

The concept that a cancer can arise from any cell in the body, along with the stochastic model of tumorigenesis, has recently been challenged.[104–107] Although tumor heterogeneity is a well-established concept, a new dimension to heterogeneity has been established that suggests that a tumor may contain a hierarchical structure similar to many normal organ systems. Recent evidence suggests the existence of CSCs (sometimes termed *tumor-initiating cells*), which form the founder cell population for a tumor. It was first extensively documented for leukemia and multiple myeloma that only a small subset of cancer cells are capable of extensive proliferation. For example, when mouse myeloma cells were obtained from mouse ascites, separated from normal hematopoietic cells, and put in in vitro colony-forming assays, only 1 in 100 to 1 in 10,000 cancer cells were able to form colonies. Even when leukemic cells were transplanted in vivo, only 1% to 4% of cells could form spleen colonies.[106–114] Because the differences in clonogenicity among the leukemia cells mirrored the differences in clonogenicity among normal hematopoietic cells, the clonogenic leukemic cells were described as "leukemic stem cells."

It has also been shown for solid cancers that the cells are phenotypically heterogeneous and that only a small proportion of cells are clonogenic in culture and in vivo.[114–117] For example, only 1 in 1000 to 1 in 5000 lung cancer, ovarian cancer, or neuroblastoma cells were found to form colonies in soft agar. Just as in the context of leukemic stem cells, these observations led to the hypothesis that only a few cancer cells are actually tumorigenic and that these tumorigenic cells could be considered CSCs. Although the field and concept of CSCs is a controversial one, CSCs may prove to be a common constituent of many, if not all, cancer types. Features of the CSC model also fit well with a view of metastasis in which only a small number of cells within a tumor have the ability (and plasticity) to endure the stresses of metastatic progression, survive during a dormant period, and then progress, proliferate, and differentiate into the complex heterogenous metastatic lesion.

If tumor growth and metastasis are driven by a small population of CSCs, this might explain the failure to develop therapies that are consistently able to eradicate solid tumors.[104–107] Although currently available drugs can shrink tumors, these effects are usually transient and often do not appreciably extend the life of patients. One reason for the failure of these treatments is the acquisition of drug resistance by the cancer cells as they evolve; another possibility is that existing therapies fail to kill CSCs effectively.

Stem cell populations have been identified in human breast, bone, brain, colon, pancreas, liver, ovary, and skin cancers.[108–112] The actual origin of CSCs within solid tumors has not been clarified and may actually vary among tumor types. In some tumors the resident adult or somatic stem cell may serve as the tumor-initiating cell, and in other tumors the initiating cell may be the resident progenitor or transit-amplifying cell. A characteristic of the CSCs is that they undergo asymmetric division and self-renew, providing a continual resident population of highly resistant cancer cells.

Existing cancer therapies have been largely developed against the bulk population of tumor cells because they are often identified by their ability to shrink tumors. Because most cells within a cancer have limited proliferative potential, an ability to shrink a tumor mainly reflects an ability to kill these cells. It seems that normal stem cells from various tissues tend to be more resistant to cytotoxic therapy than mature cell types from the same tissues. If the same is true of CSCs, then one would predict that these cells would be more resistant to cytotoxics than tumor cells with limited proliferative potential. Even therapies that cause complete regression of tumors might spare enough CSCs to allow regrowth of the tumors. Therapies that are more specifically directed against CSCs might result in much more durable responses and even cures of metastatic tumors. In veterinary oncology putative stem cell populations have been identified for breast, bone, brain, and liver tumors.[104–107,118–120] Interestingly, stem cell populations appear to have altered DNA repair pathways, which may explain their resistance to conventional drugs. Identification of these populations, coupled with the availability of microarray and microRNA array technology, is allowing the identification of potential therapeutic targets.

Recent research has linked the acquisition of CSC characteristics with the EMT program, described subsequently in the section on metastasis.[120] Cells that undergo EMT also take on characteristics reminiscent of the CSC phenotype. For example, they have the ability to self-renew and may support the ability of cells to colonize outside of the primary tumor. One may speculate that the signaling processes that support EMT may also serve to maintain the CSC population within a tumor and may also suggest plasticity in CSC populations.

Endothelial Cells

Much of the heterogeneity in tumors is found in the stromal compartment, and many of these cells are EC, which form the tumor-associated vasculature. VEGF and basic fibroblast growth factor are two prominent signaling molecules in the formation of these vessels. More modern sequencing techniques also have identified new pathways that may represent important signaling systems for neoangiogenesis and may represent therapeutic targets (e.g., Notch signaling).[121]

Pericytes

Pericytes are mesenchymal cells that wrap around the endothelial tubing of the blood vessels. Pericytes are considered a major cell type supporting the tumor vasculature.[122]

Immune Inflammatory Cells

As described previously, an environment of chronic inflammation is an important enabling characteristic that supports the acquisition of cancer-related traits. Cells of the innate immune system are particularly crucial for the maintenance of the tumor environment. In particular, tumor macrophages with a specific protumor phenotype can enhance cellular proliferation, invasion, and neoangiogenesis.[80]

VetBooks.ir

Cancer-Associated Fibroblasts

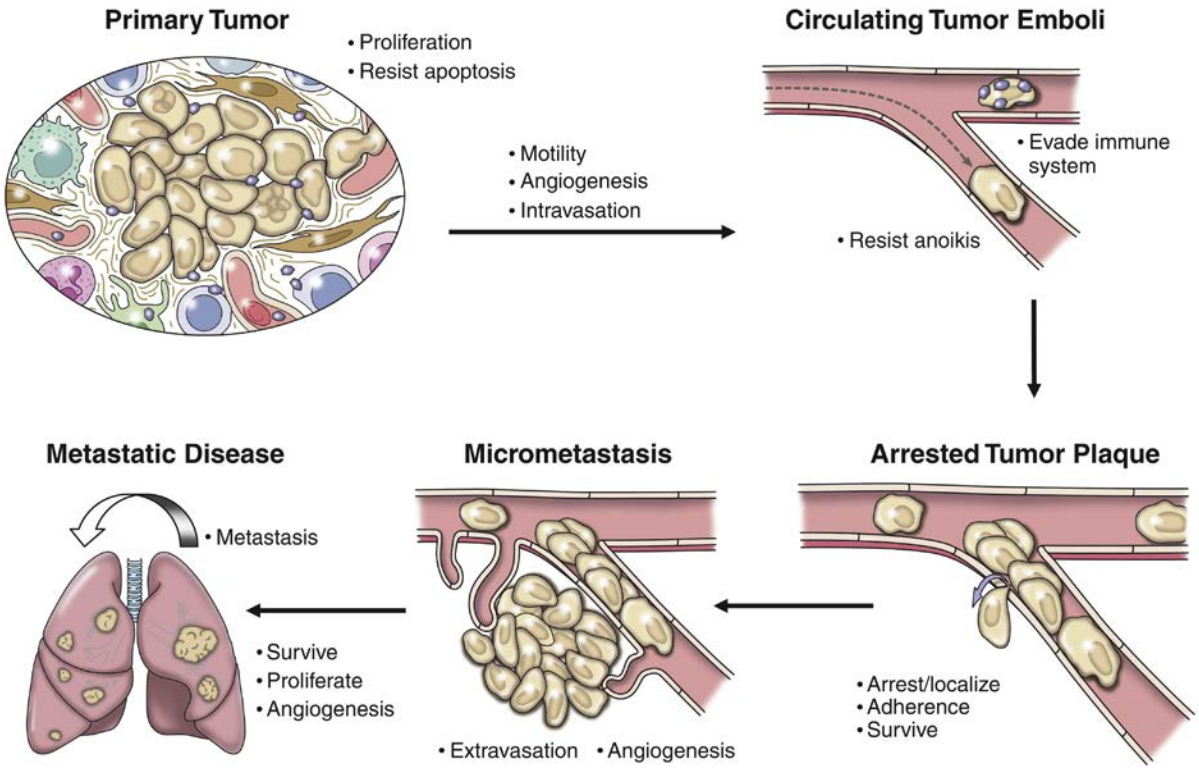
Cancer-associated fibroblasts make up the supporting structure for many tumors but can also promote invasion, cell proliferation, and neoangiogenesis.[47] The importance of the various cell types that make up the TME cannot be overstated. Although a complex signaling network exists between and within cancer cells that maintains the cancer phenotype, superimposed on this are the complex signaling networks between stromal components and cancer cells. Although the potential evolution of cancer cells from early disease to late-stage disease has been discussed, it is quite possible that a similar evolution occurs in the supporting structures, dictated by the cancer itself. For example, incipient tumors may recruit stromal elements, which reciprocate by promoting cell proliferation and angiogenesis. Evolution of the cancer population may then feed back on the stromal population to further reprogram these cells to support the growing tumor. Of course, this could be extended to show the role of the stroma in promoting invasion and metastasis. These mechanisms underpin the complexity of understanding cancer pathogenesis, because the process is highly dynamic and context dependent.[123]

Key Points

- Cancer arises through multiple molecular mechanisms underpinned by changes at the genetic and/or epigenetic level.
- Cancer has been defined as the acquisition of eight fundamental characteristics shared across multiple cancer types. These hallmarks are enabled and supported by underlying genomic instability and tumor-associated inflammation.
- The normal circuitry in cells is reprogrammed to support these hallmarks and drive tumor progression.
- These circuits are interconnected and are also supported by cross-talk from cells making up the tumor microenvironment.
- Cancer stem cells may play a major role in maintaining the tumor in a way similar to the maintenance of normal organ systems by adult stem cells.

The Process of Tumor Metastasis

Metastasis is defined as the dissemination of neoplastic cells to discontinuous secondary (or higher order) sites, where they proliferate to form a macroscopic mass. Implicit in this process is the presence of a primary tumor. Metastases are not a direct extension of the primary tumor and are not dependent on the route of spread (i.e., hematogenous versus lymphatic versus peritoneal dissemination). The process of metastasis is believed to occur through the completion of a series of step-wise events. For this process to occur, a cancer cell must leave the site of the primary tumor, pass through the tumor basement membrane, and then through or between endothelial cells to enter the circulation (extravasation). While in the circulation, tumor cells must be able to resist anoikis (programmed cell death associated with loss of cellular contact), evade immune recognition and physical stress, and eventually arrest at distant organs. At that distant site the cell must leave the circulation and survive in the hostile microenvironment of the foreign tissue. These secondary sites are believed to be primed to receive metastatic cells through effects that are directed and mediated by the primary tumor itself (premetastatic niche). The distant site may be the eventual target organ for metastasis or may be a temporary (sanctuary) site. In either case, the cancer cell is thought to lie dormant for a variable and often protracted period before moving to its final location. After a break in dormancy, cells receive signals to proliferate, create new blood vessels (angiogenesis) or co-opt existing blood vessels, and then successfully grow into a measurable metastatic lesion. Further progression likely is associated with the repetition of this process, resulting in the development of metastases from metastases. As such, the steps outlined here continue not only after the detection of the primary tumor, but also after the detection of metastases. From a therapeutic perspective, therefore it is never too late to target the biologic steps associated with metastatic progression as a means to improve outcomes for patients. The basic tenets of this model of metastasis have been intact for more than 40 years; however, a greater understanding of the biologic principles associated with each metastatic process is emerging.[124]



Metastasis-Associated Genes and Metastasis Suppressor Genes

Cancer cells are not unique in their ability to complete the individual steps required for metastasis (Fig. 2.9). For example, leukocytes and neuronal cells have the ability to invade tissue planes and cross vascular barriers. Several types of leukocytes demonstrate the phenotype of intermittent adherence to vascular endothelium and are able to resist anoikis. It is also true that stem cells of various phases of differentiation are able to perform many of these steps during development and in the adult.[125,126] Metastatic cells are unique in that each cell must be able to perform all the steps required for successful metastasis. An extension of this argument is that the genetic changes that permit the metastatic process are not unique to a metastatic cancer cell; however, the metastatic cell must have the appropriate set of genetic changes available to complete all the steps of the metastatic cascade.

Literally hundreds of genes and their resultant proteins have been suggested to contribute to the development of cancers and to their eventual ability to metastasize. A single genetic change in cancer can contribute many of the metastasis-associated processes (e.g., metastasis super enhancer), or several genes can work together toward a single metastasis-associated process. Metastatic cancers may achieve the metastatic phenotype through distinct constellations of genetic and epigenetic events that in their respective sums complete the list of necessary metastasis-associated processes needed for successful metastasis.[127]

Two classes of genes have been broadly defined as contributing to the metastatic phenotype. These include metastasis promoting genes[128,129] and metastasis suppressors.[129,130] These genes have functions in normal development and physiology (i.e., cell migration, tissue invasion, and angiogenesis, discussed earlier) that are subverted by the cancer cell in the acquisition of the metastatic phenotype.

The use of high throughput and genome-wide investigations has uncovered many putative metastasis-associated genes in cancer. It should be noted that many metastasis-associated genes have functions that also contribute to tumor formation and progression. Several of these metastasis-associated genes have been validated in canine and feline cancers.[131,132] For example, the metastasis-associated gene ezrin was identified using genomic approaches in murine and human studies of metastasis.[133] Ezrin is a membrane-cytoskeleton linker protein that functionally and physically connects the actin cytoskeleton to the cell membrane. The degree of ezrin expression in the primary tumor of dogs with osteosarcoma (OSA) was shown to predict a more aggressive course of disease, defined by metastasis to the lung. Furthermore, recent studies have confirmed the connection between ezrin and protein kinase C (PKC) signaling in murine, canine, and human OSA cells.[134,135]

• **Fig. 2.9** The metastatic cascade. The metastatic cascade describes a set of discrete steps that cells must move through as a part of the process of metastasis. This complexity begins with the recognized complexity associated with primary tumor development, in which tumor cells must proliferate, resist apoptosis, and develop interactions with many host cells in the microenvironment. Subsequent steps allow metastatic cancer cells to enter and survive in the circulation. Cells then arrest at distant locations, extravasate, and survive in the microenvironment of the distant locations. Arrest of cells may be at the eventual secondary organ where metastasis becomes clinically evident, or cells may initially arrest at a "sanctuary site," where they may lie dormant before moving on to the eventual secondary site. The cellular programs that result in a break of dormancy are not well understood. Survival of cells at these sites of dormancy or the eventual secondary site is a significant hurdle for metastatic cells to overcome. Indeed, the majority of cells that arrive at distant locations are unable to survive in these distant locations. At secondary sites, tumor cells may proliferate and progress after the development of the angiogenic phenotype. It is likely that successful metastatic lesions at secondary sites are then the source of subsequent metastases within these secondary sites.

Metastasis suppressor genes have been identified in several human cancers. These genes also are thought to have normal functions in the regulation of motility, invasion, and angiogenesis. The loss of these genes is not thought to be associated with the formation of tumors; however, their loss is thought to contribute to specific steps in the metastatic cascade. The characterization, biology, and clinical effect of metastasis suppressor genes have been recently reviewed elsewhere.[136] The loss or reduced expression of metastasis suppressors has not been documented in canine or feline cancers to date.

The succeeding sections provide descriptions of the critical metastasis-associated processes (see Fig. 2.9). Examples of genetic changes or resulting protein changes that contribute to each process are highlighted in each section, with particular emphasis on those with demonstrated associations with veterinary malignancies.

Intravasation

After the successful growth of the primary tumor, intravasation of a cancer cell into the vascular or lymphatic circulation is the first necessary step in the metastatic cascade. The process of intravasation requires that a tumor cell be motile and able to digest, modulate, or escape the ECM.[137–139] The specific mechanisms used by cancer cells to invade and intravasate include the classic model of enzymatic degradation of the ECM referred to as *mesenchymal invasion* (see later discussion on EMT). Unlike in mesenchymal invasion, tumor cells may also develop so-called *amoeboid invasion,* in which they individually slip between fibers of the ECM without evidence or a need for enzymatic degradation.[140] Finally, a distinct method, termed *collective invasion,* refers to the en masse regional extension of a tumor into surrounding tissues.[141] Such collective invasion is observed clinically in dogs with oral SCC and biologically high-grade/histologically low-grade fibrosarcoma. The low rate of distant metastasis associated with collective invasion suggests a lack of functional attributes necessary for true distant metastasis. It is likely that individual metastatic tumors may use distinct invasion programs at distinct points during metastatic progression. Not surprisingly, studies with intravital imaging (single cell imaging of cancer cells in animals) have demonstrated that only a minority of the cells in the primary tumor develop any of these forms of invasion.[142,143] Efforts are underway to define the genetic features of this minority population.[144,145]

In the classic mesenchymal form of invasion, matrix proteases and metalloproteases (MMPs) are believed to be necessary for the invasive phenotype. Expression of members of this enzyme family has been found in most human and several canine and feline

VetBooks.ir

malignancies, including canine OSA.[146–149] The activity of MMPs in OSA and mast cell tumors has been correlated with grade and metastatic propensity.[149,150] Similar correlative studies have been undertaken in human patients.[151] The importance of MMP activity during this early step in metastasis prompted the development of pharmacologic inhibitors of MMPs. Anticancer activity of these agents in preclinical animal models and in sporadic human patients was evident; however, in randomized trials, clinical benefit was not observed.[152,153] The failure of these clinical trials may be explained at many levels and does not refute the importance of invasion as a critical step for a metastatic cell. Rather, these results suggest potential redundancy in the types of invasion (mesenchymal versus amoeboid) that may exist within a given cancer.[154,155] Recent evidence also suggests that the expression of matrix-degrading enzymes and other growth factors may not be necessary in the tumor cells themselves but may be provided by inflammatory cells (i.e., macrophages) recruited by the growing tumor.[156]

Epithelial-Mesenchymal Transition

Observed primarily in the context of epithelial malignancies, the ability of tumor cells to engage in the early steps in the metastatic cascade has been linked to a transcriptional program referred to as EMT.[157] This transcriptional program has been largely ascribed to the effects of a family of transcription factors, including *twist, snail,* and *slug.*[158] Activation of these and other EMT transcription factors is not necessarily associated with a morphologic change in the cancer cell but may be associated with a loss of polarity (apicobasal) in epithelial cells, a greater proportion of cells losing cell-to-cell contacts similar to mesenchymal cells (observed in vitro), cell motility, and invasion. In the "mesenchymal" state, suggested by EMT, epithelial cancer cells (similar to cells involved in embryogenesis) develop the phenotypic ability to undergo invasion, migration, and intravasation.[159] Interestingly, cells that are able to take on these "mesenchymal" features share signaling programs and other phenotypes with tumor-initiating cell populations.[160]

Opponents of the EMT hypothesis are most critical of the use of the term *transition,* which suggests a switch in the phenotype of individual cells from an epithelial to a mesenchymal form. However, it is reasonable and generally agreed that the effects of EMT transcription factors contribute to the early phenotypes needed for metastatic progression. Limited data also suggests a need for mesenchymal cells to take on attributes of epithelial cells (likely later during metastatic progression) for successful metastasis, the so-called *mesenchymal-epithelial transition* (MET). For epithelial cancers MET is also understood to be a final step in EMT in which after the activation, development of an invasive phenotype, and colonization of a distant site, cells will revert to their original epithelial phenotypes.

The process of intravasation concludes when a cancer cell successfully enters the vascular or lymphatic circulation. Tumor cells may enter the circulation through established blood vessels, small arterioles, venules, or lymphatics, or through tumor-associated (or lined) blood vessels in a process referred to as *vasculogenic mimicry.*[161] For larger vascular structures the process of intravasation requires penetration of adventitial cells, including pericytes; digestion of the vascular basement membrane; and penetration between or through EC.[162] Penetration of the tumor-associated vasculature may be easier than invasion through normal vessels and may require only transit from the extracellular environment between EC into the circulation.

Survival in the Circulation (Resisting Anoikis)

Frisch and Francis reported the induction of apoptosis after disruption of the interaction between epithelial cells and the ECM.[163] This phenomenon was termed *anoikis,* from the Greek word for homelessness. In normal tissues, anoikis is a mechanism for maintaining tissue homeostasis and integrity.[164] For the metastatic cancer cell, survival during dissemination requires resistance to anoikis. In normal tissues, anoikis is prevented by two systems: cell-matrix anchorage and cell-cell interactions.[165] Anchorage of cells to the ECM is mediated primarily by transmembrane receptors referred to as *integrins.* The formation of active heterodimers triggers an intracellular cascade, resulting in activation of effectors of growth and survival.[166] Integrin family members have been identified in canine sarcomas and lymphomas.[167–172] Cell-cell anchorage in many epithelial tissues is mediated by cadherins, a family of calcium-binding glycoproteins. Intracellularly, cadherins form complexes with members of the catenin protein family that link them to the actin cytoskeleton, in addition to survival-promoting signal transduction cascades.[173] Loss of either cell-cell or cell-matrix interaction in normal cells triggers the activation of the caspase proteases, the hallmark of apoptotic cell death. Metastatic cancer must resist this contact-dependent death to be successful and must do so through two non–mutually exclusive mechanisms. The first is by maintaining cell-cell contacts with other tumor cells (homotypic interactions) or with host cells, such as platelets and inflammatory cells (heterotypic interactions), during metastatic progression. Both homotypic and heterotypic interactions generate intracellular signals that prevent the initiation of anoikis. Additionally, cancer cells may overexpress proteins that directly inhibit anoikis. For example, the integrin pair $\alpha_v\beta_3$ is frequently overexpressed in malignancy, including prostate cancer and melanoma.[174,175] This overexpression subverts the need for ligand binding and results in the generation of survival signals.[176] Proteins reported to be involved in resistance to anoikis include tropomyosin receptor kinase B (TrkB), focal adhesion kinase (FAK, the immediate effector of integrin signaling), galectin-3, and TGF-β, among others.[177] Several other molecular mediators of anoikis resistance have been identified and are reviewed elsewhere.[178] These molecules may be valuable novel antimetastasis targets.

Evasion of the Immune System

At all stages of metastatic progression, metastatic tumor cells must evade detection and destruction by the immune system. The ability of the host immune system to recognize and destroy tumor cells (immunosurveillance) was first proposed by Paul Ehrlich in 1909. Molecular support of the theory of immunosurveillance has come with studies of mice deficient in immunomodulatory and proinflammatory molecules, such as interferon-gamma (IFN-γ), interleukin-12 (IL-12), and perforin. Mice deficient in these molecules are known to develop tumors more readily than wild-type mice.[80] Clinical evidence for immunosurveillance against cancer was first reported by Coley more than 100 years ago. Through the administration of bacteria, Coley's toxin, Coley was able to induce fever and tumor regression in patients with cancer. Evidence in dogs with OSA further supports the potential value of cancer immunotherapy.[179] Indeed, survival times in dogs developing bacterial infection at the site of a limb salvage surgery are significantly longer than in dogs that do not develop infection. Interestingly, similar parallels may be seen in human OSA patients.[180] It is believed that in immunocompetent hosts, immunosurveillance removes a large number of cancer cells from the primary tumor, from the circulation, and at distant metastatic sites. Cancer cells use a wide variety of mechanisms to effect this evasion. The mechanisms for immunosurveillance and evasion of immunosurveillance by cancer are reviewed elsewhere and are summarized in Chapter 14.[181]

VetBooks.ir

Modification of the immune system to treat cancer and prevent metastasis continues to be an attractive therapeutic strategy.[182] Clinical trials based on this concept have been reported throughout the veterinary literature in dogs with melanoma, soft tissue sarcoma, hemangiosarcoma, OSA, and others, using a variety of immune-based therapies.[185] This principle has been the basis for the development and approval of a therapeutic vaccine directed against a melanoma antigen in dogs with melanoma.[186]

Arrest in Target Tissues

The arrest of circulating tumor cells at distant sites is thought to occur by two distinct but potentially overlapping mechanisms. These include size-dependent "trapping" of tumor cells within the lumens of small vessels (capillaries and veins) in the target organ, and/or receptor-mediated interaction involving the tumor cell and the host vasculature.[187] Data supporting the trapping phenomenon comes from single-cell imaging studies in which metastatic cancer cells were observed to arrest primarily at distant vascular beds as a result of size-dependent restrictions of large tumor cells in small blood vessels.[188,189] This work was conducted primarily for metastasis to the liver and more recently for metastasis to the brain.[190] This trapping phenomenon suggests that the site for metastasis from a primary tumor is guided largely by the location of the first (small vessel) vascular bed encountered by a tumor cell. Alternatively, several groups have suggested the role of specific adhesion molecules as being necessary for initial tumor arrest in the microenvironment of the secondary metastatic sites.[191–193] Both of these mechanisms likely play a role in the initial seeding of distant metastatic target organs. The dominant mechanism of arrest may be primarily defined by tumor type or target organ.

Early Survival at Distant Sites

Once the cancer cell or cancer embolus has arrested at its distant sites, it may immediately move out of the circulation into the target organ or may stay within the circulation.[194] In either location the cancer cell must survive in a new microenvironment. Early survival of metastatic cells at secondary sites is a significant hurdle for the cancer cell. Several studies have shown the ability of cancer cells to arrest at multiple organs in the body. Within hours the number of remaining cells is reduced dramatically, and within days the number of viable cells may be as low as 0.1% of the original number of cells, even for the most aggressive cancer models.[195] To a large extent organ selectivity for cancers is defined by the organs in which a cancer cell can survive after initial arrest. The "seed and soil" hypothesis first articulated by Paget and then more recently by Fidler et al[193,213] suggests that the success of a cancer, or metastasis, is defined by interactions between the seed (tumor cell) and the soil (the tumor microenvironment).[196]

Arrest of tumor cells in target organs may or may not be receptor mediated (discussed earlier); however, adhesion requires receptor-ligand interactions. Contributors to these steps include the cell adhesion molecules (CAMs). Multiple CAMs have been identified and are named based on their cell specificity (e.g., N-CAM for neural and L-CAM for liver). CD44 is a specific adhesion molecule (H-CAM for homing) initially identified as the receptor for the matrix component hyaluronic acid on hematopoietic cells. Expression of splice variants of CD44 on tumor cells has been demonstrated to correlate with a poor prognosis in a wide variety of human tumors, from acute myelogenous leukemia (AML) and Hodgkin's disease to breast and colon cancer and OSA.[197] Chemokines are a class of chemotactic cytokines that function in leukocyte trafficking and function. In metastasis chemokines may also contribute to the metastatic process through enhanced metastatic cell survival.[198] Chemokines may be active in the recruitment of a leukocytic infiltrate to intravasated, circulating tumor cells, therein creating an embolus that can better resist shearing stress associated with circulation or through the generation of matrix-degrading proteins at the distant metastatic site.

The Premetastatic Niche and Modulation of the Microenvironment

It is increasingly clear that the sites (microenvironments) of successful secondary metastasis are modulated by the presence of a primary tumor and then by the arrival of metastatic cells at the secondary site. The concept of the premetastatic niche suggests that a primary tumor modulates the microenvironment of a secondary site before the arrival of most metastatic cells.[199] The modulation of the premetastatic niche appears to be accomplished by primary tumor–induced mobilization and recruitment of specific, primarily bone marrow–derived cells (bone marrow niche) to the secondary microenvironment.[200] These bone marrow–derived cells are myeloid in origin and express VEGFR. Interestingly, the sites of metastatic tumor arrest appear preferentially to include sites in which these myeloid-derived cells were first recruited. Furthermore, targeting these VEGFR-positive cells using pharmacologic and genetic tools has effectively prevented metastatic development in murine models.[201] Ongoing studies likely will uncover greater complexity of the populations of cells recruited to the premetastatic niche and potentially therapeutic targets for antimetastatic therapy.

After survival at the distant site, the tumor cell must proliferate and modulate its new environment. In most cases cancer cells are believed to extravasate from the circulation and then proliferate in the new organ. However, proliferation also may occur within blood vessels, in a process referred to as *intravascular metastases,* and then expand into the local tissue before further proliferation occurs.[201] In both situations modulation of the new environment is necessary for appropriate growth and progression of the metastatic lesions. We now recognize that part of this modulation is based on tumor-induced changes in the stroma.[202,203] These stromal changes may result in the production of growth factors or signals that are used by the tumor for further growth. These stromal cell–derived growth factors provide important signals for tumor cell proliferation and progression, including angiogenesis. The importance of tumor-stromal interaction suggests that the "induced" tumor-stroma may be a credible target for novel cancer therapeutics.[204]

Metastasis from Metastases

For most solid tumors the appearance of a single metastatic nodule is followed shortly by the development of additional metastases within the same target organ and tertiary sites. All these metastatic sites are unlikely to emerge from distinct and unique clones within the primary tumor and nearly simultaneously progress through the metastatic cascade to yield synchronous metastases at the distant site. It is reasonable, and perhaps more likely, that metastases develop from other metastatic sites. In this hypothesis a small number of successful clones colonize distant sites. As these clones move through progression to become successful metastases, the process of metastasis continues, resulting in metastasis from metastases. Although data supporting this hypothesis is limited, the implication for the treatment and management of cancer

VetBooks.ir

patients is substantial. If true, the process of metastasis from metastases would suggest that all steps in the metastatic cascade occur continuously, both before and after detection of metastases in patients. As such, all of the steps in the metastatic cascade may be targets for future therapeutic intervention.[205–211]

Ongoing Controversies and Areas of Research in the Field of Metastasis

Does the Metastatic Propensity for Tumors Emerge Early or Late in the Biology of Cancer?

The development of the metastatic phenotype traditionally has been believed to be a process that happens late in carcinogenesis. In this model, referred to as the *progression model,* the genetic changes responsible for primary tumor development in most cases are distinct and precede the steps that result in the metastatic phenotype.[212–213] The progression model argues that the metastatic phenotype is acquired within a small fraction of cells within the heterogeneous primary tumor. Support for the progression model came from work by Fidler and others, who demonstrated the ability to select for rodent cancers with greater metastatic potential, through the serial passage of metastatic tumor nodules back to naïve mice. This selection phenomenon suggested that a minority of tumor cell clones within a primary tumor were endowed with the metastatic phenotype and that this small proportion were enriched in the metastases compared with the primary tumor. Application of the progression model would suggest that a period exists between primary tumor development and acquisition of the full metastatic phenotype. This model was thought to be the basis of the improved outcome associated with early detection of cancers and the belief that effective and definitive therapy was most likely if a diagnosis was made early. Work from Ramaswamy et al provided data to support an alternative model, "the early oncogenic model" for metastasis.[214–217] This alternative suggests that the genetic events that contribute to initial primary tumor development are the same or emerge at the same time as the events that contribute to the metastatic phenotype. As such, the early oncogenic model suggests, the biology of a cancer is defined early and may not be something that can be reduced through early identification of a cancer. This is not to say that early detection of a cancer is not helpful for a patient, but rather that bad cancers may be "born" bad. This model may explain the phenomenon of "metastatic carcinoma of unknown primary site," in which metastatic disease is detected without an apparent primary tumor.

To add complexity to the question of the emergence of the metastatic phenotype, increasing evidence indicates that host (genomic) differences can influence the metastatic behavior of cancers without necessarily influencing primary tumor growth.[214,215] Using a genetically engineered mouse model of mammary cancer, Hunter et al have been able to identify specific host genes that influence metastatic behavior of tumors.[214–217] These findings have several important implications. First, they suggest that individuals might be predisposed to aggressive metastatic progression before the development of a tumor. In addition they suggest that some families in the population may be at high risk, not necessarily for tumor development, but for an aggressive metastatic course once a tumor develops. Most important, if a significant part of a patient's metastatic risk is encoded within the patient's constitutional genome rather than within the mutated tumor genome, it may be feasible to identify individuals at high risk for metastatic disease at the time of diagnosis of the primary tumor, or potentially before. This finding may be particularly relevant in the field of veterinary oncology, in which breed-associated genomic differences may explain the more aggressive course of disease seen in some dog breeds compared with others. Taken together, the risk for metastatic progression is partly defined by the genetics of the patient, genetic changes that develop early in the process of tumor development, and the subsequent and incremental emergence of aggressive metastatic cells.

Where Is the Inefficiency in "Metastatic Inefficiency"?

As devastating as the metastatic process is, it is equally inefficient. Estimates of this inefficiency in animal models suggest that less than 1% of cancer cells that successfully enter the circulation are able to survive at distant sites.[218] The true metastatic efficiency of human cancers is likely to be much lower. In most studies to date it does not seem that entry of cancer cells into the circulation is the major barrier for successful metastases. Recent studies have identified high numbers of circulating tumor cells in cancer patients who are free of metastatic disease. The clinical importance of high numbers of circulating tumor cells is not clear[219]; however, for some cancers high numbers of circulating cancer cells apparently do not necessarily correlate with the risk for metastasis. Butler and Gullino estimated that 1 to 4×10^6 cells/g of tumor enter the systemic circulation each day in human cancers.[220] This data suggests that, although intravasation is necessary for metastasis, it is not sufficient nor is it process limiting. After removal of the primary tumor, these circulating cell counts drop, and in many cases no gross metastases develop. Although arrest at target organs may be a limitation for some cancers, early survival of cancer cells at distant sites appears to be a major hurdle for successful metastases and therefore is a significant contributor to metastatic inefficiency. Metastatic cancer cells appear to be highly vulnerable to death early after their arrival at a secondary site. The microenvironment of the secondary site is distinct from that of the primary tumor site and the initial tissues of origin of the cancer cell. These differences include changes in oxygen tension, pH, growth factor availability, and cellular binding partners. Collectively, these changes represent unique stressors to metastatic cancer cells.[221]

Metastatic cells must recognize, adapt, and endure these stresses to survive. Furthermore, appropriate modulation of the secondary microenvironment before the cancer cells arrive (premetastatic niche) and as a result of early and effective interaction with stromal and inflammatory cells within the new environment allow select populations of cells to survive and proliferate. The duration of this initial vulnerable state during metastatic progression may extend for the entire period of dormancy (see later). Also, metastatic cells likely must pass successfully through additional vulnerable states later during metastatic progression. Targeting metastatic cancer cells during these vulnerable states may be an effective treatment strategy for cancer metastasis.[222]

What is Dormancy and Where Do Dormant Cells Reside?

In spite of effective control of the primary tumor and aggressive multiagent and multimodality adjuvant therapy, the risk for metastases to distant sites remains high for several cancer histologies. Because most patients are free of gross metastases at the time of diagnosis, the development of metastases is presumed to emerge from microscopic cells that are not identifiable at the time of initial patient presentation.[223] The location, size, angiogenic state, and proliferative/apoptotic state of these microscopic cells are largely unknown. Indeed, these dormant cells may exist as single cancer cells or microscopic clusters; they may exist in a quiescent (outside the cell cycle) or balanced state of proliferation and apoptosis; they may lie dormant in the eventual secondary metastatic tissue site (e.g., the lung); or they may persist in sanctuary sites (e.g., the

VetBooks.ir

bone marrow). Recent insights gleaned from the CSC model may provide further support for the hypothesis that metastatic cells are capable of residence in transient sites such as the bone marrow, where they may rest in a dormant state before being recruited into the metastatic cascade. The signals that induce these presumed small populations of cells to break dormancy and emerge into gross metastases likely also involve TME interaction.[224,225]

Metastasis Biology: New Perspectives

Metastasis is a nearly universally grave development for cancer patients, irrespective of specific cancer histology. An emerging hypothesis proposes the existence of unique settings during the metastatic cascade when metastatic cells are vulnerable and stressed. Cellular adaptation to stress in these vulnerable cells is the most defining feature of metastatic proclivity and could be a target for new cancer drug development. Conversely, proliferation, apoptosis, invasion, and migration are neither sufficient nor necessary for metastatic success and therefore do not necessarily represent ideal targets for metastatic therapy.

Consistent with the *vulnerable cell hypothesis* is the concept of primary tumor reseeding. Some studies suggest that metastatic cells that leave the primary tumor likely distribute to all tissues in the body by hematogenous spread; however, survival of rare single metastatic cells at distant sites predicts the future development of gross metastases. Included in this list of metastatic sites is the microenvironment of the primary tumor, suggesting that local recurrence is also a product of distant metastasis. This *tumor reseeding hypothesis* also suggests a rationale to study the value of increased "surgical dose" in patients with nonlocalized tumors as a means to improve long-term outcomes. Conversely, the fact that the vast majority of metastatic cells in an organ will never survive or become a clinical problem should have us asking about the definitions of a metastatic site and the value of surgical resection of tissues that have microscopic evidence of metastasis but no clinically appreciated disease (i.e., a firm, fixed, and effaced lymph node).

Summary and Future Directions

This chapter has sought to simplify as far as possible the mechanisms of carcinogenesis and metastasis. Clearly, genomic instability and an environment of chronic inflammation support and provide a basis for the acquisition of the eight fundamental cancer characteristics. The identification of these pathways is providing excellent clues to the underlying mechanisms in cancer and the identification of potential therapeutic targets. However, despite the ability to make small molecules or antibodies, which aim at key targets in cancer survival, we are still a long way from a cure. The reasons for this are many but include inherent tumor heterogeneity (in part supplied by the existence of tumor stem cells), continual tumor evolution, and the immense and underestimated contribution of the tumor microenvironment. Unquestionably, multiple approaches will be required to maximize any possibility of therapeutic benefit.

The Pathology of Neoplasia

DEBRA A. KAMSTOCK, DUNCAN S. RUSSELL, AND BARBARA E. POWERS

Veterinary pathologists play a critical role in the management of companion animal neoplasia by providing diagnostic information that ultimately affects the prognosis and therapeutic decisions. The clinician should have an understanding of how these diagnoses are generated and communicated, while also having an awareness of the limitations of routine histopathologic assessment. A functional interdisciplinary working relationship between the pathologist and the clinician is essential to determine the optimal treatment for the cancer patient, especially as the diagnosis and treatment of neoplasia in veterinary medicine continues to become more complex. The cell of origin (histogenesis), which indicates the tumor type, needs to be identified as accurately as possible, and tumor subtypes should be identified, where applicable, especially when prognostically significant. Histologic grading of tumors is increasingly important, because for a number of tumor types, this has been shown to be a strong prognosticator of biologic behavior. Evaluation of surgical margins to assess excisional completeness also is often a critical component that may significantly affect the prognosis and therapeutic direction. Ancillary diagnostics, such as immunohistochemistry (IHC), immunocytochemistry (ICC), transmission electron microscopy (TEM), flow cytometry, or polymerase chain reaction (PCR) may be necessary to identify the tumor type or subtype correctly, to better estimate the prognosis, or to predict the response to therapy. As research and discovery continue in the field of veterinary neoplasia, prognostic and predictive markers, in addition to tumor classification, for practical application will continue to evolve.

Sample Handling

Multiple steps are involved in sample handling, from tissue procurement to the completed slide for the pathologist's review. Each step can affect the specimen's quality and the final microscopic interpretation. At the onset, the biopsy sample should be visually inspected by the clinician to confirm that the appropriate tissue has been obtained. If the biopsy is a needle-core or incisional specimen, the sample should be of sufficient size and consistency that it remains intact in formalin and is not lost in processing. Samples less than 1 mm^3 are usually inadequate, although a needle-core sample 1 mm wide but at least 5 mm long can be sufficient. If the biopsy samples are needle-core samples, more than one core of tissue should be obtained, if possible. Samples composed of extensive blood, mucus, fat, or necrotic debris are typically nondiagnostic and repeat biopsy should be considered.

Very small samples can be easily lost during shipping or in processing because of sample shrinkage during fixation and processing. Given these considerations, some techniques can be used to minimize tissue loss and maximize the likelihood of diagnosis. Samples less than 3 mm in size can be placed on paper (e.g., surgical glove paper) before fixation. These samples will be tacky and adhere to the paper. Very small or pale samples can be circled with pencil to draw attention to the samples at the laboratory. The paper can be folded around the sample, and the entire package can be placed in formalin for fixation and shipping. Alternatively, commercially available screened tissue cassettes can be used to house the sample during fixation and shipment. The sample is placed in the screened cassette at the time of surgery, and the cassette with the sample is placed directly into formalin for fixation. Extremely small samples can also be dyed with India ink or other commercially available dyes to assist in the identification of the sample.

If the specimen is an excisional biopsy, the entire sample should be submitted, if feasible, and margins of concern should be identified with suture or ink.[1] If the entire mass cannot be submitted, it is best to submit five or six sections, in the event some are nondiagnostic. When representative samples are taken, regardless of the tumor site, sections from the tumor/nontumor interface should be included. This allows evaluation of the interaction of the tumor with the surrounding normal tissue (e.g., invasiveness). If the clinician wishes to select sections that also contain surgical margins of interest, this should be explicitly stated on the submission form, and the physical tissue margins should be definitively marked (e.g., surgical ink). For large splenic tumors, multiple representative sections of solid or heterogenous tumor tissue, in addition to regions at the tumor/nontumor interface, should be collected if the entire spleen cannot be submitted; necrotic and hemorrhagic areas that are friable and collapse easily on manipulation should be avoided. Ultimately, caution should be used in handling all specimens; compression or crushing during the biopsy procedure or before fixation and excessive use of electrocautery, cryosurgery, or laser surgery all can cause specimen artifacts, which can reduce the sample's quality and impede diagnosis, particularly in small specimens.[2,3,4]

Biopsy samples for routine histopathology need to be preserved in a fixative. The most widely used fixative is 10% neutral buffered formalin, which is readily available and frequently supplied in individual specimen containers by many laboratories. During excessively cold weather, samples can freeze during shipment, which causes significant destructive tissue artifact. The addition of

VetBooks.ir

20% ethylene glycol or ethanol to the formalin can prevent freezing and maintain tissue integrity. Before immersion in fixative, larger samples may need to be partially sectioned (bread-loafed) to facilitate appropriate fixation, which is critical to preserve microscopic tissue architecture; one side, such as the deep edge, should be left intact to retain tissue orientation.[1] Slices less than 1 cm thick should be avoided because the fixed tissue may curl and distort. The volume of tissue to fixative should approximate 1:10. If this is not feasible because of large tumor size, multiple representative sections can be submitted. The remaining biopsy sample should be retained in formalin, if possible, in case preliminary sections are nondiagnostic. When large samples are mailed, smaller volumes of fixative may be adequate if the specimen has been in the recommended initial volume for at least 12 hours, or the sample can be shipped chilled (without fixative) if previously in fixative for 48 to 72 hours.[1]

Submissions must include the biopsy sample and all necessary paperwork. Sample *containers* (not just the lid), must be properly labeled because samples can inadvertently become separated from submitted paperwork. A critical determinant of accurate biopsy results is the *information provided by the clinician,* typically on the submission form.[1] This information should include, but is not limited to, signalment, relevant clinical history, clinical findings, disease progression, imaging results, treatments (prior treatments can affect tissue/cellular features microscopically), clinical impression, and primary clinical differentials. The pathologist uses this information to generate and validate the microscopic diagnosis (or differential diagnoses). Without this, the diagnosis and/or prognostic interpretation may be inaccurate, culminating in improper patient management.[2,5] Clear communication of the anatomic location, which may include a photograph or drawing, is also important, especially in the consideration of specific tumor types (e.g., periarticular neoplasia), the prognosis (e.g., melanoma of the nail bed versus other cutaneous sites), and margin determination. If margins or areas of special clinical interest are marked on the sample, a clear description of these markings should be included on the submission form.

Once at the laboratory specimens are accessioned, visually examined, trimmed into processing cassettes, processed into paraffin blocks, sectioned, and stained. In most laboratories completed slides are ready for examination by the pathologist 24 to 48 hours after receipt. Samples such as bone require decalcification before trimming and sectioning and therefore take longer to process. Larger samples that are incompletely fixed, extremely bloody samples (e.g., spleen), or samples with abundant fatty tissue (e.g., mammary gland) may also require additional time for fixation. Once the specimen has been trimmed, most laboratories hold the remaining "wet" (fixed) tissues for a specified period in the event further evaluation is needed. Many laboratories file formalin-fixed paraffin-embedded (FFPE) tissue blocks and/or glass slides for prolonged periods, which allows for case review, additional diagnostics, or retrospective case studies.

Although the technique is infrequently used, frozen sections can provide the surgeon with a more rapid diagnosis. Samples are quick-frozen, sectioned on a cryostat, fixed, stained, and examined within 20 to 35 minutes. This technique is typically performed during surgery to assist with intraoperative decisions; essential requirements are appropriate equipment on site and a pathologist with expertise in interpreting frozen sections. Frozen sections may be helpful in establishing the identity of the tissue, completeness of excision, or adequacy of the tissue for more routine processing. Sometimes a provisional diagnosis can be made, or at least a distinction between benign and malignant processes can be determined. Frozen-section diagnoses are always confirmed by routine histopathology, often using the same tissue sample.[5]

Molecular-based tests, such as IHC and PCR, have become commonplace in veterinary medicine and can be performed on FFPE tissue. These samples often are viable indefinitely for these tests, although the time before fixation, time in fixation, fixative used, and storage time can negatively affect test performance. Exposure to sunlight or extreme temperatures during storage should also be avoided. Such factors should be considered in the interpretation of results. Individual laboratory guidelines for the samples required and shipping methods used should be followed to ensure optimal results. IHC requires unstained FFPE tissue sections on positively charged slides. PCR typically requires thick sections (10–20 μm FFPE curls) containing ample nonnecrotic tumor tissue to assure adequate DNA or RNA amounts. These can be sent to the testing laboratory at room temperature in an airtight container.

Terminology

The word *tumor* is derived from the Latin word for swelling (tumere: to swell), which initially was recognized as a hallmark of inflammation in the 1st century. In modern usage the term *tumor* typically refers to a neoplasm, which may be benign or malignant. *Neoplasia* is the formation of a new, abnormal growth of a tissue that is not responsive to normal physiologic control mechanisms and may be benign or malignant. The growth of this mass is not affected when the inciting stimulus is removed. *Cancer* specifically refers to a malignant neoplasm.[6] *Benign* tumors can be space occupying and can cause tissue distortion; however, they do not metastasize or have a high mortality. In contrast, *malignant* tumors (cancer) are more locally destructive, have the potential to metastasize, and may lead to death if left untreated.

All neoplasms arise in normal tissue and thus are composed of parenchymal and stromal cells; some may also be associated with inflammation. Tumor histogenesis and differentiation can be assessed with histopathology; they are based on the appearance of the tumor cells, their organization, and their association with the supporting stroma. Differentiation is controlled at the molecular level by gene expression. The potentially reversible process of *hyperplasia* (a nonneoplastic increase in the number of cells present) is also composed of parenchymal cells and stroma. Retention of near-normal architecture, similar to well-differentiated neoplasms, can make distinguishing between hyperplasia and benign neoplasia difficult. Neoplasia can also be defined as *clonal expansion* (uncontrolled proliferation of a clonal population of cells) that is no longer responsive to homeostatic mechanisms. Molecular techniques to determine clonality, such as PCR for antigen receptor rearrangement, can help differentiate these conditions. These tests are best recognized for use in canine and feline lymphomas.[7]

Metaplasia is the transformation of normal differentiated tissue of one kind into differentiated tissue of another and is not neoplastic. Metaplasia can reverse with cessation of the chronic inciting stimulus. An example is squamous metaplasia of the columnar epithelium of the prostate gland under the influence of estrogen. If stimuli persist and promotional events occur, metaplastic cells can become targets for carcinogenesis (e.g., bronchial squamous metaplasia in human smokers). In such cases metaplastic cells often acquire dysplastic changes. *Dysplasia* refers to abnormal epithelial growth and differentiation and can be a feature of neoplasia, but it is not necessarily a neoplastic condition. Dysplasia, such

VetBooks.ir

as in squamous epithelium exposed to ultraviolet radiation, can be a preneoplastic condition. *Anaplasia* is a loss of differentiation or atypical differentiation and is a feature of many, but not all, malignancies.

Tumor nomenclature often denotes the histogenesis and expected biologic behavior (benign or malignant) (Table 3.1). Benign tumors of both epithelial and mesenchymal origin typically are associated with the suffix *–oma* (e.g., papilloma, adenoma, osteoma, fibroma). Exceptions exist, such as melanoma – which, when considered malignant based on histopathologic features, should be classified specifically as *malignant* melanoma (it may be referred to as *melanocytoma* when benign). Mesothelioma and lymphoma are other examples that have no benign counterparts. *Leukemia,* a malignancy of blood cells in circulation (occasionally referred to as "liquid tumors"), also has no benign counterpart, although a leukemoid reaction is a nonmalignant condition that mimics leukemia.[2,5,8] Malignant tumors of epithelial origin are typically carcinomas (e.g., squamous cell carcinoma [SCC], transitional cell carcinoma [TCC]), whereas those of mesenchymal origin typically are associated with the suffix *–sarcoma* (e.g., osteosarcoma [OSA], fibrosarcoma [FSA], leiomyosarcoma). Some tumor classifications do not inherently denote biologic behavior (e.g., mast cell tumor [MCT], plasma cell tumor), and determination of such often depends on assessment of specific reported histopathologic features and/or published clinical studies.

Therefore a knowledge of the terminology used to describe tumor-associated histopathologic features is critical to a true understanding of the pathology report. Pathologic descriptions serve to communicate tumor histogenesis and histomorphologic evidence of malignant potential (Table 3.2). A low magnification assessment of the tumor periphery often provides insight into whether a tumor might be benign (e.g., well demarcated, compressive) or malignant (e.g., infiltrative). The tumor architecture may inform histogenesis—cords, rows, nests, rafts, and acini generally indicate epithelial origin; streams and bundles suggest mesenchymal origin; and solid sheets often indicate hematopoietic (round cell) origin. In addition to the overall appearance of a mass, detailed cellular features in the pathology report may also confer malignant potential (see Table 3.2). Cellular shape is significant because it indicates the cell of origin (histogenesis) and weighs heavily on the diagnosis. Shape may be reported as round, polygonal, spindle, or other. The degree of cellular *differentiation* is typically noted, which refers to the phenotypical maturation and subsequent recognition of a cell; marked *atypia* and *anaplasia* tend to reflect poor differentiation and often preclude cellular identification. *Monomorphic* and *pleomorphic* describe the overall cell population and refer to uniformity or variability, respectively, of the cell sizes and shapes and/or their respective nuclei. *Anisocytosis* and *anisokaryosis* refer specifically to cellular and nuclear size, respectively, and more specifically reflect the variability or range of size throughout the neoplastic cell population. *Karyomegalic* cells refer to those with extremely large nuclei.[9] Additional nuclear features reported may include binucleated or multinucleated cells, bizarre nuclei, and/or prominent or multiple nucleoli, in addition to mitotic figures. A *scirrhous* (also *desmoplastic*) response reflects fibroblastic proliferation with collagen deposition, observed in some malignant neoplasms, typically carcinomas.[10,11] *In situ* refers to a malignancy, usually limited to lesions of epithelial origin, that has not yet invaded beyond the natural confines of the basement membrane.[2,5]

Neoplasia can arise from any cell type, resulting in a significant number of different tumor types and classifications. As research continues to identify tumor-associated and cell-specific molecular alterations, tumor classifications and subclassifications are likely to change accordingly. Molecular techniques (e.g., IHC, PCR, flow cytometry) ideally will keep pace with new findings to support diagnostic application of newly discovered molecular characteristics and biomarkers. Broad encompassing techniques for large genomic, proteomic, and metabolomic fingerprinting of tumors are used as discovery tools to scan for alterations that define subclasses of tumor types previously unidentified by more traditional methods. The identification of specific genetic mutations, varied cell surface receptor expression, altered signaling pathways, or altered cellular metabolic responses to these genetic modifications may identify unique fingerprints for a tumor; these, when combined with traditional histologic methods, could allow more accurate subclassification, prognostication, and personalized treatment (see Chapter 8).

Histopathologic Features of Neoplasia

Despite advances in molecular techniques and other ancillary diagnostics, light microscopy remains the standard technique for tumor diagnosis. Neoplasia has certain histologic features that distinguish it from hyperplasia or inflammation, and some features differentiate benign from malignant neoplasia. In some cases these features can be difficult to observe. Definitive diagnosis of malignant versus benign, or even neoplasia versus inflammation or hyperplasia, may not always be possible. In these cases repeat biopsy or additional ancillary tests may be necessary to facilitate a definitive diagnosis.

When inflammation is present, reactive fibroblasts and endothelial cells (ECs) can display features similar to neoplasia[2] however, in reactive tissue with inflammation, the fibroblasts and ECs are oriented perpendicular to one another (reactive granulation tissue) and the lesion is associated with substantial cellular inflammation. Epithelioid macrophages in granulomatous inflammation can be mistaken for tumor cells, but the pattern of tissue involvement and the presence of other inflammatory cells (mixed inflammation) help rule out neoplasia. In some tumors, especially those with surface ulceration or intratumoral necrosis, an extensive amount of inflammation can obscure neoplasia. Other tumors, however, may be associated with inflammation as a defining histopathologic feature that influences tumorigenesis (e.g., feline injection-site sarcomas [ISSs], posttraumatic ocular sarcomas). In still other tumors, inflammatory infiltrates may be a recognized tumor-associated immune response (e.g., lymphocytic infiltrate in histiocytomas).[12]

Benign tumors may be most difficult to distinguish from hyperplasia (see Table 3.2) because both have a proliferation of well-differentiated cells that resembles normal tissue. Distortion or loss of normal tissue architecture occurs in benign neoplasia, and usually the tumor grows in an expansive manner, causing compression of adjacent tissue. These tumors typically are well demarcated and may have a fibrous tumor capsule. Hyperplasia tends to retain normal tissue orientation, does not compress adjacent tissue, and lacks a fibrous capsule. In general, if allowed to grow, benign neoplasia attains a larger size than a hyperplastic lesion. In some instances, such as sebaceous gland adenoma versus sebaceous gland hyperplasia or feline benign thyrofollicular proliferations (thyroid adenoma versus adenomatous hyperplasia), the distinction between adenoma and hyperplasia may be clinically irrelevant.[13]

VetBooks.ir

TABLE 3.1 Nomenclature of Common Tumor Types in Veterinary Medicine

Tissue or Cell of Origin	Benign	Malignant
Epithelial		
Squamous	Squamous papilloma	Squamous cell carcinoma
Transitional	Papilloma	Transitional cell carcinoma
Glandular	Adenoma, cystadenoma	Adenocarcinoma, cystadenocarcinoma
Mesenchymal		
Fibrous tissue	Fibroma	Fibrosarcoma
Adipose tissue	Lipoma, infiltrative lipoma[a]	Liposarcoma
Cartilage	Chondroma	Chondrosarcoma
Bone	Osteoma	Osteosarcoma, multilobular osteochondrosarcoma
Muscle (smooth)	Leiomyoma	Leiomyosarcoma
Muscle (striated/skeletal)	Rhabdomyoma	Rhabdomyosarcoma
Endothelial cells, blood vasculature	Hemangioma	Hemangiosarcoma
Endothelial cells, lymphatic vasculature	Lymphangioma	Lymphangiosarcoma
Synovium	Villonodular hyperplasia (nonneoplastic)	Synovial cell sarcoma
Mesothelium	—	Mesothelioma
Melanocytes	Benign melanoma (melanocytoma)	Malignant melanoma, Melanosarcoma
Peripheral nerve	—	Malignant schwannoma, neurofibrosarcoma, peripheral nerve sheath tumor
Perivascular wall	—	Perivascular wall tumor (PVWT) (previously hemangiopericytoma)
Uncertain origin[b]	—	Malignant fibrous histiocytoma (MFH)
Hematopoietic and Lymphoreticular		
Lymphocytes	—	Lymphoma (tissue involvement) with subclassifications and leukemic (in circulation) forms
Plasma cells	Cutaneous plasmacytoma	Multiple myeloma, plasmacytoid or plasmablastic lymphoma
Granulocytes	—	Myeloid leukemia
Red blood cells	—	Erythroid leukemia
Platelets	—	Megakaryocytic or megakaryoblastic leukemia
Histiocytes (macrophages or dendritic cells)	Histiocytoma	Histiocytic sarcoma, malignant histiocytosis
Mast cells	—	Mast cell tumor[c]
Thymus[d]	Thymoma, noninvasive	Malignant thymoma (invasive), thymic carcinoma
Neural		
Glial cells	Astrocytoma, oligodendroglioma	Astrocytoma, glioblastoma multiforme, oligodendroglioma
Meninges	Meningioma	Malignant meningioma
Gonadal		
Germ cells[e]	Seminoma, dysgerminoma	Seminoma, Dysgerminoma
Supportive cells[e]	Sertoli cell tumor, granulosa cell tumor	Sertoli cell tumor, granulosa cell tumor
Interstitial cells[e]	Interstitial (Leydig) cell tumor, thecoma, luteoma	Interstitial (Leydig) cell tumor

[a]Infiltrative lipomas can be locally aggressive but do not metastasize.

[b]Histogenesis remains controversial; myofibroblasts, peripheral nerve sheath, or perivascular wall origin are considered. May be diagnosed by some as pleomorphic or anaplastic sarcoma.

[c]Theoretically, all mast cell tumors are potentially malignant, but grade I or low-grade mast cell tumors are often clinically benign.

[d]Thymic lymphoma can be classified as a hematopoietic neoplasm; however, thymoma and malignant thymoma (thymic carcinoma) are epithelial in origin.

[e]The terminology of these tumors does not distinguish between benign and malignant forms.

VetBooks.ir

TABLE 3.2 Histologic Features of Hyperplasia and Benign and Malignant Neoplasia

Histologic Feature	Hyperplasia	Benign Neoplasia	Malignant Neoplasia
Tissue demarcation	Blends with normal tissue	Expansive and/or compressive, possibly encapsulated, well demarcated	Invasive, infiltrative, unencapsulated, poorly demarcated
Organization/architecture of cell population	Retention of normal tissue architecture	Fairly uniform, typically some retention of normal architecture	Moderately to markedly haphazard, loss of normal architecture
Cellular differentiation	Normal	Well differentiated	Moderately to poorly differentiated or undifferentiated
Cell and nuclear pleomorphism	None	Minimal	Moderate to marked
Cellular and nuclear atypia	None	Minimal to none	Moderate to marked; binucleated, multinucleated, karyomegalic, or bizarre nuclei may be observed
Anisocytosis/anisokaryosis	None	Minimal to none	Moderate to marked
Nucleoli	Normal, indiscernible	Normal, typically indiscernible	Prominent, large and/or multiple
Mitotic figures	Typically low	Typically low[a]	Typically high[a]
Necrosis	None	Minimal to none	Moderate to marked
Stromal reaction	None	None	Scirrhous or desmoplastic response[b]
Vascular invasion (blood or lymphatic vasculature)	Not present	Not present	Potential to exist

[a]Exceptions exist; see Table 3.3.

[b]Especially as can be seen with squamous cell and transitional cell carcinoma.

Histopathologic features that distinguish benign from malignant neoplasia were introduced in the earlier section Terminology and in Table 3.2. Ultimately, malignancies typically are characterized by invasive growth with effacement of normal tissue and poor organization of the tumor tissue itself. Cellular features of malignancy include increased cellular and nuclear pleomorphism; increased anisocytosis and anisokaryosis; increased and variable nuclear:cytoplasmic ratio; presence of binucleated, multinucleated, and/or karyomegalic cells or bizarre nuclei; abnormal nuclear chromatin; increased number of mitotic figures; bizarre mitotic figures; and abnormal, large, prominent and/or multiple nucleoli. Increased necrosis also is recognized as a feature of malignancy. Unequivocal intravascular (hematogenous or lymphogenous) invasion, histologic evidence of lymph node (LN) involvement, or widespread metastasis (confirmed by submission of multiple lesions at various sites) conclusively establish malignancy, regardless of other histopathologic features.[2,5,14]

In some tumors the histopathologic features do not correlate with expected biologic behavior. Examples include canine cutaneous histiocytoma, benign plasmacytoma, and pleomorphic feline cutaneous MCT.[15–17] These typically display some histologic features of malignancy but clinically are benign. Histologically low-grade yet biologically high-grade FSAs of the canine oral cavity have benign histologic features but are clinically malignant.[18] Similarly, bronchial carcinomas in cats retain organized epithelial structures composed of well-differentiated, ciliated, pseudostratified columnar epithelium even at distant metastatic sites, including the digit, eye, heart, and kidneys.[19] In these instances knowledge of the clinical history and tumor behavior is essential to distinguish benign from malignant neoplasia.

Challenges may also be encountered during evaluation for possible recurrence after therapy (surgery, radiation therapy [RT], chemotherapy, or a combination thereof) because histopathologic features of treatment-associated tissue responses can be difficult to distinguish from overt neoplasia. This may be especially true after RT, which can induce the formation of bizarre reactive cells, including fibroblasts (*radiation atypical fibroblasts*), that display many features of malignancy, although these cells are not neoplastic.[20] Inflammation, fibrovascular proliferation, and EC and/or epithelial hyperplasia are other possible treatment-associated tissue responses that may preclude or obscure an appropriate assessment of neoplasia. If tumor cells are identified, the clinician may wish to know if these cells are viable, dead, or rendered viable but sterilized (reproductively dead) by RT or chemotherapy. Although the latter is not possible with routine microscopy, the presence of mitotic figures in the tumor cell population would indicate replicative potential.

Mitotic Figures

Mitotic figures (MFs) are observable, quantifiable tumor-associated histopathologic features that have been proven to be a reliable prognostic indictor for some tumors. The terminology, methodology of acquisition, and reporting of MFs, however, has varied over the years and thus is addressed here to provide the clinician with some insight and guidance when interpreting the MF information provided in the pathology report.

A MF provides visual confirmation of an actively dividing cell, specifically in mitosis. Mitosis occurs during the M-phase when replicated chromosomes of the cell are separated into two separate nuclei and, ultimately, cytokinesis gives rise to two separate cells. Mitotic stages are divided into prophase, prometaphase, metaphase, anaphase, and telophase, any of which may be visualized on routine microscopic evaluation, and all are considered

TABLE 3.3 Tumors That Tend to Defy the Typical Paradigm of Mitotic Figures and Expected Biologic Aggressiveness

High Mitotic Figures but Typically Benign	Low Mitotic Figures but Typically Malignant
Histiocytoma, trichoblastoma	Acanthomatous ameloblastoma, Adrenocortical carcinoma, Chondrosarcoma, Hepatocellular carcinoma, High/low fibrosarcoma of the canine oral cavity, Islet cell (β-cell) carcinoma, Malignant melanoma, Thyroid follicular cell carcinoma

MFs. MFs represent cell division and thus provide information about the growth fraction (GF) of a neoplastic mass. Through numerous studies, the presence of MFs in neoplastic tissue has proven to be a prognostic indicator of biologic behavior, either as an independent variable or as one factor in a grading scheme considered with other phenotypically observable histopathologic features (e.g., cell differentiation, nuclear features, necrosis).[9,21–30] In general, a higher number of MFs typically reflects a higher GF and increased potential for biologic aggressiveness; however, multiple exceptions exist (Table 3.3). Additionally, when the relevance of MFs for a specific tumor type has not been proven scientifically, caution is advised in simply extrapolating an interpretation of biologic behavior based on "high" or "low" "numbers of MFs.

The terminology used in histopathology reports and published veterinary studies to quantitatively report MFs (e.g., MFs, mitotic index, mitotic rate, mitotic activity, number of mitoses, mitotic count) has lacked standardization, as has the method of acquisition. This can create confusion as to how to interpret the pathology report and can complicate accurate comparison of data across studies. Additionally, even if the methodology is similar, microscopes can have variable lenses and magnifying components that affect the field of view (FOV) such that the area of tissue visualized at 400× magnification of one microscope may differ from that of another. Moreover, the advent and ever-increasing presence of digital pathology has introduced yet another variable with which to consider the FOV and total area of tissue evaluated, especially as it relates to previous studies and data acquired via traditional microscopic evaluation.

An effort to standardize terminology and the FOV, regardless of the instrument or technology used, recently has been introduced.[31] It has been proposed that the profession use the term "mitotic count" and that a standardized area of 2.37 mm^2 be the total area evaluated (this is most commonly acquired by evaluating 10 fields with a 40× objective, 22 field number ocular, and no tube lens); the number of fields viewed may vary, depending on equipment. The *region* of the tissue examined is yet another variable in need of standardization. Examples of various region approaches in the literature are consecutive regions, regions of highest mitotic activity, regions at the invasive edge, and random fields.[21,24,32,33] The authors believe that daily diagnostic application by pathologists should replicate the study-specific methods when a published grading scheme or published MF value as an independent variable is applied. The clinician should be familiar with the study-specific methodologies from which MFs and associated prognostic conclusions were drawn and should be aware of how the number of MFs reported on the pathology report were obtained. Standardization of regions to be evaluated should be considered moving forward. Regions with the highest mitotic activity, whether at the invasive edge or elsewhere, may be the most representative of the GF.

Although efforts to improve standardization in methods for evaluating and reporting MFs certainly will be beneficial, the authors highlight that (1) applying such terminology or techniques to previously published studies may cause confusion and perhaps more inaccuracy; and (2) reporting of MFs is an estimate of biologic activity and is only one parameter of cell proliferation (reflective only of M-phase), as other evaluable proliferation indices (e.g., Ki67, PCNA, AgNORs) exist. The broader histopathologic picture still should be considered, as should all tumor-associated clinical parameters, including stage of disease, in the management of the cancer patient.

Lymph Node Metastasis

Histopathologic evidence of LN metastasis is a feature of malignancy, a negative prognostic indicator, and has a profound effect on the therapeutic plan. When LN "metastasis" is reported on a biopsy report, it is important the clinician recognize that this is the pathologist's *interpretation* based on histopathologic features observed. To that end, no firmly established nor standardized histologic criteria for LN metastasis in veterinary medicine exists, although recent attempts to establish a foundation have been made.[34] Ultimately, if a neoplastic cell population has colonized a tissue distant from its primary site, is forming a new mass lesion at that site, and is effacing and replacing the normal tissue architecture, these are irrefutable histopathologic features of overt metastasis. Similar findings in LN tissue are unequivocally supportive of metastasis. However, alternative findings may consist solely of individualized/isolated tumor cells (ITCs) or small aggregates of tumor cells in sinusoids and/or parenchyma, and these may be sparsely or frequently present.[34] Without standardized histologic criteria for metastasis, these types of histologic findings can result in interpathologist variability in interpretation and reporting of metastasis.

For this reason (1) the clinician should be cognizant of the histopathologic description of the LN on the pathology report, especially if the diagnosis itself states LN metastasis; and (2) outside of overt histopathologic evidence of metastasis as described previously, the pathologist should try to reserve an interpretive diagnosis (e.g., LN metastasis, no evidence of metastasis) and instead work to provide a descriptive diagnosis (e.g., rare isolated tumor cells are noted in the subcapsular sinus). Clinicians may find this frustrating and may not know how to interpret these descriptive findings, but until further research is pursued, the significance of these findings or the expected biologic behavior of the tumor simply remains unknown. In human medicine, evaluation for LN metastasis typically is reported as negative, ITCs, micrometastases, or macrometastases; however, the clinical and prognostic significance of ITCs and micrometastases is still under investigation.[35–39]

To improve the sensitivity of identification of nodal metastasis, perioperative or intraoperative evaluation for the sentinel LN (SLN) is becoming more commonplace in veterinary medicine (Chapter 9).[40] The pathologist also can improve sensitivity by using IHC (e.g., cytokeratin for carcinomas) or histochemical stains (e.g., toluidine blue for metachromatic granules in MCTs). This can aid in the identification of aberrant nodal cells and/or improve the efficiency by which these cells are detected visually.[34,41] Serial sectioning or multilevel sectioning can also improve detection sensitivity of metastasis by increasing the overall amount

VetBooks.ir

of tissue area evaluated.[41,42] The clinician should remember that the designation "clean" or "negative" node is based only on the tissue section (4–5 μm thick) or sections evaluated; on a routine basis, this is often less than 1% of the total tissue area. One study of 20 retrospectively evaluated LNs found that 25% of previously "negative" LNs could be reclassified after more comprehensive sectioning and staining.[41] Gross examination of the tissue by a pathologist or trained histotechnologist may assist with trimming in more suspicious areas based on color and/or texture, but an understanding of the total tissue area evaluated microscopically relative to the total area of the tissue submitted remains important.

Histologic Grading and Clinical Staging of Neoplasia

In certain tumors, histologic grading, which is based on microscopic evaluation of defined histopathologic criteria (many of which have been presented previously) is predictive of biologic behavior.[2,5,14] Grading can be a powerful estimate of expected clinical progression or clinical outcome, such as metastatic potential, disease-free interval, or overall survival. For some tumors, such as human and canine soft tissue sarcoma (STS), the histologic grade is more important than the tumor type.[2,22,32] Grade frequently affects clinical decisions, such as recommendations for adjuvant therapy. Although this grade can be a valuable component of the clinical picture, no grading scheme accurately predicts behavior in 100% of patients.[43] This introduces the critical difference between histologic grading and clinical staging; grading is based almost exclusively on histomorphologic characteristics of the primary tumor and does not typically incorporate clinical staging components, such as the presence of metastases or LN involvement.

Histomorphologic features used to determine grade may include cellular differentiation, number of MFs, invasiveness, necrosis, cellular or nuclear pleomorphism or atypia, nucleolar size and number, stromal reaction, and overall cellularity. For many routinely applied grading schemes, histologic features are described categorically (i.e., range of MFs, invasion pattern, percentage necrosis, degree of differentiation) and assigned a score. These grading schemes are time efficient, cost-effective, involve no new technology, and easily can be applied to routine diagnostic specimens. To ensure valid clinical application, grading must use the same methods and criteria as described in the relevant publication; clinicians should be familiar with these studies and ensure that accurate methods were applied by the pathologist in reporting grade.

Because of the nature of grading criteria, there is potential for subjectivity, and reproducibility between pathologists can be variable.[14,43,44] Despite this limitation, one human study of 440,000 cases found that interobserver variation did not alter the relationship between grade and outcome.[14] A recent international study that applied the World Health Organization (WHO) system of lymphoma classification to canine lymphomas demonstrated an overall accuracy of 83% among 17 pathologists.[45] With preparative training and careful application to well-described criteria, reasonable accuracy can be achieved. If the criteria are more loosely defined, pathologist concordance likely will be reduced.[44]

Some degree of grading variation is inevitable because of known biologic variation that defines tumor types and even individual tumors. Tumors often have considerable morphologic heterogeneity – this might directly reflect the expansion of differing clonal subpopulations and genetic instability that characterize many advanced tumors.[46] If heterogeneity is present, the most malignant-appearing areas (usually defined by cellularity, degree of differentiation, and mitotic activity) should be assessed for grading purposes. Grading of specific tumor subpopulations, such as those at the "invasive front," might also help to better prognosticate behavior.[47] Human biases have the potential to amplify natural biologic variation in tumors. In small biopsy samples, the sampling procedure can affect the representation of different components in a heterogeneous tumor. Some studies have demonstrated that pretreatment incisional biopsies are a reasonably accurate estimation of grade in the excisional sample; however, results might vary between tumor types.[48,49] If necrosis is considered directly in the grade, clinicians and/or pathologists might avoid these areas for diagnostic sampling. Therefore incisional biopsies could have a tendency to underestimate tumor grade.[48,49]

Guidelines for evaluating the prognostic utility of grading schemes have been described.[43,50] An awareness of study design, assessment of clinical outcomes and endpoints, statistical analysis, methods of marker evaluation, and specific study conclusions should all influence decisions to assign clinical relevance to specific histopathologic features and/or grade. Table 3.4 lists tumors for which strong data suggest that grade and/or specific histologic features are prognostic in dogs. Other canine tumors in which histomorphology has been linked to the prognosis include appendicular OSA[51,52]; multilobular osteochondrosarcoma (MLO)[53,54]; mandibular OSA[55]; chondrosarcoma[56]; hemangiosarcoma (HSA)[57]; urothelial carcinoma[10]; SCC of the tongue[58]; splenic sarcoma (nonangiomatous/nonlymphomatous)[59]; primary lung tumors[60]; ocular melanoma[61]; splenic liposarcoma[62]; and lingual HSA.[63] In cats, histologic features may be relevant in cutaneous MCTs[64,65]; primary lung tumors[66]; mammary carcinoma[67,68]; and uveal melanoma.[30,69] Independent validation of many veterinary grading schemes is limited, and some have been questioned in the recent literature.[43,70,71] In canine malignant mammary tumors, the histologic subtype may be more relevant than conventional grading.[72] As with MFs, grade is ultimately an estimate of biologic activity to be taken into account with other parameters and the overall clinical picture.

For tumors where grading systems are not well established, the pathologist may still estimate presumed biologic behavior based on the overall degree of tumor differentiation. This might be convenient for those tumors where there are insufficient data to directly associate histomorphology and prognosis. In these cases, the terms *well differentiated, moderately differentiated,* or *poorly differentiated* may infer a low-grade, medium-grade, and high-grade malignancy, respectively.[73] Pathologists who advocate for evidence-based medicine may chose not to include this in the final diagnosis unless clearly defined criteria and clinically validated data justify its prognostic utility; however, the degree of differentiation, should be reported in the histopathologic description.[74]

Many histomorphologic grading criteria are likely proxies for underlying molecular mechanisms that define most malignant tumors (Table 3.5). In human breast cancer morphologic phenotypes and grading criteria are associated with molecular signatures.[75] Tumoral necrosis, measured in multiple different grading schemes, might be related partly to inadequate perfusion, hypoxic injury, and vascularization. Tumoral neoangiogenesis is a hallmark of most malignant neoplasms and can be estimated by microvessel density. Important mediators in this process include the vascular endothelial growth factor (VEGF), thrombospondin-1, and hypoxia-inducible factor-1α. Underlying molecular mechanisms

TABLE 3.4 Canine Neoplasms with Grades or Histologic Features with Prognostic Significance

Tumor Type	Grades Given	Features of Importance	References
Mast cell tumor, cutaneous	I, II, III	Cellularity, nuclear: cytoplasmic ratio, cell morphology, mitotic figures,[a] depth, necrosis, granularity	21
	2-tier: High, low	Mitotic figures (≥7 in 10 hpf) karyomegaly (nuclear diameter in ≥ 10% cells varying by at least twofold), multinucleation (3 or more nuclei), bizarre nuclei (≥3 in 10 hpf)	9
	I/Low, II/Low, II/High, III/High	Combination of the two previous grading schemes	9, 21 OPWG 2017 Consensus (http://vetcancersociety.org/vcs-members/vcs-groups/oncology-pathology-working-group/)
	Subcutaneous	Mitotic index ≤4, >4; growth pattern; multinucleation (two or more nuclei)	111
Soft tissue sarcoma	1, 2, 3	Differentiation, mitotic figures, necrosis	22,29
Lymphoma	Low, intermediate, high; I, II, III	Mitotic figures: low (0–5 mitoses in one 400× field), intermediate (6–10 mitoses), high (>10 mitoses) Nuclear size: small (<1.5× a RBC), intermediate (1.5–2× a RBC) and large (>2× a RBC) Nuclear morphology: centroblastic, immunoblastic, centrocytes to centroblasts Architecture and immunophenotype: diffuse large B-cell (DLBC), peripheral T cell not otherwise specified (PTC-NOS), T-cell lymphoblastic lymphoma (T-LBL), indolent nodular lymphoma (T-zone, marginal zone [mantle cell, and follicular])[b]	32,45,147–149
Oral, lip, cutaneous and digital melanoma	Poor prognostic features	Mitoses: ≥4/10 hpf (oral/lip) or ≥3/10 hpf (cutaneous/digit); pigmentation: in <50% cells (oral/lip) or no to slight pigmentation (cutaneous/digit); atypical nuclei: in ≥30% (oral/lip) or in ≥20% cells (cutaneous/digit); Ki67 Index: >19.5 (oral/lip) or >15% (cutaneous/digit)	33,83,150,151
Mammary gland carcinoma	Prognostic significance by histologic subtype (per 2011 classification system)	Prolonged survival: carcinoma arising in benign mixed tumors, complex carcinoma, simple tubular carcinoma; Decreased survival: tubulopapillary carcinoma, intraductal papillary carcinoma, malignant myoepithelioma, adenosquamous carcinoma, comedocarcinoma, solid carcinoma, anaplastic carcinoma, carcinosarcoma	72,152,94
	System 1: Well, moderately, and poorly differentiated	Invasion, nuclear differentiation, lymphoid response	153–155
	System 2: Grades I (low), II (intermediate), III (high)	Tubule formation, nuclear pleomorphism, mitotic index	
Periarticular tumors	Tumor type/histogenesis dependent prognosis; (histiocytic sarcoma, synovial myxoma, synovial cell sarcoma)	Molecular markers (CD18, vimentins, cytokeratin, smooth muscle actin) and tumor constituents, (myxomatous matrix) that may assist in determining histogenesis.	156–159
Multilobular osteochondrosarcoma[c]	1, 2, 3	Borders, lobule size, organization, mitotic index, nuclear pleomorphism, necrosis	53,54
Pulmonary carcinoma[c]	1, 2, 3	Overall differentiation, nuclear pleomorphism, mitotic index, necrosis, nucleolar size, fibrosis, invasion	60

[a]Terminology regarding mitotic figures throughout the table reflects the terminology used in the respective study.

[b]The most common canine lymphoma subtypes, which have also been shown to carry prognostic relevance (the revised REAL/WHO Classification describes > 30 subcategories of lymphoma; prognostic significance is not validated for all subtypes). In general, the indolent subtypes have less aggressive biologic behavior. Mantle cell and follicular cell lymphomas are uncommon but are listed here for completeness. Of note, late stage indolent lymphomas may take on an aggressive phenotype.

[c]These studies do not meet the robust criteria recently described; however, because they remain the foundation of grading for these tumor types, they are included here with the caveat that clinicians should be cognizant of the limitations of study design.[50]

TABLE 3.5 Molecular Features Underlying Grading Criteria

Grading Criteria	Underlying Molecular Mechanisms
Mitotic activity	Cyclins, cyclin-dependent kinases (CDKs), proliferating cell nuclear antigen (PCNA), Ki67, bromodeoxyuridine (BrdUrd), labeling index (LI)/ growth fraction (GF)
Percent necrosis	Inflammatory mediators, including eicosanoids (prostaglandins), cytokines; microvessel density (MVD), including vascular endothelial growth factor (VEGF), thrombospondin-1 (TSP-1), and hypoxia-inducible factor 1-α
Invasiveness	Matrix metalloproteinases (MMPs), plasminogen activators (PA), integrin expression, cell adhesion molecules (E-cadherin, N-cadherin)
Stromal reaction	Transforming growth factor beta (TGF-β), platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), VEGF, MVD mediators
Nucleolar size	RNA transcriptional activity, silver staining nucleolar organizing regions (AgNORs)
Overall cellularity	Growth fraction, apoptosis factors (i.e., FasL, caspases), tumor doubling time

typically co-occur and, similarly, morphologic grading criteria are likely interconnected (e.g., tumoral necrosis, inflammation, stromal response, and invasive growth).[46]

As digital technologies become more readily available, grading schemes may change. Digitization has the potential to transform previously categorical morphologic criteria into more objective and repeatable continuous variables; it also will help assess the value of individual morphologic criteria used to estimate the prognosis.[76–78] Automated computerized morphologic examination is not routinely available in veterinary diagnostic pathology, but it might soon overcome the current limitations.

Grading may be supplemented by ancillary diagnostics to provide a more accurate prognostic estimate. For example, internal tandem duplications in exon 11 of the *c-kit* proto-oncogene have been linked to tumor grade, survival, and response to tyrosine kinase inhibitor therapies.[79–82] Measures of tumor growth fraction (e.g., Ki67 index) have been successfully applied to canine oral melanocytic tumors, particularly when routine morphologic interpretation offers an ambiguous assessment of the biologic course.[83] Recognition of cancer stem cells and an enhanced knowledge of tumor heterogeneity may continue to influence approaches to tumor grading.

The pathologist may assist in staging by assessing tumor size, depth of invasion, LN involvement, or confirmation of the neoplastic process at distant sites. This information is needed to stage tumors into WHO's TNM system (i.e., ***t***umor size and/or invasion; ***n***odal involvement; and distant ***m***etastasis).[14] Categories for tumor size and depth of invasion vary according to tumor type. In human melanoma the Clark and Breslow scales are used to determine tumor size and depth of skin involvement. In human bladder cancer, tumor staging is largely based on the depth of tumor invasion into the bladder wall.[3,5] Similar concepts might be applicable for veterinary patients with tumors such as canine urothelial carcinoma and feline gastrointestinal lymphoma.[10,84] Cytologic assessment (i.e., fine-needle aspirate) of draining LNs has been shown to be a sensitive alternative to histopathology for LN metastasis needed for staging.[85,86] However, if the cytologic assessment is negative, histologic evaluation still should be considered. In both processes of tumor grading or tumor staging, these procedures are useful only if they have been shown to correlate with clinical behavior.

Assessment of Tumor Margins

Margin assessment is an essential component of oncologic specimen review, especially when the surgical goal is curative-intent.[1,87] Although several important limitations are associated with this practice, routine histopathology is the most widely available method of determining excisional completeness. Histologic margins are a predictive marker of surgical treatment; however, margin status does not predict recurrence with absolute certainty.[1,87,88] Additionally, margin status at a primary site does not address the potential for metastases or the likelihood of a disease-free state.

The *surgical edge* refers to the surgically incised edge/excisional edge of the biopsy specimen. The *gross surgical margin* refers to the region between the surgical edge and the physically palpable and/or visual mass; typically determined before the surgical procedure and presumed to be tumor free. Microscopically the *histologic surgical margin* (histologic tumor-free margin [HTFM]) is the quantifiable tumor-free tissue between the neoplastic process and the surgically incised edge. Microscopic margin assessment should be performed for both benign and malignant lesions, although detailed characterization of the HTFM (e.g., objective measurement, tissue constituents and viability) may be limited to malignancies because recurrence of benign tumors is uncommon. Crucial determinants for obtaining accurate surgical margin information on the pathology report are (1) specimen handling and information submitted by the clinician; (2) the method of tissue trimming performed at the laboratory; and (3) observations reported by the pathologist.[1]

Histologic surgical margins should be interpreted with a knowledge of the intrinsic limitations of histopathology and factors that influence the pathologist's interpretation. The clinician is responsible for communicating the surgical goals as they relate to excisional outcomes (i.e., debulking versus curative-intent) and which tissue edges require microscopic scrutiny. In some cases annotated sketches or images might assist with trimming (regions selected from the gross specimen at the laboratory for processing and microscopic evaluation). Inking is the preferred method of identifying a surgical edge because it can be visualized at both the gross and microscopic levels.[5,89] Grossly the surgical ink affects regions of the specimen that are selected during trimming for microscopic examination. Importantly, ink allows the pathologist to identify a true surgical edge appropriately under the microscope (as opposed to artifact) and report the margin as it relates to a specific gross anatomic region. Surgical ink should be placed only on regions of the specimen that are true surgically incised edges or areas of specific clinical concern. Ink should also be allowed to dry according to the manufacturer's instructions (approximately 15 minutes) before fixative immersion. Even under ideal conditions, inking can be associated with a number of artifacts that may influence the histologic interpretation.[90] Continuous suturing of postexcisional specimens might mitigate artifacts associated with tissue alignment and cohesion.[91]

Histologic surgical margin outcomes are influenced by the method used to trim specimens at the laboratory.[1,92,93] One study

VetBooks.ir

of low-grade canine MCTs found that 23% of margin outcomes changed according to the sectioning technique.[94] The most common method of trimming for routine specimens is the *cross-sectioning* or *radial method.* The mass is bisected along its short axis, after which each remaining half is bisected along its long axis, creating quarter sections. This method is perpendicular sectioning and facilitates numeric quantification of the deep and four circumferential (lateral) margins. The overall amount of margin tissue evaluated is minimal, and this method may be particularly problematic for tumors with irregular geometry or discontinuous growth patterns (i.e., microsatellites). Additional techniques that can increase the overall percentage of margin tissue evaluated include *parallel, modified* (a combination of parallel and cross-sectioning), and *tangential* sectioning.[1] Tangential sectioning (sections taken parallel to the surgical edge) captures a greater percentage of the margin but can generate only a dichotomous margin outcome (i.e., tumor cells present versus not present). Shaved margins taken from the tumor bed might bypass some limitations associated with examination of the excised specimen.[87] Shavings from the tumor bed may be submitted in addition to the excised mass but should be submitted in a separate, appropriately labeled container. Möhs surgical technique is the most comprehensive histologic margin evaluation, but it is not widely available in a veterinary surgical setting.[95]

Reporting of the histologic surgical margins should be clear, concise, and thorough, furnishing the clinician with essential information needed to make informed decisions and recommendations for further management. Reporting should include (1) a description of the neoplastic cells closest to the surgical edge (e.g., individual cells, nests of cells, cells at the periphery of the mass itself); (2) an objective measurement of the HTFM (precluded for tangentially trimmed sections); and (3) a description of the tissue constituents (e.g., adipose tissue, dense connective tissue, muscle) and the quality of these constituents (e.g., normal, necrotic, inflamed), because different tissue types provide variable barriers against invasion and infiltration of neoplastic cells.[1,96,97] Vague terminology, such as clean, dirty, close, or narrow, should be avoided because these are subjective terms that introduce interpretative variability. Even though a pathologist might use *complete excision* to communicate a HTFM greater than 0 mm, this terminology introduces ambiguity by virtue of the fact that minimally adequate margins are poorly defined for most veterinary oncologic specimens.[87]

Of note, a quantified histologic surgical margin may be significantly less than a gross surgical margin. Margin measurements are influenced by architectural changes that begin at excision (inherent postexcisional tissue retraction) and end with sectioning and mounting of paraffin-embedded tissue onto the slide. Cadaveric canine skin undergoes a notable physical tissue length reduction ("shrinkage") immediately after excision, approximately 14% for circumferential measurements.[98] Myofibril contraction and tissue elasticity account for much of this effect.[98] This same process may result in increased tissue thickness, which can be influenced by tissue composition.[99] Tissue shrinkage also is affected by formalin fixation, and the degree of shrinkage varies relative to the tissue type.[99–101] For cutaneous biopsy specimens, shrinkage can be up to 30%.[99,100] Specimens may also undergo considerable tissue distortion during fixation, and this distortion may affect the observed HTFM.[87,98] In one study the reduction between the in vivo grossly normal surgical margin and the HTFM, once microscopic tumor infiltration had been taken into account, was reported to be as much as 30 mm and 24 mm in canine MCTs and STSs, respectively.[102]

Many tumor-specific studies have been performed with the goal of correlating surgical margins to clinical outcome. For canine MCTs a number of studies have reported positive associations between histologically complete margins and improved clinical outcomes.[88,103,104] Complete excision of canine STSs also has proven beneficial; dogs with incomplete margins have been reported as 10.5 times more likely to experience local recurrence.[22,26] Incomplete margins also have been linked to local recurrence of canine SCCs of the digit,[105] nasal planum,[106] and oral cavity[107,108]; MLOs[53]; and malignant canine mammary tumors.[72] Excisional status has been linked to survival time in canine noncutaneous HSA.[57]

Although the histologic margin status is an important clinical consideration, incompletely excised malignancies do not always recur, even after protracted follow-up periods. This is illustrated in canine low-grade STSs,[22,109] canine cutaneous MCTs, and subcutaneous MCTs.[110,111] Conversely, some neoplasms with highly invasive and/or metastatic phenotypes have a recurrence potential that is not necessarily related to complete histologic margin status. Recurrence is especially well recognized in feline ISSs, likely because of the tumor's infiltrative nature and pattern; one study of 13 recurrent tumors had only one that was histologically incomplete.[112] For canine oral malignant melanoma, the survival implications of excisional status are also ambiguous.[113] High-grade canine MCTs have a significant risk of local recurrence that is not associated with margin width.[114] Biologic factors that contribute to the potential for recurrence may include molecular signatures, field cancerization, tumor heterogeneity, and overall changes in the tumoral and peritumoral microenvironment.[87,115,116]

Histologic margin interpretation fundamentally centers on a morphologic, light microscopic interpretation by a trained anatomic pathologist. By definition this requires accurate identification of cells at the "leading front" of the neoplasm and recognition of the surgical edge (ideally identified by the presence of ink). Some degree of variation in margin measurement is expected. One study of canine MCTs found a median standard deviation of almost 2 mm in circumferential MCT measurements.[90] Although this difference may not be relevant in wide excisions, marginal excisions are especially prone to interpretive differences, particularly if the margins are classified as dichotomous variable (i.e., complete or incomplete).[90] Sometimes differentiating between inflammatory or reactive and neoplastic cells can be challenging, as with the edges of canine MCTs, granulation tissue in STSs, and carcinoma cells undergoing epithelial-mesenchymal transition.[87] The pathologist's approach to margin evaluation, and subsequent clinical interpretation, might also take into account growth patterns at the invasive front, which differ between tumor types.[78] In one study of low-grade canine MCTs and low/intermediate-grade canine STSs, circumferential and deep infiltration was 4 mm or 2 mm, respectively, from the subgross tumor edge.[78] Asymmetric invasion has been associated with a greater likelihood of incomplete excisions in canine MCTs.[78]

Collective data suggest that the adequacy of excision, and subsequent indications for possible adjuvant therapy, should not rest solely on the histologic margin status. Assessment of the likelihood of recurrence should be interpreted in parallel with a number of other variables, including tumor lineage, histologic grade where applicable, frequency of MFs, growth pattern, trimming technique, and margin composition.

Ancillary Diagnostics

Most oncologic cases in human medicine can be diagnosed by light microscopy using hematoxylin and eosin (H&E) stains.[5]

This likely reflects the situation in veterinary medicine. In a subset of cases, and for clinicians seeking further prognostic and/or predictive information, ancillary tests, such as histochemical stains, IHC, TEM, PCR, and flow cytometry, may be necessary (see Chapter 8). As molecular and genomic research in veterinary oncology continue to evolve, new ancillary tests also will likely emerge, resulting in greater sophistication in tumor diagnoses, prognostication, and theranostics, including more frequent identification of novel therapeutic targets.[117]

Special Histochemical Stains

Histochemical stains consist of chemical substances that, when applied to tissue sections, result in a direct chemical reaction with the tissue's constituents. For all intents and purposes, routine H&E is a histochemical stain in which hematoxylin reacts with nucleic acid and eosin with cytoplasmic protein. Some common histochemical stains that can be used in veterinary oncologic pathology to assist in the diagnosis of certain poorly differentiated tumors are listed in Table 3.6. Stains that identify extracellular matrices that may indirectly support tumor histogenesis include Masson trichrome (collagen; fibrocytic tumors), Alcian blue (proteoglycans; myxoma, myxosarcoma), and Congo red (amyloid; plasma cell tumors, amyloid producing odontogenic tumors). Although histochemical stains often are used for poorly differentiated tumors, the stains themselves do not differentiate between benign and malignant. With the advancement of IHC, many histochemical stains have lost popularity; however, they are still available and can be useful in the appropriate setting. Silver staining of nucleolar organizer regions (AgNOR) is an additional histochemical staining technique that has demonstrated prognostic relevance in canine lymphoma,[118] MCTs,[119] and mammary tumors.[120]

TABLE 3.6 Special Histochemical Stains to Support Tumor Histogenesis

Tumor Type (Reactive Constituent)	Histochemical Stain	Reference
Granular cell tumor (cytoplasmic lysosomes)	Periodic acid-Schiff (PAS)	160,161
Liposarcoma and lipid-rich neoplasms (lipid)	Oil Red-O, Sudan stains (black, III, IV)[a]	162–165
Mast cell tumor (cytoplasmic granules)	Toluidine blue, Giemsa, PAS[b]	17,34
Melanoma (melanin)	Fontana-Masson[c]	166,167
Neuroendocrine tumor (cytoplasmic granules)	Silver stains (Pascual's, Grimelius, Sevier-Munger), Churukian-Schenk	168,169
Plasma cell tumor (amyloid), APOT (amyloid)	Congo red	170–172
Rhabdomyosarcoma (myocyte cross striations)	Phosphotungstic acid-hematoxylin (PTAH)	173

[a]These stains must be performed on nonprocessed tissue because exposure to xylene during processing dissolves lipid components.

[b]May be used in feline and ferret mast cell tumors because the granules in these species are often better visualized with PAS.

[c]Reacts with melanin, which is also visible on routine light microscopy and therefore may be beneficial when trying to confirm melanin versus an alternative cellular pigment (e.g., hemosiderin, lipofuscin). Melanin bleach may provide similar information.

Immunohistochemistry

IHC can aid the classification of several tumors in veterinary medicine and is a widely used diagnostic technique. IHC is a staining procedure that uses commercial antibodies to identify specific cellular and extracellular molecules ex vivo, such as cytoplasmic intermediate filaments, cell surface markers, or even secretory substances; all "molecules" or "markers" are tissue proteins, also referred to as *tissue antigens*. IHC can be performed on frozen sections or specimens routinely fixed in formalin and processed into paraffin blocks. Tissue sections are incubated with primary antibodies to specific cell proteins (antigens). Sections with bound primary antibody are then exposed to secondary antibodies directed against the primary antibody. The secondary antibodies are linked to peroxidase or avidin-biotin peroxidase complexes. The peroxidase catalyzes a reaction in the presence of dye that precipitates at the site of the complex and is visible with light microscopy.[121,122] As an alternative, alkaline phosphatase enzyme systems also are available. A list of common diagnostic IHC markers used in veterinary oncology, and the respective tumor types for which their use is indicated, is provided in Table 3.7. ICC uses similar technical aspects; however, it is performed on cytologic samples obtained from an aspirate or impression smear; this technique has been increasing in popularity over recent years.[123]

IHC also may be prognostically useful; for example, it can assist in evaluating proliferation or the tumor growth fraction through detection of markers such as Ki67 (MIB-1) and PCNA.[124] Prognosis also has been linked to markers of multidrug resistance (e.g., P-glycoprotein)[125] and altered proto-oncogenes or tumor suppressor genes (e.g., *p53, c-kit/CD117, p21, Rb,* and *PTEN*).[81,82,126–128] Other immunohistochemically detectable markers linked to the prognosis include VEGF and its receptors,[129] cyclooxygenase-2,[68,130–132] and platelet-derived growth factor receptor.[133] Many other potential prognostic markers in a variety of veterinary tumor types detectable by IHC have been and continue to be studied, (e.g., epidermal growth factor receptor, human epidermal growth factor receptor-2, urokinase plasminogen activator, heat shock proteins).[134–136] As the realm of IHC in veterinary medicine continues to expand, so, too, will the discovery of tumor-specific diagnostic markers and markers for prognostic (biologic aggressiveness) and predictive (therapeutic responsiveness) utility.

Although IHC can be a valuable tool, some complicating factors exist. A negative stain does not exclude a certain cell type. Technical components or tumor cell dedifferentiation, with loss of antigen expression, may result in a negative result. One of the more common technical problems that can cause negative staining is prolonged formalin fixation that results in excessive cross-linking of the antigenic components or loss of soluble proteins into the fixative. Antibody-specific antigens (epitopes) that have been masked by protein cross-linking often can be "unmasked" by pretreating sections with trypsin or pepsin or by using heat-induced epitope retrieval techniques.[121,122] Decalcification of tissue may also result in alteration of target proteins so that they are no longer recognized by the respective antibody. The type and duration of decalcifying solution, however, may mitigate these deleterious effects.[136,137] Areas of tissue necrosis, autolysis, hemorrhage, section drying, and sometimes collagenous matrix components can

VetBooks.ir

TABLE 3.7 Common Diagnostic Immunohistochemical Markers/Panels and Respective Tumor Types in Cats and Dogs

Tumor Type	Molecular Marker(s)	Localization/Expression	Comments	References
Carcinoma	Cytokeratin^{+}[a] Vimentin^{-}	Cytokeratin, Vimentin = Cyto	Coexpression can occur in mesothelioma and may reflect EMT in carcinomas.	47,174–176
Gastrointestinal stromal tumor (GIST) (interstitial cell of Cajal [ICC] origin)	KIT/ CD117$^{+/-}$ SMA$^{+/-}$ Desmin^{-} S-100^{-} Dog-1^{+}	KIT = PM & Cyto SMA, Desmin = Cyto S-100 = N & Cyto Dog-1 = PM & Cyto	DOG1/TMEM16A. Mature ICCs do not express SMA but SMA positivity has been reported; suggested because of the close association of ICCs and intestinal smooth muscle or as ICCs and smooth muscle cells may arise from the same primitive stem cell.	177–179
Hemangiosarcoma/ Lymphangiosarcoma	Factor VIII-RAg/vWF+ CD31/PECAM-1^{+}	Factor VIII-RAg/vWF = Cyto CD31/PECAM-1 = PM & Cyto	Factor VIII-RAg and CD31 do not differentiate between blood and lymphatic endothelial cell origin. Lymphatic endothelial-specific markers such as LYVE-1 and Prox-1 have been suggested as diagnostic markers. CD31/PECAM is also expressed, in lower levels, by monocytes, granulocytes, and subsets of T-cells.	180–184
Histiocytic sarcoma (HS)	CD18^{+}, CD3^{-}, CD79a^{-}, Pax5^{-}, Iba1^{+}[b] Lysozyme$^{+/-}$	CD18, CD3, CD79a = PM Pax5 = N Iba1, Lysozyme = Cyto	CD18 is expressed on all leukocytes. Its expression is typically highest on, yet not specific for, histiocytic cells. Iba1 expression shown in monocyte/macrophage lineage, dendritic cells and associated tumors. Additional, yet not commonly used, markers for subsets/ subclassification of histiocytic tumors: CD11d^{+} Hemophagocytic histiocytic sarcoma; CD90/Thy-1^{+} Cutaneous and systemic histiocytosis–canine dermal dendritic cell origin.	185–187
Leiomyoma, leiomyosarcoma	KIT/CD117^{-} SMA^{+} Desmin$^{+/-}$ S-100^{-} Dog-1^{-}	KIT = PM & Cyto SMA, Desmin = Cyto S-100 = N & Cyto Dog-1 = PM & Cyto	Desmin confirms myogenic origin but does not differentiate between smooth, striated, or cardiac muscle.	177–179
Lymphoma, B cell	CD18$^{+/-}$, CD3^{-}, CD79a^{+}, Pax5^{+} CD20^{+}	CD18, CD3, CD79a = PM Pax5 = N CD20 = PM	CD18 expression is generally weak or absent. Pax5 (*BSAP),* a member of the highly conserved paired box (PAX) domain family of transcription factors. Expressed from early pro B to plasma cell where it is downregulated. CD20 = expressed in increasing concentrations from late pro-B to activated B cell (not plasma cells).	188–192
Lymphoma, T cell	CD18$^{+/-}$, CD3^{+}, CD79a^{-}, Pax5^{-}	CD18, CD3, CD79a = PM Pax5 = N	As for Lymphoma, B cell	189–191
Lymphoma, null cell	CD18^{-}, CD3^{-}, CD79a^{-}, Pax5^{-} (and exclusion of other round cell tumors)	CD18, CD3, CD79a = PM Pax5 = N	As for Lymphoma, B cell	188
Mast cell tumor	Tryptase^{+} KIT/ CD117^{+}[c]	Tryptase = Cyto KIT/CD117 = PM and/ or cytoplasmic (Type I, II or III expression pattern)	*Histochemical* stains toluidine blue and Giemsa may be used to confirm mast cell origin. Tryptase IHC is fairly uncommon but is available if other diagnostic parameters are unrewarding. KIT/CD117 is not specific for mast cells (see table legend).	126,193
Melanocytic neoplasms (melanotic and amelanotic)	Melan-A$^{+/-}$ [d] PNL2$^{+/-}$ Tyrosinase$^{+/-}$ TRP-1$^{+/-}$ TRP-2$^{+/-}$ Vimentin^{+} S-100^{+}	Melan-A = Cyto PNL2 = Cyto Tyrosinase = Cyto TRP-1&2 = Cyto Vim = Cyto S-100 = N & Cyto	Melan-A/MART-1. PNL2 is melanocyte-specific save for myeloid cells, especially neutrophils. Use of an immunohistochemical "cocktail" containing PNL2, Melan-A, TRP-1 and TRP-2 is reported to have excellent specificity and sensitivity. Both vimentin and S-100 have good sensitivity but poor specificity.	194–198
Mesothelioma	Cytokeratin$^{+/-}$ Vimentin$^{+/-}$	As above	Coexpression expected for many mesotheliomas. TEM may demonstrate microvilli.	137,199
Neural astrocytic tumors (astrocytoma, glioblastoma, oligodendroglioma)	GFAP^{+} S-100$^{+/-}$ Olig2$^{+/-}$	GFAP = Cyto S-100 = N & Cyto Olig2 = N	Astrocytomas are glial tumors, as are oligodendrogliomas; however, oligodendrogliomas are negative for GFAP. Olig-2 may also be expressed in some astrocytic tumors.	200–202

TABLE 3.7 Common Diagnostic Immunohistochemical Markers/Panels and Respective Tumor Types in Cats and Dogs—cont'd

Tumor Type	Molecular Marker(s)	Localization/Expression	Comments	References
Neuroendocrine tumors	Chromogranin A$^{+/-}$ Synaptophysin$^{+/-}$ NSE^{+} *[Hormone-specific antibodies (e.g., antiglucagon, insulin, thyroglobulin and calcitonin (see Thyroid Tumor, later), may help determine specific histogenesis].*	Chromogranin = Cyto Synaptophysin = Cyto NSE = Cyto	All are generic markers of NE origin. Recommended to run in concert because NE tumors are often variably immunoreactive. NSE is found in a number of cell types and therefore NE specificity, but it is useful in combination with other NE markers.	138,174,203
Plasma cell tumor	MUM-1/IRF4^{+} CD18$^{+/-}$ CD3^{-} CD79a$^{+/-}$ (Pax5^{-})	MUM-1 = N CD18, CD3, CD79a = PM Pax5 = N	In humans, plasma cell neoplasms, multiple myeloma, and plasmablastic lymphomas are typically negative for Pax5. Pax5 expression via IHC in similar canine tumors, has not been reported.	204
Rhabdomyoma, rhabdomyosarcoma	Vimentin^{+} Desmin^{+} Myoglobin$^{+/-}$ SMA^{-} (MyoD1$^{+/-}$ Myogenin$^{+/-}$; see comments)	Vimentin, Desmin, Myoglobin = Cyto MyoD1 and myogenin = N	Desmin (see Leiomyoma, leiomyosarcoma). Myoglobin is typically a late-stage marker; may be negative in poorly differentiated rhabdomyosarcomas. Myo-D1 and myogenin can be useful in undifferentiated tumors. (MyoD-1 and myogenin are not routinely available). PTAH is a histochemical stain that may highlight cross striations of skeletal muscle.	206–208
Sarcoma	Vimentin^{+} [e] Cytokeratin^{-}	Cyto		174–176
Synovial cell sarcoma	Vimentin^{+} Cytokeratin$^{+/-}$ CD18^{-}	Vimentin, cytokeratin = Cyto CD18 = PM	Histogenesis is controversial. Relevance of cytokeratin expression has been questioned. May recruit large numbers of CD18+ histiocytes, making distinction from articular/periarticular histiocytic sarcoma challenging.	209,210
Thyroid tumor: follicular epithelial origin (follicular carcinoma; follicular, solid, or mixed subtypes)	Thyroglobulin^{+} TTF-1^{+} Calcitonin^{-} Chromogranin A^{-} Synaptophysin^{-} NSE^{-}	Thyroglobulin = Cyto TTF-1 = N Calcitonin = Cyto	Thyroglobulin = provides iodination sites for the production of thyroid hormones, TTF-1 = nuclear transcription factor specific to thyroid tissue save for pulmonary epithelium, calcitonin = polypeptide secreted by thyroid C-cells; counteracts effects of PTH by reducing blood Ca^{2+}	205,211–213
Thyroid tumor: C-cell /parafollicular cell origin (medullary C-cell carcinoma)	Thyroglobulin^{-} TTF-1^{+} Calcitonin^{+} Chromogranin A^{+} Synaptophysin^{+} NSE^{+}	As above	As for Thyroid tumor: follicular epithelial origin	211–213

This table provides common diagnostic immunohistochemical markers used in veterinary oncologic pathology on formalin-fixed, paraffin-embedded tissue sections. Immunohistochemical stains should always be interpreted in conjunction with routine (hematoxylin & eosin) histopathologic evaluation and in the presence of appropriately stained positive and negative control tissues. *Positive immunoreactivity* supports histogenesis; however, *negative immunoreactivity* does not definitively rule out histogenesis because of the potential dedifferentiation of neoplastic cells with loss of antigen expression, in addition to the potential for technical error (false negative).

Ab, antibody, *BSAP,* B-cell–specific activator protein; *Cyto,* cytoplasmic; *DOG1,* discovered on gastrointestinal tumor 1; *EC,* endothelial cell; *EMT,* epithelial-mesenchymal transition; *Factor VIII-RAg/vWF,* factor VIII–related antigen/von Willebrand factor; *GFAP,* glial fibrillary acidic protein; *Gp,* glycoprotein; *IFP,* intermediate filament protein; *IHC,* immunohistochemistry; *MKs,* megakaryocytes; *MUM-1/IRF4,* multiple myeloma 1/interferon regulatory factor 4; *N,* nuclear; *NE,* neuroendocrine; *NSE,* neuron-specific enolase; *PECAM,* platelet endothelial cell adhesion molecule; *PM,* plasma membrane; *PTH,* parathyroid hormone; *PTAH,* phosphotungstic acid-hematoxylin; *RTK,* tyrosine kinase receptor; *SMA,* smooth muscle actin; *TEM,* Transmission electron microscopy; *TRP,* tyrosinase-related protein; *TTF-1,* thyroid transcription factor-1; *Vim,* vimentin.

[a]Generic marker for tumors of epithelial origin.

[b]Iba1 may be helpful in differentiating histiocytic tumors from other round cell tumors.[187]

[c]KIT/CD117 is supportive of but should *not be* considered diagnostic for mast cell tumor because it is not mast-cell specific; it has been shown to carry prognostic relevance in canine cutaneous mast cell tumor based on its cellular localization/expression pattern determined by means of IHC.[116]

[d]Rare positivity in amelanotic melanomas.

[e]Generic marker for tumors of mesenchymal cell origin.

VetBooks.ir

result in excessive nonspecific background staining. A skilled pathologist who is familiar with the IHC stain should be asked to differentiate background stain from tumor-specific stain and to navigate technical difficulties. As with histochemical stains, IHC does not distinguish between neoplastic and nonneoplastic tissue. For example, normal bladder mucosal epithelium (urothelium), urothelial hyperplasia, and urothelial carcinoma (TCC) would all be immunopositive for cytokeratin. The distinction between neoplastic and nonneoplastic is made on routine H&E light microscopy based on hallmark features of neoplasia.

Evaluation and interpretation of IHC results should be performed with the knowledge of antibody sensitivity and specificity. For example, both vimentin and cytokeratin are highly sensitive for sarcomas and carcinomas, respectively, but lack specificity. S-100 can be used to support melanomas with good sensitivity, but it lacks specificity because it is expressed in a broad variety of cells, especially neural crest derivatives (e.g., Schwann cell, nerve, cartilage, bone, smooth muscle, adipose). Because most tumor markers have limitations, the best and most reliable results may be obtained using a panel of IHC stains, for which both marker-specific immunopositive and immunonegative results may be anticipated (e.g., rhabdomyosarcoma should be immunopositive for vimentin and desmin, but immunonegative for smooth muscle actin), rather than relying on a single stain. Additionally, IHC stains can be appropriately interpreted *only* in conjunction with appropriate species-specific controls. To support the diagnosis or determine the immunophenotype of feline intestinal lymphoma, appropriate positive control tissue, such as feline LN, spleen, or tonsil, must be run simultaneously. It must be of feline origin and contain normal lymphoid tissue if the pathologist is to confirm that the IHC stain was performed successfully and to interpret appropriately the immunoreaction of the test tissue. Similarly, a negative control, which consists of the test tissue treated either with nonspecific antibody or omission of the primary antibody, must also be run to assist in ruling out background/nonspecific staining. Laboratories that offer IHC should ensure all tests have been optimized and validated relative to each species for which the test is offered.

IHC can be a powerful tool for providing information that could not be otherwise determined on routine microscopy alone (e.g., confirmation of a tumor's histogenesis based on molecular markers). However, an IHC stain should never be interpreted in and of itself; rather, it always should be evaluated in conjunction with routine light microscopic findings and the relevant clinical information.

Transmission Electron Microscopy

As other ancillary diagnostic procedures have become more widely used, TEM is performed less frequently on tumor biopsy specimens, but it is still a notable ancillary resource. TEM requires specific technical support and equipment and is available only at a few diagnostic laboratories. Specimen preparation involves preserving very small representative tumor samples (1 × 1 mm) in special fixatives (e.g., glutaraldehyde), processing tissue into epoxy-based plastic blocks, and sectioning at 1 μm for thick sections to determine the adequacy of the sample and inclusion of appropriate tumor cells. Subsequently, sectioning is done at about 600 Å; the samples are stained with heavy metal–based stains and then examined with the aid of an electron microscope. Samples fixed in formalin can be used, although the quality of the subsequent sections is suboptimal.

TEM can help identify specific cellular features, such as intercellular junctions or basal lamina in epithelial cells, melanosomes in melanocytic cells, granules in mast cells, neurosecretory granules in neuroendocrine cells, mucin droplets in certain epithelial cells, and villous projections of mesothelial cells.[17,137,138] These features may be useful in distinguishing carcinoma from lymphoma and identifying melanoma, MCT, neuroendocrine tumor, and mesothelioma. TEM ultimately provides a level of magnification to visualize specific and detailed cellular components that cannot be appreciated with routine light microscopy.

Flow Cytometry and Polymerase Chain Reaction

Both flow cytometry and PCR have become fairly routine procedures in veterinary oncology and often are combined with histopathology, cytopathology, IHC, and/or ICC. These techniques can be useful for tumor classification and/or confirmation (especially hematopoietic tumors), particularly when H&E and/or IHC interpretation is ambiguous.[139–141] These techniques are discussed in detail in Chapter 8.

Clinical-Pathological Correlation and Second Opinions

Establishing a definitive histopathologic diagnosis can be precluded by the absence of relevant and necessary clinical information.[2,5] This may be especially true regarding primary bone tumors versus secondary tumors involving bone. Diagnosis of a surface or juxtacortical OSA depends both on imaging results and histopathologic features. Similarly, an osteoma may be difficult to distinguish from reactive bone without a corroborative radiograph. Periarticular neoplasia may be difficult to distinguish from other sarcomas, or even inflammatory or immune-mediated joint disease, unless radiographic or gross evidence of joint involvement and bone invasion is seen. Acanthomatous ameloblastoma may be difficult to distinguish from benign periodontal ligament tumors unless bone invasion is identified. Confirming bone involvement depends on deep biopsy samples that capture underlying bone or on clinical information that indicates bone involvement. The importance of communicating clinical data might be best illustrated by histologically low-grade yet biologically high-grade FSAs of the canine oral cavity.[18] Histologically these tumors may be mistaken for benign fibrous tissue, but the clinical presentation is a rapidly growing, invasive and destructive mass that often recurs after conservative surgery.[18] These examples demonstrate the need to furnish the pathologist with an accurate and thorough clinical history, all relevant clinical findings, and the results of all other diagnostic tests. Ultimately, providing any previous imaging scans (or other) results and reports themselves may be the easiest and most accurate means of relaying this information.

When extensive treatment may be pursued or *if a pathology diagnosis is not consistent with the clinical impression,* a second opinion should be considered.[142,143] In human medicine a review of mandatory second opinion surgical pathology at major hospitals revealed 1.4% to 5.8% major changes in the diagnosis that resulted in a change of therapy or prognosis. It was concluded that despite the extra cost, mandatory second opinions should be obtained whenever a major therapeutic endeavor is considered or if treatment decisions are based primarily on the pathologic diagnosis.[144–146] In veterinary medicine, diagnostic disagreement between first and second opinion pathology has been

VetBooks.ir

reported to be as high as 19%, including differences in histogenesis (tumor type) and benign versus malignant status, and up to 37% for differences that would affect the prognosis or treatment choices.[142,143]

The two major categories of errors that may occur at the pathology laboratory are technical errors (e.g., improper labeling, trimming, other) and errors in interpretation of the tissue.[2] If tissue is processed improperly because of equipment malfunction or because it is poorly sectioned, artifacts can occur that make the tissue specimen impossible to interpret. Errors in the pathologist's interpretation may occur in the absence of relevant (or receipt of erroneous) clinical information, or simply because the case is a challenging one. If a pathology service is staffed by medical rather than veterinary pathologists, certain tumors may be misdiagnosed (e.g., histiocytoma, MCT, transmissible venereal tumor, or perianal gland adenoma) because these do not have human counterparts. Many pathologists informally seek opinions from other pathologists when confronted with challenging cases. However, the clinician, should *never hesitate to ask for an official second opinion, nor should the original pathologist be offended by such a request.* A second or even a third pathologist can offer a different perspective on a difficult case and may suggest an alternative diagnosis, confirm the diagnosis of the primary pathologist, or confirm that an accurate diagnosis is not possible and suggest additional ancillary tests for diagnostic clarification. Because patient management is affected significantly by the histopathologic diagnosis, it is not at all unreasonable for the clinician to request a second opinion. A misdiagnosis can result in costly, ineffective, and ultimately unnecessary treatments (e.g., surgery, chemotherapy, RT, other) that can cause morbidity for patients and unwarranted stresses and costs for the client. Misdiagnoses may also result in insufficient treatment, resulting in cancer progression and, perhaps of greatest concern, unwarranted euthanasia. Considering these possible scenarios, second opinions are not only prudent but highly recommended.

For optimal management of the veterinary cancer patient, it is critical for the clinician to have a firm understanding of the procedures and processes involved in generating a diagnosis from a biopsy sample—from the time of tissue acquisition to the generation and interpretation of the final report. An awareness of the limitations of histopathologic assessment and an understanding of potentially beneficial ancillary tissue-based diagnostics also are paramount. However, biopsy assessment is only one aspect of a case; other components (e.g., history, clinical presentation, imaging or other diagnostic results, comorbidities) all should be considered collectively. Important factors are the willingness and ability of the clinician and pathologist to work collaboratively, with mutually open and receptive communication, to establish the most accurate diagnosis and optimal care for the veterinary cancer patient.

Epidemiology and the Evidence-Based Medicine Approach

AUDREY RUPLE, BRENDA N. BONNETT, AND RODNEY L. PAGE

Epidemiology is defined as the study of the distribution and determinants of disease in populations. Historically epidemiologic methods were used primarily in veterinary populations for the investigation of outbreaks and/or epidemics of infectious disease, yet the philosophies, attitudes, methodologies, and application of epidemiology are in fact more broadly applicable to research and clinical practice, regardless of species, disease, or discipline. In fact, epidemiologic principles form the foundation of evidence-based medicine (EBM), an approach to the practice of health care that is now well accepted in the human and veterinary medicine fields. For a clinician, using the EBM approach involves a commitment to base all decisions on the best available evidence and to be explicit about the level and quality of evidence on which decisions are based. An extensive literature is available on EBM and evidence-based practice in the human medicine field (e.g., The Cochrane Collaboration [http://www.cochrane.org/]) and in the veterinary field (e.g., Evidence-Based Veterinary Medicine Association [https://ebvma.org/]). The EBM approach can and should be applied to all interventions, including diagnosis and prognosis, choice of preventive and clinical therapies applied to individuals, and decisions about health policy or control programs for populations.

Pathophysiology forms the basis of our understanding of health and disease, but this knowledge, even combined with clinical acumen and experience, is not sufficient grounds for decision making across the spectrum of activities of health professionals. To have confidence that our interventions will be beneficial, we need to understand that personal and expert opinion are only anecdotal evidence, unless they are based on a valid appraisal of available evidence from the literature. In addition to embracing the philosophy of EBM, all clinicians must develop the knowledge and skills, such as information management, critical appraisal, and causal reasoning, that are needed to assess evidence to determine that their chosen interventions are both efficacious and effective (see glossary of terms in Table 4.1). Unfortunately, especially in veterinary medicine, there are many gaps in our evidence base, in terms of both validity and relevance of published studies.

In veterinary medicine, in general and in certain specialties including oncology, the trend has been toward a heightened sophistication of practice, including the use of advanced technologies in diagnostic testing (e.g., state-of-the-art imaging techniques and molecular characterization of tumors), therapeutic interventions (e.g., interventional surgery and targeted, small-molecule chemotherapy), and the expanding field of genomics in cancer research. This is attributable in part to the presumption that most clients want care for their pets at a level similar to that they themselves receive. Therefore many approaches and interventions have been adopted from human medicine and applied to animals despite considerable gaps in evidence as to their efficacy and/or effectiveness in the veterinary clinical situation. In addition, even where a sufficient quantity of studies is present, the quality and consistency of reporting is frequently inadequate to allow systematic review or adequate comparison between studies.[1] This issue is not unique to oncology and has spawned efforts to improve the reporting of veterinary studies, with a longer term goal of improving the quality of work.[1–7] To approach a level of care in veterinary oncology truly similar to that in humans, there will need to be an increased focus on EBM. Further information and articles pertinent to challenges of applying EBM in practice can be found on the website of the Evidence-Based Veterinary Medicine Association (https://ebvma.org) and the Centre for Evidence-Based Veterinary Medicine (http://www.nottingham.ac.uk/cevm/).

In this chapter, we focus on quantifying the occurrence of cancer (incidence, prevalence) and risk factors for cancer (causal reasoning, associations). An evidence-based approach to diagnosis, prognosis, and selection of therapeutic interventions will be proposed, although other authors in this text will present specific details of diagnosis, prognosis, and therapy for specific cancers. Rather than presenting an exhaustive or systematic review of the literature in this chapter, we will highlight the relevant literature. Our aim is to provide a guide for the application of epidemiologic principles to oncology, in general and for clinical practice.

Measures of Disease Occurrence

Complete and accurate cancer surveillance data are the foundation needed to make appropriate conclusions about the burden of disease, to make recommendations for cancer prevention and control, and for the design of analytic studies to identify causal associations between exposures and cancer risk. Here we cover the measures used to quantify cancer occurrence such as incidence, prevalence, and proportional measures and the types of data used to calculate them.

VetBooks.ir

TABLE 4.1 Glossary of Terms

Term	Definition	Comments
Efficacy	How well a treatment works in those who receive it (e.g., correct formulation, dose).	May be proved in laboratory studies or clinical trials.
Effectiveness	How well a treatment works in those to whom it is offered.	Studies must occur in the environment and under conditions and with patients typical of those to whom it will be offered in practice.
Compliance	How closely a treatment protocol is followed.	Influenced by clinician, client, patient, formulation, duration, and so forth.
Coherence	How well findings reflect our understanding of biologic relationships/pathophysiology.	Limited by our current understanding.
Consistency	The extent to which new findings agree with previously published findings.	Limited by the current literature, traditional approaches, funding, and so forth.
Experimental studies	Traditional research approach done in a laboratory or highly controlled environment.	Potential for high validity, generally lower relevance to the clinical situation.
External validity	The extent to which a study's findings can be extrapolated to a wider population. Similar terms include relevance and generalizability.	A function of the study population, methods, data collection, treatments, and so forth.
Incidence rate	The rate at which new events occur in a population: (Number of new events in a specified period) ÷ (Number of individuals at risk during this period) × 10^n	Cancer incidence rates are available from population-based data (e.g., cancer registry data) or prospective (cohort or longitudinal) studies.
Internal validity	The extent to which a study's findings are likely correct for that study population.	Likelihood that systematic bias is responsible for the study findings reduces its validity (e.g., because of bias in selecting study participants, measuring the exposure, and confounding).
Observational studies	Epidemiologic studies that use existing comparisons in the species of interest in its "natural" environment (often client-owned animals, perhaps in veterinary practice settings).	Examples: (1) Case-control study: Researcher observes/describes exposures in individuals selected based on presence/absence of the outcome; (2) Cohort study: Individuals with different exposures are followed and incidence of outcome(s) is observed.
Randomized controlled trial (RCT)	*Randomized* refers to the random allocation of exposure. *Controlled* refers to appropriate comparison groups (e.g., placebo or standard treatment). *Trial* is generally conducted in a clinical setting.	Researcher exerts control over which individuals receive which treatments or exposures and observes outcomes.
Prevalence	The number of events in a given population at a designated time: Number of events at a designated time ÷ Number of individuals at risk at the designated time.	Taking the number of canine cancers that are observed in a clinic or several clinics during a designated period of time and dividing by the total number of patients seen during the same period is a proportional measure, *not* prevalence.
Proportional morbidity or mortality	The number of events (e.g., disease, death) in a limited population (e.g., animals presenting to the clinic, total deaths) at a designated time.	Proportional measures are used when the underlying population at risk is not known.

Incidence

Incidence, or the number of newly diagnosed cancer cases divided by the total population at risk over a specified period of time, is the most useful disease occurrence statistic for comparison between populations over time. Incidence data are especially valid when they are generated from a large population-based cancer registry with histologically confirmed cases and complete ascertainment of the population at risk within a defined geographic area or theoretically from large prospective, longitudinal, or cohort studies. True incidence data are rarely obtainable in veterinary populations because of the scarcity of animal cancer registries and lack of information about the total animal population (census data) at risk.

Cancer incidence data has been provided from several population-based cancer registries (Table 4.2). Estimates of canine cancer incidence range from 99.3 to 804 per 100,000 dog-years.[8–17] Variation in estimates may be due in part to differences in actual cancer risks and/or variation in the base population. These registries included information from all cancer cases identified within a specified geographic region from a well-defined and enumerated population. One of the earliest, well-known cancer registries for

VetBooks.ir

TABLE 4.2 Characteristics of Population-Based Companion Animal Cancer Registries and Cancer Incidence

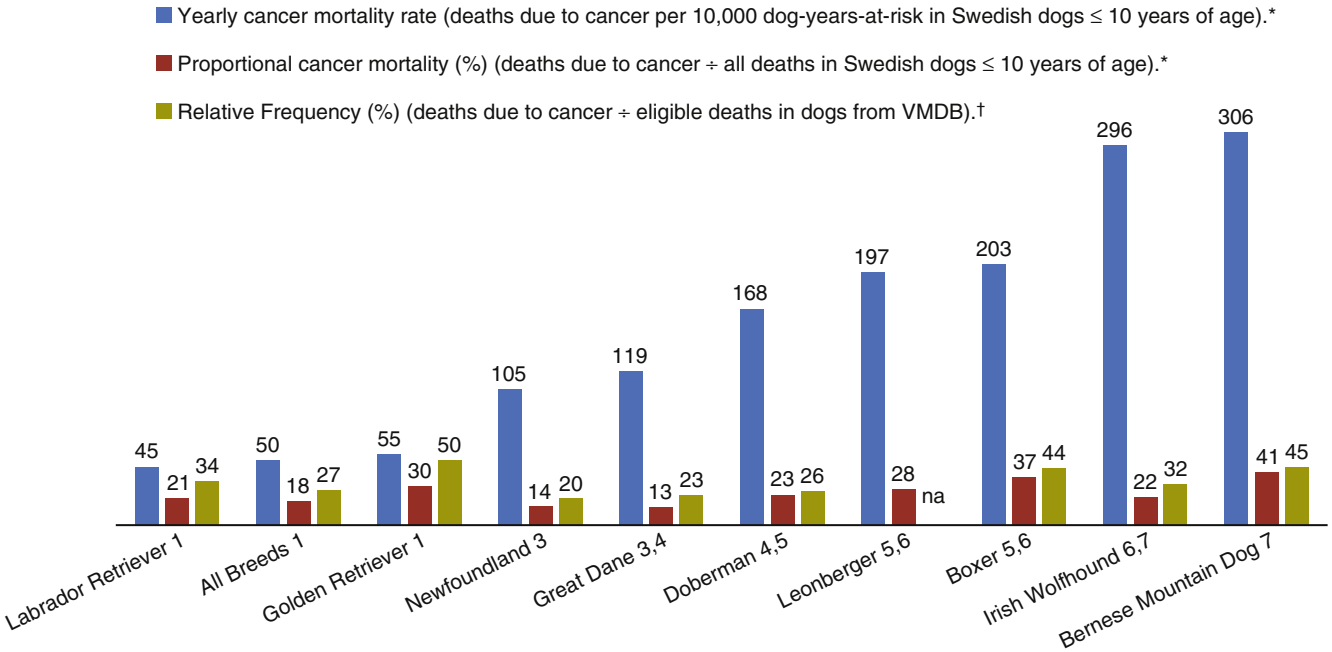
Registry	Period	Cases/Population at Risk	Incidence/Prevalence
California Animal Neoplasm Registry (CANR)[8,9]	1963–1966	1624/80,006 dogs 448/54,786 cats	381.2/100,000 dogs over 3-year period. 155.8/100,000 cats over the 3-year period.
Tulsa Registry of Canine and Feline Neoplasms[10] (Tulsa, Oklahoma)	1972–1973	899 cases/63,504 dogs; 59 cases/11,909 cats	1126 cases per 100,000 dogs; 470 cases per 100,000 cats
Norwegian Canine Cancer Registry[11,12] (Oslo, Norway)	1990–1998	14,401 tumors/census of dogs in Norway in 1992–93[13]	Boxers: 28 and 14/1000 dogs per year for total and malignant tumors, respectively. Bernese mountain dogs: 10 and 4/1000 dogs/year for total and malignant tumors, respectively.
Genoa Registry of Animal Tumors[13] (Genoa, Italy)	1985–2002	3303/107,981; 1,943,725 dog-years	Males: 99.3/100,000 dog-years Females: 272.1/100,000 dog-years, for total tumors (malignant and benign).
Animal Tumor Registry[14] (Venice, Italy)	2005	2509 dogs; 494 cats/296,318 dogs; 214,683 cats	282, 143 and 140/100,000 dogs for total, malignant and benign tumors, respectively; 77, 63, 14/100,000 cats for total, malignant and benign tumors, respectively.
Swiss Cancer Registry[15]	1955–2008	Registered Swiss dog population	13/100,000 dogs in 1955 to 695/100,000 dogs in 2008.
Danish Veterinary Cancer Registry (DVCR)[16]	2005–2008	1523 dogs/dogs registered in the Danish Dog Registry as of August 2006	Breeds with standardized morbidity ratios ≥2: Boxer, Bernese mountain dog, and West Highland white terrier. Measures for all dogs were not provided.
Piedmont Canine Cancer Registry[17]	2001–2008	1175 tumors/dogs recorded in registration system in Piedmont, Italy	804/100,000 dogs for malignant tumors; 897/100,000 dogs for benign tumors

companion animals was the California Animal Neoplasm Registry.[8,17] This comprehensive effort began in 1963 with the goal of identifying all neoplasms diagnosed over a 3-year period among animals living in the San Francisco Bay Area Counties of Alameda and Contra Costa. The denominator was estimated by conducting a survey in a probability sample of households in Alameda County to derive the age, sex, and breed distribution of pets and to determine whether the household had used veterinary services. Additional information on former and existing cancer registries for companion animals has been comprehensively reviewed.[18,19]

Prevalence

Cancer prevalence information from population-based registries is also useful for surveillance and comparison between populations. Prevalence is the number of total cancer cases divided by the number of dogs in the population at risk at one point in time. For example, the prevalence of canine cancer in April 2005 was 143 per 100,000 dogs in an Italian population (Table 4.2).[8,9]

Feline cancer prevalence has been reported from a population-based registry in Italy as 63 per 100,000 cats[14] (see Table 4.2). These data were based on a telephone survey conducted among 214,683 residents of two provinces in northern Italy over a 3-year period starting in 2005. Earlier prevalence data for feline cancers have ranged from 51.9/100,000 cat-years from the California Animal Neoplasm Registry[8,18] to 470.2/100,000 cat-years from the Tulsa Registry.[10]



In addition to population-based cancer registries, cancer occurrence data are abundantly available from veterinary teaching hospital databases and insurance databases. A caution to be noted when interpreting cancer occurrence information from hospital-based registries is that data may be inconsistently recorded or inaccurate and the size and characteristics of the underlying population at risk are not known[20,21]; thus neither true incidence nor prevalence measures can be calculated. Instead, the proportional morbidity ratio (PMR) is used to quantify cancer occurrence. For example, the PMR for a particular tumor type among a single breed is calculated as follows:

(Number of tumor type in breed ÷
number of total tumors in breed) ÷
(Number of tumor type in all other breeds ÷
number of total tumors in all other breeds).

Proportional measures are *not* to be interpreted as prevalence or incidence of cancer occurrence. As an example, Craig et al presents

proportional statistics from a necropsy database and concludes that golden retrievers have an increased "risk" of tumors similar to that for Boxers.[22] However, only the proportion of dead dogs that had cancer are available in that study, and these data cannot be used to estimate risk. Although proportional measures, such as those presented in an article by Fleming et al,[23] have some usefulness for describing patterns within a breed, they are very risky to use for comparison across breeds in which population-based measures are unavailable and the degree of referral bias is unknown. In addition, in those data, 40% of deaths could not be classified pathologically and the unclassified proportion showed extreme variation across breed (e.g., 16%–60%). Fig. 4.1 shows a comparison between proportional mortality ratios and true mortality rate using a subset of data from Bonnett et al, a study with information on the population at risk and data from the Veterinary Medical Database (VMDB) study.[23,24] For golden retrievers, 30% of deaths (before 10 years of age in the Swedish insurance population) were a result of cancer.[24] For Leonbergers and Boxers, the proportional mortality was 28% and 37%, respectively.[24] Proportional values for these three breeds may be similar, but, in fact, Leonbergers and Boxers have a risk for death resulting from cancer (before 10 years of age) that is almost four times as high as that for golden retrievers (approximately 200 deaths per 10,000 years-at-risk versus 55 [$p > 0.05$]).[24] Irish wolfhounds and Bernese mountain dogs (BMDs) have an equal risk (approximately 300 deaths resulting from tumors per 10,000 dog-years at risk [DYAR]), but tumors account for more than 40% of deaths in BMDs and only 22% in Irish wolfhounds.[24] Note that these are deaths before 10 years of age. Comparing the proportional mortality values between the two studies, values for BMDs are very similar (42%, 45%), perhaps because almost all dogs of this breed would die before 10 years of age, whereas the values for golden retrievers are somewhat different (30%, 50%). Of course, there may be true differences between the two study populations, and/or the differences may be influenced by referral bias and the high proportion of unclassifiable deaths in the VMDB study.

To further illustrate this example, using just the breeds in Fig. 4.1 and data from the Swedish insurance database, if one ranked the breeds based on actual numbers of dogs that died because of tumors (e.g., perhaps how an oncology clinician would perceive the "risk" based on dogs that present to a specialty clinic), golden retrievers would be number one because they are among the more numerous breeds in this population. Likewise, if one ranked the breeds by the proportion of dead dogs that had tumors (e.g., similar to what would be reported in analysis of postmortem data), the top three would be BMDs, Boxers, and golden retrievers. So, in these examples, as has been frequently reported in the United States, based on proportional statistics, golden retrievers would be labeled as one of the highest risk breeds. However, in looking at the true incidence based on these Swedish data, they do not have an increased risk (before 10 years of age) compared with all breeds. There is likely considerable misunderstanding of the occurrence of cancer in dogs in the United States because of the lack of accurate incidence data and confusion about the interpretation of proportional statistics. Of course, where a breed is very common, such as the golden retriever, and given that a considerable proportion of them die of cancer, that will represent an important population burden of disease, even if they are not truly the "highest risk" breed. This is why golden retrievers were selected for the largest prospective cohort study conducted in a dog population, the Golden Retriever Lifetime Study (GRLS), to investigate the

• **Fig. 4.1** Comparison of true mortality rate (blue column) and proportional mortality (red column) for selected dog breeds. True mortality is reported as the total number of deaths resulting from cancer per 10,000 dog-years-at-risk (e.g., the cancer mortality in Labrador retrievers was 45 deaths per 10,000 dogs per year). The proportional mortality is reported as the percentage of deaths resulting from cancer compared with all deaths reported in that breed (e.g., 21% of deaths in Labrador retrievers were caused by cancer). The 95% confidence intervals for mortality rates overlap for breeds with the same number (e.g., mortality risk in Labrador retrievers and golden retrievers was not different from that for all breeds combined, but was different from the other breeds listed in the table).[24,25]

VetBooks.ir

risk factors for occurrence of cancer.[25] In addition, the Swedish data only include dogs up to 10 years of age; it is unknown how the statistics would look if dogs of all ages were included. As the authors of this study discuss, for cancer (or any cause of death) that occurs at older ages, a dog must live long enough to experience it (i.e., not die at a younger age because of any other cause), and deaths before 10 years of age are relevant to focus on for cancer prevention.[24]

Sources of Information on Cancer Occurrence

One of the largest clinic-based databases is the VMDB.[26] This database was started in 1964 by the National Cancer Institute, includes patient data from 26 university teaching hospitals in the United States and Canada, and contains more than 7 million records from all species covering the full range of diagnoses, including cancer. The VMDB is a widely used source of cancer surveillance information for companion animals; however, as discussed previously (and presented in Fig. 4.1), there is no information on the base population in these studies and only proportional measures can be calculated. Given that the data sources are teaching hospitals, the patients and disease diagnoses represented are likely to be influenced by referral bias, resulting in estimates of disease frequency that may not be typical of those seen in the general dog and cat population. In an analysis using VMDB medical records it was concluded that substantial referral bias may indeed exist in the data set, and the authors suggested the accuracy of prevalence estimates measured from the VMDB could be improved by statistical adjustment on the basis of geographic proximity of the patient's residence to the nearest university teaching hospital.[27]

The use of primary care data for investigations regarding the occurrence of cancer in companion animals is less affected by referral bias, but may be influenced by misclassification bias.[28] To date, primary care data have been an underused resource for determining cancer incidence, but advances in large-scale data collection and management suggest primary care data may become increasingly accessible for this purpose. For instance, the Veterinary Companion Animal Surveillance System (VetCompass), which began collecting clinical data from primary practices in the United Kingdom in 2009, now holds data on nearly 6 million animals collected from more than 500 veterinary practices across the United Kingdom (as of August 2017).[29] VetCompass began collecting clinical data in Australia in 2016[30] and pilot projects are underway in Spain, Germany, and New Zealand.[31] Projects related to cancer outcomes in companion animals are already underway,[29] and these data will likely become an increasingly important source of information for research concerning cancer occurrence.

Two well-established insurance databases are from the United Kingdom[32] and from Sweden.[24,32,33] A notable limitation of these databases is that not all cases are histologically confirmed. The benefits and limitations of these data have been discussed extensively in the literature.[34] From the UK database, using data from 1997 through 1998, cancer incidence among 130,684 dogs at risk was 747.9 per 100,000 dog-years.[35] From the Swedish data, the overall mortality rate for cancer was 50 per 10,000 dog-years-at-risk (which equates to 500 per 100,000).[24] Osteosarcoma (OSA) incidence rates were 6.1 and 5.0 dogs per 10,000 dog-years for males and females, respectively,[36] and among females, breast cancer incidence was 111 dogs per 10,000 dog-years.[37] The limitations of the Swedish data are that deaths are mainly in dogs 10 years of age or younger and it is unknown whether the diagnosis has been validated by histology,[20] but comparison across breeds within the Swedish data is quite informative given that the limitations occur equally across breeds. Crudely comparing overall mortality rates for cancer, BMDs were approximately six times more likely to die of cancer compared with all dogs combined (306 versus 50 per 10,000 DYAR, respectively).[24] Where it was possible to do more sophisticated analyses, BMDs were shown to be 17 times more likely to die of cancer, compared with baseline, and adjusting for age, gender, and breed.[33] Even if specifics of the population may not be the same as other populations, data such as these are important for identifying high-risk breeds. Comparison across populations and over time is needed, with due consideration of data issues.

Studies on Swedish insurance data have also presented statistics on morbidity and mortality in cats.[38,39] As with dogs, the diagnoses are made by veterinarians, but further details are unavailable. The overall age-standardized mortality rate for death resulting from cancer in insured Swedish cats (generally <12 years of age) was 37 per 10,000 cat-years at risk. The most common types of cancer in the Swedish data were mammary, stomach/intestinal, and lymphoma. Siamese breeds were at increased risk of death caused by neoplasia; mammary cancer was the most common type,[40] in agreement with an earlier study.[41] Differences between populations and data are no doubt affected by differences in various factors (e.g., spay/neuter rates and age structure of the populations). Further study of neoplasia in cats is needed.

Notwithstanding the previous discussion on the relative paucity of population-based, histologically confirmed data on the incidence of cancer, there is no doubt that certain breeds are at high risk for cancer (e.g., the BMD, flat-coated retrievers, Boxers, and Scottish terriers). In the section that follows, we will present an overview of known and suspected risk factors for specific cancers, including breed-specific risks, which is not strictly limited by the level of evidence or quality of studies or data but that reflects the current state of knowledge. An important concern for the future, however, is that without true incidence data we are limited in our ability to track changes in occurrence over time, as proportional measures are influenced by changes both in the numerator and denominator. In other words, an increase in the popularity of a breed may lead to its apparent overrepresentation in proportional cancer measures; a change in the distribution of breeds may affect cancer prevalence, without any actual change in breed risk. Without incidence measures, it would be impossible to accurately evaluate the effectiveness of programs aimed at preventing or controlling disease.

Factors Associated with Cancer Risk

Observational studies are the tools of epidemiology used to identify and characterize the determinants of cancer risk. Information from descriptive studies such as case series may help generate hypotheses but is not adequate as a basis for evidence-based cancer prevention strategies. Results from case series are also no longer accepted for publication in at least one major veterinary medical journal.[6] Analytic observational studies such as case-control and cohort designs, on the other hand, are used to test research hypotheses, and when well designed, can provide valuable information for cancer prevention strategies.

The case-control study design is the most commonly used observational study design in veterinary epidemiology research and in cancer epidemiology research in general. This is the most efficient study design, in terms of cost and time, when evaluating associations with relatively rare outcomes, such as specific

cancers. Unfortunately, as data collection is often retrospective, many potential sources of bias must be considered. The features of an ideally conducted study (e.g., with the least opportunity for systematic bias) include the complete ascertainment of all newly diagnosed cases with histopathologic confirmation of primary tumors and a random (or matched) selection of controls from the same base population as the cases. In a population-based case-control study design,[42,43] we can assume that if a control subject had been diagnosed with the tumor of interest, that control would have been a case in the study (i.e., the controls are from the same base population as the cases). The goal of the control group is to represent the exposure experience of the base population. For this reason, we are not interested in selecting the "healthiest" subjects as our comparison group.

In a hospital-based case-control study, both cases and controls are selected from the same hospital(s). The limitation with this design is that we cannot generalize the study results to a clearly defined base population. However, this design is valid and can still provide meaningful results. When using hospital-based case-control study design, it is preferable to randomly or systematically sample from the noncase population and to not include animals that have been diagnosed with other cancers.[44,45]

In a prospective cohort study, a group of animals is defined on the basis of exposure and followed over time to compare the incidence of disease (or other specified outcome) among the exposed and unexposed groups. The results obtained from a prospective cohort study are advantageous compared to results obtained from a case-control study for many reasons. One primary advantage is that we can assume temporality, or that the exposure came before the disease, when associations are observed from prospectively collected data. Systematic errors resulting from selection bias (e.g., referral bias) and differential recall bias (e.g., misclassification of exposure by disease status) are also not major concerns when interpreting results from a well-performed prospective cohort study. There is a need for more longitudinal (as opposed to retrospective), preferably population-based studies to strengthen the quality of evidence in the field of veterinary oncology.

Regardless of the observational study design used, nondifferential exposure misclassification will be a major concern, and the possibility and extent of misclassification should be considered when interpreting observational study results. Methods by which exposure misclassification can be reduced include using a precise and accurate questionnaire that has been properly validated or incorporating the use of biomarkers of exposure that can be quantified into the study design.

To estimate the magnitude of an association between an exposure and a cancer type, the relative risk, or risk ratio (RR), and odds ratio (OR) are calculated from data collected from cohort studies or cross-sectional and case-control studies, respectively. The RR is calculated as follows:

$$\text{RR} = \text{Incidence among exposed subjects} \div \text{Incidence among unexposed subjects}$$

where incidence is the number of events divided by total animal-time of follow-up. The OR can be used to estimate the RR when incidence data are not available. The OR is calculated as follows:

$$\text{OR} = (\text{Number of exposed cases} \div \text{number of unexposed cases}) \div (\text{Number of exposed controls} \div \text{number of unexposed controls})$$

TABLE 4.3 Guidelines for Interpreting Clinical Relevance from Odds Ratios or Relative Risk Measures

Inverse Association ≈ Decreased Risk	Clinical Relevance	Positive Association ≈ Increased Risk
1.0	Not evident	1.0
0.7 to <1.0	Weak	>1.0–1.5
0.5 to <0.7	Moderate	>1.5–2.0
0.3 to <0.5	Strong	>2.0–3.5
<0.3	Very strong	>3.5

The RR and OR are similarly interpreted. A value greater than 1.0 indicates that the exposure is positively associated with disease (increases risk), whereas a value less than 1.0 indicates that the exposure is inversely associated with disease (decreases risk). A value of 1.0 indicates there is no association between exposure and disease. The 95% confidence interval (CI) indicates the precision of the RR or OR, and if the 95% CI includes 1.0, we interpret the RR or OR to be statistically nonsignificant. It must be remembered, however, that statistical significance does not necessarily equate with clinical importance. For the latter, the magnitude of the effect is also important to consider. Table 4.3 shows suggested guidelines for interpretation of risk estimates. When considering whether to implement preventive measures or health interventions at the population level, the following, in addition to the risk estimate, are also relevant: prevalence of the factor (i.e., likelihood of exposure) and the prevalence of the disease. These values are used to estimate the attributable risk or risk-reduction measures.

Findings from all observational studies are influenced by systematic error to some degree because there is inherent bias in the methods used to select the study population, measure exposures, and identify the outcome. The opportunity for any one study to report an association that is due in part to chance is a real concern, even with the use of valid study design methods and statistical analyses. Confidence in the evidence for a particular association is strengthened when it is observed repeatedly in multiple populations and with the use of more and more rigorous study design methods. Meta-analysis is a technique whereby results from multiple, similar studies can be combined to increase the power of findings. Several examples are available from the human literature relating to nutritional risk factors associated with pancreatic, breast, and colon cancer.[46–48] Unfortunately, in small animal oncology, studies have neither been performed nor reported consistently enough nor are there an adequate number of studies conducted to support meta-analyses being conducted regularly at this time. Notwithstanding these limitations, Table 4.4 presents risk factors, including breed risks, for some of the more common cancers in dogs and cats for which there are at least reasonable estimations of association.

The identification of modifiable risk factors for canine cancers is the first step in eventually reducing incidence. Table 4.5 presents analytic studies used to test hypotheses that selected factors were either associated with an increased or decreased risk of canine and feline cancers. Characteristics of the study design and analytic methods are highlighted as strengths

VetBooks.ir

TABLE 4.4 Commonly Diagnosed Cancers and Suspected Risk Factors

Cancers	Suspected Risk Factors
Common Canine Cancers	
Mammary carcinoma	Obesity, increasing age, high dietary fat intake, late age at spay, and some breeds (e.g., English Springer spaniel, pointer, poodle, Boston terrier, Dachshund, German shepherd, Chihuahua)
Osteosarcoma	High weight, high height, increasing age, early castration/spay, some breeds (e.g., Irish wolfhound, Saint Bernard, Great Dane, Rottweiler, Irish setter, Doberman Pinscher, golden retriever, Labrador retriever, Leonberger)
Transitional cell carcinoma of the urinary bladder	Being neutered, exposure to phenoxy-acid containing herbicides, frequent flea dipping, increasing age, some breeds (e.g., Scottish terrier, Beagle, Shetland sheepdog, Wirehaired fox terrier, West Highland white terrier)
Mast cell tumors	Some breeds (e.g., Boxer, Rhodesian ridgeback, Vizsla, Boston terrier, Weimaraner, Chinese Shar-Pei, Bullmastiff, Dutch pug, Labrador retriever, American Staffordshire terrier, golden retriever, English setter, English pointer), increasing age
Lymphoma	ETS, exposure to chemicals containing 2,4-dichlorophenoxyacetic acid, increasing age, some breeds (e.g., Bullmastiff, Boxer, Scottish terrier, Gordon setter, Irish wolfhound, Basset hound, golden retriever)
Common Feline Cancers	
Lymphoma	FeLV, FIV, ETS increasing age
Sarcoma	Vaccine injection
Cutaneous squamous cell carcinoma	Solar irradiation

ETS, Environmental tobacco smoke; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus.

TABLE 4.5 Selected Observational Studies of Canine and Feline Cancers by Type of Exposure

Exposure	Main Findings	Strengths/Limitations
ETS		
Reif, 1998[54]	Positive trend for number of packs smoked by owner and increased risk of canine nasal cancer among long-nosed (dolichocephalic) dogs.	Strengths: Evaluation of nose size as an effect modifier with biologic plausibility; collected information on potential confounders. Limitations: Use of controls with cancer.
Reif, 1992[55]	Statistically nonsignificant positive association for living with ≥1 versus no smokers and canine lung cancer risk. Association was stronger among short-nosed dogs (brachycephalic or mesocephalic).	Strengths: High participation rates among cases and controls. Limitations: Use of controls with cancer; limited statistical power.
Marconato, 2009[43]	Any ETS exposure was positively associated with canine lymphoma, compared with no exposure.	Strengths: Population-based study design. Limitations: Use of controls with cancer; limited ETS exposure information was collected.
Bertone, 2002[56]	Strong, statistically significant association for any household ETS exposure and malignant lymphoma in cats. Statistically significant trend reported for a stronger association with increasing years of ETS exposure.	Strengths: Statistical power to evaluate trends; cases confirmed by biopsy; respectable response rate among the cases and controls (>65%); use of a detailed questionnaire to assess ETS and other environmental exposures. Limitations: No clear biologic mechanism for the observed association.
Bertone, 2003[57]	Clinic-based case-control study had ETS exposure positively associated with feline oral SCC. Overall, results do not support a causal relationship between ETS exposure and feline SCC.	Strengths: Cases confirmed by biopsy; good response rates; use of a detailed questionnaire (see previous entry). Limitations: Prevalence of ETS exposure was low; limiting the statistical power to evaluate more than two levels of exposure.

TABLE 4.5 Selected Observational Studies of Canine and Feline Cancers by Type of Exposure—cont'd

Exposure	Main Findings	Strengths/Limitations
Pesticides		
Hayes, 1991[63]	Any use of chemicals containing 2,4-dichlorophenoxyacetic acid (2,4-D) positively associated with canine malignant lymphoma, compared with no use. Lymphoma risk increased with greater number of applications of 2,4-D–containing chemicals.	Strengths: Complete ascertainment of newly diagnosed cases; high participation rates among cases and controls; collected extensive information on chemical use on lawns/yards (self-applied and commercially applied). Limitations: One control group composed of dogs with other cancers. NOTE: This and other limitations were addressed in subsequent analyses.
Glickman, 1989[65]	Residence location within one mile of a marsh (where chemicals were used for mosquito control) positively associated with canine TCC of the urinary bladder. Receiving flea dips more than two times/year versus no use was positively associated with TCC.	Strengths: Collected information on numerous sources of chemical exposure, including residential location to industries, pesticide use, flee/tick treatments. Limitations: 45% of control dogs had malignant neoplasia; information was not collected on individual dog exposure to the marsh or on specific chemicals used around the house/yard.
Glickman, 2004[44]	Access versus no access to phenoxy herbicide–treated lawns/yards positively associated with TCC of the urinary bladder among Scottish terriers. No association was observed for lawns/yards not treated with phenoxy herbicides.	Strengths: Collected information on brand name and active ingredients for household, lawn, and garden chemicals; results were specific for phenoxy herbicide exposure. Limitations: Limited statistical power to conduct subgroup analyses.
Raghavan, 2004[111]	Use of topical flea/tick products (e.g., shampoos, dips, powders, sprays, and collars) not associated with TCC of the urinary bladder among Scottish terriers.	Strengths: Collected detailed information on use of flea/tick products (e.g., type, brand, pattern of use) Limitation: 24% of control dogs had cancer; numbers for cases and controls were not presented by exposure level.
Environmental Pollutants		
Bettini, 2010[112]	Pulmonary anthracosis (high versus none) positively associated with canine lung cancer risk.	Strengths: Histologic confirmation of primary diagnosis of lung cancer; exposure assessment determined by histologic scoring of anthracosis; strong biologic mechanism supporting the a priori hypothesis. Limitations: Small number of cases limited the statistical analyses.
Marconato, 2009[43]	Living in geographic areas exposed to toxic waste positively associated with canine cancer risk (all tumors and lymphoma), compared with living in an unexposed area. No associations observed for canine mast cell tumors, canine mammary cancer, or feline cancers.	Strengths: Population-based study design, histologic confirmation of cases; odds ratios were adjusted for age, sex, and breed. Limitations: Same eligibility criterion (i.e., living at same address for 2 years before enrollment) was not applied to controls.
Gavazza, 2001[66]	Living in an industrial neighborhood was positively associated with canine lymphoma risk, compared with living in any other neighborhood. Use or storage of paints and solvents was positively associated with lymphoma risk, compared with no use of chemicals.	Strengths: Histopathologic or cytologic confirmation of cases; information was collected on potential confounders. Limitations: Very low prevalence of exposed cases and controls; only univariate analyses were conducted.
Bukowski, 1998[113]	Cumulative kerosene or coal heat exposure was positively associated with sinonasal cancer risk.	Strengths: High participation rate; covariate information was compared between respondents and nonrespondents; histopathologic confirmation of cases. Limitations: Use of controls with cancer.

VetBooks.ir

TABLE 4.5 Selected Observational Studies of Canine and Feline Cancers by Type of Exposure—cont'd

Exposure	Main Findings	Strengths/Limitations
Endogenous/Exogenous Sex Hormones		
Sonnenschein, 1991[75]	Earlier age at spaying was inversely associated with canine mammary cancer. Trend of decreasing risk was observed for younger age at spaying.	Strengths: Cases were limited to mammary carcinoma or adenocarcinoma. Limitations: Controls may not be representative of the base population.
Ru, 1998[76]	Neutered dogs, regardless of gender, had a greater risk of osteosarcoma, compared with intact dogs.	Strengths: Histologic or radiologic confirmation; large study size; collected information on potential confounders. Limitations: Medical conditions of the controls were not clearly described.
Glickman, 2004[44]	Neutered status versus intact was a risk factor for TCC of the urinary bladder among Scottish terriers.	Strengths: Cases were histologically confirmed. Limitations: Small study size did not permit for analyses by age at neutering.
Dias Pereira, 2008[114]	No overall association was observed for COMT genotype and canine mammary cancer risk. Older age at mammary cancer diagnosis was observed by COMT genotype.	Strengths: Strong biologic rationale for research hypothesis; cases were histologically confirmed. Limitations: Very small numbers in subgroup analyses; selection methods were not provided; information was not collected on potential confounders (e.g., hormone-related exposures).
Cooley, 2002[72]	Neutering before 1 year of age increased risk of canine osteosarcoma among Rottweilers, regardless of gender. Incidence rates decreased with later age at neutering. Reproductive factors (number of litters, number of live births, age at first pregnancy) were not associated with osteosarcoma among female dogs.	Strengths: Radiographic or histologic confirmation of cases; retrospective cohort study design. Limitations: Low participation rate.
Stovring, 1997[42]	MPA use was positively associated with canine mammary cancer.	Strengths: Population-based study design; histologic confirmation of cases. Limitations: Information was not collected on details of MPA use (e.g., frequency, dose, age at first use).
Teske, 2002[77]	Castration was positively associated with canine prostate cancer risk, compared with intact status.	Strengths: Strong biologic plausibility. Limitations: Only cytology was used to make cancer diagnosis.
Bryan, 2007[78]	Neutered versus intact status was a risk factor for the following canine cancers: TCC of the urinary bladder, prostate carcinoma, prostate adenocarcinoma, and TCC of the prostate.	Strengths: Histopathologic confirmation of cases; included analyses by histologic subtype. Limitations: Statistically nonsignificant measures were not presented.
Misdorp, 1991[115]	Ovariectomy was inversely associated with feline mammary cancer risk. Regular administration of progestogens increased risk. No association was observed for irregular progestogen administration or for parity.	Strengths: Histologic confirmation of cases; collection of detailed exogenous progestogens (frequency, brand, type); large study size. Limitations: Cases and controls were selected over different time periods.
Overley, 2005[116]	Intact versus neutered status was a risk factor for feline mammary cancer. Cats spayed before 1 year of age were at lower risk of mammary cancer than those spayed after 6 months of age. There was no risk benefit in cats spayed after 2 years of age.	Strengths: Histologic confirmation of cases; large study size. Limitations: Univariate analyses were performed, although detailed information was collected on exogenous hormone use, parity, and number of litters; large amount of missing data because of veterinarian nonresponse.
Torres de la Riva, 2013[79]	Male golden retrievers were more likely to develop lymphoma when neutered <1 year of age compared with intact dogs; Female golden retrievers were more likely to develop hemangiosarcoma when neutered at >1 year of age	Strengths: Large study size. Limitations: Cases were not histologically confirmed, only one breed of dog included.

Continued

VetBooks.ir

TABLE 4.5 Selected Observational Studies of Canine and Feline Cancers by Type of Exposure—cont'd

Exposure	Main Findings	Strengths/Limitations
Zink, 2014[80]	Neutering increased risk of developing mast cell tumors, hemangiosarcoma, lymphoma, and all other cancers in Vizslas compared with intact dogs. Neutering at <6 months of age was not associated with increased risk of developing cancer compared with neutering at older ages.	Strengths: Large study size, multivariable analyses were performed. Limitations: Cases were not histologically confirmed, only one breed of dog included.
Hart, 2014[81]	Neutering male golden retrievers and male and female Labrador retrievers or at any age had no significant effect on cancer occurrence compared with intact dogs; Neutering female golden retrievers at any point beyond 6 months of age was associated with increased risk of developing any cancer with the exception of lymphoma which was associated with an increased risk if neutering occurred before 6 months of age.	Strengths: Large study size, Cox proportional hazard models were used. Limitations: Population limited to dogs visiting a single Veterinary Teaching Hospital, only two breeds of dogs included, age categories at time of neutering were not consistent among analyses.
Hart, 2016[117]	Cancer occurrences in this population of German shepherd dogs were rare and there were no associations reported between neutering at any age and cancer outcomes.	Strengths: Large study size, Cox proportional hazard models were used. Limitations: Population limited to dogs visiting a single veterinary teaching hospital, only one breed of dog included, potential data quality issues.
Diet		
Perez Alenza, 1998[118]	Higher intake of red meat (as percentage of total calories) was positively associated with canine mammary carcinoma risk. No differences were observed for intake of fruits and vegetables, or biomarker levels of selenium, retinol, or individual fatty acids.	Strength: Used biomarkers of exposure; multivariable analyses included covariates for body conformation. Limitations: Use of a retrospective study design is not recommended for evaluating biomarkers of exposure and cancer risk because of possible disease and/or treatment effects on the biomarker measurement.
Sonnenschein, 1991[75]	Higher intake of fat and table food (as percentage of total calories) was inversely associated with canine mammary carcinoma. No associations were observed with protein or carbohydrates intake.	Strengths: Cases and controls were matched by age, spay status, and breed size, thus reducing the opportunity for confounding by these factors; the dietary assessment tool was validated using a 7-day food record, Limitations: Study size was too small to evaluate diet-cancer associations in subgroups.
Raghavan, 2005[119]	Vegetable intake (≥3 versus 0 times/week) was inversely associated with TCC of the urinary bladder in Scottish terriers. A trend was observed with greater servings of vegetables per week and decreased risk of TCC. No association was observed for weekly vitamin supplement intake, compared with no intake.	Strengths: Histopathology and/or cytology confirmation; use of a comprehensive dietary questionnaire; multivariable analyses. Limitations: Used a volunteer population; 61% of the cases were deceased at the start of the study; 24% of control dogs had neoplastic diseases.
Body Size		
Perez Alenza, 1998[118]	Obese body condition at 1 year of age and at 1 year before diagnosis was positively associated with canine mammary cancer, compared with normal or underweight body condition at the same time points.	Strengths: Objective measurements of weight and height were collected at presentation; body conformation was determined by a clinician at presentation. Limitations: Height, weight, and body conformation at 1 year of age and 1 year before diagnosis were based on owners' reports.
Sonnenschein, 1991[75]	Spayed dogs that were thin at 9–12 months of age had a lower risk of mammary cancer. Intact dogs that were not overweight in adulthood had a lower risk of mammary cancer.	Strengths: Cases were limited to mammary carcinoma or adenocarcinoma; designed to assess a timely hypothesis that early life factors are related to mammary cancer risk. Limitations: Controls may not be representative of the base population; subgroup analyses did not have ample statistical power to calculate precise measures.
Weeth, 2007[45]	BCSs ≥6 were inversely associated with canine cancer risk (all cancers, sarcomas, and carcinomas), compared with BCSs of 4–6. BCSs <3 were inversely associated with canine sarcoma risk, compared with scores of 4–6.	Strengths: Very large study size; 9-point BCS determined by physical examination; analyses were conducted by cancer type (sarcoma, carcinoma, round cell tumors) Limitations: Selection of cases and controls depended on availability of BCS in medical records; the inverse associations with higher BCS may be a result of reverse causation.

VetBooks.ir

TABLE 4.5 Selected Observational Studies of Canine and Feline Cancers by Type of Exposure—cont'd

Exposure	Main Findings	Strengths/Limitations
Ru, 1998[76]	Height (>61 versus <35.5 cm) and weight (>45 versus <23 kg) were positively associated with canine osteosarcoma risk, after adjusting for age and standard weight and height, respectively. Longer length of hind limbs and front limbs was positively associated with canine osteosarcoma risk, compared with shortest length.	Strengths: Histologic or radiologic confirmation; large study size; collected information on potential confounders. Limitations: Medical conditions of the controls were not clearly described; a proxy measure for height was used; there was a large percentage (22.5%) with missing weight information.
Glickman, 2004[44]	Greater weight was positively associated with TCC urinary bladder risk in Scottish terriers, comparing third versus first tertile. Greater weight-to-height ratio was also a risk factor for TCC.	Strengths: Cases were histologically confirmed. Limitations: Weight and height information was based on owners' reports.
Vaccines/Injection Site		
Kass, 2003[91]	Cats with sarcomas at a vaccine injection site ($n = 662$) were compared with cats with basal cell tumors or noninjection site sarcomas ($n = 473$). Univariate analyses showed no difference in the vaccine type (FVRCP, rabies, FeLV) between cases and controls. There were no differences between time at vaccination and tumor diagnosis between the two groups.	Strengths: Histologic confirmation of cases and controls; collected extensive vaccine information (date of injection, manufacturer, type, brand, site of injection). Limitations: Cases were identified on a volunteer basis from participating clinics; heterogeneous sarcoma case group.
Kass, 1993[90]	In 345 cats diagnosed with fibrosarcoma, 53.6% had tumors at the vaccine injection site. The time from FeLV vaccination to tumor diagnosis was significantly shorter among cats that had tumors at the cervical/interscapular region than cats that had tumors at noninjection sites.	Strengths: Biopsy-confirmed diagnoses; vaccination history was validated by veterinarian; collected vaccination details allowing for analyses by type of vaccine, time since vaccination and location of injection site. Limitations: Differential missing data by exposure status.
FeLV/FIV		
Hutson, 1991[120]	Among 1160 cats identified from an oncology referral and a general practice clinic, 2.5% were FIV positive. Of the FIV-positive cats, 62% were diagnosed with neoplasia (myeloproliferative disease, lymphoma, and SCC).	Strengths: Descriptive information of neoplasia among FIV-positive cats. Limitations: No evident population base; only count data were presented.
Gabor, 2001[121]	Among 101 cats with lymphosarcoma, 50% were FIV positive. These cats were more likely to be male domestic crossbreeds.	Strengths: Histopathologic confirmation of cases; FIV antibodies were determined using Western blot. Limitations: Convenience study population was used.
Shelton, 1990[96]	Coinfection with FIV and FeLV was present in 14.4% of 353 cats collected in several US cities. FIV and FeLV infection were strongly associated with risk of leukemia or lymphoma. A very imprecise positive association was also reported for coinfection and leukemia/lymphoma risk.	Strengths: FIV antibodies were determined using ELISA and Western blot. Limitations: Base population and subject recruitment methods were not well defined; low prevalence of coinfection among controls limited statistical power.
Solar Irradiation		
Dorn, 1971[122]	Among white cats, the observed incidence of SCC of the skin was greater than the expected incidence ($p < 0.001$). For SCC of the mouth–pharynx, white cats had no difference between observed and expected incidence.	Strengths: Population-based study population. Limitations: Amount of sun exposure was not quantified; the number of cats with SCC of the mouth–pharynx was small ($n = 29$).

BCS, Body condition score; *COMT,* catechol-*O*-methyltransferase; *ELISA,* enzyme-linked immunosorbent assay; *ETS,* environmental tobacco smoke; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *FVRCP,* feline viral rhinotracheitis-calicivirus-panleukopenia; *MPA,* medroxyprogesterone acetate; *SCC,* squamous cell carcinoma; *TCC,* transitional cell carcinoma.

and weaknesses. Studies with the strongest level of evidence included several characteristics related to study design (e.g., hypothesis-driven, population-based, large study size, validated exposure assessment) and results (e.g., a precise measure of association, a modest-to-strong magnitude of association, statistically significant measure of association, statistically significant trend between exposure level and magnitude of association).

Highlighted Findings from Observational Studies

In this section, we discuss risk factors for which there is relatively strong evidence, those that relate to key issues in animal or human oncology, and those for which important controversies need to be addressed by further research. These categories coincide with those shown in Table 4.5.

VetBooks.ir

Environmental Exposures

The identification of environmental exposures that are related to canine cancer risk have a broad public health interest, given the shared environments of companion animals and their owners, and they have similar etiology of some cancers.[49] In a comprehensive review, a historic perspective is provided on how studies in pet populations have informed human health with respect to the specific exposures of air pollution, environmental tobacco smoke (ETS), and pesticides.[50] The shared etiologic characteristics of cancers such as lymphoma, OSA, and mammary cancer also support the utility of looking to both pet and human populations to investigate environmental–cancer associations.[51]

There is experimental evidence for an underlying biologic mechanism for the compounds of cigarette smoke to have a causal relationship with canine carcinogenesis.[52,53] There are few observational studies that were designed to specifically evaluate associations between ETS exposure and canine cancer risk.[54,55] There is support for a positive association (3.4-fold increased risk) between ETS and lymphoma[43] and sinonasal cancers,[54] but not for lung cancer.[55] In a clinic-based case-control study, household ETS exposure was strongly associated with feline lymphoma.[56] The OR for any exposure, compared with no exposure, was 2.4, and statistically significant trends were reported for more years of ETS exposure, more smokers in the household, and number of cigarettes smoked per day in the household. In contrast, there is only weak observational evidence for ETS as a risk factor for oral squamous cell carcinoma in cats.[57] In summary, avoiding ETS exposure may reduce the risk of lymphoma in cats and dogs and the risk of sinonasal cancers in dogs.

Pesticides are a heterogeneous group of chemicals, some of which are known human and canine carcinogens.[58–60] Dogs may be exposed to pesticides in the home, in the yard/garden, and on application of flea and tick treatments. The most consistent observational evidence for pesticide exposure as a cancer risk factor is for phenoxy acid–containing herbicides and lymphoma risk, both in humans and dogs.[61] These data, however, have not been deemed strong enough to establish causality.[62] In a large case-control study (n = 491 cases and n = 945 controls), any use of pesticides that contained dichlorophenoxyacetic acid (2,4-D) was associated with a 30% increased risk of lymphoma compared with no use.[63,64] Although modest, the positive association also demonstrated a dose-dependent effect in which more frequent use of 2,4-D pesticides resulted in a stronger positive association with lymphoma risk (p for trend <0.02). Additional support for 2,4-D and canine bladder cancer risk is from the result of a small case-control study in Scottish terriers.[42]

Residential proximity to environmental hazard–containing sites has been used to estimate chemical exposure and canine cancer risk in several observational studies.[43,65,66] A 2.4-fold increase in risk of lymphoma was observed among dogs living in the cities containing illegal waste sites compared with dogs living in other cities.[43] No association was observed with mast cell tumors (MCTs) or breast cancer. Mortality caused by cancer is also higher among human populations living near the same waste sites compared with the general population.[67] Chemical mixtures that have been identified at hazard waste landfills include organic solvents, polychlorinated biphenyls, and heavy metals. These can reach human and pet populations through contaminated air, water, and/or soil,[68] and have been causally related to adverse human health effects, including childhood lymphoma.[69] The biologic plausibility and the observational findings from Marconato et al[43] both help strengthen the evidence that living near the waste sites increases risk of canine lymphoma.

Exposure misclassification is a primary limitation of using geographic proximity as a marker of exposure to an industrial or waste site because it may or may not be a good proxy for individual-level exposure. For example, a validation study would need to be conducted that provides information on whether dogs that live close to an industrial site are necessarily exposed at higher levels to environmental hazards compared with dogs that live further from the site. Misclassification of exposure that does not differ by disease status (e.g., nondifferential misclassification) typically results in an underestimate of the exposure–cancer association, although there are situations when the observed association results in an overestimate of the true association.[70,71]

Hormones and Neuter Status

Hormones may act as either growth factors or inhibitors, depending on the sex of the dog and the tissue type.[72–74] For some cancers, such as breast cancer, less exposure to sex hormones is protective; whereas for others, such as OSA, lymphoma, and prostate cancer, less exposure has been reported to increase risk.[72,75–82] Neuter/spay status and age at neuter/spay are the most commonly used measures of endogenous hormone exposure. In spite of some newer studies, there is limited evidence that the age of the dog at the time of neuter/spay can have an effect on the risk of developing cancer in certain breeds of dogs.[79,81] Given the widespread recommendation for early spay/neuter, especially in North America, this is a topic in need of further study.

In a mammary cancer case-control study, there was clear evidence that spayed dogs were at lower risk of mammary cancer.[75] In particular, the earlier age at which dogs were spayed the lower their mammary cancer risk compared with dogs that were not spayed. This finding has been supported by other observational studies of spay status and mammary cancer risk.[83]

Contrary to human epidemiologic and experimental evidence,[84,85] exposure to sex hormones such as androgens may be protective for canine prostate cancer.[82] From two case-control studies using large veterinary teaching hospital databases, neutered dogs had a 2.8- and 3.4-fold increased risk of prostate cancer compared with intact dogs.[77,78] The apparent opposite associations between hormone exposure and prostate cancer risk in men and dogs are likely a result of the higher rate of androgen-independent tumors in dogs than in men.[86,87]

Neuter status is also a risk factor for OSA and transitional cell carcinoma of the urinary bladder,[44,72,76,78] regardless of sex.[72,76] Cooley et al conducted a retrospective cohort study in 1999 among 683 Rottweilers and used a self-administered questionnaire to test the hypothesis that neuter/spay status was related to the development of OSA.[72] The owners were identified through eight national Rottweiler breed specialty clubs and had a purebred Rottweiler that was alive on January 1, 1995. The participation rate ([number of participants] ÷ [total number of invited owners] × 100) was 49%. This low participation rate suggests that selection bias may have influenced the results of this study. In other words, the participants of the study are likely to have systematic differences compared with those who did not participate. However, a strength of this study is the ability to calculate incidence because the total number of dog-months of observation were estimated retrospectively among dogs that were neutered/spayed and those that were not. During a total of 71,004 dog-months of observation, there were 86 cases of OSA. Collectively, the findings of a positive association between neuter/spay status and OSA from both case-control and cohort studies, and the biologic plausibility of the association, provide strong evidence that neutering/spaying dogs, regardless of sex, increases risk of OSA.

VetBooks.ir

A number of reports have linked the age of dogs at the time of neuter/spay to increased risk of developing hemangiosarcoma, lymphoma, and MCTs in select breeds of dogs.[79–81] Using a retrospective analysis of medical records including dogs younger than 8 years of age from the Veterinary Medical Teaching Hospital at the University of California, Davis, an increased risk of developing hemangiosarcoma and MCTs was identified in female golden retrievers neutered at 12 months of age or older compared with intact female golden retrievers.[79] The same analysis revealed an increased risk of developing lymphoma in male golden retrievers neutered before 12 months of age compared with intact male golden retrievers.[79] A subsequent report that used a larger data set from the same location reported similar risks in golden retrievers, but showed there was no difference in risk of cancer occurrence in Labrador retrievers associated with neuter status.[81] Research from the same institution that examined cancer-related mortality in golden retrievers found that increasing age increased the odds of cancer-related mortality regardless of neuter status.[88] Neutered female golden retrievers were found to live statistically significantly longer than intact females and it was this increase in longevity that affected the rate of cancer occurrence rather than the hormonal differences caused by neutering. This conflicting result may be because of the fact that dogs of any age were included in this study whereas the previous reports limited results to dogs aged 8 years or younger.[79,81,88] Results of a survey of Vizsla owners indicate that neutering at any age was associated with increased risk of developing lymphoma and MCTs regardless of sex.[80] Increased risk associated with development of hemangiosarcoma was also indicated in both sexes regardless of the timing of neutering with the exception of males neutered at less than 12 months of age, which had no difference in risk compared with intact males.[80] Prospective research conducted to examine associations between age at neutering and cancer outcomes is needed in a wider variety of dog breeds before current recommendations regarding spay/neuter can be modified.

Risk Factors in Cats

In cats, the epidemiology of injection-site sarcomas has been well studied. A review from 2011 provides information on the current epidemiology, etiology, and clinical knowledge of feline injection-site sarcomas (FISSs).[89] Kass et al conducted one of the first epidemiologic studies investigating the hypothesis that vaccinations were related to feline fibrosarcoma risk in the early 1990s.[90] A main finding of this study was the shorter time interval from vaccination to FISS compared with the interval from vaccination to non-FISSs. This finding was not supported by a second, larger case-control study.[91] Although there is no doubt that the phenomenon of FISS exists, the administration of an injection itself is not sufficient to cause development of an FISS. The component causes (e.g., the nature of vaccines and adjuvants in the injected material and the role of the resulting inflammatory reaction), in addition to the physical injection that leads to the development of an FISS, are not well characterized. Further epidemiologic research designed with due consideration of the challenging methodological issues is needed to identify the various factors associated with FISSs.[92]

Cats infected with the feline immunodeficiency virus (FIV), the feline analog to the human immunodeficiency virus (HIV), are at increased risk of certain cancers.[93] FIV is a lentivirus typically transmitted by biting.[94] Lymphomas, particularly those of B-cell origin, are the most commonly diagnosed neoplasia among FIV-infected cats. Persistent feline leukemia virus (FeLV) infection is also known to have a strong role in feline neoplasia development,[95] and coinfection with FIV and FeLV may have synergistic effects on feline neoplasia risk.[96]

Diagnosis and Screening

As mentioned previously, numerous reporting guidelines have been produced for the human medical literature (e.g., http://methods.cochrane.org/mecir). One of these describes an approach to complete and accurate reporting of studies of diagnostic accuracy (Standards for Reporting of Diagnostic Accuracy [STARD]).[97,98] The application of this and another instrument in the veterinary field has been discussed.[99] Unfortunately, relatively few diagnostic interventions in veterinary medicine have been examined or evaluated as fully, in terms of reliability, accuracy, efficacy, and effectiveness, as is needed to support EBM practices. Guidelines for prognostic studies in veterinary oncology have also been reported.[100]

It may also be appropriate to use clinical trial methodology to evaluate the outcomes of diagnostic tests, for example, whether the animal is better off for having had the test performed.[101] In addition, recommendations about diagnostic tests and screening programs may have both positive and negative effects beyond any individual, on populations of animals and owners. Although new, sophisticated diagnostic tests used in humans are being evaluated for use in companion animals, it is important to remember that beyond the benefit in a specific case, efficacy and effectiveness of tests should consider the broadest aspects of cost–benefit. In human oncology, there has been much discussion about the problems inherent in certain widely applied screening processes and the consequences of false positives and negatives (e.g., prostate-specific antigen test for prostate cancer[102]). Owing to space constraints, we cannot expand on this crucially important area of cancer epidemiology.

Therapeutic Interventions

A review published in the *Journal of Veterinary Internal Medicine* highlighted that the quality of reporting of oncology studies in dogs and cats has not improved appreciably over time and that quality of reporting is highly correlated with the rate of positive outcomes (i.e., well-described studies are more likely to report positive effects of a treatment).[103] This may also be exacerbated by the fact that the profession increasingly depends on corporate contracts for funding of research, and, in addition to this having a major effects on which treatments are investigated, there may also be underreporting of studies in which either beneficial effects were not seen or where there were deleterious side effects. As mentioned previously, efforts are underway to produce reporting guidelines for companion animal intervention studies. However, guidelines for appropriate study design for clinical trials have been widely available for many decades, and the need for appropriate trials in oncology has been specifically advocated (see Chapter 18).[104] Longer-term analyses of survival after diagnosis and treatment, including both outcome and cost–benefit analysis, are needed to provide the information that owners and veterinarians need to choose the best options, with due consideration of quality-of-life issues.

Although there are good examples of randomized, controlled, blinded trials in veterinary oncology,[105,106] essentially all studies have some limitations in terms of either quality (validity) or relevance (extrapolation to other situations). For example, because many trials are performed on clients at specialty practices or veterinary teaching hospitals, animals have passed through numerous filters to be

VetBooks.ir

available for the study (e.g., referral, have a willing and capable owner, live long enough to have a confirmed diagnosis). Although this may improve the validity of the study (e.g., by increasing compliance and reducing loss to follow-up), it reduces the relevance to, for example, primary practice. Therefore clinicians must be able to apply the rules of evidence to determine both the quality and relevance of information for their specific situation and patients. Other authors in this text will present current information on treatments for cancer, and a further review of the literature is beyond the scope of this chapter. Hopefully, the quality of the veterinary literature will continue to improve over time, and the application of appropriate reporting guidelines and production of evidence-based reviews will assist clinicians to interpret and apply published information.

Knowledge Gaps and Future Directions

Even though systematic reviews and meta-analyses may not be currently possible, evidence-based reviews of the existing oncology literature in dogs and cats are needed to further elucidate what we know about breed risks, other risk factors, appropriate use of diagnostic and screening aids, therapies, prognoses, and so forth, and to identify the most crucial gaps in our knowledge. Appropriate assessment of existing oncology prevention and treatment strategies is also needed.

With increasingly available genomic information, our understanding of breeds and breed risk may change.[107,108] It is especially important to recognize the value of studying populations from different areas or countries. There are important differences and similarities in genetics (across and within breeds), environments, diets, and activities that will inform cancer etiology and management. Such complex relationships will be fully understood only by a multidisciplinary approach using various methodologies and study designs. These should include more population-based, longitudinal observational studies and outcomes-based approaches.[56,57,109] Although these may not yield results for many years, relying solely on traditional approaches (case-control studies and clinical trials of invasive or risky treatments) is not an effective strategy to reduce the population burden of cancer. In addition and beyond the scope of this chapter, there are important complex issues of human–animal interactions, in general and specifically related to the field of oncology. Thus there is a need for an increased understanding of the social and emotional factors underpinning many aspects of this diverse field.[110]

Paraneoplastic Syndromes

DENNIS B. BAILEY

VetBooks.ir

Paraneoplastic syndromes (PNSs) are cancer-associated alterations in bodily structure and/or function that are not directly related to the physical effects of the primary or metastatic tumor. PNSs are most commonly caused by tumor production of small molecules (e.g., hormones, cytokines, or peptides) that are released into circulation, tumor depletion of normal small molecules, or host responses to the tumor (often immune mediated).[1]

Many PNSs parallel the underlying malignancy, and successful treatment of the tumor leads to disappearance of the PNS. Conversely, recurrence of the PNS after successful treatment can signal tumor recurrence and might even precede clinically detectable tumor. Some PNSs do not consistently resolve with treatment of the underlying malignancy, especially cancer cachexia and those of an immune or neurologic etiology.[1]

A PNS might be the first sign of malignancy, and a specific PNS often is associated with a relatively small group of tumor types. Therefore an understanding of PNSs is paramount for early cancer detection and appropriate therapy. In addition, a PNS may result in greater morbidity than that associated with the actual tumor. Therapy directed at the PNS might be warranted, especially when there is substantial morbidity and/or the underlying cancer cannot be effectively treated. Box 5.1 summarizes the most common PNSs of dogs and cats and the tumors associated with them.

Gastrointestinal Manifestations of Cancer

Cancer Anorexia and Cachexia

Several mechanisms contribute to weight loss in cancer patients. Hyporexia or anorexia is common in veterinary patients with advanced cancers, often a result of an enhanced inflammatory state and cytokines such as interleukin-1 (IL-1) and IL-6 interfering with the normal balance of anorexigenic and orexigenic signals.[2] Cancer cachexia is a profound destructive process characterized by skeletal muscle wasting, with or without loss of fat mass, and harmful abnormalities in fat and carbohydrate metabolism in spite of adequate nutrient intake.[2,3] Tumor necrosis factor-alpha (TNF-α), IL-1, and IL-6 play primary roles in cancer cachexia by inducing anorexia, increasing energy metabolism, and accelerating loss of lean body mass.[2] This results in large part from activation of nuclear factor kappa-B (NF-κB), which in turn activates the ubiquitin proteasome pathway. TNF-α, via NF-κB signaling, also upregulates myostatin, a member of the transforming growth factor-beta (TGF-β) superfamily that negatively regulates muscle mass.[2] TNF-α also interferes with the anabolic effects of growth hormone (GH) and insulin-like growth factor-1 (IGF-1).[2]

The exact diagnostic criteria for cancer cachexia continue to be debated, but moderate to severe weight loss is reported in 30% to 70% of people with various cancers.[4,5] Having said this, 40% to 60% of people are overweight or obese at the time of cancer diagnosis, and fewer than 10% have obvious malnutrition.[4] Therefore evidence of cachexia and sarcopenia was prevalent across all body mass index (BMI) categories.[4] Similarly, when body condition score (BCS) and weight loss were evaluated in dogs with various malignancies, 29% were classified as markedly overweight (BCS ≥7), and only 4% were classified as emaciated (BCS ≤3).[6] However, muscle wasting was identified in 35% of these dogs, and over the 12 months before cancer diagnosis, 14% of these dogs had lost 5% to 10% of body weight and 23% had lost >10% of body weight.[6] When BCS and muscle wasting were evaluated in cats presenting with various cancers, 44% had a BCS <5, although it is worth noting that a high percentage of these cats were diagnosed with gastrointestinal lymphoma or oral squamous cell carcinoma (SCC), tumor types in which difficulty with food intake or absorption may have been the primary causes for weight loss.[7] Muscle wasting was identified in 93% of cats, including 72% of cats with a BCS ≥5.[7] Across tumor types, low body weight and low BCS were negative prognostic factors for survival.[7]

For a detailed discussion regarding the metabolic alterations associated with cancer and nutritional support for veterinary cancer patients, the reader is directed to Chapter 16, Section B.

Gastrointestinal Ulceration

Mast cell tumors (MCTs) are the most common cause of PNS-associated gastrointestinal (GI) ulceration. Hyperhistaminemia is regarded as a main factor contributing to GI ulceration and perforation.[8,9] Histamine binds to gastric parietal cell H_2 receptors, stimulating gastric acid secretion. In addition, histamine exerts direct effects on the gastric mucosa, causing increased vascular permeability, localized protein exudation, and increased mucosal blood flow.[8] Histamine release can be spontaneous, or it can be triggered by tumor manipulation, chemotherapy, or radiation therapy (RT). Plasma histamine concentrations are elevated in dogs with macroscopic MCTs, although concentrations are not predictive of clinical signs of GI ulceration.[8,9] Symptomatic therapies such as histamine H_2 blockers, proton-pump inhibitors, misoprostol, sucralfate, and rehydration are warranted in dogs and cats with clinical signs of GI ulceration or prophylactically in patients with advanced-stage tumors. MCTs are covered in greater detail in Chapter 21.

An additional cause of PNS-associated gastroduodenal ulceration is gastrinoma, a gastrin-secreting pancreatic tumor, likely arising from the islet D-cells. Although these tumors are relatively rare, they have been reported in both dogs and cats.[10–13] Zollinger–Ellison syndrome refers to the triad of hypergastrinemia, a non–beta cell neuroendocrine tumor in the pancreas, and GI ulceration. Gastrinomas are covered in greater detail in Chapter 26.

Endocrinologic Manifestations of Cancer

Hypercalcemia

Cancer is diagnosed in 60% of dogs and 30% of cats with hypercalcemia.[14–16] In dogs, hypercalcemia of malignancy (HM) is associated most commonly with T-cell lymphoma (35%–55% of dogs with T-cell lymphoma develop HM) and anal sac apocrine gland adenocarcinoma (25% of dogs affected dogs develop HM).[15,17–22] Other reported cancers in dogs associated with HM include acute lymphoblastic leukemia, adrenal carcinoma, ameloblastoma, chronic lymphocytic leukemia, clitoral adenocarcinoma, hepatocellular carcinoma, nasal carcinoma, penile adenocarcinoma, pulmonary carcinoma, thymoma, osteosarcoma, mammary carcinoma, melanoma, multiple myeloma, pheochromocytoma, renal angiomyxoma, renal cell carcinoma, thymoma, and thyroid carcinoma.[17,23–32] In cats, HM is most commonly associated with lymphoma, SCC, and multiple myeloma.[16,33,34] Other reported HM-associated cancers in cats include fibrosarcoma, acute leukemia (including erythroleukemia), osteosarcoma, pulmonary carcinoma, renal carcinoma, thyroid carcinoma, and undifferentiated sarcoma.[16,35–37] Primary hyperparathyroidism, which usually is caused by a functional benign parathyroid adenoma or adenomatous hyperplasia, can also occur dogs and cats.[14–16]

HM is most commonly caused by soluble mediators released by the tumor cells into circulation that can then act on bone and kidneys through endocrine and paracrine pathways, which is referred to as humoral hypercalcemia of malignancy. Parathyroid hormone-related protein (PTHrP) is involved most commonly. PTHrP normally is released by fetal parathyroid glands and the placenta, where it is thought to play an important role in calcium transport across the placenta into the developing fetus, and by mammary glands, where it acts in a paracrine fashion to assist with mammary gland development and lactation.[38] PTHrP also is expressed in a wide variety of normal canine tissues: skin, anal sac, thyroid gland, mammary gland, tongue, esophagus, stomach, kidney, bladder, and lung.[39] Its function in many of these tissues is not well understood. There is 70% sequence homology of the first 13 N-terminal amino acids of PTHrP compared with PTH, which permits PTHrP to bind and activate PTH receptors on osteoblasts and renal tubular cells when released into circulation by tumor cells.[17,18,40,41]

Various other cytokines can also contribute to the pathogenesis of humoral HM, including IL-1, IL-6, TNF, and calcitriol.[17,18,40,41] HM can also be caused by osteolysis when tumors invade or metastasize to bone. Paracrine release of factors including IL-1, IL-6, TNF, receptor activator of nuclear factor kappa-B ligand (RANKL), TGF-α and -β, and prostaglandins (especially PGE_2) can increase local osteoclast number and activity.[17,18,37]

In dogs, hypercalcemia is commonly associated with polyuria/polydipsia (PU/PD), anorexia, vomiting, and occasionally muscle weakness or twitching. In cats, hypercalcemia is most commonly associated with anorexia and vomiting; PU/PD is much less common.[16,37] PU/PD initially develops as a result of impaired action of antidiuretic hormone (ADH) on the tubular cells of the collecting duct. Dehydration is common. Renal damage can then result from renal vasoconstriction; mineralization of renal tubules, basement membranes, or interstitium; tubular degeneration or necrosis; and/or interstitial fibrosis.[37] Azotemia might or might not be reversible depending on the contributing underlying etiologies.

Measurement of ionized calcium is more accurate than total calcium, and equations that correct total calcium are not recommended.[42] However, in both dogs and cats, serum total calcium levels associated with HM tend to be higher compared with other etiologies.[15,16] In dogs and cats with humoral HM that are euhydrated and not azotemic, serum phosphate should be low to low-normal. When HM is suspected based on history, clinical signs, and baseline blood work, initial diagnostic evaluation should include a physical examination including careful palpation of peripheral lymph nodes and digital rectal examination (dogs), CBC, chemistry profile, urinalysis, thoracic radiographs, and abdominal ultrasound. If an underlying malignancy is not yet identified then cervical ultrasound; measurement of serum PTH, PTHrP, and calcitriol levels; survey bone radiographs; and/or bone marrow aspiration should be considered. Serum PTH should be low. Serum PTHrP usually is elevated, but it can be normal (not detectable). Serum calcitriol typically is normal, but it can be increased or decreased.[17,37,43]

The most effective treatment for HM is removal of the underlying cause: surgically removing the tumor or inducing a remission with chemotherapy or RT. Concurrent supportive care directed specifically at the hypercalcemia (Box 5.2) should be considered in patients that have a serum calcium concentration >16 mg/dL, patients with a calcium (mg/dL) times phosphate (mg/dL) product >60, patients that are clinically ill or azotemic, and patients with cancers that cannot be surgically removed and are unlikely to respond to chemotherapy or other therapies.[37,43] Intravenous fluid therapy with 0.9% sodium chloride (NaCl) is recommended first to correct existing dehydration and then to slightly volume expand to increase glomerular filtration rate and the filtered load of calcium. The high sodium content from 0.9% NaCl competes with calcium for renal tubular absorption, further enhancing

• BOX 5.2 Treatment for Hypercalcemia of Malignancy

Elimination of the inciting tumor is the primary goal for all categories of hypercalcemia.

Mild Hypercalcemia and Minimal Clinical Signs

Fluid therapy with 0.9% NaCl—rehydrated with subcutaneous or intravenous treatment

Moderate to Severe Hypercalcemia and Clinical Signs

Fluid therapy with 0.9% NaCl—correct dehydration over 4 to 6 hours, then continue at 100 to 125 mL/kg/day (1½–2 times maintenance rate)
Furosemide (2–4 mg/kg every 8–12 hours IV, SC, or PO)
Note: Only use after patient is fully rehydrated.
Prednisone (1–2 mg/kg q12–24 h PO)
Note: Only use after diagnosis obtained (see text).
Pamidronate (1.0–2.0 mg/kg diluted in 250 mL of NaCl IV over 2 hours every 2–4 weeks)
Zoledronate (0.1–0.25 mg/kg diluted in 60 mL of NaCl IV over 15 minutes every 2–4 weeks)

VetBooks.ir

calciuresis. Once rehydrated, the loop diuretic furosemide can be used with continued saline diuresis to further promote urinary calcium loss. More refractory cases can be treated with bisphosphonates, which inhibit osteoclast-mediated bone resorption.[44] Pamidronate (1.0–2.0 mg/kg IV) is effective for treating HM in dogs induced by various cancers, and it also has been shown to be an effective treatment in both dogs and cats with hypercalcemia secondary to nonneoplastic conditions.[45] In humans, zoledronate is more effective at inducing normocalcemia and maintains normocalcemia for a longer duration.[46] It also is less nephrotoxic than pamidronate.[44,47] Zoledronate has not been evaluated for HM in veterinary patients, but it has been used safely in dogs with malignant osteolysis (dose 0.1–0.25 mg/kg IV).[47] In those rare situations in which marked hypercalcemia with life-threatening consequences (e.g., coma) require immediate correction, the use of salmon calcitonin (4-8 IU/kg, S.C., q8–12 hours) will more rapidly lower blood calcium than bisphosphonates; however, its use is limited by expense, availability, and the propensity for tachyphylaxis (rapid resistance to effects) to occur within days.[37]

Glucocorticoid steroids can quickly induce a rapid reduction in serum calcium level. However, *it is essential that a definitive cause for hypercalcemia be identified before any steroid therapy is initiated.* If lymphoma or another hematopoietic tumor is the underlying cause of HM, the premature use of steroids can interfere with the ability to confirm a diagnosis, necessitating additional diagnostics and/or discontinuation of the steroids and waiting for the cancer to become clinically evident again. In addition, steroids can induce resistance to other chemotherapy agents, decreasing the ability to attain a complete remission and shortening the length of survival.[48]

Hypoglycemia

The most common cause of paraneoplastic hypoglycemia in the dog is insulinoma (pancreatic beta-cell tumor).[49,50] Functional pancreatic beta-cell tumors typically produce excess amounts of insulin, but rarely they can also release IGF-1 or IGF-2.[51,52] The reader is directed to Chapter 26 for a discussion of insulinomas.

The non–islet cell tumors most commonly associated with paraneoplastic hypoglycemia are primary liver tumors (hepatocellular adenocarcinoma and adenoma) and smooth muscle tumors (leiomyosarcoma and leiomyoma, with tumors arising from liver, stomach, duodenum, and jejunum).[53–57] Case reports also exist for paraneoplastic hypoglycemia associated with a variety of other tumors, including hemangiosarcoma (HSA), lymphoma, lymphocytic leukemia, mammary carcinoma, melanoma, plasma cell tumor, renal adenocarcinoma, and salivary adenocarcinoma.[53,58–60] Tumor cell production of IGF-2 is the most common mechanism for paraneoplastic hypoglycemia in non–islet cell tumors.[1,53,54,61] Other mechanisms include production of IGF-1 or somatomedins, hypermetabolism of glucose, production of substances stimulating insulin release, production of hepatic glucose inhibitor, insulin binding by a monoclonal immunoglobulin (plasma cell tumors), insulin receptor proliferation, or rarely, ectopic insulin production.[1]

Insulinomas usually are small, and visualization on abdominal ultrasound is inconsistent.[49,50] The diagnosis is most often made by documenting hypoglycemia along with an inappropriately elevated serum insulin level. In contrast, most intraabdominal non–islet cell tumors causing hypoglycemia are large and readily identifiable on abdominal palpation or ultrasound.[53–56] The reader is directed to Chapter 26 for an extensive discussion of the clinical consequences, diagnosis, and therapy of tumor-induced hypoglycemia.

Hyperestrogenism

The tumor most commonly associated with hyperestrogenism is the Sertoli cell tumor. Overall, 25% to 50% of dogs with Sertoli cell tumors will display clinical signs of hyperestrogenism.[62–64] Approximately half of canine Sertoli cell tumors develop in cryptorchid testes, and clinical hyperestrogenism occurs more commonly when Sertoli cell tumors develop in cryptorchid testes.[63–65] Therefore a Sertoli cell tumor must remain a differential diagnosis when a dog presents with clinical signs of hyperestrogenism, even if a testicular mass is not palpated on physical examination. Ultrasound is then indicated to screen for an inguinal or intraabdominal tumor. Paraneoplastic hyperestrogenism also can occur rarely in dogs with seminomas, interstitial cell tumors, and ovarian granulosa cell tumors.[66–68] This PNS has not been reported in cats.

Dogs with Sertoli cell tumors have significantly higher plasma estradiol-17β levels compared with healthy controls.[69] Sertoli cell tumors also have lower expression of 5α-reductase type 1 than normal testes, and plasma testosterone levels were lower in affected dogs.[69,70] Clinical signs of feminization secondary to Sertoli cell tumors correlated best with reductions in the testosterone/estradiol ratio rather than absolute increases in estradiol-17β.[69]

Clinical signs of hyperestrogenism include bilaterally symmetric alopecia, cutaneous hyperpigmentation, epidermal thinning, gynecomastia, galactorrhea, pendulous prepuce, penile atrophy, atrophy of the contralateral testicle, either prostatic atrophy or prostatomegaly (the latter secondary to squamous metaplasia), and attraction of other males.[62,63] Estrogen also can have myelotoxic effects. Bone marrow toxicosis is characterized initially by a transient increase in granulocytopoiesis and neutrophilic leukocytosis, followed by progressive bone marrow hypoplasia or aplasia leading to aplastic anemia (nonregenerative anemia, thrombocytopenia, and leukopenia).[63] Severely pancytopenic dogs can present with additional clinical signs associated with anemia (weakness, lethargy, pale mucous membranes, tachycardia), thrombocytopenia (petechia, ecchymoses, epistaxis, GI bleeding) and/or leukopenia (infection, sepsis). The clinical signs of hyperestrogenism will resolve with surgical removal of the Sertoli cell tumor, but this can take several months. Consequently, the mortality rate for dogs with severe myelotoxicosis and pancytopenia is high.[62,63]

Acromegaly (Hypersomatropism)

In cats, acromegaly is caused by hypersomatropism—excessive GH secretion by a functional pituitary adenoma arising from somatotroph cells.[71–73] In contrast, canine acromegaly most commonly results from progestin-induced GH secretion by mammary ductal epithelium. However, there are case reports of two GH-producing mammary tumors and one GH-producing pituitary tumor in dogs.[74,75]

GH antagonizes insulin by reducing insulin receptors and interfering with a wide range of postreceptor processes.[71–73] The vast majority of cats initially present with diabetes mellitus, and insulin resistance is common. Over time, the chronic exposure to excess GH results in overgrowth of connective tissue, bone, and viscera. Cats can develop broad facial features, prognathica inferior, diffuse thickening of the oropharyngeal tissues, hepatomegaly, renomegaly, adrenomegaly, hypertrophic

cardiomyopathy, clubbing of the paws and distal extremities, and degenerative arthropathy.[71–73] Many effects of GH are mediated by IGF-1, and because GH assays are not readily available, measurement of serum IGF-1 remains the most practical way to confirm feline hypersomatotropism.[73] The reader is directed to Chapter 26 for a more detailed discussion regarding feline acromegaly.

Ectopic Adrenocorticotropic Hormone Syndrome

The ectopic production of adrenocorticotropic hormone (ACTH) or ACTH-like substances is a common PNS in humans.[1] About 3% to 5% of people with small cell lung cancer develop hyperadrenocorticism. This PNS also is reported in people with other carcinomas, including pancreatic carcinoma, thymic carcinoma, and carcinoids. This PNS results from expression of the proopiomelanocortin gene, which contains not only ACTH, but also melanocyte-stimulating hormone, lipotropin, endorphins, and enkephalins.[1] As a result, patients present with clinical signs typical of hyperadrenocorticism (Cushing's disease), but occasionally will also have other clinical signs such as hyperpigmentation. The diagnosis is made based on documentation of increased urine cortisol, a dexamethasone suppression test where serum cortisol is consistently suppressed, and elevated plasma levels of ACTH or ACTH precursors.[1] This PNS is very rare in veterinary oncology, with single case reports in dogs with a primary lung tumor, a metastatic neuroendocrine tumor arising in the pancreas, and a hepatic carcinoid.[76–78] When clinical signs cannot be controlled with surgery, trilostane is an effective alternative.[77]

Hematologic Manifestations of Cancer

Hyperglobulinemia and Bence Jones Proteinuria

Hyperglobulinemia, or more specifically monoclonal gammopathy or paraproteinemia, is seen most commonly with multiple myeloma, but also has been reported with all other myeloma-related disorders (MRD) including solitary plasma cell tumor of bone, extramedullary plasmacytoma (cutaneous and noncutaneous), IgM (Waldenström's) macroglobulinemia, plasma cell leukemia, Ig-secreting lymphoma, and Ig-secreting chronic lymphocytic leukemia.[79–82] MRD tumor cells typically produce an overabundance of a single type or component of immunoglobulin, which is referred to as the M component. On serum electrophoresis, a narrow-based spike typically is identified in the gamma region (i.e., monoclonal gammopathy), although on rare occasion it can extend into the beta region.[83] Biclonal spikes also have been reported in both dogs and cats.[80,84,85] M components can interfere with coagulation primarily by coating platelets, inhibiting platelet aggregation to damaged endothelial surfaces and release of platelet factor 3.[79,83] M components also can lead to hyperviscosity syndrome (see later).

Intact Ig molecules usually are released by plasma cells, but occasionally there is an imbalance in heavy and light chain production. If there is an excess of free light chain, they will be excreted in the urine—Bence Jones proteinuria. Bence Jones proteinuria is diagnosed on urine electrophoresis; it is not detected on routine urine dipstick.[86,87] Bence Jones proteins can cause light-chain renal tubular casts, leading to interstitial nephritis and possibly renal failure.[79,83]

Hyperviscosity Syndrome

Hyperviscosity syndrome refers to a constellation of clinical signs caused by an increase in blood viscosity. It can occur in patients with MRD (see Hyperglobulinemia, earlier), polycythemia vera (see Chapter 33, Section C), or paraneoplastic erythrocytosis (see Erythrocytosis, later).[79,88–91] In patients with MRD, hyperviscosity syndrome occurs most frequently in patients with IgM macroglobulinemia because IgM typically forms a high molecular weight pentamer.[79,91] When it occurs in patients with multiple myeloma, the M-component is more commonly IgA than IgG, as the former exists as a dimer and occasionally will polymerize, and the latter is a monomer.[79]

The clinical signs of hyperviscosity syndrome result from sludging of blood in small vessels, ineffective delivery of oxygen and nutrients, and coagulation abnormalities. Reported neurologic signs include stuporous mentation, ataxia, and seizures.[79,88,89] Ocular abnormalities include enlarged and tortuous retinal vessels, retinal hemorrhages, and retinal detachment, often resulting in acute-onset blindness.[79,88,92] Bleeding diathesis, hypertrophic cardiomyopathy, and congestive heart failure can also occur.[79,83,88,93]

In severe cases of hyperviscosity syndrome, emergency treatment is warranted. Plasmapheresis is indicated when hyperviscosity is caused by serum proteins.[93,94] Phlebotomy and intravenous fluids are indicated when hyperviscosity is caused by erythrocytosis.[90]

Anemia

The true prevalence of anemia in veterinary cancer patients is unknown, but it is likely one of the most common PNS observed. Anemia is reported in 30% to 43% of dogs and 43% to 58% of cats with lymphoma, and it is a negative prognostic factor in both species.[83,95–97] It also is commonly reported in dogs and cats with leukemias and HSA, and dogs with disseminated MCT and histiocytic sarcoma (HS).[83] The pathogenic mechanisms common to all anemias—blood loss, increased red blood cell (RBC) destruction (hemolysis), and decreased RBC production—can each play a role in cancer-related anemia, and multiple mechanisms can simultaneously contribute to the anemia observed in a given patient.

Anemia secondary to hemorrhage classically is regenerative, although it can take 2 to 3 days after the onset of bleeding for reticulocytosis to be present, and is accompanied by hypoproteinemia.[98] Acute, severe hemorrhage is most commonly associated with splenic HSA, but it also can occur in dogs with other benign and malignant splenic tumors, adrenal medullary and cortical carcinomas, hepatocellular carcinoma, and thyroid carcinoma.[98–101] Chronic, low-grade hemorrhage can occur with tumors involving the GI tract, nasal cavity, urinary bladder, and with tumors causing paraneoplastic GI ulceration (see earlier).[83] With chronic external hemorrhage iron deficiency can result, characterized by microcytosis, hypochromasia, low serum iron, and low saturation of transferrin.[102]

Hemolytic anemias can be immune mediated or non–immune mediated. Immune-mediated hemolytic anemia (IMHA) is characterized by severe anemia that is usually but not always adequately regenerative, along with spherocytes, autoagglutination, and/or a positive direct agglutination test (Coombs test).[103] Hemoglobinemia and/or hyperbilirubinemia are also commonly seen. IMHA is most commonly idiopathic in dogs and secondary to feline leukemia virus (FeLV) infection in cats, but it can be secondary to neoplasia in both species.[83,103] Lymphoma and leukemias are the cancers most frequently associated with IMHA in both small animals and humans.[83,103]

VetBooks.ir

Non–immune mediated hemolytic anemia can arise secondary to microangiopathy, tumor cell erythrophagocytosis, or oxidative damage to erythrocytes. Microangiopathic hemolytic anemia (MAHA) is caused by endothelial cell injury and fibrin deposition, most commonly seen in patients with disseminated intravascular coagulation (DIC), and by inherent abnormalities in tumor vasculature, most notably with HSA.[83,104,105] These pathologic alterations cause shearing and destruction of erythrocytes, resulting in increased numbers of schistocytes in peripheral blood. Clinically significant tumor cell erythrophagocytosis is seen most commonly with HS, particularly the hemophagocytic variant.[106–108] In addition to a markedly regenerative anemia, common clinicopathologic abnormalities include a negative direct agglutination test, thrombocytopenia, hypoalbuminemia, and hypocholesterolemia. Erythrophagocytosis, with or without secondary anemia, has also been documented in dogs with lymphoma, plasma cell tumors, and acute megakaryoblastic leukemia, and in cats with lymphoma and mast cell tumor (MCT).[83] Oxidative injury to erythrocytes is characterized by Heinz bodies and/or eccentrocytes. In retrospective studies, 15% of dogs with eccentrocytosis, and 11% of cats with Heinz body anemia had underlying malignancies.[109,110] Lymphoma was the most common cancer for both species.

Nonregenerative anemias result from cancers directly or indirectly affecting erythropoiesis. Cancer cells can infiltrate the marrow and replace normal hematopoietic tissue, a condition called myelophthisis. This is seen most commonly with hematopoietic cancers, such as acute leukemias, lymphoma, multiple myeloma, mast cell neoplasia, and disseminated HS.[83,104,108,111–114] Aplastic anemia can result from paraneoplastic hyperestrogenism (see earlier). Decreased serum folate and cobalamin (vitamin B_{12}) concentrations have been reported in cats with GI lymphoma.[115] One of the most common causes of anemia in cancer patients is anemia of inflammatory disease (AID, also called anemia of chronic disease). This is characterized by a mild to moderate nonregenerative, normocytic, normochromic anemia. Inflammatory cytokines such as TNF-α, interferon-gamma (IFN-γ), IL-1, IL-6, and IL-10 reduce the production of endogenous erythropoietin in the face of hypoxemia, and suppress the erythroid progenitor response to erythropoietin.[102] IL-6 increases production of hepcidin by the liver. Hepcidin is an acute phase protein that causes increased cellular internalization and degradation of ferroportin, a membrane bound protein that exports iron from macrophages, hepatocytes, and duodenal enterocytes into the peripheral blood.[83,102] The net effect is the sequestration of iron, resulting in hypoferremia and decreased availability of iron for erythropoiesis.

Erythrocytosis (Polycythemia)

Paraneoplastic erythrocytosis has been reported in dogs with a variety or renal tumors (carcinoma; adenocarcinoma; fibrosarcoma; and lymphoma, with or without other organ involvement), nasal fibrosarcoma, cecal leiomyosarcoma, and spinal cord schwannoma.[60,116–124] It also has been reported in cats with renal adenocarcinoma.[125] Paraneoplastic erythrocytosis is associated with increased serum erythropoietin levels. The erythropoietin is most often produced by the tumor cells.[117,118,121,123] However, it also has been hypothesized that elevated erythropoietin levels might result from impaired renal blood flow causing local tissue hypoxia.[90,121] In people, paraneoplastic erythrocytosis can also result from tumor cells producing androgenic hormones and prostaglandins that enhance the effects of erythropoietin.[1]

It is important to rule out other causes for erythrocytosis. Relative erythrocytosis results from dehydration. Absolute erythrocytosis can be primary (polycythemia vera) or secondary to chronic respiratory disease, heart disease causing right-to-left shunting, or nonneoplastic renal disease.[90] Classically, dogs and cats with paraneoplastic erythrocytosis will have elevated serum erythropoietin levels, but there is considerable overlap with dogs and cats that are normal and even those with polycythemia vera.[90,126]

Paraneoplastic erythrocytosis typically resolves with removal of the primary tumor. However, patients presenting with hyperviscosity syndrome might require emergency treatment before surgery or chemotherapy induction (see Hyperviscosity Syndrome, earlier).[90,125]

Leukocytosis

Mild to moderate neutrophilic leukocytosis is common in dogs and cats with cancer, and is usually attributable to inflammation or tissue necrosis associated with the cancer; however, extreme neutrophilic leukocytosis (≥70,000 cells/μL), often with a left shift, monocytosis, and eosinophilia, has been reported in dogs with pulmonary carcinoma, renal tumors, intestinal T-cell lymphoma, metastatic fibrosarcoma, and adenomatous rectal polyps, and in cats with pulmonary SCC and dermal tubular adenocarcinoma.[83,127–133] This is thought to arise because of tumor production of granulocyte colony-stimulating factor (G-CSF) and/or granulocyte-macrophage colony-stimulating factor (GM-CSF).[83,131,132] Extreme neutrophilic leukocytosis, also referred to as a leukemoid response, can be difficult to distinguish from chronic myelogenous leukemia (CML), as the prevalence of the characteristic cytogenetic abnormalities identified in people with CML, although identified in dogs, has not been determined.[134,134b] This PNS is generally thought to have minimal clinical significance, although a retrospective study evaluating dogs with severe leukocytosis (≥50,000 white blood cells [WBC]/μL, with >50% neutrophils) resulting from a variety or neoplastic and nonneoplastic etiologies identified a high mortality rate.[135]

Eosinophilia is an uncommon PNS in veterinary cancer patients, but is seen most frequently in dogs and cats with MCT and lymphoma, particularly T-cell lymphoma.[136–140] Mast cells produce the eosinophilic cytokine IL-5 and other eosinophil chemotactic factors, and in people T-cell lymphomas have been documented to produce IL-5.[136,139] Eosinophilia also has been reported in dogs with oral fibrosarcoma, mammary carcinoma, and leiomyosarcoma, and in cats with oral SCC and bladder transitional cell carcinoma.[83,141–144] Eosinophilia is also frequently seen as part of a leukemoid response.

Thrombocytopenia

Thirteen percent to 36% of dogs with cancer present with thrombocytopenia before any treatment,[145,146] and 39% of thrombocytopenic cats are diagnosed with underlying neoplasia.[147] In both species, thrombocytopenia is especially common with hematopoietic and vascular cancers.[145–147] General mechanisms for thrombocytopenia include decreased platelet production, increased platelet destruction, increased platelet sequestration, and increased platelet consumption. However, in a series of 214 thrombocytopenic dogs with cancer, 61% had no identifiable explanation for their thrombocytopenia, although not all dogs had exhaustive diagnostic evaluations.[146]

VetBooks.ir

As with anemia, decreased platelet production can result from myelophthisis and hyperestrogenism (see earlier). Cancer-associated immune-mediated thrombocytopenia is most commonly associated with lymphoma, multiple myeloma, and HS, but also has been reported with mammary adenocarcinoma, MCT, HSA, nasal adenocarcinoma, and fibrosarcoma.[148–151] Non–immune-mediated platelet destruction in cancer patients most commonly occurs secondary to microangiopathy. The spleen normally stores about one third of the body's platelets, and tumors causing diffuse splenomegaly can increase platelet sequestration. This occurs most commonly with splenic lymphoma and feline splenic MCT, but also can occur with highly vascularized tumors such as hemangioma and HSA.[83,151] Increased consumption can occur secondary to hemorrhage. Severe, acute hemorrhage frequently causes thrombocytopenia.[98] Chronic low-grade hemorrhage is more likely to cause thrombocytosis; thrombocytopenia results only when the regenerative capacity of the bone marrow has been exhausted.[151] More importantly, increased platelet consumption can result from the hypercoagulable state that is common in cancer patients (see later).[83,151] Platelet counts and kinetics were evaluated in 52 tumor-bearing and 24 normal dogs.[152] Tumor-bearing dogs had significantly lower platelet counts and shorter mean survival time of circulating platelets. In addition, mean platelet survival time was the shortest for dogs with metastatic cancers.

Coagulopathies and Disseminated Intravascular Coagulation

Hypocoagulability can result from thrombocytopenia and alterations in platelet function secondary to paraproteinemia (see earlier). Hemorrhagic diathesis also can result from blood hyperviscosity (see earlier). The most common clotting factor dysfunction seen in veterinary cancer patients results from the release of heparin by MCT, which acts as a cofactor for antithrombin III to inactivate clotting factors XII, XI, X, and IX.[139]

Hypercoagulability is much more common in cancer patients. In human cancer patients, thromboembolic disease can manifest as deep venous thrombosis, pulmonary thromboembolism (PE), migratory superficial thrombophlebitis (Trousseau's syndrome), nonbacterial thrombotic endocarditis, and DIC.[83] In dogs with various untreated cancers, platelet aggregation in response to agonists (collagen, adenosine diphosphonate, or platelet-activating factor) was significantly greater compared with healthy control dogs.[153,154] Thromboelastography documented hypercoagulability in 56% of dogs with lymphoma and 50% of dogs with various other cancers.[83,155] Although many of these patients did not necessarily have clinical manifestations of hypercoagulability, underlying cancer was identified in 27% of dogs with portal vein thrombosis, 30% with PE, and 54% with splenic vein thrombosis.[156–158]

DIC is a syndrome of systemic activation of coagulation, leading to widespread microthrombosis. Consumption of platelets and clotting factors can then lead to uncontrollable hemorrhage. Cancer is one of the most common causes of DIC. One study estimated 10% of dogs with cancer to have DIC.[159] Tumors with the highest incidences include HSA (with up to 50% of dogs affected at initial evaluation), mammary adenocarcinoma (particularly inflammatory mammary carcinoma), and pulmonary adenocarcinoma.[105,159,160] It is worth noting, though, that these studies focused primarily on acute phase DIC, characterized by obvious laboratory abnormalities and clinical signs of organ dysfunction caused by microthrombosis and/or hemorrhage. The compensated chronic phase, where time exists for replenishment of coagulation factors, anticoagulation proteins, and platelets, is more difficult to diagnose and likely even more prevalent.[83]

The pathogenesis of thromboembolic disease in cancer patients is complex and multifactorial. One of the major causes for hemodynamic derangement is the inherent abnormalities of tumor microvasculature, including absent or incomplete endothelial coverage, vessel tortuosity, variations in vascular caliber, and blood flow turbulence.[83,105] Hyperviscosity or tumor invasion into blood vessels can further contribute.[83] There also is considerable "cross talk" between the inflammatory and coagulation pathways. Tissue factor, expressed on monocytes and endothelial cells during inflammation and on some cancer cells, complexes with factor VIIa to activate the extrinsic clotting cascade.[161] This is the major stimulus for thrombin production in DIC. In addition, TNF-α, IL-1, and IL-6 can directly activate certain clotting factors and downregulate protein C-thrombomodulin expression on endothelial cells.[83,161]

Thrombosis initially was thought to be merely a consequence of cancer, but more recent evidence supports that it might be a necessary intrinsic step in cancer progression. Fibrin deposition around neoplastic foci forms a provisional extracellular matrix for angiogenesis.[83,162] In addition, the formation of fibrin–platelet–tumor cell complexes increases adhesion to endothelium and enhances metastatic efficiency.[83,162]

Cutaneous Manifestations of Cancer

Nodular Dermatofibrosis

Nodular dermatofibrosis (ND) is a well-recognized PNS characterized by multiple slowly growing cutaneous collagenous nodules in association with bilateral renal cystadenocarcinomas or cystadenomas.[163–168] Almost all reported cases have been in German shepherd dogs, and pedigree analysis strongly indicates autosomal dominant inheritance.[168] The ND-associated mutation was mapped to the *BHD* gene on chromosome 5.[169] This is the causative gene for the human renal cancer syndrome Birt–Hogg–Dubé syndrome, which bears some similarities to renal cystadenocarcinoma/nodular dermatofibrosis. The function of folliculin, the protein encoded by the *BHD* gene, is unknown.

Most dogs present with multiple firm cutaneous nodules ranging in size from 2 mm to 5 cm that are not painful or pruritic (Fig. 5.1). Lesions are found predominately on the limbs, although the head and trunk may be affected in advanced cases. Histologically, the nodules consist of irregular bundles of dense, well-differentiated collagen fibers in the dermis or subcutis.[165,166] ND almost always precedes systemic signs of illness related to tumor-induced renal failure or metastasis by months to years, although microscopically detectable renal changes can occur at a young age. Affected females almost always have concurrent uterine leiomyomas that carry little clinical significance.[163,164]

Currently, there is no effective therapy for the underlying cancer. Affected dogs develop multiple tumors bilaterally, precluding surgery, and chemotherapy has not been evaluated. Palliative surgical removal of cutaneous nodules can be considered when they are ulcerated or interfering with function. Mean time from first observation of ND until death is about 2.5 years.[163,168]

VetBooks.ir

• **Fig. 5.1** Diffuse nodular dermatofibrosis (ND) in a German shepherd dog. The nodules are composed of extremely dense but well-differentiated collagen tissue (collagenous nevi) and are found predominately on the limbs, although the head and trunk may be affected in advanced cases.

Superficial Necrolytic Dermatitis

Superficial necrolytic dermatitis (SND) is seen most commonly in dogs with hepatic disease (i.e., hepatocutaneous syndrome),[170–173] but it also reported as a paraneoplastic syndrome in dogs and cats with glucagon-secreting tumors in the pancreas and liver.[163,171–178] Necrolytic migratory erythema (NME) refers to the human analog of paraneoplastic SND.

The major dermatologic findings of SND are erosions and ulcerations, with alopecia, exudation, and adherent crusts on the feet, pressure points (such as the elbow or hock), flank, perineal area, muzzle, facial mucocutaneous junctions, and/or oral cavity. Hyperkeratosis and fissuring of foot pads occurs in all affected animals. Lesions may be painful and pruritic. Hypoaminoacidemia is a common feature in both paraneoplastic SND and hepatocutaneous syndrome.[163,171–174] It has been hypothesized that the elevated glucagon levels sustain gluconeogenesis and amino acid catabolism, resulting in hypoaminoacidemia that then leads to epidermal protein depletion and subsequent keratinocyte necrolysis.

Resolution of SND was reported in one dog with a solitary pancreatic glucagon secreting tumor that underwent surgery.[175] However, most dogs present with metastatic disease. Another dog was successfully treated with the somatostatin analog octeotride.[176] Amino acid infusions have been used in people with NME and dogs with hepatocutaneous syndrome.[163,171,172]

• **Fig. 5.2** Feline thymoma-associated exfoliative dermatitis. Regional alopecia involves the head, neck, and dorsal thorax with extensive scaling and focal crusts.

Feline Paraneoplastic Alopecia

Feline paraneoplastic alopecia has been reported in cats with pancreatic carcinoma and biliary carcinoma.[163,179–183] It is a nonpruritic, symmetric, progressive alopecia affecting primarily the ventrum and medial aspect of the limbs. Hair is easily epilated, and skin is shiny, inelastic, and thin, but not fragile. Foot pad involvement also is common. Affected pads are painful and can be dry, crusted, and fissured, or moist and erythematous. One study showed that *Malassezia* spp. dermatitis is rare in cats, and 7 of 15 affected cats had skin biopsy changes consistent with feline paraneoplastic alopecia, and pancreatic carcinoma was confirmed in 4 of these cats.[184] Given the aggressive biologic behaviors of pancreatic and biliary carcinomas, most cats presented with metastatic disease and were euthanized soon after diagnosis. However, in one cat with a solitary pancreatic tumor, skin changes resolved after surgery.[180]

Feline Thymoma-Associated Exfoliative Dermatitis

Paraneoplastic exfoliative dermatitis has been reported in cats with thymoma.[163,185–187] It begins as nonpruritic scaling and mild erythema on the head and pinnae, and then progressively involves the neck, trunk, and limbs (Fig. 5.2). With time, the scaling intensifies and alopecia develops. Keratosebaceous debris accumulates between the digits, in the nail beds, and in the ear canals. Crusts and ulcers may develop. One reported cat also had a secondary concurrent *Malassezia* spp. infection.[186] The underlying mechanism is unknown, but the presence of an interface dermatitis and lymphoid cellular infiltrate on histopathology suggests a tumor-induced immune-mediated process.[185] Most cats reported in the literature did not undergo treatment for their thymoma, but one that did undergo surgical removal had complete resolution of skin lesions.[186]

VetBooks.ir

Renal Manifestations of Cancer

Glomerular Disorders

A variety of paraneoplastic glomerular disorders have been reported in people. Membranous nephropathy is reported most commonly and is associated with a variety of solid tumors.[1,188] It is hypothesized that tumor antigens are deposited in the glomeruli, and antibodies then bind to form immune complexes that activate complement.[1] Paraneoplastic glomerular disorders likely are underreported in veterinary cancer patients with only two case reports, one in a dog with primary erythrocytosis and one in a dog with lymphocytic leukemia.[189,190]

Miscellaneous Syndromes

Paraneoplastic nephrogenic diabetes insipidus was reported in a dog with intestinal leiomyosarcoma.[191] In addition, PU and PD and renal damage are commonly reported in dogs with paraneoplastic hypercalcemia, and occasionally in cats (see earlier). PU and PD also were reported in the rare cases of ectopic adrenocortoctropic hormone syndrome identified in dogs (see earlier).

Neurologic Manifestations of Cancer

Myasthenia Gravis

Paraneoplastic myasthenia gravis (MG) is reported most commonly in dogs and cats with thymoma,[192–200] but it also has been reported in dogs with osteosarcoma, cholangiocellular carcinoma, oral sarcoma, and nonepitheliotropic cutaneous lymphoma.[201–204] As with all forms of acquired MG, this is an immune-mediated disease where antibodies are formed against nicotinic acetylcholine (ACh) receptors on the postsynaptic sarcolemmal surface within the neuromuscular junction. Interestingly, patients with thymomas have been diagnosed with a variety of other immune-mediated diseases as well: exfoliative dermatitis and pemphigus vulgaris in cats;[185,200] polyarthritis, masticatory muscle myositis, perianal fistula, immune-mediated thrombocytopenia, and hypothyroidism in dogs.[192]

Generalized MG is associated with appendicular muscle weakness that is often but not always exercise induced. Concurrent weakness involving the muscles of the esophagus (megaesophagus), face, pharynx, and/or larynx can be present as well. Focal myasthenia gravis most commonly involves these latter muscle groups. The definitive diagnosis for acquired MG usually is made by demonstrating circulating antibodies against ACh receptors, although a small percentage of patients are seronegative. A positive edrophonium chloride challenge test is also helpful in dogs with generalized MG.

Surgical removal of the thymoma and/or RT is recommended to help reduce anti-ACh receptor antibody levels and improve clinical signs of MG, but response is inconsistent.[195–198] In recent studies, neither MG nor megaesophagus affected prognosis in dogs or cats with thymoma.[192,198,199] However, patients with megaesophagus have a high risk of aspiration pneumonia, and this is a common cause of perioperative morbidity and mortality.[192,193,198] Therefore, whenever possible, it is recommended that clinical signs of MG be controlled before anesthesia and surgery. Consultation with a neurologist regarding anticholinesterase therapy (pyridostigmine bromide) and immunosuppressive therapy is recommended.

Peripheral Neuropathy

Paraneoplastic peripheral nerve lesions are relatively common. When peroneal and ulnar nerve fibers were analyzed from dogs with a wide variety of cancers, paranodal/segmental demyelination and remyelination were seen most commonly, followed by axonal degeneration manifested by myelin ovoids and myelin globules.[205,206] These lesions are also reported in normal dogs with increasing age, but 16 of 21 dogs had a significantly greater number of lesions compared with age-matched controls.[205] Tumors associated with the highest percentages of abnormalities were bronchogenic carcinoma, mammary adenocarcinoma, melanoma, insulinoma, and osteosarcoma. Interestingly, though, none of the dogs in that study showed clinical signs consistent with a diffuse or localized neuropathy. Clinical paraneoplastic polyneuropathies, usually characterized by diffuse lower motor neuron signs, are much less common. They have been reported in dogs with insulinoma, multiple myeloma, lymphoma, fibrosarcoma, leiomyosarcoma, anaplastic sarcoma, pancreatic adenocarcinoma, prostatic adenocarcinoma, combined mixed mammary gland adenoma and pulmonary adenoma, and combined pulmonary carcinoma and metastatic HSA, and in a cat with renal lymphoma.[207–213]

Miscellaneous Manifestations of Cancer

Hypertrophic Osteopathy

Hypertrophic osteopathy (HO) is a generalized osteoproductive disorder of the periosteum that affects the long bones of the extremities, typically beginning on the digits and then progressing proximally. Lesions typically are bilaterally symmetric and involve all four limbs.[214] Paraneoplastic HO is most commonly associated with primary lung tumors or tumors that have metastasized to the lungs. Two studies both reported that the majority of dogs with paraneoplastic HO presented with pulmonary metastasis, and the most common tumor type was osteosarcoma.[214,215] Paraneoplastic HO without evidence of pulmonary involvement has been reported in dogs with renal transitional cell carcinoma and nephroblastoma, urinary bladder botryoid rhabdomyosarcoma, hepatocellular carcinoma, esophageal adenocarcinoma, prostatic carcinoma, and malignant schwannoma derived from the vagus nerve,[132,216–221] and in cats with adrenocortical carcinoma and renal adenoma.[222,223] Nonneoplastic diseases associated with HO include infectious/inflammatory lung disease, *Dirofilaria immitis* infection, bacterial endocarditis, patent ductus arteriosus with right-to-left shunting, *Spirocera lupi* esophageal granulomas, esophageal foreign body, and congenital megaesophagus.[214] Idiopathic HO has been reported in cats.[224,225] Cats with primary lung tumors can also develop digital metastasis, which can have a similar clinical presentation to HO.[226]

Affected patients most commonly present with swelling and/or edema of the distal limbs and lameness or difficulty ambulating. Limbs are often painful on palpation and/or warm to the touch.[214,215] One study also reported a high incidence of concurrent bilateral serous to mucopurulent ocular discharge and episcleral injection.[214] Fewer than half of affected patients have respiratory signs at the time of initial presentation.[214] When radiographs are taken of the distal extremities, symmetric periosteal new bone formation appears nodular or speculated, classically radiating 90 degrees from the long axis of the affected bones (Fig. 5.3). There also is often evidence of adjacent soft tissue swelling and edema.

• **Fig. 5.3** Hypertrophic osteopathy (HO), seen radiographically in the distal forelimb of a dog with a primary lung tumor. Note the spiculated periosteal new bone formation radiating 90 degrees from the long axis of the radius, ulna, and metacarpal bones.

The pathogenesis of HO is not well understood. The classic pathophysiologic changes are increased peripheral blood flow, proliferation of vascular connective tissue, and ultimately bone spicule formation.[214] A neural reflex that originates in the thorax and is carried by afferent vagal fibers has been proposed,[132,214,220,221,227] and regression of HO has been reported in dogs after undergoing vagotomy.[221,227] More recently, humoral mechanisms have been hypothesized. People with lung cancer and HO have higher levels of serum growth hormone, growth hormone–releasing hormone, vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF).[228] Elevated levels of these and other hormones might result from tissue hypoxia, along with decreased pulmonary clearance because of pathologic shunting.[214,228] It also has been shown that circulating megakaryocytes and platelet clumps that normally become trapped in pulmonary capillary beds can bypass these capillaries, again due to pathologic shunting, and they subsequently can become lodged in the distal extremities and release PDGF.[229]

Whenever possible, the treatment for HO is removal of the underlying cancer. However, dogs more commonly present with pulmonary metastasis rather than a solitary lung mass. Pulmonary metastatectomy can be considered when there are only a few metastatic lesions.[230] Chemotherapy can be used for sensitive cancers as well.[231] In people, pamidronate and zoledronate are effective palliative treatments to control pain.[232] They have not been evaluated in veterinary patients with HO, but they have been used successfully to manage pain associated with primary bone tumors (see Chapter 25) and are thus a rational choice.

Fever

Paraneoplastic fever can result as part of an innate immune response against tumor antigens or areas of tumor necrosis. Fever is mediated primarily by TNF-α, IL-1, and IL-6 on the hypothalamus. These cytokines activate the arachidonic acid cascade, producing prostaglandin E_2, which acts on the thermoregulatory center of the hypothalamus.[233] The exact incidence of paraneoplastic fever is unknown, but in retrospective studies of fever of unknown origin, fewer than 10% of dogs were ultimately diagnosed with cancer.[234–236] Hematopoietic cancers were identified most frequently.

When an animal with cancer presents with fever, it is important to rule out concurrent infection. Tumors can become secondarily infected, especially if they are ulcerated or have large areas of necrosis. Gastrointestinal tumors can perforate the GI tract, resulting in septic peritonitis Sepsis secondary to myelophthisic leukopenia can also occur. Infections also can develop as a complication of cancer treatment: postoperative healing complications, severe neutropenia secondary to chemotherapy and sepsis, vomiting secondary to chemotherapy and subsequent aspiration pneumonia. A diagnosis of paraneoplastic fever is often made by ruling out other causes for fever. Paraneoplastic fever is most effectively treated by eliminating the inciting cancer. When this is not possible, if the fever is affecting quality of life then symptomatic treatment with and NSAID or antiinflammatory dose of steroids should be considered.

6 Diagnostic Imaging in Oncology

STEPHANIE NYKAMP AND ELISSA RANDALL

Diagnostic imaging is essential in the diagnosis, clinical staging, and evaluation of response to therapy of cancer patients. Radiography, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and nuclear scintigraphy can all be used to evaluate the cancer patient. Advanced functional imaging (e.g., PET/CT, PET/MR) may also prove valuable in predicting response to therapy. The choice of modality is dependent on availability and desired outcome, with each modality having advantages and disadvantages in regard to cost, sensitivity, and specificity. When evaluating the primary tumor, accurate detection of tumor margins is paramount. When evaluating for metastasis, the ideal modality would be both highly sensitive and specific so that all lesions are detected accurately. If such a modality is not available, initial imaging should be done with a modality that is highly sensitive and followed with one that is more specific.

The use of advanced imaging and improved techniques for functional imaging are improving the accuracy and precision of cancer imaging.[1] It should be noted that this can also result in stage migration. The effect of this additional information is not fully understood for many and should be used with caution when predicting outcome.[2] This chapter outlines the principles of each modality and their utility in assessing the veterinary cancer patient.

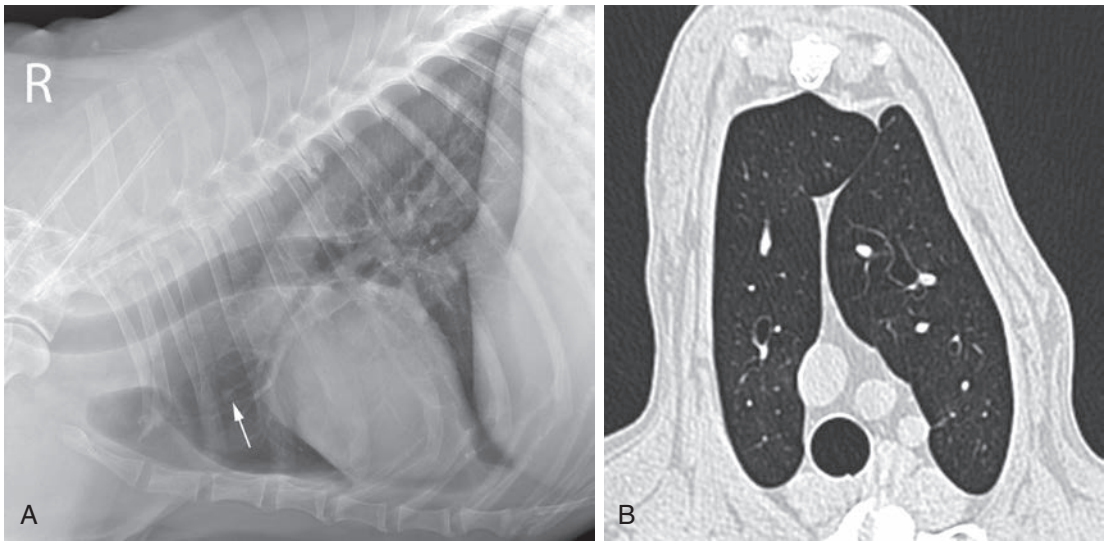
Imaging Modalities

Radiography

Conventional radiography has historically been the primary modality for assessment of cancer patients because it is readily available at a low cost, but it is gradually being replaced with other modalities that are more sensitive, specific, and becoming more readily available.

With few exceptions, radiography is a screening test rather than providing a definitive diagnosis. The most common application for radiographs is screening for pulmonary metastasis. In dogs and cats, thoracic radiographs are obtained with the patient in a recumbent position, and this results in atelectasis of the dependent lung. Three views (left and right lateral and dorsoventral or ventrodorsal) are recommended because this position-dependent atelectasis can reduce lesion conspicuity. The diagnosis would change in 12% to 15% of patients when only two views are obtained, with left lateral and ventrodorsal views being less sensitive than right lateral and ventrodorsal views.[3–5] Although the sensitivity of radiographs is lower than that of CT for the detection of pulmonary metastasis, they will likely continue to remain the initial screening test because of the low cost and high availability (Fig. 6.1).[6–8]

Radiography is also the primary method for the diagnosis and monitoring of dogs and cats with tumors of the appendicular skeleton (Fig. 6.2).[9] Detection of an aggressive bone lesion on radiographs is not definitive for neoplasia, but signalment, history, clinical signs, and travel history can help differentiate neoplasia from infectious causes.[9] Although radiographs remain the primary diagnostic tool for appendicular bone tumors, CT and MRI are more accurate for determining tumor margins, which is necessary to optimize outcomes when using advanced treatment techniques such as limb-sparing surgery or stereotactic radiosurgery.[10]



Limitations of radiography include superimposition of overlying structures and the relatively limited contrast resolution.[8] Radiology software exists that can suppress overlying bony structures using advanced processing and pattern recognition algorithms, which significantly increase sensitivity for detection of lung nodules[11]; however, they are of limited availability in veterinary medicine, and other imaging modalities have been used to overcome this limitation. When the preferred imaging modality is not immediately available, radiographs can be useful in detecting masses in other body regions (e.g., abdomen) as well. Radiographs may provide evidence that a mass is present such that abdominal ultrasound, CT, or MRI can then be performed to detect the origin of the mass.

Ultrasonography

Ultrasound is widely available and relatively inexpensive, resulting in widespread usage as a first-line diagnostic modality for a variety of diseases, including cancer diagnosis and staging and for restaging or evaluating response to treatment. The ability to evaluate the internal structure of organs and to better evaluate body cavities in the presence of effusion has resulted in ultrasound replacing survey and contrast radiographs as the primary method of abdominal imaging.

Ultrasound is very good for identifying and localizing lesions, but the sonographic appearance may not be specific to the nature of the lesion.[12–21] The lack of specificity is more apparent when assessing multicentric diseases, such as lymphoma and mast cell tumor, where the sonographic appearances are variable and a

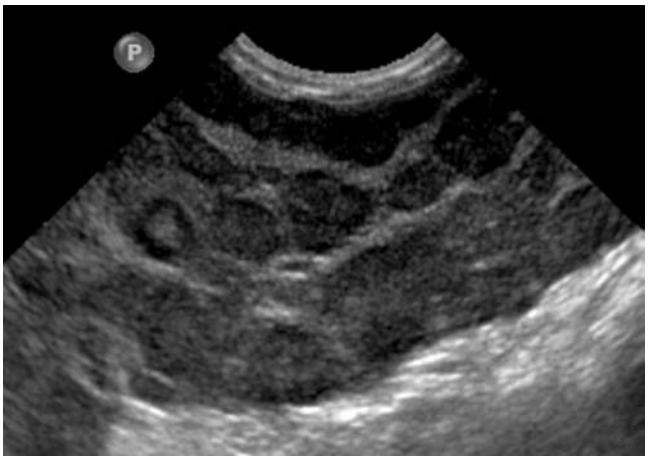
• **Fig. 6.1** A right lateral radiograph of the thorax (A) shows a pulmonary nodule in the ventral aspect of the second intercostal space *(arrow)*. Transverse CT image of the thorax at the same level (B) showed no evidence of the nodule, indicating this was a summation artifact on the radiograph resulting in a false-positive test for pulmonary metastasis.



• **Fig. 6.2** Orthogonal radiographs of the stifle demonstrate an aggressive bone lesion in the proximal tibia that is characterized by moth-eaten bone lysis and cortical loss. The primary modality for the initial assessment of bone tumors remains radiography.

normal sonographic appearance does not necessarily exclude the presence of disease.[2,19] This limitation is overcome by the use of ultrasound-guided sampling techniques. Abdominal ultrasonography is also useful for the detection of comorbidities that may have an effect on treatment options for cancer patients.[2,19,20]

Although ultrasound findings are generally not specific, there are patterns that may be more indicative of neoplasia. Target lesions and focal nodules with a hyperechoic central region and hypoechoic rim have been associated with a higher predictive value for malignant neoplasia (Fig. 6.3). The positive-predictive value for malignancy is 74% when a single nodule is identified in either liver or spleen, and 81% when multiple target lesions are identified in one organ.[17] However, owing to the small sample size in this study, positive-predictive values may be overestimated. In dogs and cats with gastrointestinal disease, the loss of normal wall layering is strongly predicative of neoplasia compared with nonfungal inflammatory diseases.[15,22] Connecting peritoneal masses may be indicative of carcinomatosis in cats (Fig. 6.4).[23] Hypoechoic subcapsular thickening of the kidneys is associated with renal lymphoma in cats.[24] Ultrasound can also increase the suspicion of multiple organ involvement or detect intraabdominal metastases. This information will help guide sampling recommendations and may affect differential diagnoses and treatment decisions.

Color Doppler can be used to assess vascular invasion and the vascularity of masses (Fig. 6.5). Color Doppler displays the mean flow velocity and directional information using a color map, and this allows for visualization of smaller blood vessels and overall vascular pattern and distribution.[25] Spectral Doppler is required to determine maximum flow velocity, but this is more technically

VetBooks.ir

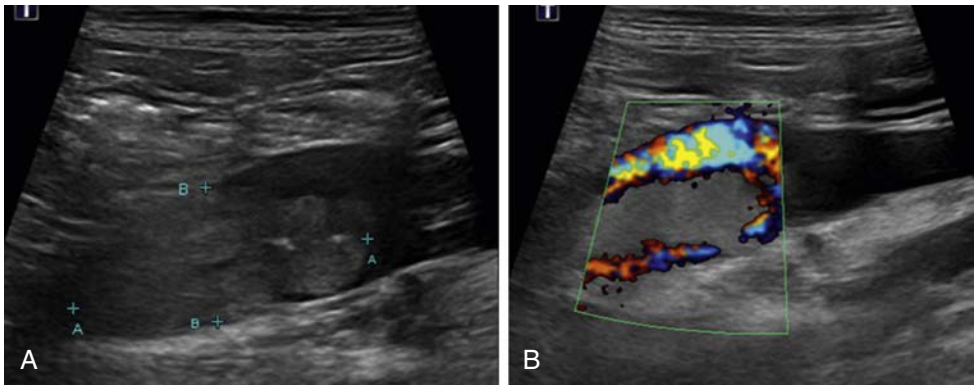
• **Fig. 6.3** A transverse ultrasound image of the liver demonstrates multifocal nodules, several of which have a target appearance with a central hyperechoic focus and a hypoechoic rim. Target lesions are associated with a higher positive-predicative value for malignant nodules than other sonographic patterns.

• **Fig. 6.4** A sagittal image of the midabdomen shows coalescing hypoechoic nodules within hyperechoic mesenteric fat and a moderate amount of echogenic abdominal fluid. These findings are strongly suggestive of carcinomatosis.

challenging. Vascular patterns may also be helpful in diagnosing malignant lesions. Owing to neovascularization of tumors, their blood supply tends to be more tortuous, with higher velocities than noted in normal tissue.[26–29] Ultrasound can also detect tumor invasion into local vasculature, which may influence the ranking of differential diagnoses and treatment decisions (e.g., adrenal mass invasion into the caudal vena cava) (Fig. 6.5).

Contrast-enhanced ultrasound improves detection of small blood vessels compared with power Doppler imaging because of reduced motion artifact and allows for evaluation of tissue perfusion.[30] First-generation contrast agents contained air within microbubbles, whereas second-generation agents contain perfluorocarbon or sulfur hexafluoride.[31] The microbubbles in second-generation ultrasound contrast agents are generally <2.5 μm, resulting in an intravascular agent that has a flow pattern similar to that of red blood cells and therefore can demonstrate the presence of blood vessels and can assess arterial, portal, and late phases in the liver.[31] There is some evidence that vascular tortuosity can be used to predict malignancy, but this finding is not consistent.[32,33] In one study of liver masses, arterial hypervascularity was noted in the majority of hepatocellular carcinoma masses, but not other benign or malignant hepatic masses.[34] Multiphase evaluation of enhancement patterns with contrast-enhanced ultrasound can be used to differentiate between benign and malignant lesions. In both the liver and spleen, a nodule that remains hypoechoic in both the early vascular phase (5–10 seconds after injection) and late vascular phase (25–30 seconds after injection) is more commonly seen with malignant lesions whereas benign nodules most often become isoechoic to the surrounding parenchyma in both phases.[21,32,33,35,36] However, this distinction is less clear for renal lesions.[37] This differential contrast pattern has also been shown to increase the sensitivity for the diagnosis of liver metastasis.[31]

Elastography uses ultrasound to assess the relative hardness of tissues. This is an emerging technology in both human and veterinary medicine to increase the specificity of ultrasound for the diagnosis of various disease processes. In strain elastography, external pressure is applied with the transducer and the mechanical properties of the tissues are illustrated with a color map; hard tissues are typically displayed in yellow to red colors and soft tissues in green to blue colors.[38] Tissue stiffness tends to increase with disease.[39] Limitations include susceptibility to operator variability and the need to compare tissues with adjacent structures.[40] More research is required in this area to determine the utility of elastography in oncologic imaging.



Ultrasound-guided tissue sampling is fast and safe. Image guidance allows for direct needle placement in the lesion of interest, thus minimizing patient risk and increasing diagnostic accuracy.[41,42] Serious complications from image-guided biopsies are uncommon, but include needle-tract seeding of transitional cell carcinoma.[43] The most common complications of percutaneous lung biopsy are pulmonary hemorrhage and pneumothorax, but these are typically minor and self-limiting. The risk of these complications is higher when the needle passes through aerated lung before entering the lesion.[44,45] Hemorrhage associated with ultrasound guided sampling occurs in fewer than 6% of cases and is self-limiting in all but 1%.[46,47]

Ultrasound accuracy is dependent on the experience of the operator and quality of the images. CT and MRI provide advantages when evaluating abdominal disease because obtaining complete high-quality images is less user dependent and images can be reviewed by a radiologist more confidently. In addition, CT and MRI provide advantages in evaluating larger abdomens, complex or extensive masses, masses of undetermined origin, and areas difficult to assess with ultrasound, such as the cranial-dorsal abdomen, pelvic region, and retroperitoneal space.

Computed Tomography

In veterinary medicine, CT is still typically performed under general anesthesia, but with the increasing availability of faster multislice scanners more CT scans are being performed with sedation alone. This is particularly true for thoracic CTs to screen for pulmonary metastasis. This can also be facilitated with the use of Plexiglas tubes for restraint.[48] There are clear advantages in terms of speed and cost when anesthesia is not used, but pulmonary atelectasis can still occur, particularly if the patient was sedated, and this may have an effect on interpretation of thoracic CTs.[48]

The basic principles of CT will be discussed, but more detailed descriptions of CT protocols can be found elsewhere.[49] Slice thickness is an important consideration, as it affects both image

• **Fig. 6.5** Ultrasound images from a 10-year-old female spayed mixed breed dog. (A) A soft tissue mass is originating from the left adrenal gland (not visible) and invading into the caudal vena cava. (B) Color Doppler evaluation of the caudal vena cava with evidence of blood flow around the mass, but approximately 60% occlusion of the vessel by the mass and associated thrombus.

noise and partial volume averaging artifacts. Partial volume averaging can result in blurry margins, false attenuation measurements (Hounsfield units), and pseudolesions. Thin-slice images will have increased noise that can be offset by increasing mAs setting. This will improve image quality, but will also increase the radiation dose to the patient. Thin-slice imaging is more challenging on older scanners, as the heat load on the x-ray tube can slow the scan time, but newer generation CT scanners, particularly multislice helical scanners, have largely overcome the challenges, allowing large areas to be scanned quickly. The scan field of view (SFOV) is the area from which the image can be reconstructed. Because the reconstruction matrix size is constant, keeping the SFOV only as large as the anatomy to be imaged will improve spatial resolution. This is not critical for the majority of body parts, but a large SFOV used with whole-body CT can result in decreased resolution.

Although CT has decreased spatial resolution compared with radiographs, the reduced anatomic superimposition and superior contrast resolution result in CT being more sensitive to detect lesions throughout the body. For assessment of noncardiac thoracic disease, CT provides more information on the presence, location, and extent of disease in the majority of patients compared with survey radiographs.[6,50] Accuracy for detection of tracheobronchial lymphadenopathy is 93% for CT and 57% for radiographs, with a sensitivity of 83% and 0% respectively (using size, shape, and contrast enhancement on CT).[4] CT is also being used more frequently to evaluate the abdomen for primary and metastatic disease. The ability to image pelvic canal contents and visualize anatomy deep to gas-filled structures improves the sensitivity for detection of lesions.[51] For example, CT evaluation of insulinomas is superior to ultrasound, detection of sacral lymph node (LN) metastasis within the pelvic canal in dogs with apocrine gland anal sac adenocarcinomas is superior with CT compared with ultrasound, and the margins of soft tissue tumors, such as sarcomas and lipomas, are better delineated with contrast enhancement.[51–55] Tumors of the nasal cavity and head and neck have superior delineation on CT compared with radiographs or ultrasound.[53]

CT is also superior to palpation in determining tumor extent, as has been shown in cats with injection-site sarcomas,[54] and this is important implications in defining the aggressiveness of treatment with surgery and/or radiation therapy (RT). However, it is not possible to differentiate between peritumoral inflammation and local invasion, so more normal tissue may be included in the treatment plan than necessary.[55,56] Detection of local tumor invasion is an important finding on CT and is evident by loss of adjacent fascial planes and vascular filling defects.[56] Large masses can cause compression of adjacent structures and, in these cases, it can be difficult to differentiate compression from invasion.[57] Although imaging characteristics are rarely pathognomonic for a specific tumor type, the CT appearance of fatty masses is highly predictive of lipoma, infiltrative lipoma, and liposarcoma.[58] Three-dimensional reconstructions are also very valuable for assessing skeletal structures and surgical planning (Fig. 6.6).

• **Fig. 6.6** A 3D reconstruction of a dog with a skull tumor can aid in assessment of tumor extension and surgical or radiation planning.

CT is more sensitive than radiographs in the detection of pulmonary metastasis and allows for detection of nodules as small as 1 mm in diameter compared with 7 to 9 mm for radiography.[7,8,50] In people, the high sensitivity of CT also results in detection of more benign lesions (up to 80%), with nodules <5 mm infrequently developing into metastasis.[59,60] The incidence of benign pulmonary nodules has not been fully investigated in veterinary medicine, but all nodules detected on CT developed into radiographically visible metastasis in one study of osteosarcoma in dogs.[50]

Ground-glass pulmonary lesions, also referred to as subsolid nodules, are characterized by an increased density that does not

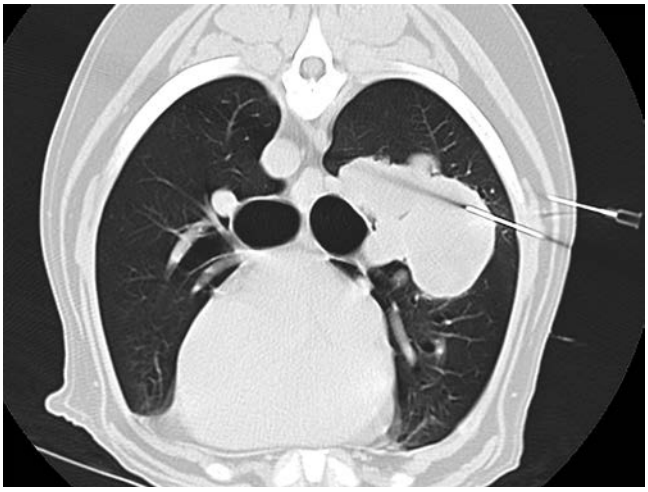
• **Fig. 6.7** Transverse computed tomography of the caudal thorax shows a focal ground-glass nodule *(arrow)* in the right caudal lung lobe. Ground-glass pulmonary lesions, also referred to as subsolid nodules, are characterized by an increased density that does not obscure the underlying pulmonary structures.

• **Fig. 6.8** A 3D volume rendering of computed tomography angiography of a thyroid mass shows the feeding blood vessels and highly vascular nature of the mass, consistent with a thyroid carcinoma.

obscure the underlying pulmonary structures (Fig. 6.7).[61] These nodules may be pure or mixed (containing some solid components). These lesions are frequently detected in people being staged for pulmonary metastasis, with up to 70% being caused by transient inflammation or hemorrhage.[62] Pure ground-glass lesions >8 mm have a high probability of malignancy, whereas those <4 mm are considered benign.[63] Lesions >22 mm, mixed lesions (partially ground-glass and partially solid), mixed lesions where the solid component grows to >2 mm in maximal diameter, and pure ground-glass lesions progressing to mixed lesions have a higher risk of being malignant.[61–63] Ground-glass lesions have not been fully investigated in veterinary medicine, but 75% of dogs with ground-glass lesions went on to develop radiographically visible metastasis in one pilot study.[50] To clearly discern the characteristics of pulmonary nodules, thin-slice techniques are required to avoid partial volume averaging, as this artifact can result in pure ground-glass nodules appearing to have a solid central component.[64]

Because CT has higher sensitivity to lesion detection than ultrasonography and radiography, there is increasing use of whole-body CT for cancer staging. In tumors with high metastatic potential, CT may detect muscular metastasis that may have been otherwise missed.[65] Whole-body CT for dogs with osteosarcoma has not been shown to be superior to radiography or nuclear scintigraphy for the detection bone metastasis, but concurrent neoplasia has been detected, and this may alter treatment options and prognosis.[50,66] Detection of metastatic and concurrent disease may be better with newer scanners and higher resolution reformatted images.

CT angiography (CTA) is being performed routinely to assess tumor vascularity, perfusion, and vascular invasion (Fig. 6.8). Multiphase CTA can improve detection of small tumors, such as insulinomas, and may be helpful in differentiating between benign and malignant lesions.[67,68] CTA is also advantageous in evaluating patients with pericardial effusion and thus enabling the detection of cardiac masses.[69] CTA may assist in predicting malignancy of hepatic and splenic masses and nodules, although more research is needed.[70] CTA also provides more accurate assessment of cranial mediastinal and thyroid masses, which may assist in the determining the preferred treatment options for these patients.[71,72]



CT-guided biopsy is useful for the sampling of intracavitary lesions, such as pulmonary nodules, not readily identified with ultrasound. Manual CT-guided biopsy is performed using the internal laser of the scanner to orient to the transverse plane that includes the lesion of interest. Needle placement is assisted by radiopaque markers in bands in the sagittal or parasagittal plane. Barium can be used to create radiopaque bands, but commercially available opaque grids are also available that can be adhered to the skin (Fig. 6.9).[73]

Although MRI provides superior contrast resolution, CT is used for RT planning because it provides a map of electron density information that is used by most planning computers to calculate dose distribution.[74] Fusion of CT and MR images can aid in RT planning by maximizing both the spatial resolution of CT and the contrast resolution of MR. In human cancer therapy, CT combined with PET (PET/CT) is also used for RT planning, particularly with pulmonary lesions as PET/CT can differentiate between tumor and atelectic lung, which is not always possible with CT alone.[74]

Magnetic Resonance Imaging

MRI provides superior soft tissue resolution to CT and is highly sensitive to detection of pathology. MRI is generally considered superior to CT for neurologic and soft tissue imaging, but a study of feline injection-site sarcomas showed no difference in the evaluation of peritumoral lesions between CT and MRI.[75] MRI is also excellent for detecting infiltrative diseases of the musculoskeletal system, including accurate determination of the local extent of appendicular osteosarcoma lesions.[10,76]

With MRI, numerous imaging sequences are used to provide complementary information. T1-weighted images provide good spatial resolution to assess anatomy and are used with contrast

• **Fig. 6.9** Computed tomography (CT)-guided biopsy of the lung mass was facilitated by placement of a hypodermic needle into the body wall along the laser line that corresponded with the location of the mass. After placement of the marker needle, CT images were obtained to determine the best placement of the biopsy needle relative to the marker needle. This image shows the biopsy needle being placed ventral to the marker needle and perpendicular to the body wall. The tip of the needle is visible in the pulmonary mass.

to show vascular enhancement of tissues. T2-weighted images are water-weighted sequences that provide high-contrast images of water-dense pathology. On both T1- and T2-fast spin echo sequences, fat has a high signal intensity (bright) that can mask the margins of the pathology. The use of fat suppression techniques on T1 postcontrast and T2 images (e.g., Short-tau Inversion Recovery [STIR]) is important in cancer imaging to allow for clear assessment of the extent of pathology (Fig. 6.10). Diffusion-weighted imaging measures the random Brownian motion of water molecules in a voxel of tissue. Highly cellular tissues and swollen cells have restricted motion of water that can be detected with diffusion-weighted imaging.[77] Although this has been evaluated in humans, there is limited information on the effectiveness in veterinary medicine. Veterinary studies have found diffusion-weighted images and apparent diffusion coefficient maps helpful in diagnosing acute infarcts, which is hyperintense on diffusion-weighted images and hypointense on apparent diffusion coefficient maps.[78,79] However, in one study of 37 dogs, there was a wide range of apparent diffusion coefficient distribution within disease groups and significant overlap between groups when evaluating multiple tumor types, inflammatory disease, and infarcts.[80]

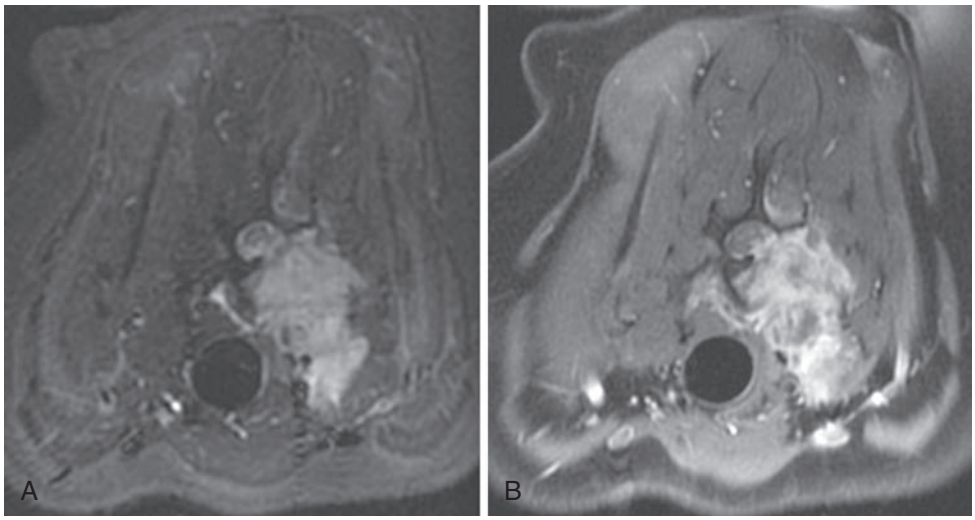
Because of the high contrast resolution, whole-body MRI has also been investigated in cancer patients. Whole-body diffusion-weighted MRI provides similar results to PET/CT in people with diffuse B-cell lymphoma.[81] In veterinary medicine, a protocol using large overlapping imaging fields and focused high-contrast sequences showed whole-body MRI can be performed in a reasonable time with sufficient quality to identify known lesions, but images were suboptimal for the skeletal system.[82] Further investigation to optimize protocols for veterinary patients is necessary.

Recently hepatocyte-specific MR contrast agents, such as gadoxetate disodium (Gd-EOB-DTPA), have been evaluated.[83,84] These agents accumulate in normal hepatocytes, potentially allowing for the differentiation between benign liver nodules and metastatic lesions, and aid in identification of primary liver tumors on delayed imaging.[84–86] These agents cause shortening of the T1 and T2 relaxation times, resulting in increased T1 signal intensity compared with tissues that do not contain normal hepatocytes, allowing for the differentiation between hyperplastic and malignant nodules.[87]

Nuclear Scintigraphy

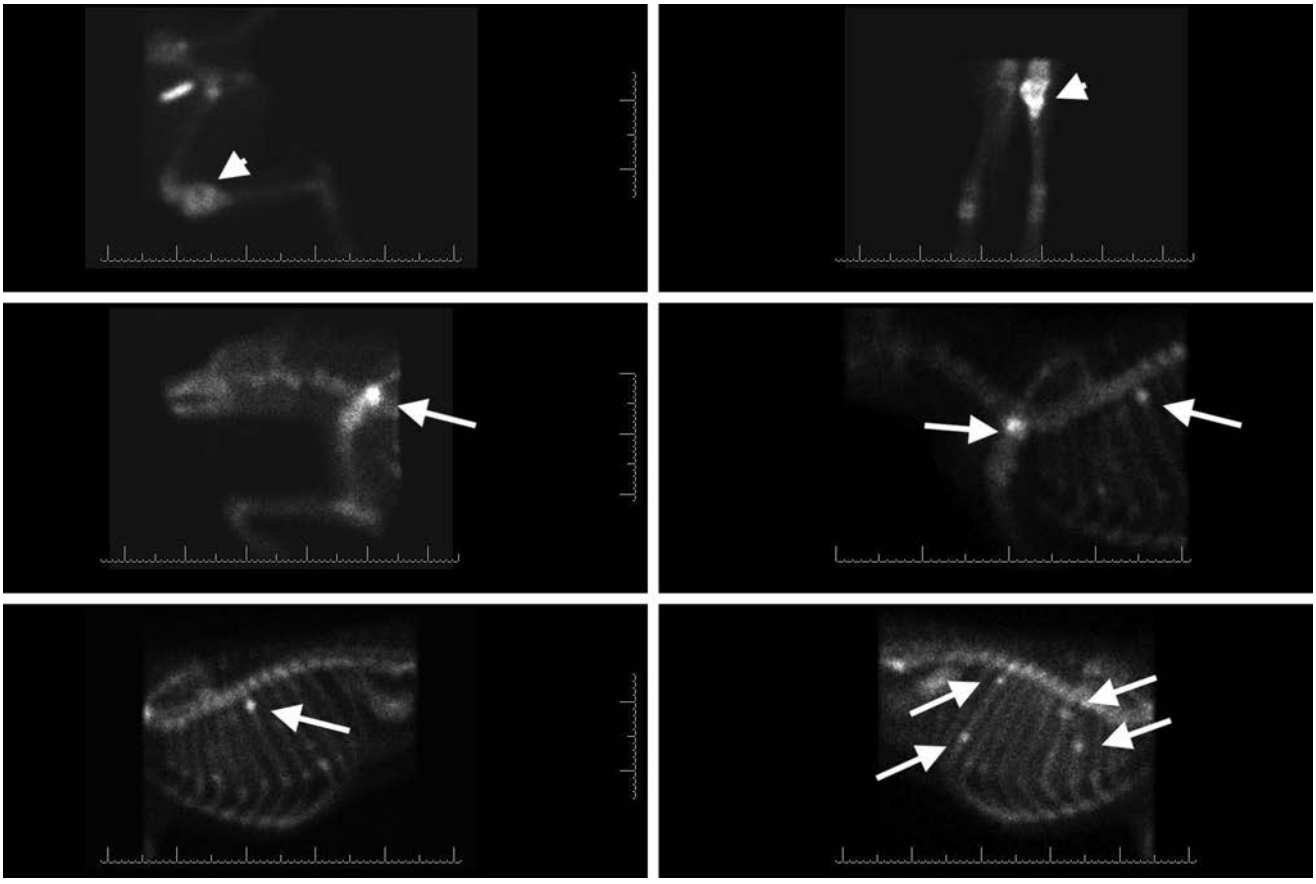
Nuclear medicine uses radiopharmaceuticals that accumulate in areas of interest based on physiologic processes. The low spatial resolution of these images precludes anatomic detail, but the functional information provided is advantageous in differentiating between occult and active disease processes. Scintigraphy lacks specificity, so it cannot differentiate between benign inflammatory lesions and malignant lesions. The two studies most commonly performed in cancer patents are thyroid and bone scintigraphy.

Bone scintigraphy provides physiologic information by detecting areas of increased bone activity (Fig. 6.11). Scintigraphy is highly sensitive for increased metabolic activity, but is not specific, and this can lead to false-positive diagnoses.[88,89] To reduce the risk of false-positive diagnoses, the use of supplementary imaging modalities, such as radiography, of suspected bone lesions is recommended.[50] Radiographs require at least a 30% to 50% change in mineral density to be detected, which means that early or small lesions may be missed on radiographs but detected with more sensitive CT scans.[50,90]



Thyroid scintigraphy is used to evaluate patients with ventral cervical masses. Thyroid scintigraphy can be used for the diagnosis of adenomatous hyperplasia in cats and can raise suspicion for thyroid carcinoma in cats and dogs. In cats, thyroid carcinoma typically has a large amount of hyperfunctional tissue, and ectopic hyperfunctional tissue may be present extending into the thorax (Fig. 6.12).[91] Thyroid carcinomas in dogs and cats are typically heterogeneous with irregular margins.[91,92] Imaging is typically performed with 99m-technetium pertechnetate ($^{99m}TcO_4^-$ There is a superscript negative sign beside the O and over the 4.) because of its availability and cost effectiveness.

Renal scintigraphy can be performed when nephrectomy is being considered for cats and dogs with a renal tumor or in cases in which adrenal tumors have invaded the renal vessels or compromised the adjacent kidney. A nuclear medicine glomerular filtration rate (GFR) study provides an assessment of global GFR, as well and right and left kidney GFR, so that the function of the single remaining kidney can be predicted.[93]

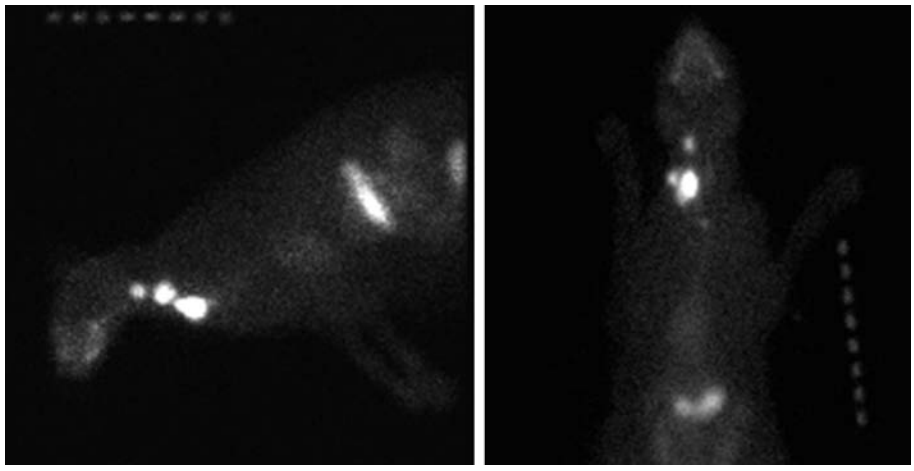


PET/CT or PET/MR is often preferred to scintigraphy to overcome some of the spatial limitations of nuclear scintigraphy.

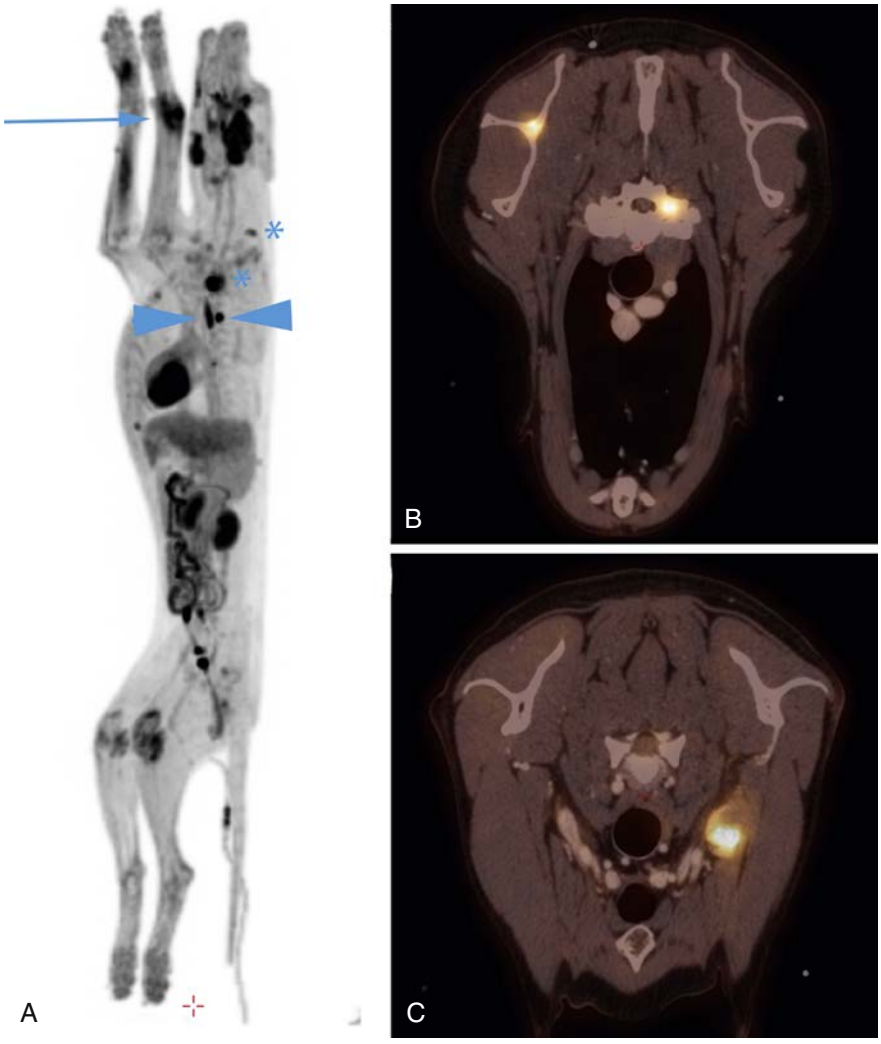
Positron Emission Tomography/Computed Tomography (PET/CT) and MRI (PET/MR)

PET/CT and/or PET/MR combines the functional imaging of a nuclear medicine study and the high spatial resolution of CT and MR. The most commonly used radiopharmaceutical with PET imaging is the glucose analog 2-deoxy-2-^{18}F-fluorodeoxyglucose (FDG) bound to the positron emitter fluorine-18 (F-18). As a glucose analog, FDG is transported into hypermetabolic cells, where it becomes trapped after phosphorylation by hexokinase, as it is not a suitable substrate for glucose-6-phosphatase.[94] The F-18 portion of the radiopharmaceutical allows for it to be imaged, as the positrons emitted create two annihilation photons that travel 180 degrees from each other. These photons are detected by the PET detector ring.[94] Both tumors and inflammation result in increased glucose metabolism; therefore detection of a hypermetabolic lesion is not definitively indicative of neoplasia.

• **Fig. 6.10** A transverse Short-T1 Inversion Recovery (STIR) image (A) and T1 postcontrast image with fat suppression (B) shows the delineation of a peripheral nerve sheath tumor.



• **Fig. 6.11** Bone phase scintigraphy of the pelvic limbs *(top images)*, thoracic limbs and head *(middle images)*, and thorax *(bottom images)* show multifocal areas of increased radiopharmaceutical uptake *(hot spots)* in the ribs and scapula, consistent with bone metastasis *(arrows)*. The primary bone tumor is in the proximal tibia *(arrowhead)*.



However, F-18 FDG is the most commonly used PET radiopharmaceutical in human and veterinary medicine for detecting and staging cancer and evaluating response to treatment. Performing whole-body PET/CT provides additional information compared with traditional staging with thoracic radiographs and abdominal ultrasound; and, because of the metabolic component, can detect metastatic lesions before they would be detected with routine imaging, including CT alone (Fig. 6.13).

Other PET agents have been investigated in veterinary medicine. Labeling F-18 with sodium fluoride (NaF) results in a

• **Fig. 6.14** A dorsal plane reconstruction of the head obtained 3 minutes after injection of a contrast medium around a rostral right mandibular mass demonstrates multiple lymphatic vessels draining into the right mandibular lymph node *(arrow)* identifying this as the sentinel lymph node. It is important to note that further cytologic or histopathologic assessment of the sentinel lymph node is required to determine whether there is evidence of metastasis within this lymph node.

bone-specific radiopharmaceutical that enables generation of highly detailed skeletal images that are superior for detection of bone metastasis compared with planar or single-photon emission computerized tomography (SPECT) imaging with Tc99m-methyl diphosphonate (Tc99m-MDP).[95] To date, the only reported use of NaF F-18 is in equine orthopedic disease and in four normal immature dogs.[96,97] Labeling F-18 with the thymidine analog FLT (3′-deoxy-3′[^{18}F]fluorothymidine) allows the imaging of proliferating tissues, including neoplastic tissues. FLT reflects DNA synthesis and was successful in detecting initial disease, response to therapy, and predicting relapse in a small group of dogs with lymphoma.[98] PET/CT functional imaging of tumor hypoxia using dogs with spontaneously arising nasal tumors injected with copper(II)-diacetyl-bis(N^4-methylthiosemicarbazone) (Cu-ATSM) has also been performed and evaluated for radiation boost planning.[99]

The baseline metabolic rate of normal tissues must be known to accurately interpret PET images. The standardized uptake value (SUV) is a semiquantitative measure of FDG uptake that is directly proportional to the metabolic activity.[100] Increased SUV measurement correlates to subjective increased hypermetabolic activity visible on PET images. No specific cut-offs have been established for malignancy in veterinary medicine, whereas in human medicine an SUV_{max} >2.5 is predictive of malignancy in patients with solitary pulmonary nodules.[101] However, multiple studies have found that visual interpretation by an experienced reader is equivalent to or superior compared with SUV measurements.[102–104]

Multiple tumor types in dogs and cats have been shown to be hypermetabolic on PET or PET/CT, including but not limited to lymphoma, mast cell tumor, osteosarcoma, oral squamous cell carcinoma, mammary carcinoma, fibrosarcoma, and primary lung tumors.[98,105–111] F-18 FDG was shown to correlate with grade of mast cell tumor in a small group of dogs.[112] Further specific uses of FDG and use of targeted agents will increase the usefulness of PET/CT in the future. The utility of PET/MRI in veterinary medicine is undergoing investigation.

Lymph Node Assessment

Assessing LNs for evidence of metastasis is an important part of staging cancer patients. B-mode ultrasound, CT, and MRI provide information on the size, shape, and echogenicity of LNs, providing a good initial assessment provided the LN is accessible. For example, only the medial iliac and cranial aspect of the internal iliac LNs are typically visible with abdominal ultrasound; as a result, ultrasonography is a less sensitive imaging modality than cross-sectional imaging techniques, such as CT and MRI, for the detection of nodal metastasis from perineal tumors where the sacral node is likely to be the draining node (e.g., apocrine gland anal sac adenocarcinomas).[52,113]

Using absolute LN size to determine malignancy can be problematic because of the substantial variation in dog breed sizes and the fact that metastatic LNs are not always enlarged. Many studies have looked at normalizing LN size to account for this variation, but with variable success.[114,115] CT assessment of sternal LNs suggest that a ratio of sternal LN height to the height of the second sternebra of >1 and a precontrast attenuation of 37.5 HU or greater is highly predictive of malignancy.[115] The presence of micrometastasis is also common and may not result in an absolute change in LN size.[4] A change in the shape of an LN from oval to round, as indicated by a short axis-to-long axis ratio of >0.7, and loss of definition of the LN hilus are seen more frequently with malignant than reactive LNs.[116,117] The signal characteristics of LNs should also be considered as, in combination with other parameters, this may be helpful in differentiating benign from malignant LNs. On ultrasound, both reactive and malignant LNs tend to be hypoechoic and may have a heterogeneous echogenicity, but there is no consistent pattern to differentiate these processes. [116,118] MRI perinodal contrast enhancement is seen more commonly in cats and dogs with reactive lymphadenitis.[119]

Metastatic disease to the LNs often alters the vascularity and these changes may be evident with Doppler ultrasonography. The blood supply to normal LNs is predominantly centered at the hilus, whereas malignant LNs trend to having a peripheral or mixed peripheral and hilar distribution with a greater number of vessels.[26,117,118] Displacement of the central hilar vessels, more than one central vessel, pericapsular vessels, and peripheral vessels that do not connect with the central vessel have all been associated with malignancy.[29] Vascular resistance may increase in malignant LNs as a result of vascular compression from tumor cells, and this can be detected by measuring resistive index and pulsatility index.[120] Increases in these parameters are suggestive of malignancy when seen in combination with other sonographic findings.[26,116] Fundamentally, however, there is no one sonographic measurement that is predictive of malignancy; using a combination of size, shape, and vascularity of the LN, in addition to fine-needle aspirate cytology of the LN, is recommended to increase the predictive value for detection of metastatic disease.[120]

Detection of the sentinel or draining LN is very important in the clinical staging and determining the treatment options and prognosis for animals and people with cancer (see Chapter 9). Assessment of LNs is based on size, shape, and contrast enhancement, but there is wide variation in accuracy using these parameters due in part to the subjectivity of evaluation.[4,118]

VetBooks.ir

Micrometastasis may also be present, and this rarely alters the size or results in contrast enhancement of LNs, resulting in a false-negative diagnosis. In addition, contrast enhancement on CT may be a result of inflammation rather than metastatic disease, resulting in a false-positive diagnosis.[4] Considerable attention has been given to the evaluation of LNs with a variety of imaging modalities to determine whether there are characteristics that are specific to metastasis.[4,6]

Direct lymphangiography (injection of contrast medium into an LN or lymphatic vessel) and indirect lymphangiography (injection of contrast medium into the peritumoral tissues) can be used to image the lymphatic beds and identify the sentinel LN (Fig. 6.14).[121] Use of iodized oil contrast medium results in retention of the agent in the LN for up to 2 months after injection, which can aid in follow-up LN assessment, where contrast voids are consistent with new metastatic lesions, and make the LNs more conspicuous on radiation port films, which aids in RT planning.[121] Indirect lymphangiography is used to map the draining LNs from a superficial tumor.[122–125] A heterogeneous pattern of LN enhancement may also predict malignancy, because this pattern may be caused by loss of normal architecture secondary to tumor infiltration.[123] Sentinel LN mapping can also be performed with lymphoscintigraphy. Lymphatic drainage can be detected intraoperatively with the use of a gamma camera, hand-held gamma probe, and/or peritumoral injection of blue dyes.[126]

Diagnostic Cytopathology in Clinical Oncology

KRISTEN R. FRIEDRICHS AND KAREN M. YOUNG

In veterinary oncology, cytologic evaluation plays several important roles that aid in clinical decision making, including making a preliminary or definitive diagnosis, planning diagnostic and treatment strategies, determining prognosis through staging, detecting recurrence, and monitoring response to therapy. An understanding of the advantages and limitations of cytologic evaluation is necessary to use this diagnostic modality effectively in clinical oncology.

Advantages of cytologic evaluation include the ability to evaluate the morphologic appearance of individual cells, the relatively low risk of procedures to the patient, the lower cost compared with surgical biopsy, and the speed with which results can be obtained. Cytologic evaluation also has several limitations. The amount of tissue sampled is small compared with that obtained from a surgical biopsy; therefore cytologic specimens may not be fully representative of the lesion. Sample quality may be poor because of factors intrinsic to the lesion or poor collection technique. Importantly, the inability to evaluate architectural relationships among cells in cytologic specimens may prevent distinction between reactive and neoplastic processes or between benign and malignant tumors. Examination of histologic samples, in which tissue architecture is preserved, may be required to make a definitive diagnosis of neoplasia, determine tumor type, and assess the extent of the lesion, including metastasis. Even then, ancillary tests such as immunohistochemical staining or tests for clonality may be required. Often, cytologic evaluation precedes a surgical biopsy and provides information that assists in formulating subsequent diagnostic and treatment procedures.

Some tumors, such as lymphoma, may often be definitively diagnosed and staged using cytologic evaluation exclusively, and treatment can be initiated without the need to collect histologic specimens. For other tumors, such as well-differentiated hepatocellular carcinoma, cytologic examination permits formulation of a list of differential diagnoses, and histologic evaluation must be performed for definitive diagnosis. At a minimum, categorization of a tumor as an epithelial, mesenchymal, or discrete round cell tumor often can be determined cytologically; this may be sufficient for initial discussions with the owner about diagnosis and prognosis. Staging the malignancy, monitoring therapy, and detecting recurrence using cytologic evaluation are more easily accomplished once a definitive diagnosis has been made and cytomorphologic features of the tumor described. Staging procedures often include cytologic evaluation of regional lymph nodes (LNs). Importantly, LNs containing metastatic disease are not always enlarged, and thus normal-sized LNs should be sampled. For detection of solid tumor metastasis to regional LNs, fine-needle aspiration (FNA) is highly sensitive and specific[1]; however, metastatic disease may be present even if tumor cells are not identified in a sample collected from an LN; in this case, histologic evaluation may be required.

Sample Collection

Proper collection and preparation techniques are prerequisites to obtaining diagnostic samples of high quality. Supplies necessary for collecting cytologic samples from a variety of tissues, body cavities, and mucosal surfaces are available in most clinics. These include hypodermic needles and syringes, scalpel blades and handles, propylene urinary catheters, bone marrow aspiration needles, cotton swabs, clean glass slides, marking pencils, and collection vials and tubes (tubes with ethylenediaminetetraacetic acid [EDTA] and plain sterile tubes). For aspiration of internal lesions, obtained by guidance with ultrasonography or computed tomography (CT), longer spinal needles and extension sets (used to connect the spinal needle to the aspirating syringe) are useful. Cytologic specimens also can be made from tissues collected during surgical biopsy (see Chapter 9). All supplies should be assembled in one location for ready access. Although life-threatening situations are rarely encountered when collecting cytologic specimens, supplies and medications should be available to control bleeding and to treat anaphylaxis. The latter can occur rarely when aspirating mast cell tumors (MCTs) because of release of histamine.

For external or easily accessible lesions, such as cutaneous and subcutaneous masses or enlarged LNs, aspiration simply requires stabilization of the mass and consideration of underlying structures, such as large vessels and nerves. Some large abdominal masses can be aspirated blindly if they can be stabilized and if they are unlikely to be highly vascular or an abscess, aspiration of which may result in hemorrhage or dissemination of infection, respectively. Aspiration of intrathoracic and intraabdominal lesions is typically accomplished with guidance by imaging, either by ultrasonography or by CT, to aid in targeting the lesion and avoiding large vessels and other sensitive areas. Defects in cortical bone also

VetBooks.ir

can be identified with imaging, which can facilitate needle placement for aspiration of bone lesions. Cavity effusions are collected easily without imaging if fluid volume is significant; however, imaging can target smaller accumulations of fluid and provide a measure of safety. If there is particular concern for hemorrhage after aspiration, imaging can be repeated to look for evidence of bleeding at the aspiration site. Collection of cytologic specimens from the eye, brain, and lung requires special consideration and expertise.

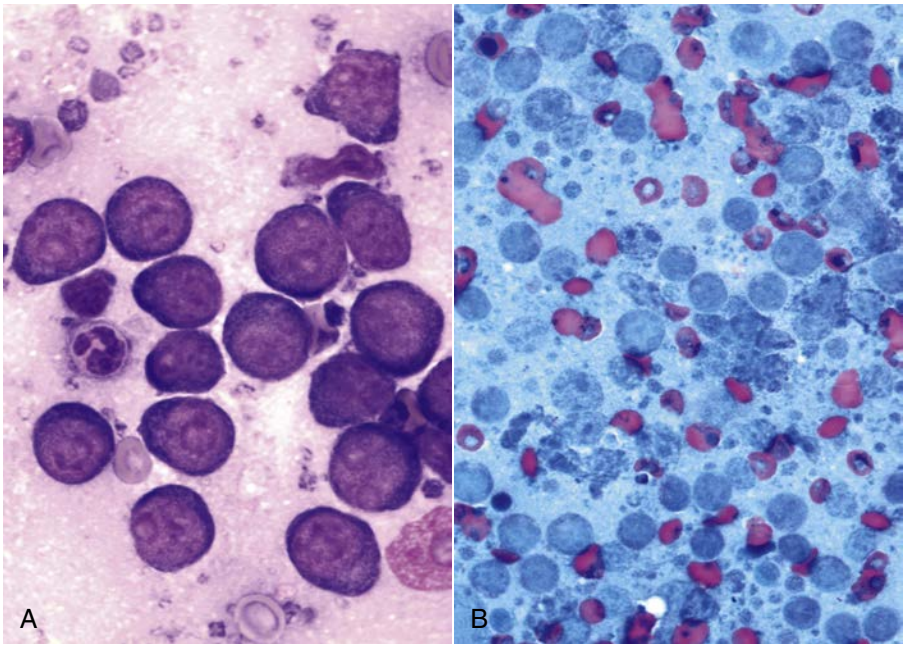
Collection Techniques

Fine-needle aspiration (FNA) is by far the most common method for collecting cytologic specimens. Small-gauge needles (22–25 g) are sufficient for smaller lesions and result in less hemorrhage. Large-gauge needles (18–20 g) may be required to collect sufficient material from masses containing abundant matrix (i.e., firm masses and sarcomas), but specimens may contain more blood. Medium-sized syringes (12–15 cc) yield more vacuum for aspiration than smaller syringes (3–6 cc). The intent of aspiration is to draw cells into the needle shaft, not to fill the syringe with material unless the lesion is fluid-filled. After the needle is inserted into the lesion, vacuum is maintained in the syringe while the needle is redirected into the tissue several times to collect a broad representation of cells. This is especially important when aspirating LNs to evaluate for metastasis. After aspiration, vacuum is released before removing the needle from the tissue, the needle is removed from the tissue and then from the syringe, the syringe is filled with air and reattached to the needle, and the cells are expelled onto a glass slide. An alternative technique, often referred to as "fenestration," is to obtain cells without aspiration by holding the needle by the hub between the thumb and middle finger while covering the hub opening with the forefinger (to prevent blood or other fluids from escaping) and rapidly and repeatedly inserting the needle into the lesion with redirection until cells are packed into the needle shaft.[2] This method often yields as much cellular material as the aspiration technique and produces less hemorrhage and patient discomfort. Similar to the aspiration technique, a syringe is used to expel the material in the needle onto a glass slide. Alternatively, a syringe, preloaded with air, can be attached to the needle used for the fenestration technique before needle insertion into the tissue of interest, which allows easy expression of fenestrated material onto slides on exit from the tissue. A second clean slide is then placed on top of the sample and the two slides are pulled apart in parallel, taking care not to exert pressure on the sample. The aim is to obtain a monolayer of intact cells. Failure to spread the specimen immediately leads to a sample that is too thick to interpret; conversely, aggressive pressure on the sample may rupture many if not all cells, also leading to a nondiagnostic specimen.

Cytologic material may be collected from mucosal surfaces such as the respiratory, gastrointestinal, and genital tracts by saline washes or with a brush or biopsy forceps inserted through an endoscope. Cytologic materials collected using an endoscopic brush are gently rolled onto a glass slide and often result in highly cellular smears. In contrast, rolling a cotton swab over the surface of a lesion is only moderately successful at collecting sufficient material for cytologic evaluation of tumors. Traumatic catheterization is the preferred method for collecting cytologic material from bladder masses because of the potential risk of seeding tumor cells when transitional cell carcinomas (TCCs) are aspirated transabdominally.[3] Traumatic catheterization is accomplished with an open-ended polypropylene urinary catheter attached to a large syringe (50–60 cc). The catheter is inserted into the urethra and bounced off the bladder wall in the region of the lesion (typically using ultrasonographic guidance), taking care not to perforate the bladder wall. Saline can be flushed into the bladder to facilitate collection of cells and cellular particles, some of which may be large enough to process for histologic evaluation.

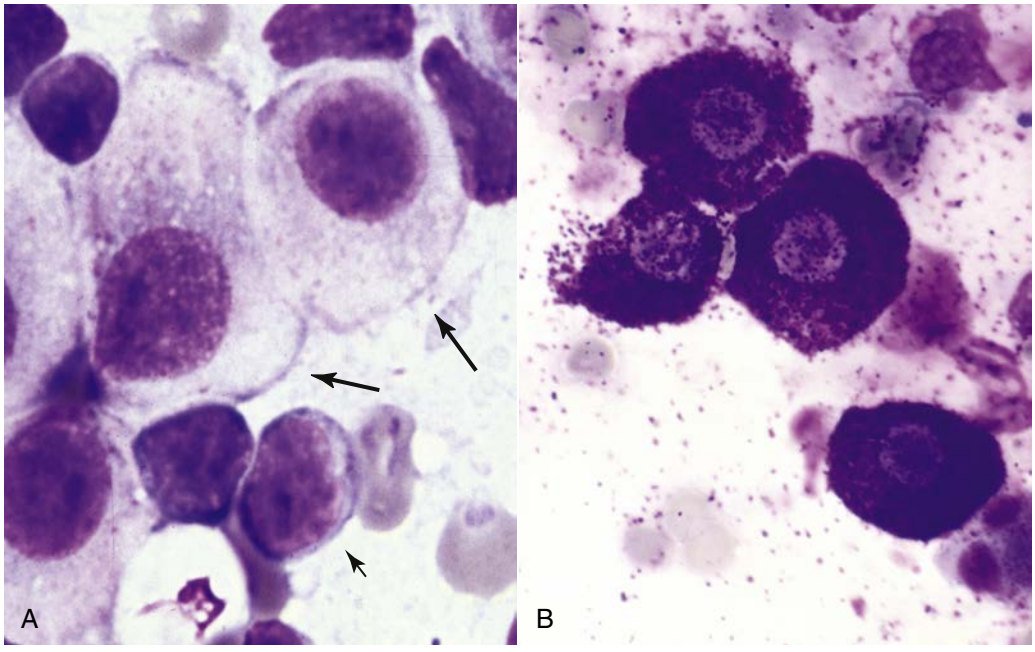
Imprinting and scraping are excellent means of preparing cytologic specimens from tissues obtained by surgical biopsy. When making imprints, a fresh surface should be exposed on the piece of tissue using a scalpel blade and then gently blotted on absorbent paper until little blood or tissue fluid appears on the paper. The tissue is held with forceps, and the fresh surface is gently pressed repeatedly onto the glass slide, using slightly different pressure with each imprint. The final specimen will contain a row of imprints of varying thickness, one or more of which should be suitable for evaluation. Common mistakes when preparing imprints include insufficient blotting and application of too much pressure, resulting in excessive blood or cellular disruption, respectively. Sometimes mucosal or connective tissue is obtained instead of tumor cells if the incorrect surface is imprinted onto the slide. When tumors such as sarcomas contain abundant matrix, imprinting will often not yield sufficient numbers of cells for evaluation. The surface of these lesions should be cross-hatched with a scalpel blade and imprinted without blotting; this may liberate cells embedded in matrix. Alternatively, the surface of firm lesions can be scraped several times in one direction with a scalpel blade held at 45 degrees to the tissue. The material on the edge of the blade is then gently spread on a glass slide. When using samples obtained by surgical biopsy to prepare cytologic specimens, care must be taken not to disrupt surfaces or margins important for histologic evaluation, especially for excisional biopsies in which assessment of tumor margins is fundamental to the evaluation.

Tissue particles or mucus collected by saline washes or by traumatic catheterization can be retrieved with a pipette and gently pressed between two glass slides. If washes or cavity fluids are cell-poor, cells in the fluid must be concentrated to prepare slides of sufficient cellularity. Collected fluid can be centrifuged, the supernatant decanted, and the cell pellet or sediment resuspended in a small amount of remaining fluid and then spread onto a glass slide. Similar to preparation of blood smears, the feathered edge of the fluid should be included on the slide because nucleated cells will accumulate there and may be best evaluated at the edge. Alternatively, when spreading the suspended cell pellet fluid on a glass slide, the spreader slide can be abruptly lifted off the slide, leaving a line of fluid—and concentrated cells—on the slide instead of a feathered edge. The best method to concentrate cells in cell-poor fluid samples is to use a cytocentrifuge, but most veterinary practices lack this equipment.



Cytologic Stains

A variety of quick stains are available for immediate examination of cytologic specimens and include quick Romanowsky stains, such as Diff-Quik. A specific set of staining jars should be kept exclusively for cytologic specimens and not used concurrently for dermatologic specimens. The jars containing the stain components should be capped between uses to prevent evaporation and contamination of the fixative and stains. Maintenance, including scheduled replacement of stain components, is important to avoid artifacts such as stain precipitate and contamination with organisms or debris that might be misinterpreted. Slides should be completely air-dried before fixation in the methanol fixative. Stains must thoroughly penetrate the smear, and in well-stained smears



VetBooks.ir

nuclei should be purple (Fig. 7.1A). A thick sample requires more contact time with the stains; understained slides (Fig. 7.1B) can be restained for a longer period of time, and overstained slides can be destained with methanol and restained for a shorter period of time. If the slides will be sent to an outside diagnostic laboratory, clinicians are encouraged to stain a slide to ensure that sufficient material was collected and that cells are intact before submitting additional unstained slides for evaluation. Additional specimens should be collected if only noncellular material is present or if all the cells are ruptured. For some lesions, the first slide prepared may be the only slide that contains cellular material. It is best to send this slide unstained to the diagnostic laboratory, but, if it is stained, be sure to include it with the other slides.

Quick Romanowsky stains provide good nuclear detail and usually sufficient cytoplasmic detail for cytologic interpretation. Mast cell granules occasionally fail to stain with aqueous quick stains (Fig. 7.2A). Wright–Giemsa and modified Wright stains provide a broader palette of colors and excellent staining of

• **Fig. 7.1** Fine-needle aspirate of a lymph node from a dog with lymphoma. (A) Well-stained specimen. Lymphocytes are three times the diameter of an erythrocyte and larger than a neutrophil and have multiple prominent nucleoli. Cytoplasmic fragments are visible in the background. Part of a swollen magenta nucleus with a prominent nucleolus is present at the lower right edge. (B) Poorly stained specimen. Cytoplasmic fragments are visible, but cellular detail is poor.

• **Fig. 7.2** Fine-needle aspirate of a mast cell tumor. (A) Granules in mast cells *(large arrows)* fail to stain when the specimen is stained with an aqueous quick stain. Small lymphocytes *(small arrow)* are also present. (B) Granules are prominent in a Wright-stained specimen from the same tumor.

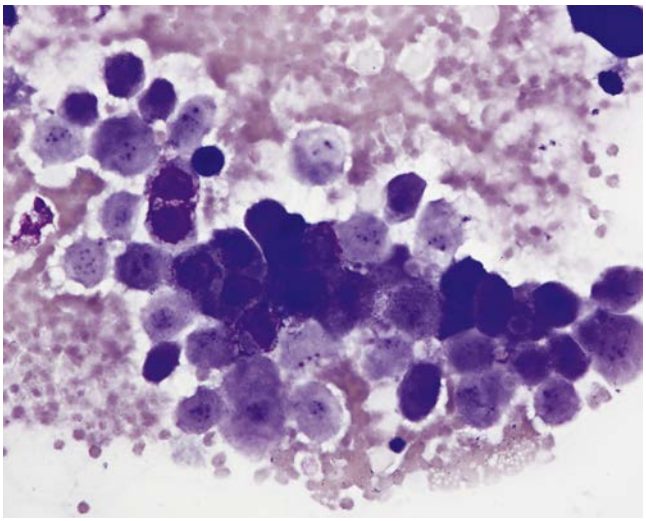
VetBooks.ir

cytoplasmic granules (Fig. 7.2B), but require more steps and longer staining times or the use of an automated stainer. Fixation of wet smears is required for Papanicolaou staining, which is not frequently used in veterinary cytology. Heat fixation is not required or recommended for cytologic specimens.

Cytochemical and immunocytochemical staining may be necessary to determine the specific tumor type. A complete list of available special stains and antibodies is beyond the scope of this chapter; consultation with a veterinary cytopathologist is recommended when considering the necessity and use of these stains. Cytochemical stains identify specific chemical compounds or structures within the cytoplasm or nucleus and include stains such as Prussian blue for iron; periodic acid–Schiff (PAS) for carbohydrates; alkaline phosphatase for identifying osteoblasts[4]; and a wide variety of leukocyte markers, including Sudan black B, peroxidase, chloracetate esterase, and nonspecific esterases. Immunocytochemical staining procedures use antibodies to identify specific proteins or peptides within or on the surface of the cells. Common antibodies used in veterinary oncology include those directed against CD3 (T cells), CD79a and CD20 (B cells), cytokeratin (epithelial cells), vimentin (mesenchymal cells), and Melan A (melanocytes). Use of a single stain or antibody is discouraged, as cell lineage is rarely identified, a single marker is often expressed by a variety of lineages, and aberrant expression by neoplastic cells can occur; a panel of stains or antibodies usually is necessary for complete identification.

Examination and Description of Cytologic Specimens

A good microscope, ideally equipped with a digital camera to document cytologic findings for the medical record or for consultation, should be used for examining cytologic specimens. The 4×, 10×, and 20× objectives are useful for scanning the slide and assessing cellular arrangements and general cell shape, whereas the 40× ("high dry") and 50× or 100× (oil-immersion) objectives are required for examining cellular detail. To improve clarity, the 40× objective requires an additional optical interface, which can be provided by applying a drop of immersion oil or permanent mounting medium to the slide followed by a coverslip. As a note of warning, the 40× objective lens is easily coated with oil applied to the slide for viewing the specimen with oil-immersion objectives; if this occurs, the lens should be cleaned immediately with glass cleaner and lens paper to prevent accumulation of oil inside the objective lens. Proper use, including correct placement of the condenser for viewing stained and unstained specimens, and maintenance of the microscope are essential to adequate examination of cytologic specimens.



Consider the following when examining the slide preparation: (1) Is the specimen of sufficient quality to permit a clinically useful interpretation? Clinical decisions should not be made from specimens that are poorly cellular or have too many ruptured cells. (2) Based on the tissue sampled, do the cells represent the expected population, an abnormal population, or both? It is important to become familiar with the cytologic appearance of "normal" cells in frequently aspirated tissues, such as lymph node and liver. (3) Does the abnormal population represent inflammation, hyperplasia, or a neoplasm? Whenever inflammation is found in a lesion suspected to be a tumor, caution is advised in making a definitive diagnosis of neoplasia. Although some tumors are accompanied by neutrophilic inflammation, experienced cytopathologists recognize that primary inflammatory lesions can convincingly mimic neoplastic lesions. (4) If neoplasia is likely, what is the tissue of origin and is the tumor benign or malignant? These questions can sometimes be answered by cytologic evaluation of the lesion but often require confirmation with histologic examination.

Specimens of Diagnostic Quality

What constitutes adequate cellularity depends on the type of tumor. Aspirates of mesenchymal tumors, which often contain extracellular matrix, tend to be less cellular than those of epithelial and discrete round cell tumors. The degree of cellularity also has an effect on the level of confidence expressed in the interpretation, and diagnostic opinions are often qualified with "possible" or "probable" for poorly cellular specimens compared with "diagnostic for" or "consistent with" for highly cellular specimens. All cytologic specimens contain some ruptured cells, but to render a meaningful interpretation the majority of cells should be intact. Material from ruptured cells is recognized as stringy strands of chromatin or swollen magenta nuclei, often with obvious nucleoli, and free cytoplasmic fragments (see Fig. 7.1A). Large lymphocytes and cells from endocrine tumors are highly susceptible to rupture, and extra care should be taken not to exert pressure on the cells when preparing cytologic specimens from these lesions.

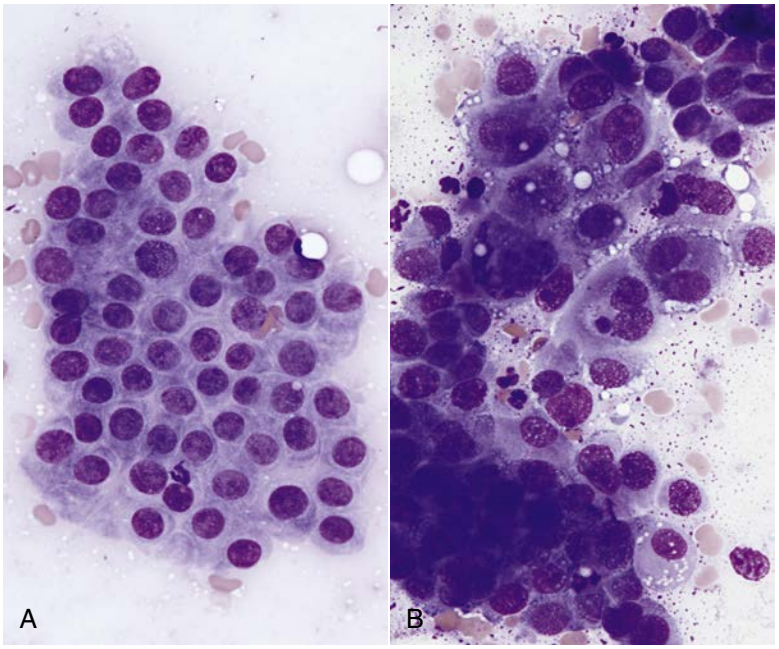
Nonneoplastic Cells and Noncellular Material Found in Cytologic Specimens

The submandibular salivary gland occasionally is aspirated instead of the mandibular LNs and is recognized by clusters of foamy cells in a background of mucin and blood. When tissue containing a metastatic tumor is aspirated, the specimen may contain only neoplastic cells or may contain normal cells from the tissue (e.g., lymphoid populations in an LN), which helps confirm location of the tumor. Necrosis can be found in tumors that have outgrown their blood supply. Necrotic cells lack detail and consist of gray-pink, indistinct cytoplasm and amorphous nuclei (Fig. 7.3); they

• **Fig. 7.3** Cells from a mass in the bladder obtained by traumatic catheterization. The cells are gray and have indistinct morphologic features, typical of necrotic cells.

VetBooks.ir

should not be confused with apoptotic or pyknotic cells, which retain distinct cytoplasmic borders that surround condensed nuclear fragments.



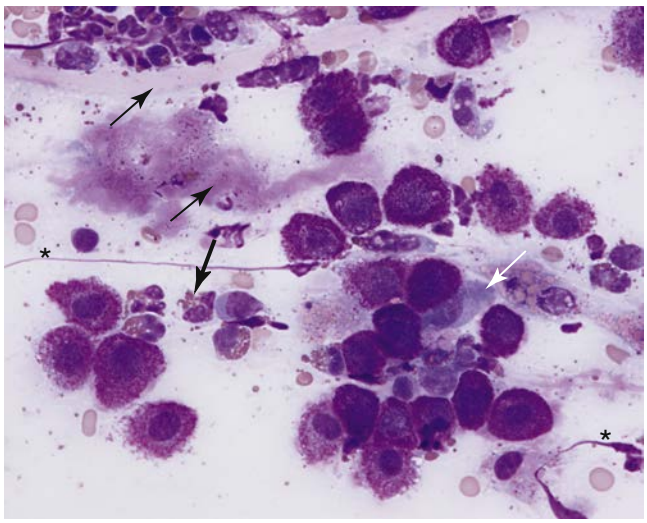
Aspiration usually results in some degree of sampling hemorrhage leading to the presence of few or many erythrocytes admixed with nucleated cells. Aspiration of splenic lesions and thyroid and vascular tumors may result in pronounced hemorrhage and abundant blood in the cytologic specimen. Preexisting intralesional hemorrhage is indicated by the presence of macrophages containing erythrocytes or hemosiderin. Small numbers of peripheral leukocytes, primarily neutrophils, will accompany hemorrhage, but the presence of neutrophils in numbers greater than their proportion in blood is supportive of inflammation. Neutrophilic inflammation may accompany tumors, most notably squamous cell carcinoma and large tumors with necrotic centers; however, inflammation can induce criteria of malignancy in nonneoplastic populations, especially fibroblasts and squamous cells, and surgical biopsy may be required to confirm suspected neoplasia when inflammation is prominent. Some tumors are associated with infiltration of specific inflammatory cells (e.g., eosinophils in MCTs).

For tumors that produce ground substance(s), such as sarcomas, or that elicit a scirrhous response, such as some carcinomas, extracellular matrix may be observed in cytologic specimens. Collagen and osteoid consist of collections of smooth or fibrillar magenta material, whereas chondroid matrix typically forms larger lakes of bright pink-to-purple material. Mucinous material may be secreted by a variety of tumors, including salivary, biliary, and intestinal carcinomas and myxomatous sarcomas. Mucin or myxoid matrix is pale blue to pink, and cells surrounded by mucin are often aligned in rows. Ultrasound gel may be a contaminant on slides prepared from ultrasound-guided aspirates if the needle is not cleaned before expelling cells onto the slide. Ultrasound gel appears as bright magenta, granular material when stained with cytologic stains and, if abundant, may impair cytologic examination.

Description of Neoplastic Populations

Determination of the number of cells exfoliated and the shape and arrangement of cells early in the cytologic evaluation aids in formulating an initial list of differential diagnoses, permitting placement of tumors in three broad categories: epithelial, mesenchymal, and discrete round cell tumors. Briefly, cells from epithelial tumors exfoliate well and are round, cuboidal, columnar, or polygonal cells arranged in cohesive sheets or clusters; cells from mesenchymal tumors exfoliate poorly and are spindle, stellate, or oval cells arranged individually or in noncohesive aggregates; and cells from discrete round cell tumors exfoliate well and are individualized round cells that are arranged in a monolayer. Cellular arrangements observed in cytologic specimens and their associated histologic correlates and tissue types have been described.[5]

Proper terminology should be used to succinctly describe cell populations and convey important information. The terms *homogeneous* and *heterogeneous* describe cell populations (Figs. 7.4 and 7.5). Homogeneous denotes a population of one cell type (excluding erythrocytes and associated leukocytes), which is typical of most tumors. Heterogeneous refers to mixed populations of cells, which are commonly found in aspirates of inflammatory lesions; however, some neoplasms will contain heterogeneous populations of cells (e.g., MCTs accompanied by eosinophils and fibroblasts [see Fig. 7.5] and squamous cell carcinomas with associated neutrophilic inflammation [see later]). The terms *monomorphic* and *pleomorphic* describe the morphologic appearance of cells within a single population. Monomorphic describes cells of a single lineage in which the cells have a uniform morphologic appearance (see Fig. 7.4A). Monomorphic features typically are associated with benign tumors, but a number of malignant tumors are cytologically monomorphic. In contrast, pleomorphic is used to describe cells of a single lineage that have variable morphologic features (see Fig. 7.4B). Pleomorphic features comprise a set of criteria

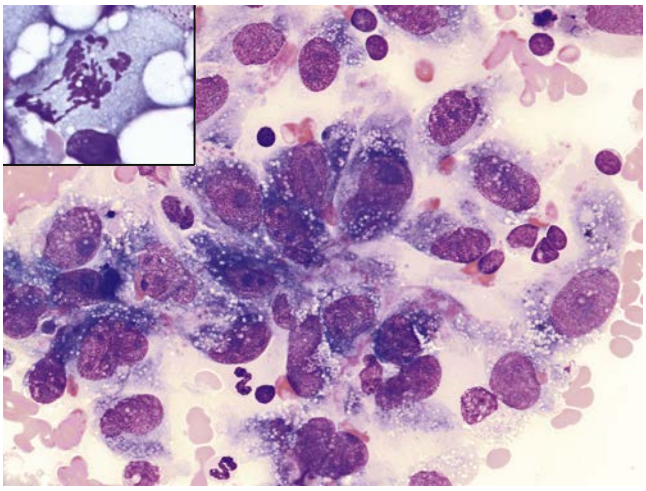


• **Fig. 7.4** Cells from a pulmonary carcinoma (A) and a transitional cell carcinoma (TCC) (B). Note that in both specimens, cells comprise a homogeneous population of epithelial cells; however, cells from the pulmonary carcinoma are monomorphic, whereas those from the TCC are pleomorphic.

VetBooks.ir

of malignancy and suggest malignant behavior, but these features may be observed in nonneoplastic cells found in primary inflammatory lesions.

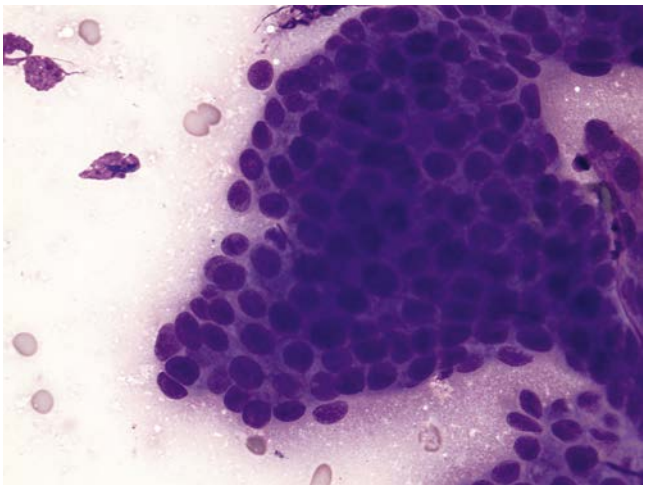
Criteria of malignancy are cellular features within a single population that suggest malignant behavior, with greater emphasis placed on nuclear criteria. The more criteria observed, the more likely the tumor is malignant. Cellular and cytoplasmic criteria of malignancy include variation in cell size (*anisocytosis*), abnormal cellular arrangement (3-dimensional [3D] clusters instead of a monolayer), cells that are smaller or larger than their normal counterpart, variable nuclear-to-cytoplasmic (N:C) ratios or N:C ratios that differ from what is expected for the cell type, intensely basophilic cytoplasm (*hyperchromasia*), abnormal vacuolation or granulation, and aberrant phagocytic activity. The nucleus is the most important component of the cell when determining the biologic behavior of a neoplasm. Nuclear criteria of malignancy include variation in nuclear size (*anisokaryosis*), unusual nuclear shape, multinuclearity, variation in nuclear size within the same multinucleated cell, nuclear fragments, multiple nucleoli that vary in size and shape within the same nucleus or among cells, increased mitoses, and nonsymmetric mitoses (Fig. 7.6). When Papanicolaou stain is used, additional nuclear features such as irregular thickening of the nuclear membrane can be evaluated. Cellular gigantism (cell >10 times the diameter of an erythrocyte) and the presence of macronuclei (>5 times the diameter of an erythrocyte) or macronucleoli (larger than an erythrocyte) are particularly disturbing criteria of malignancy. In nonneoplastic cells, the chromatin pattern is finely stippled in replicating or metabolically active cells and condensed in mature quiescent cells. Finely stippled chromatin is also common in rapidly proliferating neoplastic cells, and chromatin that is irregularly clumped or ropy is unusual and suggestive of a neoplastic process. Some nonneoplastic cells, including mesothelial cells, fibroblasts, and squamous epithelial cells, may have criteria of malignancy when they are highly proliferative in the presence of inflammation. Conversely, some malignant tumors such as apocrine gland tumors of the anal sac have few criteria of malignancy.



• **Fig. 7.5** Fine-needle aspirate of a mast cell tumor. Note the heterogeneous populations of cells, including mast cells, eosinophils *(thick arrow),* fibroblasts *(white arrow),* and lymphocytes. Extracellular matrix *(thin arrows),* likely collagen, is also present and stringy chromatin *(asterisks)* from broken nuclei is noted.

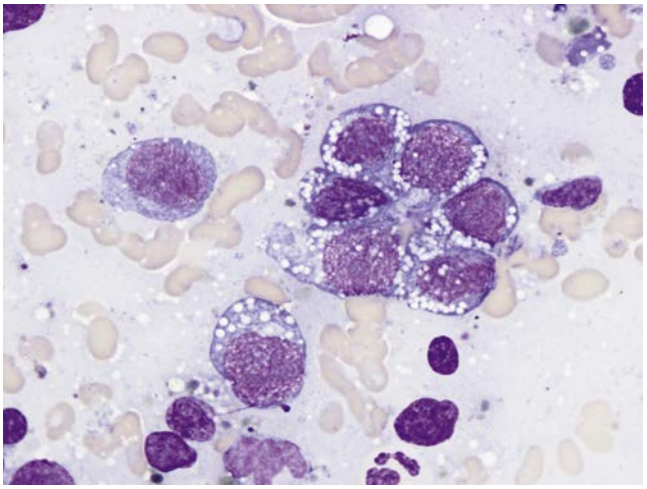
Sending Cytologic Samples to a Diagnostic Laboratory

When using a referral diagnostic laboratory, two to four unstained smears should be sent. If a highly cellular smear has been stained and examined by the oncologist for confirmation of sample quality and the cellularity of the remaining unstained smears is in question, send the stained smear in addition to the unstained smears. All slides should be packed in rigid slide containers to prevent breakage during shipment. For shipment by commercial mail services, slide holders are placed in a cardboard box with sufficient padding; padded envelopes are not recommended because these may not provide sufficient protection. Slides should not be refrigerated before or during shipment. Exposure to formalin or formalin fumes should be avoided during the preparation and shipment of cytologic specimens because this will permanently alter staining characteristics and render the sample nondiagnostic; surgical biopsy specimens preserved in formalin should be sent separately from cytologic specimens, or each type of sample should be sealed in separate plastic bags. If cavity fluids or mucosal washes are submitted, include two freshly made unstained smears along with the fluid (in EDTA) or wash (sealed container). Plain tubes (red top) or sterile vials are required for specimens that may be cultured. For all submitted glass slides, indicate how the slides were prepared and whether a concentration method was used for cavity effusions.



Interpretation of Cytologic Specimens

The final interpretation of a cytologic specimen should be based not only on the cytologic findings but also on signalment, history, clinicopathologic findings, and imaging results. This information should be provided in a concise but complete summary to the individual evaluating the sample. When submitting samples to a cytopathologist, the exact location of the lesion should be clearly described because "thoracic mass" could indicate a mass located in the skin, subcutis, body wall, mediastinum, thoracic cavity, or pulmonary parenchyma; the differential diagnoses will be different for different locations. For clinicians who perform an initial evaluation of the cytologic specimen, observational and interpretative skills can be developed by comparing their findings with



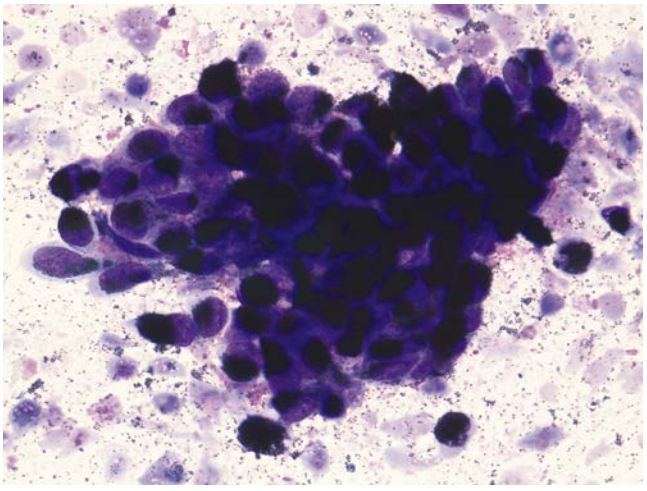
• **Fig. 7.6** Fine-needle aspirate of a hemangiosarcoma with multiple criteria of malignancy. *Inset*: An atypical mitotic figure from a liposarcoma.

VetBooks.ir

• **Fig. 7.7** Fine-needle aspirate of a basal cell tumor (trichoblastoma). Note the monomorphic population of cohesive cells aligned in rows.

• **Fig. 7.8** Fine-needle aspirate of an anaplastic colonic carcinoma. The tumor cells have high N:C ratios and are sometimes individualized.

those described in the cytopathologist's complete report and by considering the information obtained from other diagnostic tests.



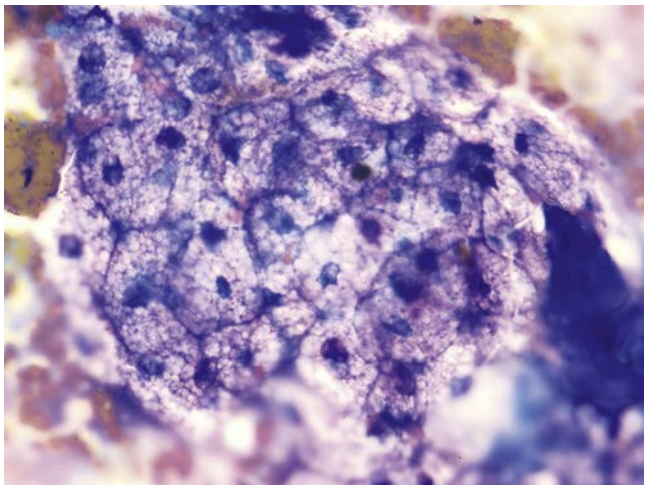
Confidence in cytologic interpretation is based on the quality of the specimen, the completeness of the clinical information provided, and the experience of the cytopathologist. Terms that express the degree of certainty, such as "consistent with," "diagnostic for," "cannot rule out," "probable," and "possible," may be used and interpreted differently by cytopathologists and clinicians.[6] If the certainty of an interpretation or diagnosis is unclear, the clinician should consult the cytopathologist. Correlations between cytologic and histologic interpretations or diagnoses are highly variable, depending on tissue types, disease processes, and methods of collection and preparation.

Epithelial, Mesenchymal, and Discrete Round Cell Tumors

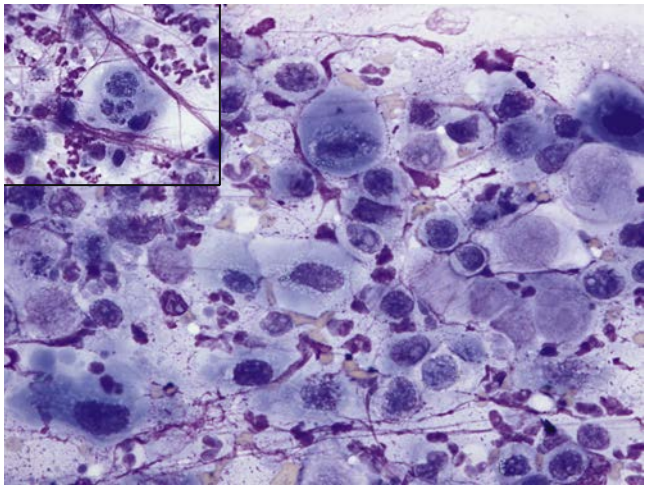
The ability to identify specific tumor types by cytologic evaluation can aid in treatment planning and prognostication. Even if a specific diagnosis cannot be made, classification of the tumor as an epithelial, mesenchymal, or discrete round cell neoplasm can provide sufficient information to formulate a differential diagnosis and plan additional diagnostic procedures.

Tumors of Epithelial Tissues

Tumors derived from epithelial tissue comprise the largest category of neoplasms and include tumors of epithelial surfaces, such as the skin and respiratory, gastrointestinal, and urogenital tracts, and tumors of glands and organs. Given their diverse origin, the cytomorphologic appearance of these neoplasms can be highly variable; however, some features are shared by most epithelial tumors. Epithelial cells have intercellular junctions that connect the cells to each other and do not elaborate extracellular matrix. Therefore cells exfoliate well, resulting in highly cellular specimens, and are arranged in cohesive sheets or clusters in cytologic smears (Fig. 7.7). The cytoplasmic borders of individual cells typically are distinct, but this can vary in certain types of tumors. Poorly differentiated epithelial tumors have few or no identifying features and tend to be round cells with moderate-to-high N:C ratios and basophilic cytoplasm. In some cases, the cells no longer have intercellular junctions and appear as discrete round cells (Fig. 7.8). Determining the tissue of origin in these cases is difficult, and histologic evaluation, with or without immunohistochemical analysis, is necessary to define the specific tumor type.



• **Fig. 7.9** Fine-needle aspirate of a basal cell tumor (trichoblastoma) in which the cells are heavily pigmented.



Tumors of Adnexa in Skin with Basilar or Sebaceous Cells

Differentiating among adnexal tumors of skin by cytologic evaluation may be difficult when identifying features are absent or when multiple cell types are present. Some of these tumors have a large component of basilar cells that are small cuboidal or round cells with high N:C ratios and are arranged in tightly cohesive sheets or in palisading rows (see Fig. 7.7). Nuclei are uniformly round with condensed to reticular chromatin, and nucleoli are indistinct or appear as a small single nucleolus. The cytoplasm is lightly basophilic and may contain black melanin granules (Fig. 7.9). Tumors that originate from the hair follicle and matrical cysts often have a central cystic space filled with mature squamous cells, keratin flakes, or keratin debris, and this material may be aspirated when the mass is sampled. Tumors with sebaceous differentiation contain clusters of large round cells filled with oily

VetBooks.ir

• **Fig. 7.10** Fine-needle aspirate of a sebaceous adenoma.

• **Fig. 7.11** Fine-needle aspirate of a squamous cell carcinoma (SCC). Note the marked anisocytosis and anisokaryosis, variable N:C ratios, perinuclear vacuolation, and angular cytoplasmic borders in some cells. *Inset*: A neutrophilic infiltrate often accompanies SCC.

appearing vacuoles that partially obscure the small central nucleus (Fig. 7.10). Necrotic cellular debris may be found in both benign and malignant forms of these tumors. Cutaneous basilar epithelial neoplasms include trichoblastoma, trichoepithelioma, pilomatricoma, feline basal cell tumors, sebaceous epithelioma, apocrine ductal adenoma, and others; histologic examination is usually required to identify the specific type. Fortunately, the majority of adnexal tumors are benign. Malignant types are infrequent; some resemble their benign counterparts but have frequent mitoses, whereas others have pleomorphic features that predict their biologic behavior.

Tumors of the Epidermis

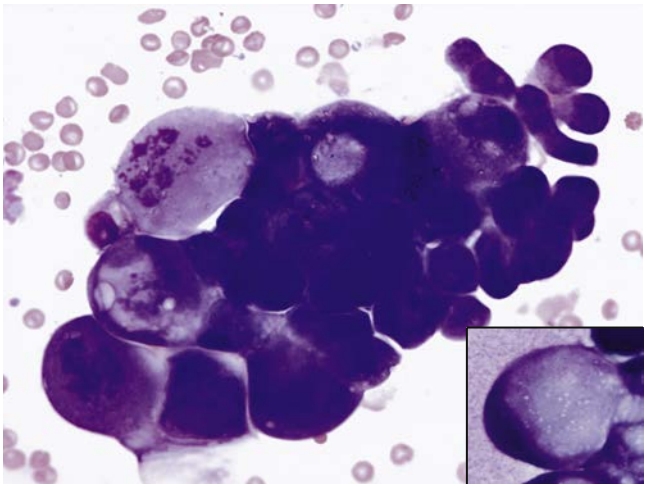
Squamous cell carcinoma (SCC) is the most common malignancy of the epidermis; the tumor has varying degrees of differentiation, even within a single tumor, and the cytologic specimen may consist primarily of basilar cells, more mature keratinized cells, or both (Fig. 7.11). Pleomorphism can be marked, including moderate-to-marked anisocytosis and anisokaryosis, hyperchromasia, and marked nuclear atypia. Keratin does not stain with Romanowsky stains, and cytologic features suggestive of keratinization include individualization of cells, sharp angular cytoplasmic margins, and smooth and glassy turquoise cytoplasm. Cells that appear keratinized may have small condensed nuclei or absent nuclei, representing a normal maturational process, but may have a large intact nucleus with fine-to-reticular chromatin and multiple visible nucleoli. An immature nucleus concurrent with mature cytoplasm signifies "asynchronous maturation." Perinuclear vacuolation or magenta cytoplasmic inclusions (keratohyaline granules) may be observed in the more mature squamous cells. Keratinization within a tumor typically is accompanied by neutrophilic inflammation (Fig. 7.11, inset). Differentiating between SCC and a primary inflammatory lesion with dysplastic squamous epithelium can be a cytologic dilemma: in both cases, the cells may have criteria of malignancy and asynchronous maturation. Location, appearance of the lesion, and ultimately histologic examination aid in differentiating inflammatory and neoplastic lesions.

Tumors of Glands

Salivary Gland Tumors

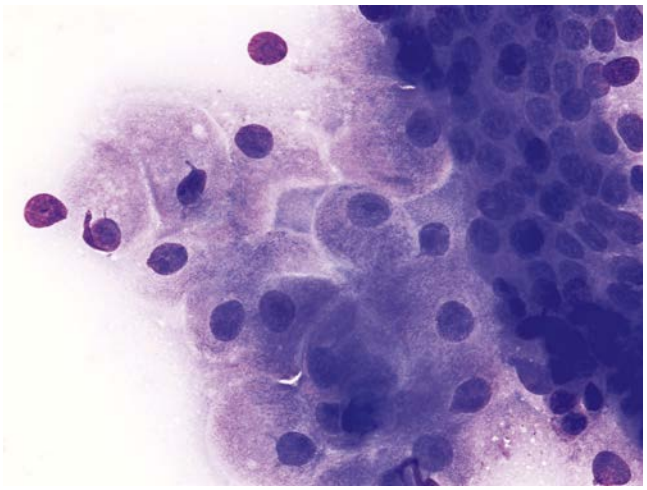
Salivary gland tumors may be composed of ductular cells, secretory cells, or both. Salivary ductular cells or poorly differentiated secretory cells resemble basilar epithelial cells with minimal pleomorphism even when these tumors are malignant; mild-to-moderate anisokaryosis may be present and nucleoli may be prominent. Tumors with a predominance of secretory cells include well-differentiated forms (acinic carcinoma) and more pleomorphic forms. The neoplastic cells are arranged in 3D clusters, sometimes resembling acini seen histologically, and have moderate and variable N:C ratios. The cytoplasm contains few-to-many secretory vacuoles of varying sizes. Cells with a single large vacuole that displaces the nucleus to an eccentric location may be noted and are referred to as *signet-ring cells.* In pleomorphic salivary adenocarcinomas, anisokaryosis and the presence of visible nucleoli of varying number, shape, and size are typical. Some tumors may produce mucin, which appears as pale pink or blue material that aligns surrounding erythrocytes into streaming rows.

Mammary Gland Tumors



Mammary gland tumors are classified histologically into benign and malignant tumors based on the type, arrangement, and invasiveness of neoplastic epithelium and on the presence or absence of neoplastic and nonneoplastic mesenchymal components. This classification system cannot be applied to cytologic specimens, nor can biologic behavior reliably be ascertained by cytology. Cytologic specimens from mammary masses may contain ductular cells, secretory cells, mesenchymal cells, or a combination of these. Cells from ductular or tubular mammary tumors resemble basilar epithelial cells with low-to-moderate N:C ratios and occasionally contain basophilic granular cytoplasmic inclusions. Pleomorphic features are mild-to-moderate, even when these tumors are malignant. Tumors of secretory origin have few-to-many criteria of malignancy, including moderate-to-marked anisocytosis and anisokaryosis, variably sized secretory vacuoles within the cytoplasm with some signet-ring formation, and nuclear criteria of malignancy (Fig. 7.12). If present, the mesenchymal component may consist of mildly to moderately pleomorphic spindle cells with or without fibrillar magenta extracellular matrix. The spindle cells represent myoepithelial cells or fibroblasts and may be neoplastic or nonneoplastic. The background of many mammary tumors contains lakes of blue secretory material, vacuolated macrophages containing similar material, and low numbers of neutrophils. Although biologic behavior is difficult to determine

VetBooks.ir



cytologically, the greater the number of malignant criteria present within any of the cell types, the more likely the tumor is malignant; however, even tumors with mild pleomorphism may be malignant. Features that define inflammatory mammary carcinomas histologically, such as the presence of tumor emboli in lymphatic vessels, cannot be appreciated cytologically, and this diagnosis is suspected when epithelial cells have cytologic criteria of malignancy and when typical clinical signs such as erythema, swelling, and warmth are identified. Mammary hyperplasia cannot be differentiated cytologically from neoplastic proliferation of tubular cells in the absence of pleomorphic features, and knowing the stage of the reproductive cycle in intact females can be helpful.

Perianal Gland Tumors

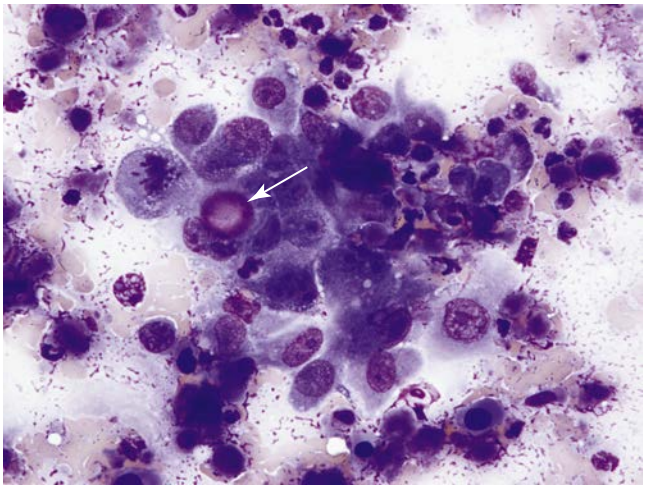
Perianal gland tumors, also called *circumanal* or *hepatoid tumors,* have a characteristic appearance and with experience can be differentiated from tumors of the apocrine gland of the anal sac. Cells are arranged in cohesive clusters and resemble hepatocytes, having uniformly low N:C ratios and abundant amphophilic granular cytoplasm with distinct margins (Fig. 7.13). Nuclei are uniformly round and centrally located, with reticular chromatin and a single nucleolus. A population of reserve cells with high N:C ratios may be found at the periphery of the clusters. Occasionally, a perianal gland tumor may consist exclusively of reserve cells and is termed a *perianal gland epithelioma.* Although the majority of these tumors are benign, pleomorphic features are not prominent even in the malignant tumors.

• **Fig. 7.12** Fine-needle aspirate of a mammary adenocarcinoma. *Inset*: Signet-ring cell.

• **Fig. 7.13** Fine-needle aspirate of a perianal adenoma with characteristic hepatoid cells *(left)* and reserve cells *(right).*

Tumors of the Apocrine Gland of the Anal Sac

Tumors of the apocrine gland of the anal sac and perianal gland tumors are the most common tumors in the perianal region and with experience can be reliably differentiated cytologically. Although not of neuroendocrine origin, apocrine adenocarcinomas resemble other tumors with a neuroendocrine appearance (see later). Even though pleomorphism is minimal, these tumors are malignant and frequently metastasize to the medial iliac LNs and eventually beyond. Pleomorphism is usually limited to mild to moderate anisokaryosis with occasional macronuclei.



Tumors of the Prostate Gland

Tumors of the prostate gland have features similar to other glandular tumors. Sometimes the cells contain circular granular eosinophilic inclusions (see Transitional Cell Carcinomas [TCCs]). Primary prostatic carcinomas cannot be easily differentiated cytologically from TCCs that arise within the prostate.

Tumors of the Urogenital System

Transitional Cell Carcinomas

TCCs may be located in the bladder, urethra, ureter, prostate, or vagina. Needle aspiration of tumor tissue is avoided to prevent potential seeding of tumor cells along the needle tract.[3] Traumatic catheterization of the bladder and prostatic washes are the preferred means of obtaining cytologic specimens. Cells from a TCC are individualized round cells with some cells forming cohesive sheets and clusters. Criteria of malignancy typically are prominent and include marked anisocytosis and anisokaryosis; variation in N:C ratios; marked basophilia; coarse chromatin patterns; and variation in nucleolar size, shape, and number (see Fig. 7.4B). Multinuclearity is common. Large circular eosinophilic or magenta granular inclusions, representing accumulations of glycosaminoglycans, occasionally are found in the cytoplasm, but this feature is not pathognomonic for TCCs (Fig. 7.14). Moderately

• **Fig. 7.14** Cells from a transitional cell carcinoma of the prostate. The *arrow* indicates a cytoplasmic eosinophilic inclusion that represents an accumulation of glycosaminoglycans.

VetBooks.ir

pleomorphic TCCs must be differentiated from hyperplastic transitional epithelium that occurs secondary to inflammatory processes in the bladder; this can be challenging because inflammation sometimes accompanies TCCs. Transitional cell polyps are sampled infrequently and typically consist of sheets of epithelial cells with a uniform or mildly pleomorphic appearance.

Tumors of Organs

Hepatocellular Tumors

In the liver, primary tumors may arise from hepatocytes or from biliary epithelium. Hepatic carcinoids may be considered as primarily hepatic in origin (see Neuroendocrine Tumors). Hepatocellular tumors include benign adenomas, or hepatomas, and carcinomas. Unfortunately, hepatic nodules and masses, whether areas of hyperplasia, regeneration, benign tumors, or malignant tumors, may be indistinguishable cytologically because all these entities may consist of well-differentiated hepatocytes with some atypia. Histologic examination is recommended for a definitive diagnosis. Features of hepatocellular atypia that should raise concern for a neoplastic process include anisocytosis and anisokaryosis, variations in N:C ratios, decreased volume and increased basophilia of the cytoplasm, and the presence of more than two nuclei per cell and multiple visible nucleoli. In addition, the cells may appear disorganized and form 3D clusters rather than appearing in a uniform monolayer. The presence of capillaries coursing through the hepatocellular sheets is suggestive of hepatocellular carcinoma.[7] In our experience, the absence of cytoplasmic lipofuscin granules suggests formation of new cells and thus a benign or malignant neoplasm. However, all these features may be observed in hyperplastic or regenerative hepatic nodules. Undifferentiated hepatocellular carcinomas may have few cytologic features that identify them as hepatocellular in origin and may resemble other undifferentiated carcinomas that have metastasized to the liver.

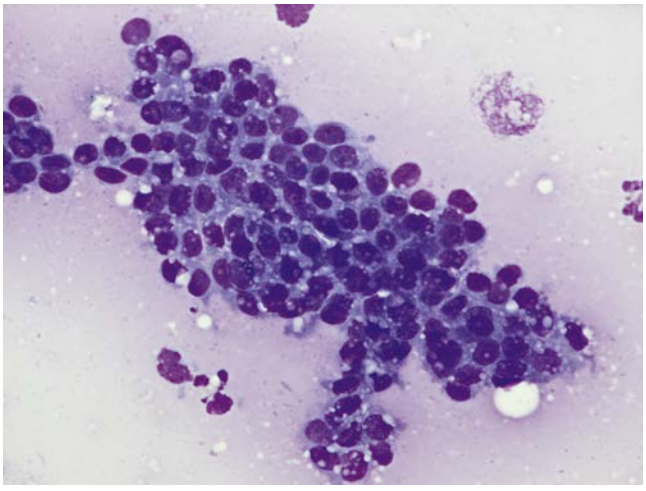
Biliary Tumors

Biliary tumors include both benign biliary cystadenomas and carcinomas. Biliary cystic tumors consist of cystic spaces lined by attenuated biliary epithelium that is indistinguishable from normal biliary epithelium. Cytologic specimens consist of small-to-large sheets of monomorphic cuboidal epithelial cells, arranged in a monolayer, with moderately high N:C ratios, basophilic cytoplasm, and uniform central round nuclei. The cytoplasm may contain secretory vacuoles. Biliary carcinomas also may have a monomorphic appearance or may be pleomorphic with polygonal cells arranged in sheets and 3D clusters; in this case, the cells may have variable N:C ratios, deeply basophilic cytoplasm, and central-to-eccentric oval nuclei. Secretory vacuoles may be numerous, single, or absent. Nuclear and nucleolar pleomorphism is prominent.

Tumors of the Exocrine Pancreas

Tumors of the exocrine pancreas may arise from ductular or acinar epithelium. Cells from ductular carcinomas resemble biliary carcinomas and consist of monomorphic sheets of cuboidal cells with high N:C ratios, basophilic cytoplasm, and central round nuclei. Nuclear pleomorphism is typically mild, but criteria of malignancy may be present. Exocrine pancreatic adenocarcinoma typically has markedly pleomorphic features. The distinctive cytoplasm of exocrine pancreas, consisting of intensely basophilic cytoplasm with numerous small eosinophilic globules, may be observed in a proportion of cells supporting pancreatic origin.

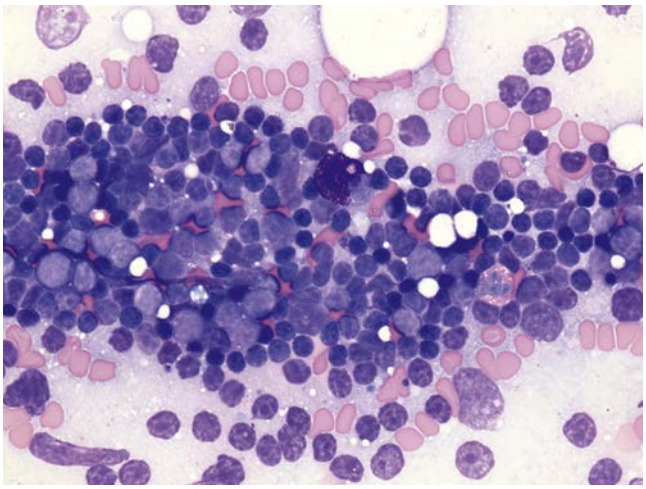
Renal Carcinomas



Renal carcinomas have few defining cytologic characteristics. Variably pleomorphic cuboidal epithelial cells may be arranged in loose sheets, clusters, tubules, and acini. The cells have moderate-to-high N:C ratios and may contain a few discrete cytoplasmic vacuoles. Nuclei are generally round and centrally or basally located, with variably distinct nucleoli. Cytologically, renal carcinomas may be mistaken for neuroendocrine tumors.

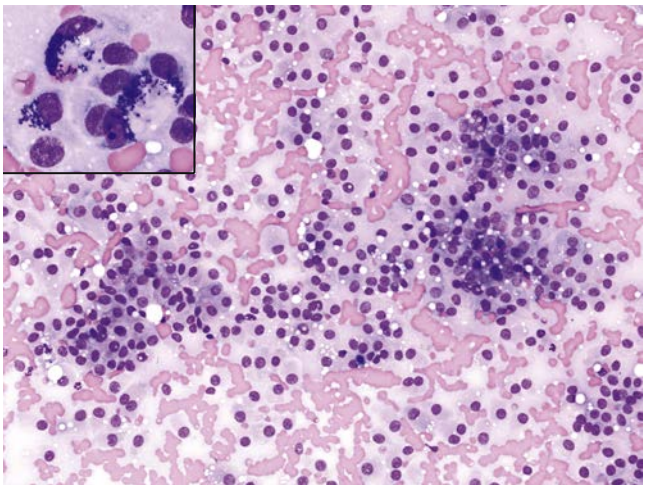
Pulmonary Carcinomas or Adenocarcinomas

Pulmonary carcinomas or adenocarcinomas may occur in animals with respiratory signs or may be found incidentally when thoracic radiographs are taken for another reason. Cats with primary pulmonary tumors may be presented for lameness resulting from metastasis to the digits. Primary lung tumors are often minimally pleomorphic (see Fig. 7.4A), although moderately to markedly pleomorphic features may be observed. Cells are cuboidal to polygonal, are arranged in cohesive sheets and clusters, and have moderate-to-high N:C ratios. Within a single tumor, some cells may contain many discrete vacuoles (Fig. 7.15). Apical cilia typically are lacking. If the tumor is large and has outgrown its blood supply, there may be large amounts of necrotic cellular debris accompanied by neutrophilic inflammation. Aspirates from the center of necrotic lesions may not contain intact epithelial cells, and repeat aspiration from the periphery of the lesion is recommended. When numerous large sheets and clusters of epithelial cells are aspirated from a pulmonary mass, a diagnosis of neoplasia is straightforward; however, when only a few small sheets of deeply basophilic epithelium are found, it is difficult to differentiate a pulmonary neoplasm from consolidated hyperplastic respiratory epithelium resulting from a primary inflammatory process.



Thymoma and Thymic Carcinoma

Thymoma and thymic carcinoma result from neoplastic transformation of the supporting epithelium in the thymus. However, neoplastic epithelial cells often comprise only a small proportion of cells aspirated from a thymoma. The majority of cells are small lymphocytes, and in dogs well-differentiated mast cells often are present (Fig. 7.16). Epithelial cells, when observed, are polyhedral cells with abundant cytoplasm and central oval nuclei and are



• **Fig. 7.15** Fine-needle aspirate of a pulmonary carcinoma. Note the monomorphic population with numerous small cytoplasmic vacuoles.

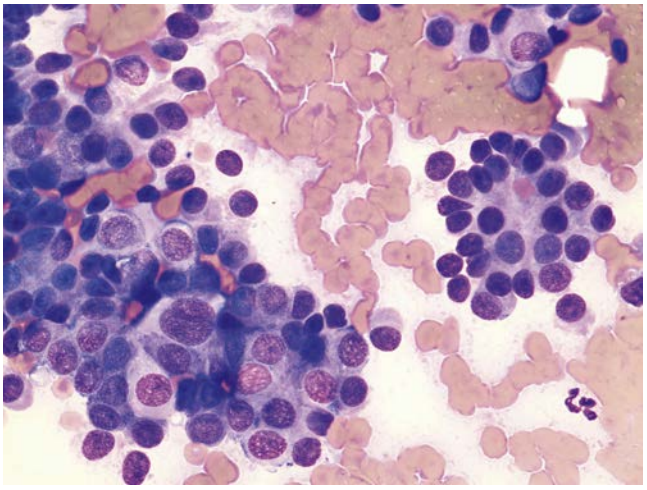
VetBooks.ir

• **Fig. 7.16** Fine-needle aspirate of a thymoma in a dog. The majority of cells are small lymphocytes. A mast cell and an eosinophil also are present.

• **Fig. 7.17** Fine-needle aspirate of a thyroid carcinoma in a dog. Note the loosely cohesive sheets of cells in a background of free nuclei and abundant blood. *Inset*: Some of the tumor cells contain blue-black granules thought to be tyrosine granules.

arranged individually or in small sheets. Criteria of malignancy among the epithelial cells are minimal in thymomas. Histologic examination or molecular diagnostic tests (e.g., flow cytometry) are often necessary to confirm a thymoma diagnosis (see Chapter 34, Section B). In thymic carcinomas, the epithelial component is much more prominent as are criteria of malignancy.

Nasal Carcinomas and Adenocarcinomas



Nasal carcinomas and adenocarcinomas, like primary lung tumors, typically are only mildly to moderately pleomorphic. Cytoplasmic vacuolation also may vary, with the majority of cells having few-to-no secretory vacuoles. Apical cilia are typically lacking. Small numbers of highly pleomorphic epithelial cells arranged in sheets or clusters accompanied by marked neutrophilic inflammation likely represent hyperplastic respiratory epithelium and not a tumor. Surgical biopsy is often required to make a diagnosis of neoplasia, especially when cytoplasmic features are not definitive and when concurrent inflammation is present.

Gastrointestinal Tumors

Epithelial gastrointestinal tumors include adenocarcinomas of the stomach, small intestine, and large intestine, and these tumors have similar cytologic features. Aspirates of these tumors typically consist of highly pleomorphic epithelial cells arranged in sheets and clusters. The cells typically contain few-to-many secretory vacuoles. The background may contain abundant mucus produced by the tumor cells or pink fibrillar collagen representing a scirrhous response secondary to the tumor. Anaplastic carcinomas of the gastrointestinal tract may resemble discrete round cell tumors (Fig. 7.8). Polyps may occur anywhere in the gastrointestinal tract and typically have a benign cytologic appearance with uniform, hyperchromatic cuboidal to columnar epithelial cells arranged in dense sheets. Occasional goblet cells with a large pale blue cytoplasmic inclusion may be observed. Histologic examination of a full thickness surgical biopsy is required to definitively differentiate invasive carcinomas and carcinoma in situ from noninvasive polyps.

Endocrine and Neuroendocrine Tumors

Endocrine and neuroendocrine tumors comprise a diverse collection of tumor types. If the primary location of the tumor is not known, a specific tumor type may be impossible to determine owing to the cytologic similarity among these tumors. In general, aspirates of endocrine and neuroendocrine tumors are highly cellular and consist of loosely cohesive sheets and clusters of epithelial cells with ill-defined intercellular junctions and cytoplasmic margins (Fig. 7.17). The cells are fragile, and numerous free nuclei from ruptured cells are scattered in the background. Nuclei of intact cells may be arranged in a rosette (Fig. 7.18), suggestive of acinar formation. Within intact cells, nuclei are round and centrally located with reticular chromatin. Nucleoli are often indistinct, but one to two nucleoli may be observed. The cytoplasm may contain a few clear, distinct vacuoles. There are usually few criteria of malignancy, even in carcinomas, and anisocytosis and anisokaryosis are mild to moderate, with large nuclei observed occasionally. Mitotic figures may be present. Some tumors of endocrine origin are biologically active, and tumor type may be identified based on clinical presentation and laboratory findings.

• **Fig. 7.18** Fine-needle aspirate of anal sac apocrine adenocarcinoma. Note the rosette of tumor cells *(right).* Mild anisokaryosis and a macronucleus are seen *(left)*, although this tumor is typically monomorphic.

VetBooks.ir

Thyroid Carcinomas

Thyroid carcinomas in dogs are highly vascularized, and aspirates may yield abundant blood as well as some hemosiderophages. In addition to displaying general features of endocrine tissue, cells from thyroid tumors may contain blue-black cytoplasmic granules (see Fig. 7.17, inset), believed to represent tyrosine granules, and amorphous pink material that may represent colloid. In the absence of these features, thyroid tumors cannot be differentiated cytologically from C-cell tumors and parathyroid tumors that occur in the same location. Most thyroid tumors in dogs are nonfunctional carcinomas, whereas in cats thyroidal masses or nodules are functional adenomas or adenomatous hyperplasia. Ectopic thyroid tissue may undergo transformation and be found in unexpected locations, such as the thoracic inlet and mediastinum.

Parathyroid Tumors

Parathyroid tumors are typically adenomas but are often functional and result in hypercalcemia through the systemic actions of parathyroid hormone. Parathyroid tumors have the typical features of endocrine tissue. Occasionally, eosinophilic spiculate inclusions are found in the cytoplasm.[8]

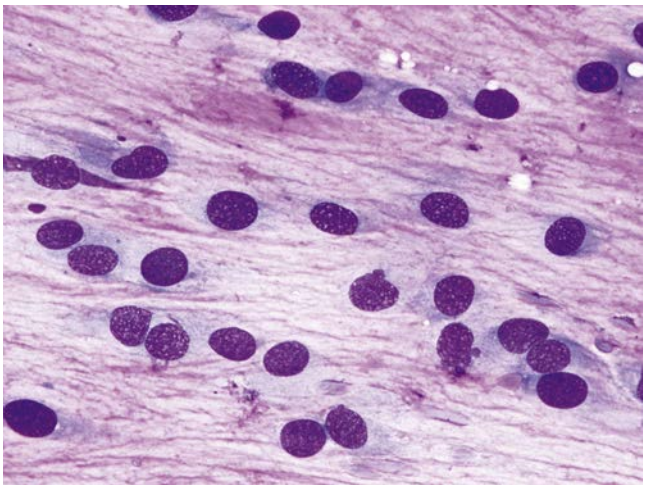
Chemodectomas or Paragangliomas

Chemodectomas or paragangliomas are neuroendocrine tumors of chemoreceptor cells found in the carotid or aortic bodies located in the submandibular region and at the base of the heart, respectively. In some tumors, the cells have numerous small pink granules. Otherwise, they do not have cytologic features that distinguish them from other endocrine tumors, such as ectopic thyroid tumors.

Adrenal Cortical and Medullary Tumors

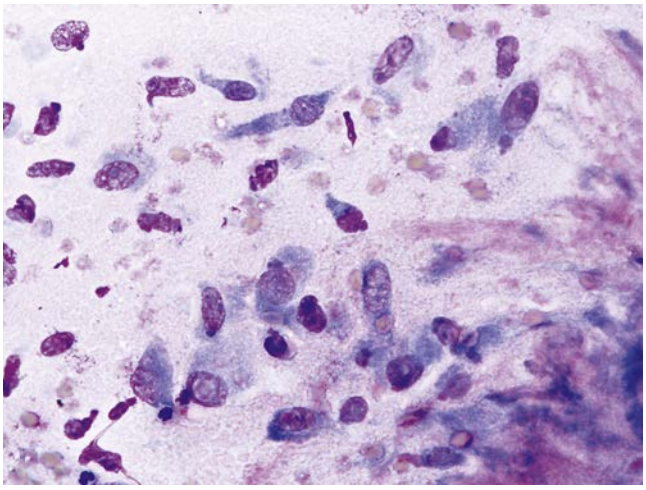
Adrenal cortical and medullary tumors are cytologically similar and have a typical neuroendocrine appearance. Adrenal cortical tumors of the zona glomerulosa and fasciculata often contain few-to-many discrete clear vacuoles. Pleomorphism is minimal and differentiation between adrenal adenoma and adenocarcinoma is not always possible cytologically. Pheochromocytomas of the adrenal medulla lack distinct cytoplasmic vacuoles but may contain pink granules and will stain positively with silver stains and express synaptophysin and chromogranin A.[9]

Insulinomas



Insulinomas, or beta-cell tumors, have typical neuroendocrine features without additional defining characteristics except for the clinical presentation of hypoglycemia. Insulinomas may metastasize to liver, regional lymph nodes, mesentery, and omentum, and these metastatic sites may be the first place the tumor is recognized.

Carcinoids of Lung, Liver, Intestine, and Colon

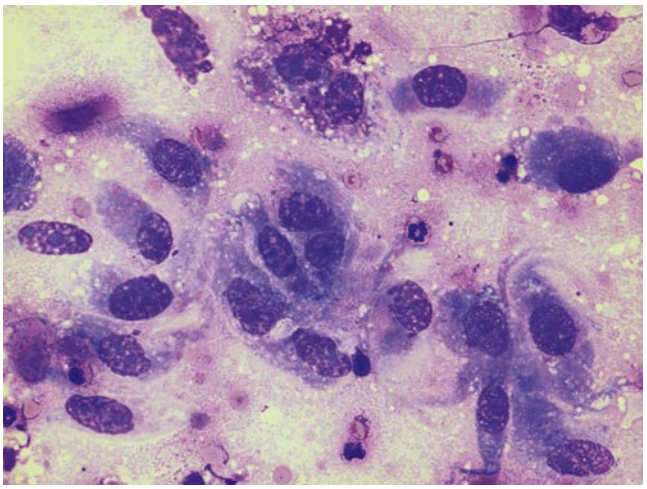


Carcinoids of lung, liver, intestine, and colon are rare neuroendocrine tumors. They must be distinguished from other neuroendocrine tumors that have metastasized based on history, clinical presentation, presence of other primary tumors, and histologic examination.

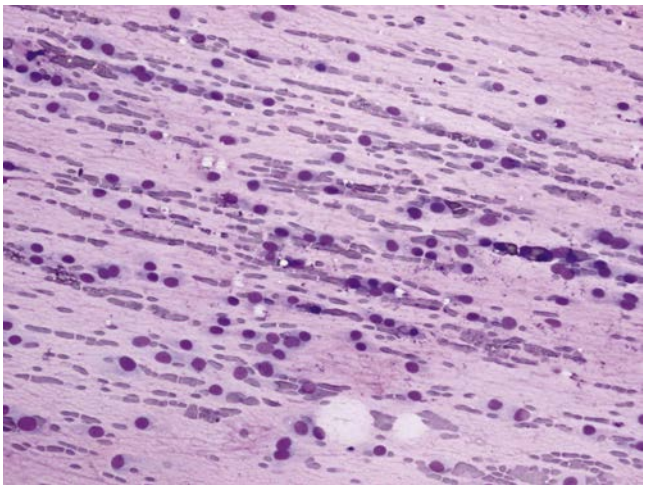
Tumors of Mesenchymal Tissues

Tumors derived from mesenchymal or connective tissues can be diverse in their cytologic appearances, but they have some common features. Cells are often embedded in extracellular matrix produced by tumor cells and exfoliate poorly. Thus cytologic samples tend to have low cellularity, although exceptions occur. Cells do not have intercellular junctions and are arranged individually

• **Fig. 7.19** Fine-needle aspirate of a myxosarcoma in a dog. Note the individualized spindle cells.



• **Fig. 7.20** Imprint of granulation tissue composed of pleomorphic fibroblasts.



(Fig. 7.19); however, in cases in which cellularity is high or when scraping and imprint methods are used to prepare slides, cells may be found in dense noncohesive aggregates that are disorganized. Cell shape is typically oval, spindle, or stellate, and the tumors are often grouped according to the most common shape. Cytoplasmic margins are characteristically indistinct, and nuclei are generally round, oval, or elongate. Some mesenchymal tumors lack further distinguishing features, and knowledge of the location and other clinical information is necessary to formulate a list of differential diagnoses in anticipation of the definitive diagnosis based on histologic and immunohistochemical staining. Even then, some of these tumors may be reported as soft tissue sarcomas without identifying the specific lineage of origin.

Reactive or hyperplastic mesenchymal cells that accompany inflammatory and neoplastic lesions present a diagnostic dilemma because these cells may have criteria of malignancy (Fig. 7.20). When a mass is composed of heterogeneous cell populations, caution is advised in making a definitive cytologic diagnosis of a mesenchymal tumor; this is especially true when concurrent neutrophilic inflammation is present. Additional diagnostic measures should be taken to confirm the presence of a neoplasm before making major treatment decisions.

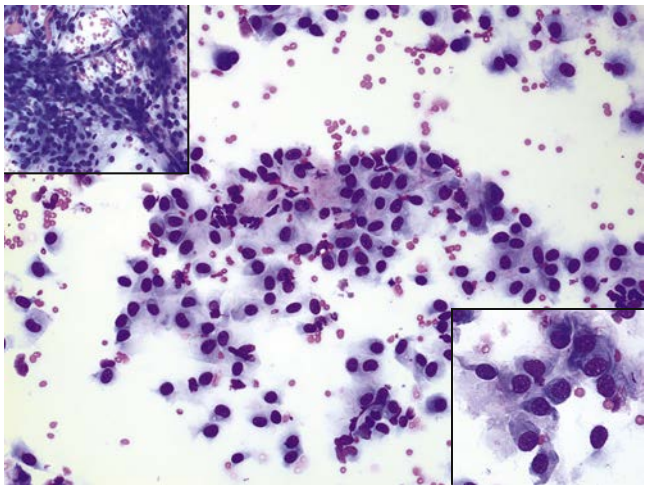
Mesenchymal Tumors Composed of Spindle and Stellate Cells

Tumors of Fibroblasts

Tumors of fibroblasts may have morphologic features of well-differentiated fibroblasts, including monomorphic elongate spindle or fusiform cells with moderate N:C ratios, basophilic cytoplasm, and central oval nuclei with one to several small nucleoli; however, a population of well-differentiated fibroblasts may represent reactive fibroplasia, as is found in scars or granulation tissue (see Fig. 7.20), a fibroma, or a well-differentiated fibrosarcoma. Unfortunately, there are no clear cytomorphologic characteristics that can reliably differentiate among these entities. The presence of accompanying inflammation warrants an interpretation of reactive fibroblasts even when pleomorphic features are present. Epithelioid macrophages found in pyogranulomatous lesions are frequently mistaken for neoplastic fibroblasts by inexperienced clinicians. High cellularity, marked pleomorphism, especially with respect to the nucleus, and absence of inflammation along with a supportive clinical picture lend credible evidence for a cytologic diagnosis of fibrosarcoma. Malignant fibroblasts may vary in shape and N:C ratio and may have numerous nuclear criteria of malignancy. Anisocytosis and anisokaryosis may be moderate to marked (Fig. 7.21). Neoplastic fibroblasts may contain pink cytoplasmic granules. Accompanying collagen, consisting of fibrillar bands of pink extracellular material, may support the origin of the cells as fibroblasts; however, similar matrix can be seen with a variety of other mesenchymal neoplasms. Cells from myxosarcoma resemble cells of fibrosarcoma, but are embedded in a lightly eosinophilic matrix that aligns the cells in streaming rows (Fig. 7.22; see Fig. 7.19). Feline injection site sarcomas (ISSs) are highly pleomorphic mesenchymal tumors, primarily of fibroblastic origin, that occur at sites of previous injections, most often of vaccines containing adjuvant. In addition to containing pleomorphic mesenchymal cells, aspirates of feline ISSs may contain large multinucleated tumor cells (Fig. 7.23) and moderate numbers of small lymphocytes.

Tumors of the Perivascular Wall or Nerve Sheath

Tumors of the perivascular wall or nerve sheath, such as hemangiopericytoma, peripheral nerve sheath tumor (PNST), and schwannoma, often exfoliate well; samples are highly cellular with cells



• **Fig. 7.23** Fine-needle aspirate of a vaccine-associated fibrosarcoma in a cat. Note the extreme atypia in the multinucleated tumor cell.

arranged both individually and in dense aggregates (Fig. 7.24). Cells are usually spindle and plump with wispy veil-like cytoplasmic extensions; oval-to-stellate forms also are found. The lightly basophilic cytoplasm frequently contains a few small clear round vacuoles. Nuclei are oval and centrally located with finely stippled chromatin and often one to three small nucleoli. Binuclearity is observed in a small proportion of cells, and multinucleate cells with peripheralized nuclei, so-called "crown cells," may be noted. Anisocytosis and anisokaryosis are mild to moderate. Linear capillaries may be embedded within aggregates of tumor cells in aspirates of perivascular wall tumors.

Tumors of Vascular and Lymphatic Endothelium

Tumors of vascular and lymphatic endothelium include hemangioma/hemangiosarcoma (HSA) and lymphangioma/lymphangiosarcoma, respectively. Tumors of vascular endothelium are more common than those of lymphatic endothelium. Aspirates of hemangioma may contain a uniform population of long thin spindle cells in a background of abundant blood; however, cellularity is rarely sufficient for a definitive diagnosis of this benign

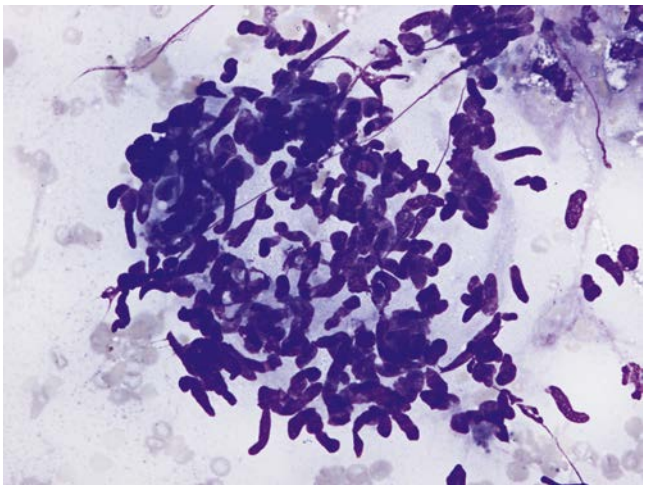
vascular tumor. Aspiration of suspected HSA is approached cautiously because of the potential consequence of hemorrhage, but cellular yields may be sufficient to reach a tentative diagnosis. The neoplastic cells are often markedly pleomorphic and consist of spindle, stellate, and oval cells that have deeply basophilic cytoplasm containing punctate vacuoles (see Fig. 7.6); some neoplastic cells may contain mature red blood cells.[10] Large, irregular, or indented oval nuclei typically have coarse chromatin and multiple prominent nucleoli that vary in shape and size. Multinucleated cells are found occasionally. Anisocytosis and anisokaryosis are often marked. A small amount of pink extracellular matrix may be associated with the neoplastic cells. Erythroid precursors and macrophages containing erythrocytes or hemosiderin may accompany HSA, especially within the spleen. Important markers of vascular differentiation are CD31 and von Willebrand factor. HSAs occur primarily in the spleen and right atrium with metastasis to liver and lung, but also occur in the dermis and subcutis and rarely arise from bone. Tumor cells are typically not found in hemorrhagic effusions that result from rupture of the tumor.

Tumors of Adipose Tissue

Tumors of adipose tissue comprise lipomas and liposarcomas. Lipomas are common tumors of dogs, and although the gross appearance and texture of these tumors is characteristic, they often are aspirated to rule out other types of tumors that require more immediate attention. Aspirates of lipomas consist of abundant lipid that often dissolves during fixation in methanol-based fixatives, leaving an acellular smear. Adipose tissue that adheres throughout the staining procedure consists of clusters of large round cells with a small nucleus peripheralized by a single clear lipid vacuole (Fig. 7.25). Supporting stromal strands and capillary vessels are sometimes visible within the cluster of adipocytes, and free fat may be present. Normal subcutaneous adipose tissue cannot be differentiated from a lipoma or infiltrating lipoma cytologically; therefore caution is recommended when making a conclusive cytologic diagnosis of lipoma if the gross appearance or texture of the mass is not typical. Liposarcomas are uncommon and can adopt a variety of cytologic appearances. Cells may be spindle, stellate, or round with variable N:C ratios. Clear lipid vacuoles of varying sizes are present within a basophilic or amphophilic cytoplasm (Fig. 7.26).

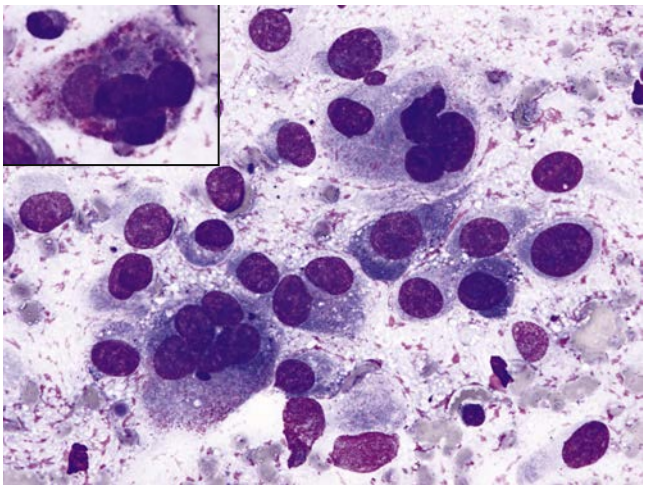
• **Fig. 7.25** Fine-needle aspirate of well-differentiated adipocytes from a lipoma.

• **Fig. 7.26** Fine-needle aspirate of a liposarcoma in a dog. Note that the polygonal cells contain lipid vacuoles. *Inset*: A large lipid vacuole in a tumor cell.



Nuclei are round to oval and often display criteria of malignancy. Confirming the presence of lipid using Oil Red O stain is best accomplished on unfixed smears. With inflammation of adipose tissue (panniculitis or steatitis), the sample often contains moderately pleomorphic fibroblasts and histiocytes that contain lipid or lipid-like vacuoles; these cells are easily mistaken for a neoplastic population. The presence of even low numbers of neutrophils within these lesions favors a conservative interpretation, and surgical biopsy should be pursued for definitive diagnosis.

Mesenchymal Tumors Composed of Thin Elongate Cells



Tumors of Smooth Muscle and Stroma

Tumors of smooth muscle and stroma, such as leiomyoma, leiomyosarcoma, and gastrointestinal stromal tumor (GIST), have a similar cytologic appearance. Aspirates of these tumors, whether benign or malignant, often are highly cellular and consist of long thin mesenchymal cells arranged in aggregates and linear bundles. Nuclei are often elongate or "cigar-shaped" (Fig. 7.27). Pleomorphism is typically mild. The most common sites for these tumors are the gastrointestinal tract and female reproductive tract, especially the uterus and vagina. Immunohistochemical detection of smooth muscle actin or KIT (CD117) expression in smooth muscle tumors and GIST, respectively, is required to distinguish these tumors.

VetBooks.ir

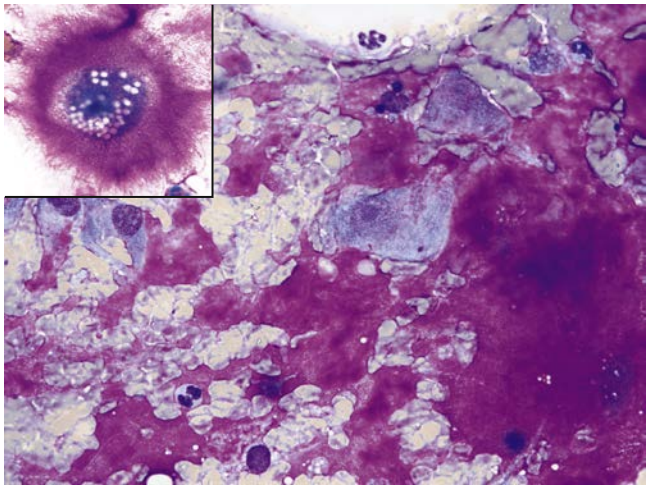
• **Fig. 7.28** Fine-needle aspirate of a proliferative and lytic lesion in bone. The diagnosis was osteosarcoma. The pleomorphic cells tend to be round or oval with eccentric nuclei and sometimes paranuclear clear zones. *Inset*: A multinucleated tumor cell contains prominent pink granules.



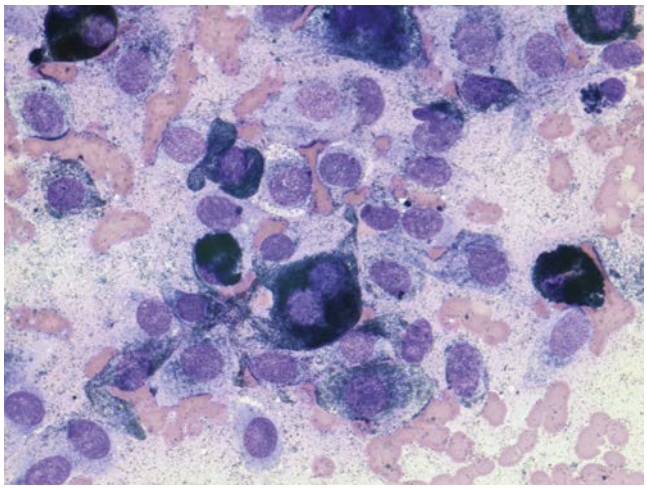
Tumors of Striated Muscle

Tumors of striated muscle, rhabdomyoma and rhabdomyosarcoma, are uncommon and can have a variety of cytomorphologic appearances. Rhabdomyomas occurring in the tongue and pharynx may present cytologically as a "granular cell tumor" composed of individual round or polygonal cells containing numerous fine pink cytoplasmic granules and a central round nucleus. Electron microscopic examination reveals the pink granules to be numerous mitochondria. Rhabdomyosarcomas typically comprise individualized pleomorphic spindle cells with low numbers of elongate strap cells that may or may not demonstrate cross-striations within the cytoplasm. Strap cells characteristically have several round-to-oval nuclei arranged in a linear row. Normal muscle fibers are bright blue, with prominent cross-striations when viewed at high magnification, and have randomly distributed pale oval nuclei.

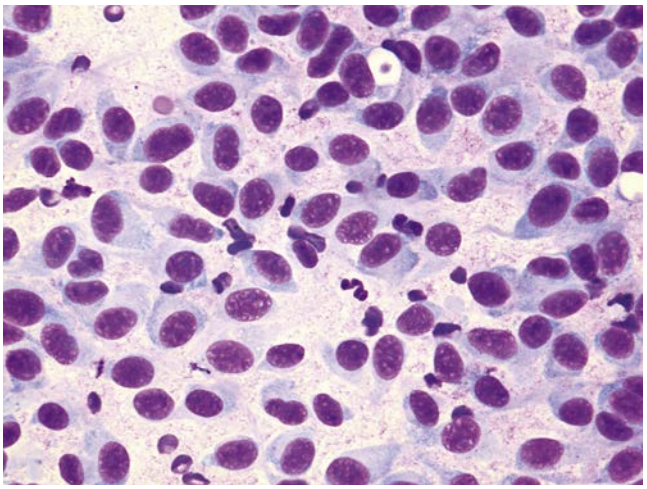
Mesenchymal Tumors Composed of Round or Oval Cells

Tumors of Bone Origin

Tumors of bone origin include osteosarcoma, osteoma, multilobular tumor of bone, and giant cell tumor of bone. Osteosarcoma (OSA) is the most common tumor of bone in dogs and results in a mixed osteolytic and osteoproliferative lesion radiographically. Aspirates of OSA may be highly or poorly cellular, depending on the collection technique and the nature of the lesion. Cytologic features that support osteoblasts as the cells of origin include oval cells with basophilic cytoplasm containing paranuclear clearing, and eccentric nuclei with criteria of malignancy (Fig. 7.28). The cytoplasm occasionally contains fine-to-coarse magenta granules or few small clear vacuoles. N:C ratios are moderate to high, and anisocytosis is moderate to occasionally marked. Alkaline phosphatase staining of cytologic samples has been shown to differentiate tumors of osteoblast origin (osteosarcoma and multilobular tumor of bone) from other vimentin-positive tumors of bone. Often, bright magenta extracellular matrix or osteoid is found. Large multinucleated osteoclasts are typically scattered among the neoplastic osteoblasts. Multilobular tumor of bone and giant cell tumor of bone are composed predominantly of osteoblasts and osteoclasts, respectively. In giant cell tumor of bone (or osteoclastoma), spindle cells are found; it is possible these cells, rather than the osteoclasts, may be the neoplastic cells. Both tumors have characteristic locations or radiographic appearances. The cytologic appearance of plasma cell tumor and OSA may overlap because both contain cells with eccentric nuclei and paranuclear clearing; for inexperienced clinicians, this may constitute a diagnostic dilemma in dogs, and less frequently in cats, that have osteolytic lesions. Clinical presentation and laboratory abnormalities may be useful in distinguishing these malignancies. Caution is recommended when making a cytologic diagnosis of OSA at the site of a pathologic fracture as hyperplastic and reactive osteoblasts may have a degree of pleomorphism that can be mistaken for a well-differentiated neoplasm.



• **Fig. 7.29** Fine-needle aspirate of a chondrosarcoma with pleomorphic tumor cells and abundant magenta matrix that sometimes surrounds the tumor cells *(inset)*.



Tumors of Chondrocytes

Tumors of chondrocytes are less common than osteosarcoma and may arise in any location where cartilage occurs, including epiphyseal bone, nasal cavity, and large airways. Although the amount of matrix present in any given tumor can vary, the most characteristic cytologic finding in aspirates of chondrosarcoma is the large amount of purple extracellular matrix that envelops and often obscures the neoplastic chondroblasts (Fig. 7.29). Neoplastic chondroblasts are round with moderate-to-high N:C ratios but may be spindle or stellate. A few cytoplasmic vacuoles or magenta

granules are common, and nuclei are round with finely stippled chromatin and variably prominent nucleoli.

Periarticular Tumors

Periarticular tumors are predominantly histiocytic sarcomas (HSs) with other sarcomas (synovial myxoma, pleomorphic sarcoma, fibrosarcoma, and undifferentiated sarcoma) diagnosed less frequently.[11] Descriptions of synovial cell sarcoma histologically as monophasic (spindle) or biphasic (epithelioid and spindle) may encompass these different tumor types or a periarticular tumor of undefined cell lineage.[12,13] Cytomorphologic appearances of periarticular tumors correspond to the specific tumor type described elsewhere under mesenchymal tumors with round or spindle cells or under tumors with frequent multinucleated cells.

Tumors of Melanocytes

In malignant melanoma, the cells can adopt the appearance of epithelial (sheets of cohesive cells), mesenchymal (individualized oval or spindle cells), or discrete round cell tumors, and all three cytologic appearance may be evident in the same tumor. Individual melanoblasts are round, oval, or spindle cells with moderately high N:C ratios, lightly basophilic cytoplasm, and round or oval nuclei with fine chromatin and distinct nucleoli. Criteria of malignancy consist primarily of anisokaryosis and nucleolar pleomorphism. Highly pigmented tumors do not present a diagnostic challenge, and fine black melanin granules may be so numerous that they obscure all cellular detail. Cells with varying degrees of pigmentation are typically found within the same tumor, and melanin granules may be sparse in some cells (Fig. 7.30). Amelanotic tumors present a greater diagnostic challenge. Usually, a faint scattering of fine gray-black melanin granules is found in a few cells to support a diagnosis, but cells may be completely devoid of pigmentation (Fig. 7.31). In these circumstances, moderately pleomorphic tumor cells aspirated from masses on the digits or in the oral cavity should alert the clinician to the possibility of this highly malignant tumor. Because melanocytes are of neuroectodermal origin, the cells may express certain neural markers, such as S-100 and neuron-specific enolase, in addition to vimentin and often Melan A.

An additional cytologic challenge is the identification of metastatic lesions within lymph nodes. Most lymph nodes draining pigmented melanomas contain melanophages, which are macrophages containing abundant melanin; in the authors' experience, this is especially true after surgical removal or biopsy of the primary mass. These melanophages may be mistaken for metastatic cells, but they differ from neoplastic melanoblasts as melanophages typically contain coarse collections of melanin within phagolysosomes rather than the fine granulation typically found within melanoblasts.

Most dermal tumors of melanocytic origin are benign and are termed *melanocytomas.* They consist of polygonal or spindle cells containing black cytoplasmic granules. Several of the adnexal tumors may contain melanin pigment and must be differentiated from melanocytomas. These typically are of epithelial origin and should be distinguished by their cellular arrangement in cohesive sheets (see Fig. 7.9).

Mesenchymal Tumors Composed of Cells Arranged in Dense Aggregates

Cells aspirated from some mesenchymal tumors, including rhabdomyosarcoma, perivascular wall tumor, PNST, amelanotic melanoma, and the epithelioid form of HSA, form dense aggregates and clusters that are more characteristic of epithelial cells. Careful examination typically reveals some spindle cells with indistinct margins and spaces between the closely packed cells indicating the lack of intercellular junctions. Slide preparation by imprinting and scraping also may yield clusters and sheets of mesenchymal cells that mimic epithelial populations.

Mesenchymal Tumors with Frequent Multinucleated Cells

Although any neoplasm can have a few multinucleated cells, multinuclearity is especially common in certain sarcomas. These include HSs, feline ISSs, pleomorphic sarcoma (also called malignant fibrous histiocytosis or anaplastic sarcoma with giant cells), rhabdomyosarcoma, and some plasmacytomas in which the multinucleated cells are part of the tumor population. In OSA, multinucleated osteoclasts are often present and are not part of the neoplastic population of cells.

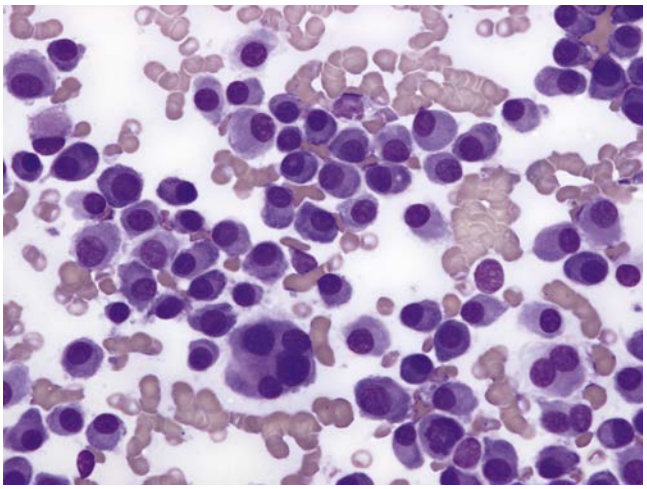
Discrete Round Cell Tumors

The majority of discrete round cell tumors are of hematopoietic origin, including neoplasms of mast cells, plasma cells,

VetBooks.ir

lymphocytes, and histiocytes. Transmissible venereal tumors (TVTs) are also included in this category, and there are a variety of epithelial and mesenchymal tumors that sometimes appear as round cell tumors. These tumors share certain cytomorphologic features. Cells exfoliate easily leading to highly cellular specimens in which the cells are individualized in noncohesive monolayers. As the moniker indicates, the cells are round and have distinct cytoplasmic margins and round nuclei, although nuclear shape may vary in pleomorphic forms of these tumors.

Mast Cell Tumors



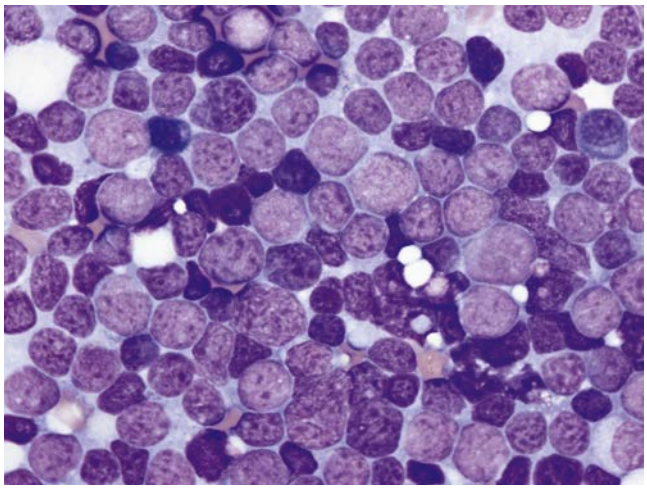
MCTs consist of cells with numerous purple cytoplasmic granules that fill the cytoplasm and often obscure the nucleus (see Figs. 7.2 and 7.5). In cats, granules are finer than they are in canine mast cells. Even in poorly granulated MCTs, there often are enough granules in some cells to suggest that they are mast cells. One notable exception is when the granules fail to take up stain when one of the aqueous quick stains is used, so clinicians using these stains should be alert to this artifact (see Fig. 7.2). The nucleus is generally centrally located but may be eccentric. Criteria of malignancy are observed infrequently and may include anisocytosis, anisokaryosis, binuclearity, multinuclearity, nuclear pleomorphism, and the presence of mitotic figures. Marked pleomorphism is uncommon and when present suggests a higher-grade tumor; however, at present grading is based on histologic findings. Markedly pleomorphic MCT cells may have sparse or absent granulation, marked variation in cell and nuclear size, and lobulated or ameboid nuclei. In dogs, aspirates of MCTs often contain numerous eosinophils along with a small proportion of reactive fibroblasts and thick bands of collagen (see Fig. 7.5). Proposed cytologic grading systems for mast tumors in dogs have not been validated yet; these systems suggest that marked pleomorphism, poor granulation, and the presence of mitotic figures may predict a more aggressive behavior. A novel cytologic grading scheme adapted from two-tier histologic grading criteria was predictive of a poorer outcome and had high sensitivity and specificity compared with histologic grading.[14]

Determining the presence of metastasis in tissues, including LNs, liver, and spleen, that have resident mast cells, may be difficult. Features that support metastatic disease include the presence of large numbers of mast cells suggestive of tissue effacement, mast cells with pleomorphic features, and mast cells arranged in groups instead of singly. If cytologic evaluation cannot distinguish between resident mast cells and metastasis, a surgical biopsy should be evaluated.

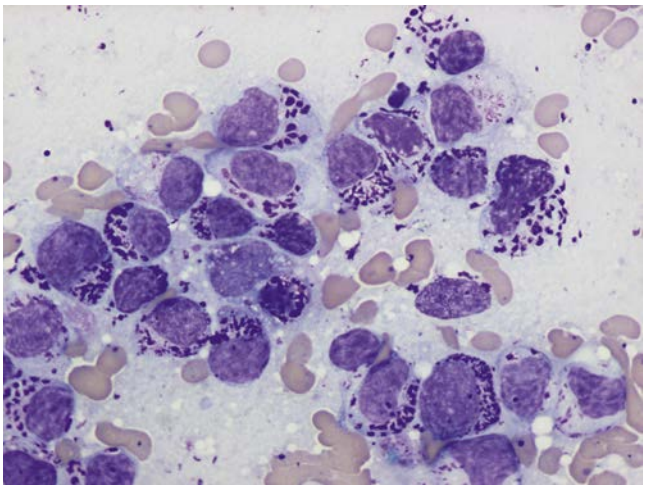
Other neoplasms in which the cells contain cytoplasmic granules may be mistaken for mast cell tumors and include granulated T-cell lymphoma, natural killer (NK) cell lymphoma, and granular cell tumors. When cells from MCTs are agranular or when the granules fail to stain with aqueous stains, the tumor may be mistaken for plasmacytoma, histiocytoma, atypical lymphoma, or squamous cell carcinoma. Reactive nonneoplastic mast cells may be found in increased numbers at sites of fibrosis because of the role mast cells play in wound healing.

Plasma Cell Tumors

Plasma cell tumors composed of well-differentiated plasma cells are easily recognized owing to the characteristic features of plasma cells—abundant royal blue cytoplasm, paranuclear clear zone (Golgi apparatus), eccentric round nucleus, and clumped chromatin. Multinuclearity is common in plasmacytomas, and in more pleomorphic forms of this tumor the nuclei may be multilobulated (Fig. 7.32). Neoplastic plasma cells may appear immature and resemble large lymphocytes with higher N:C ratios and finer chromatin. Sometimes the cells contain Russell bodies, collections of immunoglobulin within the endoplasmic reticulum, and are termed *Mott cells.* Plasma cell tumors may occur in the skin, oral mucosa, bone marrow, liver, and spleen, and the specific diagnostic criteria for plasma cell myeloma, extramedullary plasma cell myeloma, and plasmacytoma are presented in Chapter 33, Section D. Reactive plasma cell proliferations consist of a mixture of inflammatory cells and are rarely mistaken for a neoplastic process in a cutaneous mass; however, when plasmacytosis is identified in bone marrow, reactive and neoplastic conditions must be distinguished.



• **Fig. 7.32** Fine-needle aspirate of a plasmacytoma. Many cells have the characteristic appearance of plasma cells. Multinuclearity is a common feature of this tumor.

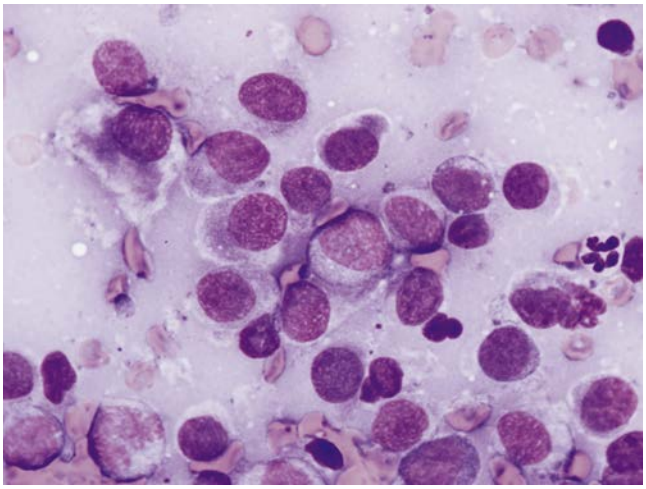


Lymphoma

Lymphoma comprises many variants, and entire chapters are written on their cytologic features. Definitive diagnosis of lymphoma based on examination of cytologic specimens is often possible; however, some types of lymphoma or lymphoma in certain tissues may be difficult to diagnose cytologically. As with many discrete round cell neoplasms, it is the homogeneity of the population, rather than the morphologic features, that suggest a neoplastic process. In lymphoid organs or other tissues in which there is a reactive or polyclonal infiltrate of lymphocytes, small lymphocytes should predominate and comprise more than 50% of the lymphoid cells, even as the proportion of large and intermediate lymphocytes increases. Plasma cells and other inflammatory cells also may be found in these reactive lesions. As the proportion of intermediate and large lymphocytes approaches or exceeds 50%, it becomes more difficult to differentiate between a reactive and neoplastic process; this is especially true for the spleen and certain LNs, such as mandibular and mesenteric nodes, that are continuously exposed to antigen. Because of this, sampling of other LNs or tissues is preferred. In addition, cats can mount strong lymphocytic responses that can cytologically resemble lymphoma. In contrast, there are certain types of lymphoma, such as T-cell-rich B-cell lymphoma and Hodgkin's-like lymphoma, that contain a mixture of clonal (neoplastic) and

VetBooks.ir

• **Fig. 7.33** Fine-needle aspirate of a lymph node from a dog with T-cell lymphoma. Note that most of the cells are about two times the diameter of an erythrocyte and that nucleoli are indistinct in many cells.

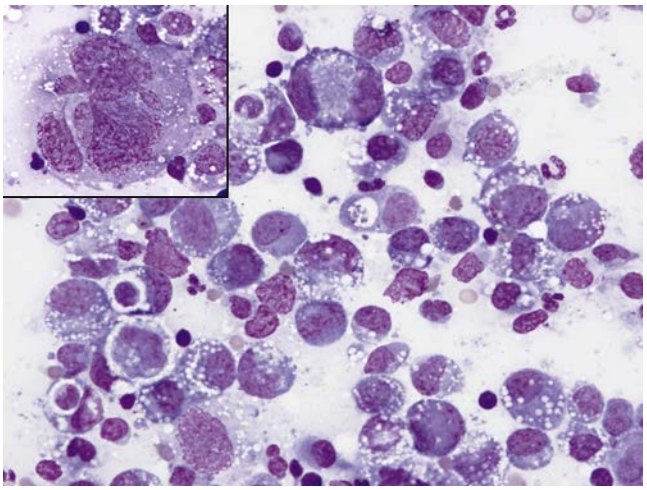


• **Fig. 7.34** Fine-needle aspirate of a mesenteric lymph node from a cat with large granular lymphoma. Note the prominent coarse eosinophilic granules in the tumor cells.

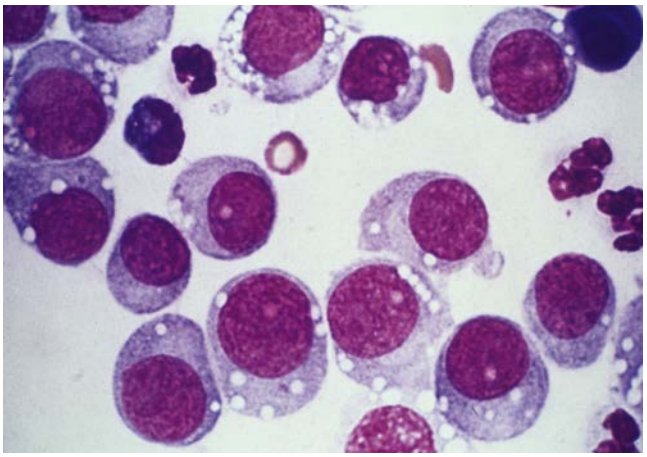
polyclonal (nonneoplastic) populations of lymphocytes. When a diagnosis of lymphoma is not obvious from the cytologic specimen, additional procedures should be performed, including surgical biopsy with histologic evaluation, immunophenotyping, assessment of clonality, or a combination of these (see Chapter 33, Sections A and B).

Lymphoma can be diagnosed cytologically when large or intermediate lymphocytes comprise the majority of the nodal population. Large and intermediate lymphocytes are defined as those larger than or the same size as a neutrophil, respectively, or that are greater than two times or one and a half to two times the diameter of an erythrocyte, respectively. Cytologic types include immunoblastic or centroblastic types, composed of large cells with visible nucleoli and deeply basophilic cytoplasm (see Fig. 7.1A), and lymphoblastic types composed of medium-sized cells often having indistinct nucleoli (Fig. 7.33). Mitotic figures and tingible-body macrophages, which are macrophages containing nuclear debris from tumor cells, may be increased, but this is not a defining characteristic. Cytologic diagnosis of small-cell lymphoma is more challenging, especially in tissues such as lymph node and spleen with a resident population of small lymphocytes or in tissues such as liver and small intestine in which lymphocytic inflammation is common. In these cases, additional diagnostic testing is required for confirmation and may include one or more of the following: histologic examination, preferably of a whole node or full-thickness piece of intestine; immunophenotyping by immunocytochemical/histochemical staining or flow cytometry; and polymerase chain reaction for antigen receptor rearrangement (PARR) to detect clonality (see Chapter 8). Because lymphocytes are fragile, free nuclei and cytoplasmic fragments frequently are observed in aspirates of lymphoma (see Fig. 7.1A); however, these features can be found in samples from reactive lymphocytic populations and are not criteria for neoplasia.

Infrequently, neoplastic lymphocytes are highly pleomorphic and exhibit moderate to marked anisocytosis, indented or deeply clefted nuclei, ameboid nuclei, multinuclearity, cytoplasmic vacuoles, and aberrant phagocytic behavior. When present, a few, some, or most of the neoplastic lymphocytes in a given tumor may have these features and may be mistaken for neoplastic histiocytes.[15] Sometimes neoplastic lymphocytes contain fine or coarse pink cytoplasmic granules, suggestive of a T- or NK-cell phenotype. In large granular lymphoma, the lymphocytes contain large, coarse, pink granules and are thought to be cytotoxic T or NK cells (Fig. 7.34).



• **Fig. 7.35** Fine-needle aspirate of a histiocytoma. Note the discrete round cells with a variable appearance. A few small lymphocytes also are present.



Tumors of Histiocytic Origin

Cutaneous Histiocytoma

Cutaneous histiocytoma originates from epidermal dendritic or Langerhans cells and is typically found on the head or limbs of young dogs. The cells are round and have pale blue to colorless cytoplasm and a round, sometimes indented, central nucleus with fine to reticular chromatin and indistinct nucleoli (Fig. 7.35). Occasionally, the cytoplasm is more basophilic, and the nucleus more eccentrically located; in these cases, the cells may be mistaken for immature plasma cells and the mass called a plasmacytoma. Finding a few mitotic figures is common, but binuclearity is infrequent. Often the tumor cells are highlighted by a pale purple proteinaceous background. In mature lesions, there may be an infiltrate of small lymphocytes representing the

• **Fig. 7.36** Fine-needle aspirate of a histiocytic sarcoma. Note extreme pleomorphism, phagocytosis, and bizarre multinucleated cell *(inset).*

• **Fig. 7.37** Fine-needle aspirate of a transmissible venereal tumor (TVT). Note the coarse chromatin and small discrete vacuoles in the cytoplasm that are often referred to as a "string of pearls." (Courtesy Dr. Robert Hall.)

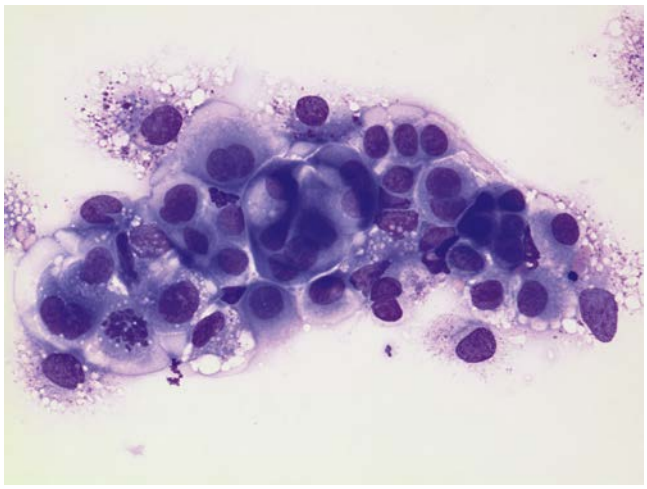
T-cell–mediated immune response that likely leads to the spontaneous resolution of these tumors. Presumed histiocytomas that do not resolve or that increase in size should undergo histologic evaluation to rule out cutaneous lymphoma or a more aggressive histiocytic neoplasm.

Histiocytic Sarcomas of Dendritic and Macrophage Lineage

Histiocytic sarcomas of dendritic and macrophage lineage are malignant tumors and are variably called HS, *malignant histiocytosis* (MH), and *hemophagocytic histiocytic sarcoma* (HHS), depending on clinical presentation, cytomorphologic appearance, and specific cell lineage (see Chapter 34, Section F). These tumors have at least three cytologic appearances. First, the tumor may be composed of a highly pleomorphic population of discrete round cells with extreme variations in N:C ratios, cell size, and nuclear size (Fig. 7.36).[16] The cytoplasm is basophilic and may contain numerous vacuoles, thought to be lysosomes, or phagocytosed erythrocytes, leukocytes, other tumor cells, or cellular debris. Nuclei are typically round but may vary in shape and have indented or irregular margins. Chromatin is coarse to clumped, and nucleoli are prominent and vary in number, size, and shape. Multinuclearity and bizarre mitotic figures are common. Many of these tumors are infiltrated by low numbers of small lymphocytes, plasma cells, and neutrophils. The second form comprises round, oval, and spindle cells with a more sarcoma-like appearance. Pleomorphism is less striking, but criteria of malignancy are present and warrant a cytologic interpretation of malignancy. Cytoplasmic vacuolation and phagocytic behavior also are less frequent. Nuclear shape is typically round to oval or elongate. These two forms are consistent with a tumor of dendritic cell origin.

The third form is HHS, in which neoplastic macrophages constitute a "wolf in sheep's clothing" because the cells resemble phagocytic macrophages found in inflammatory lesions and seldom exhibit criteria of malignancy.[17] The cells have moderate N:C ratios; vacuolated cytoplasm that frequently contains hemosiderin or phagocytosed erythrocytes, neutrophils, or platelets; and round central nuclei with reticular chromatin and one to two variably prominent nucleoli. More prominent pleomorphic features may be seen in a few cells. The neoplastic macrophages may form dense sheets in spleen, liver, or bone marrow, which may be the sole warning of their malignant nature. Rarely is a definitive diagnosis of HHS made cytologically and histologic examination is required; a clinical presentation of hemolytic anemia nonresponsive to immunosuppressive therapy, with or without other peripheral blood cytopenias, warrants consideration of HHS. In the absence of defined masses, a histologic diagnosis may also be difficult.

Differential diagnoses for these tumors depend on cytologic appearance. Few tumors are as pleomorphic as the round cell variant of HS; however, differential diagnoses may include anaplastic carcinoma and pleomorphic lymphoma. Differential diagnoses for the spindle-cell variant include a variety of other sarcomas. Differentials for HHS are not tumors at all, but include reactive macrophage proliferations secondary to other tumors or other inflammatory processes (hemophagocytic syndrome).



Transmissible Venereal Tumor

Transmissible venereal tumor (TVT) is a unique transmissible tumor thought to be of histiocytic origin. Its morphologic appearance is distinctive, and cytologic evaluation can provide a definitive diagnosis, especially when the tumor is located in typical locations, such as mucous membranes of external genitalia and nasal cavity. The N:C ratio is moderate to high. The nucleus is centrally or eccentrically located and has coarse chromatin and one or more prominent nucleoli (Fig. 7.37). The cytoplasm is lightly basophilic and contains characteristic clear vacuoles, often giving a "string of pearls" appearance. Mitotic figures are frequent. Mature lesions may contain infiltrating small lymphocytes. When found in atypical locations, such as the torso, limbs, and lymph nodes, TVT may be mistaken for lymphoma, HS, or amelanotic melanoma.

Mesenchymal and Epithelial Tumors That May Appear as Discrete Round Cell Tumors

Mesenchymal and epithelial tumors that may appear as discrete round cell tumors include amelanotic melanoma, granular cell tumor, anaplastic carcinoma, OSA, chondrosarcoma, rhabdomyosarcoma, and liposarcoma. Histologic examination of the tumor and immunohistochemical evaluation may be required to ascertain the lineage of these round cell imposters.

VetBooks.ir

• **Fig. 7.38** Reactive mesothelial cells in pleural fluid from a cat with chylothorax. These cells may be highly pleomorphic and have criteria of malignancy, but they represented hyperplastic mesothelium in this cat.

Tumor Metastases and Tumors Exfoliating into Cavity Effusions

Specific tumor types preferentially metastasize to certain organs or sites, depending on location of the primary tumor, vascular or lymphatic dissemination, and many other factors. Regional lymph nodes, lung, liver, and spleen are common metastatic sites, but any tissue or organ can be involved, including skin, bone, bone marrow, and the central nervous system. Cytologic identification of tumor metastases begins with recognizing an abnormal population of cells in the metastatic site followed by determining the tissue of origin, if possible, based on cytomorphologic features.

Both primary and metastatic tumors may exfoliate into cavities, including the thoracic, abdominal, and pericardial cavities, or into cerebrospinal or synovial fluid. Although neoplastic cells in these abnormal locations may be categorized as epithelial, mesenchymal, or discrete round cell tumors, the specific origin of the primary tumor is only rarely determined by examining cells in the effusion. A major cytologic challenge when examining cells in cavity effusions is distinguishing reactive mesothelium, mesothelioma, and carcinoma (i.e., carcinomatosis). Mesothelium undergoes hyperplasia and exfoliation whenever an effusion forms in the thoracic, abdominal, or pericardial cavities, and reactive mesothelial cells can adopt all the criteria of malignancy described for tumor cells, including marked anisocytosis and anisokaryosis, macrocytosis and macrokaryosis, multinuclearity, variation of nuclear size within the same cell, nucleolar pleomorphism, and abnormal mitotic figures (Fig. 7.38). Identification of a mass and histologic examination often are required for a definitive diagnosis.

Molecular Diagnostics

ANNE C. AVERY, KARA MAGEE, MELISSA C. PAOLONI, AND CHAND KHANNA

Goals of Molecular Diagnostic Testing in Oncology

Molecular diagnostic testing in oncology is performed to achieve one of several goals: (1) to determine whether a patient has cancer, typically in circumstances in which visual examination of tissue by cytology or histology cannot distinguish a reactive from a neoplastic process; (2) to establish a prognosis; and (3) to guide treatment. Some of these goals currently are realized in veterinary oncology; the polymerase chain reaction for antigen receptor rearrangement (PARR) assay is used to confirm hematopoietic malignancy in both canine and feline patients, and the presence of *c-kit* gene mutations can inform the prognosis in canine mast cell disease. Increasingly, global analysis of oncogenes and gene expression is being used in human oncology, and advances in technology and ongoing veterinary research will make such testing available, affordable, and informative in veterinary medicine within the next few years.

The presence of a particular mutation or chromosomal abnormality can help subclassify a tumor. For example, in people, leukemia/small cell lymphoma (CLL/SCL) and mantle cell lymphoma (MCL) are both neoplasms of mature B cells, with a similar (but not identical) immunophenotype. However, MCL almost always has a rearrangement between the immunoglobulin heavy chain locus (IgH) and the *CCND1* gene (encoding cyclinD1), whereas this rearrangement is very rare in CLL/SCL.[1] The prognosis for and treatment of these two diseases are quite different, so the distinction is important to make.

Molecular diagnostic testing also can help guide therapy. This may be best illustrated by the development of tyrosine kinase inhibitors (TKIs). These drugs inhibit signaling through tyrosine kinase receptors, such as KIT, platelet-derived growth factor receptor (PDGFR), and epidermal growth factor receptor (EGFR). Tumors with mutations in these receptors that result in their constitutive activation may respond well to TKIs, whereas those without such mutations may require different kinds of therapy. Thus testing for mutations in these genes has become commonplace in human medicine (e.g., *EGFR* in small cell lung carcinoma, stem cell factor [SCF] receptor *[c-kit]* in gastrointestinal stromal cell tumors). Similarly, mast cell tumors in dogs that harbor a *c-kit* mutation may respond better to TKIs than those without the mutation.[2]

Oncogenes and chromosomal translocations uniquely distinguish neoplastic from normal tissue. As such, sensitive detection of mutations can be used to quantify residual disease in patients that have been treated. The best example of this is detection of the *bcr-abl* fusion gene, which can allow oncologists to detect as few as $1:10^3$ neoplastic cells in the peripheral blood of people with chronic myelogenous leukemia.[4] Tumor-specific primers that recognize the unique immunoglobulin genes found in both canine and human B-cell lymphomas have been used to quantify tumor burden and monitor disease in both dogs and people with lymphoma.[1,4,5]

The previous examples describe testing for single genetic alterations that are known to be shared by most tumors of the same type. Increasingly, the field of oncology is moving toward personalized, or precision, medicine (PMED). The goal of PMED is to identify genetic mutations and activated signaling pathways that are found in an individual's cancer, even when such changes have not yet been described in a particular cancer type. (PMED is discussed at the end of this chapter.)

For the purposes of this chapter, molecular diagnostics refers to the analysis of genes and gene expression. The goal of this chapter is to review several molecular techniques useful in the diagnosis and classification of cancer. Advanced molecular methodologies and diagnostics likely will continue to improve, become increasingly inexpensive, simpler to use, and more broadly available to veterinarians over the next few years.

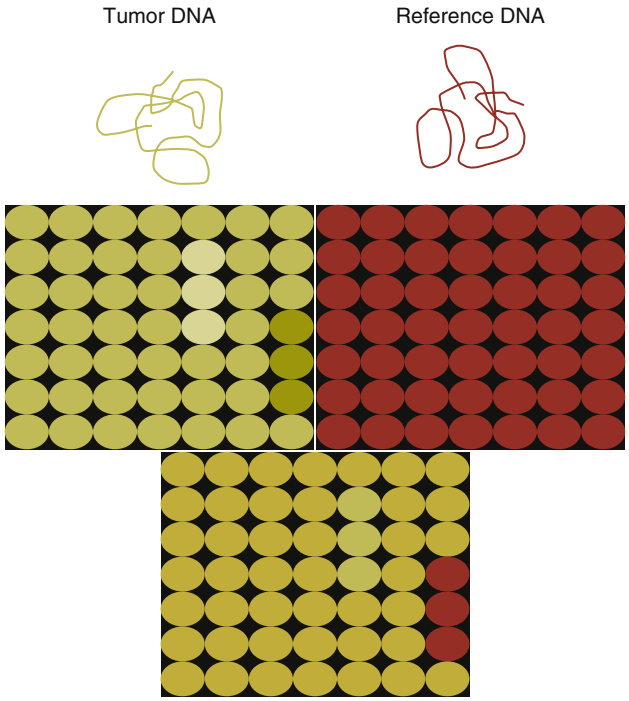
Genomic Dysregulation in Cancer

Most molecular diagnostics target genomic dysregulation that may exist in cancer cells. Such dysregulation may occur at the level of the copy number of a gene; a point mutation in that gene that changes its function; epigenetic modification of deoxyribonucleic acid (DNA) that changes the level of expression; or large-scale changes to chromosomes that remove genes from their normal regulatory environment. Different methods are required for identifying each of these types of changes.

Methods for Analyzing Genes

DNA represents the genetic code of all species. This code consists of a series of continuous nucleic acid sugar strands linked through hydrogen bonds. This series of nucleic acids takes on a tertiary folded structure through modification by binding proteins called *histones*. The folded and wrapped DNA strand is packaged within the chromosomes of the cell. The earliest techniques used to assess the genetic changes of cancer defined gains, losses, or structural changes in chromosomes, referred to as *cytogenetics.* Subsequently,

polymerase chain reaction (PCR)-based methods and high-throughput sequencing have allowed us to detect smaller discrete mutations in DNA that do not involve changes in large portions of the chromosome. Small deletions and insertions in genes, in addition to single-nucleotide changes, are now routinely detected.



Detection of Chromosomal Abnormalities

Historically these techniques involved the examination of metaphase preparations made from chromosomes. The metaphase preparations were then stained (banded) to help in the identification of distinct chromosome morphologies. These techniques allowed detection of gross abnormalities in the chromosome number (ploidy) and the presence of chromosomal translocations; they also led to the identification of genes associated with tumor development and progression. Cytogenetic analysis has been most useful in the clinical assessment of leukemias, for which metaphase preparations are relatively easy to develop from whole blood samples.[6] For most human leukemias, cytogenetic descriptors are used to define distinct subgroups into prognostic groups and to guide treatment decisions.

The use of cytogenetic approaches in the management of companion animals has been limited because of the difficulty involved in using conventional chromosomal banding to identify canine chromosomes. The development of chromosome-specific "paints" that allow the identification of specific canine chromosomes has improved the opportunity to apply cytogenetic descriptors to canine cancers. Using these techniques, Breen et al have identified a chromosomal translocation in canine chronic myelogenous leukemia and chronic monocytic leukemia that is the equivalent of the *bcr-abl* Philadelphia chromosome found in human chronic myelogenous leukemia.[3,7]

For the most part traditional cytogenetic techniques, including the use of chromosome-specific paints, are labor intensive and have been replaced by alternative modalities. Comparative genomic hybridization (CGH) arrays can define gains and losses in chromosome number in tumor specimens rapidly and with highly reproducible results. In CGH analysis the investigator labels genomic DNA from a normal individual and from a patient's tumor cells with two different-colored fluorescent probes. The labeled DNA then is hybridized to an array of DNA probes that span most of the genome. These probes are printed onto a chip or slide, such that the location of each individual probe is identified. The degree of hybridization to each probe is determined by the level of fluorescence detected by laser excitation. Equal hybridization of the DNA from both sources to an individual probe indicates a normal copy number, whereas increased binding by the tumor DNA indicates the presence of chromosomal duplication in the area of the genome covered by that probe (Fig. 8.1). Similarly, higher binding by the DNA from the normal individual indicates chromosomal loss in the area.

CGH arrays are useful for localizing chromosomal regions where investigators should focus their search for genes important to that cancer. Studies of a number of cancers have shown widespread gains and losses of genomic regions. Breen et al have shown that a subset of T-cell lymphomas (histologically defined as peripheral T-cell lymphoma, unspecified) exhibits copy number gain in regions common to most examples of this histologic type, but not present in other T-cell lymphoma subtypes.[8] This finding will help identify genes within the duplicated areas that might be useful for diagnostics and therapy and for understanding the genesis of the neoplasm. A similar study in canine malignant histiocytosis (MH) demonstrated that MH frequently exhibits loss of chromosomal regions that contain tumor suppressor genes,[9] and transitional cell carcinomas (TCCs) were found to commonly exhibit complete gain of a chromosome.[10] The latter discovery led to the development of a diagnostic test for detection of canine TCC by enumerating chromosomal copy numbers.[11] Thus such genetic characterization offers opportunities to develop specific diagnostics, therapies, and management strategies.

• **Fig. 8.1** The principle of array analysis. A chip or slide is printed such that each position on the chip (there are thousands) has a single probe, which can range in size, depending on the type of array. DNA from a tumor tested is labeled with one dye *(green),* and DNA from the reference sample with another *(red).* Both samples are hybridized to the same chip. The separate red and green panels indicate that the tumor DNA exhibits both chromosomal gain (increased green fluorescence) and loss (decreased green fluorescence). When the two DNA preparations are cohybridized, a yellow signal indicates equal degrees of red and green fluorescence. When a gain in copy number occurs in a region of DNA, the signal is green. When a loss in copy number occurs, the signal is red. This is one of several ways microarrays can be performed.

Whole genome sequencing (WGS, discussed later in the chapter) can also detect chromosomal rearrangements. Because this technology rapidly is becoming less expensive and very efficient, WGS likely will replace CGH arrays within the next decade.

PCR-Based Techniques—Detection of Mutations and Novel Genes and Assessment of Clonality

PCR is the process of amplifying a small specific segment of DNA for the purpose of further analysis. Two small segments of DNA (commonly about 20 bases long) that are complementary to the DNA sequence surrounding the area to be amplified are synthesized. These primers are then used to amplify the DNA that lies between them (typically less than 1000 bases). This amplified

DNA product can be analyzed in a number of ways for mutations and to quantify the product for measurement of gene expression; or, in the case of lymphoid malignancy, the DNA can be separated by size to look for clonal populations of B and T cells. The same methods can be applied to the analysis of ribonucleic acid (RNA) once the RNA has been transcribed into DNA (reverse transcriptase PCR [RT-PCR]).

For primer synthesis the sequence of the target gene typically must be known. The publication of good quality canine[12] and feline[13] genomes has been invaluable in this regard—it is now possible simply to use the known sequences, rather than hope for sequence similarities with mice and humans.

Detection of Genetic Insertions and Deletions

PCR-based assays commonly are used in human oncology to detect insertions or deletions in genes relevant to the prognosis or treatment of a neoplasm. In veterinary medicine detection of internal tandem duplications in the *c-kit* gene in canine mast cell tumors is now a routine part of the diagnosis for the purpose of obtaining prognostic information. The primary mutations described are internal tandem duplications (ITDs) in two different exons, exon 8 and exon 11.[14] The mutations involve the duplication of a small segment of DNA so that it is repeated, resulting in a larger gene (Fig. 8.2). Approximately 14% to 20% of canine mast cell tumors have a duplication in either exon 8 or exon 11.[14] Dogs with tumors that carry the ITDs consistently have been shown to have a worse outcome than dogs with a wild-type *c-kit* gene.[15,16]

Detection of this type is fairly simple, because the presence of a larger (or smaller, in the case of deletions) PCR product is determined by size separation. As more genes are identified as targets of therapy, such assays likely will become more frequent. Suter et al identified an internal duplication in the *flt3* gene using the same methods[17] and provided preliminary evidence that the response to a small molecule inhibitor is predicted by the presence of this mutation in cell lines. Thus we are likely to see routine use of mutation detection in the near future.

Detection of Single-Base Mutations

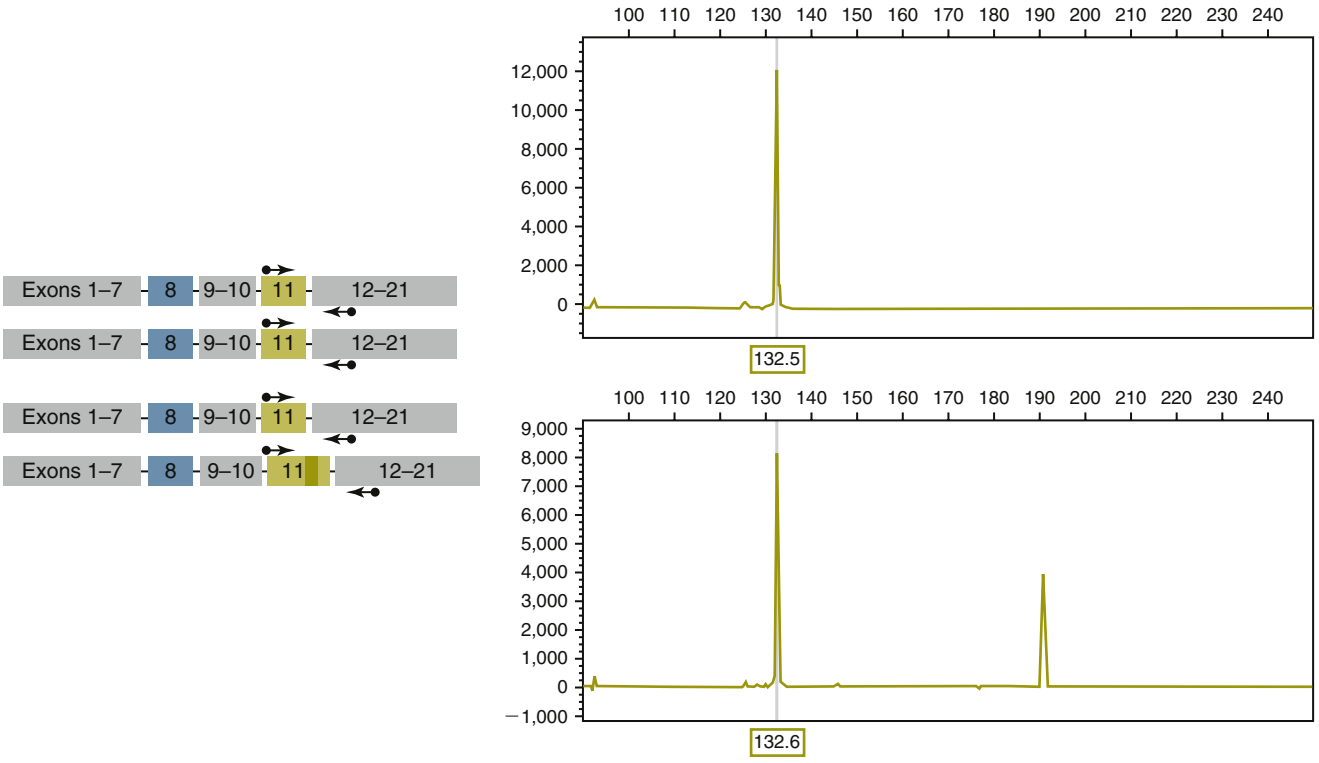
Some cancers will have predictable, single-base mutations that can be detected by standard sequencing. However, sequencing can be insensitive; therefore a variety of PCR-based assays have been developed for mutation analysis. The best example of this type of assay currently in use is detection of a single nucleotide change found in the *BRAF* gene in 80% of cases of canine TCC.[18] The mutation found in the canine gene is equivalent to a *BRAF* mutation common in a variety of human cancers (V600E), and it causes constitutive activation of the BRAF protein. BRAF is a serine/threonine kinase, which activates a series of downstream signaling pathways to drive cellular metabolism and proliferation.[19]

Breen et al developed a PCR-based assay to detect this mutation (in dogs the mutation is called V595E).[20] The purpose of the assay is to diagnose TCC in urine samples with suspicious cells, which can often be difficult by cytology alone. The method used for detection is a technique called *droplet digital PCR* (ddPCR). ddPCR can detect the V595E mutation when it is present in as little as .01% of the DNA.[20] This method was considerably more sensitive than standard sequencing, which could not detect the mutation when it was present in less than 10% of the DNA. ddPCR probably will be used more commonly in the future, because it provides a way of quantifying mutations and DNA copy number changes with high precision.

Detection of Fusion Gene Products by PCR

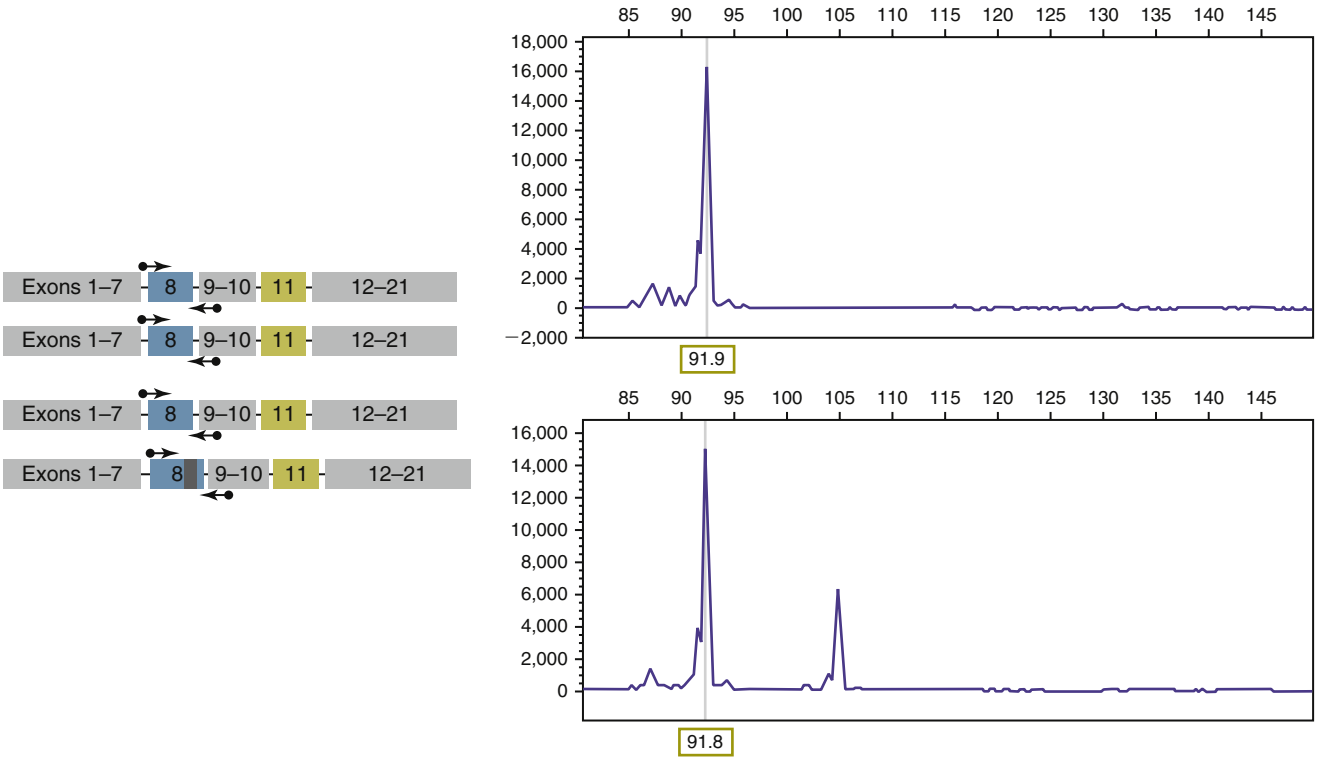
One mechanism by which chromosomal translocation causes malignant transformation of cells is to create novel proteins with altered function. The best studied of these fusion genes, the Philadelphia chromosome, is the *bcr-abl* fusion gene found in greater than 90% of all human chronic myelogenous leukemias (CMLs) and occasionally acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML).[21] ABL is a tyrosine kinase that has myriad activities in cell growth and differentiation. It is encoded on human chromosome 9, and in CML is translocated to chromosome 22. The site of the translocation varies within the *bcr* (breakpoint cluster region) gene, so that a new fusion gene, *bcr-abl,* is formed. The new fusion protein allows for the constitutive activation of the ABL tyrosine kinase, which in turn promotes the development of CML. This novel protein is the product of a novel RNA transcript, which can be readily detected by RT-PCR. This assay can detect as few as $1:10^3$ tumor cells[4] and therefore can be used both for diagnosis of CML and for quantifying residual disease after treatment.

Assays for a large number of translocations in human cancers have been developed over the past 10 years.[22] These assays are now routinely available for characterization of human tumors, particularly leukemia and sarcoma. The finding that canine leukemia and lymphoma can exhibit the same translocations as their human counterparts[7,23] suggests that detection of novel fusion genes will provide inexpensive and sensitive diagnostic testing both for detecting cancer and for monitoring disease in the near future.



Assessment of Clonality in Lymphoma and Leukemia

A clonality assay demonstrates that a group of cells is derived from a single clone. The term usually is used to refer to detection of the unique genes found in each individual B or T cell—immunoglobulin genes in B cells and T-cell receptor (TCR) genes in T cells. The portion of these genes that encodes the antigen binding region is the portion that varies between cells, both in size and sequence. Once a B or T cell is mature and divides in response to antigenic stimulation, the immunoglobulin and T-cell receptor genes are passed on to the daughter cells.[24,25]



In the course of a normal immune response to a pathogen, B and T cells are activated, expand, and eventually die, leaving behind a small number of residual memory cells. On the other hand, when a cell becomes neoplastic, it no longer responds to growth controls and undergoes unlimited expansion. Therefore if it can be established that most of the cells in a particular collection of lymphocytes have the same immunoglobulin or T-cell receptor gene, these cells most likely are neoplastic rather than reactive.[26]

When immunoglobulin and T-cell receptor genes rearrange during the course of B-cell and T-cell development, respectively, the length and sequence of the resultant gene differs from cell to cell. This happens for many reasons; for example, nucleotides are added between V, D, and J segments as they rearrange into a contiguous formation. The clonality assay takes advantage of this development. A sample consisting of many different lymphocytes, as in a reactive process (e.g., the lymph nodes of a dog with chronic pyoderma or poor dental hygiene), will have multiple, different-sized, T-cell receptor and immunoglobulin genes. On the other hand, in a sample consisting of neoplastic lymphocytes, the immunoglobulin gene or the T-cell receptor gene (depending on whether it is a B-cell or a T-cell lymphoma) will be a single size (Fig. 8.3). (All methods used in veterinary medicine to detect clonally rearranged T-cell receptor genes target the TCR gamma gene.)

• **Fig. 8.2** Detection of *c-kit* mutations by polymerase chain reaction (PCR). (A) Two different tumor types are depicted: one has two copies of a wild-type *c-kit* gene, and the other has one copy of a *c-kit* gene containing an internal tandem duplication in exon 11. On the right are shown the PCR products detected after amplification with primers surrounding the duplication *(arrows)* for each tumor. (B) Same as in (A), but in this case the second tumor has an internal duplication in exon 8, and the PCR products are amplified with primers flanking the region of the duplication.

• **Fig. 8.3** Rearrangement of immunoglobulin genes. (A) There are approximately 80 V region genes, 6 D region genes, and 5 J region genes. Single V, D, and J genes are brought together at random to create a single VDJ gene segment, which encodes the antigen-binding portion of an antibody, and the intervening sequence is removed. (B) In the process of bringing together V, D and J genes, a variable number of nucleotides *(black)* are added between V and D, and D and J. As a result, each individual B cell will have a VDJ gene segment with a unique length. When DNA from a heterogeneous population of B cells is isolated and amplified with primers bracketing the VDJ gene segment *(small arrows)*, the polymerase chain reaction (PCR) products will be different lengths. The lower panel shows the PCR products separated by size by capillary gel electrophoresis; it illustrates multiple different-sized PCR products. (C) When a population of B cells comprises cells derived from a single clone, all the VDJ gene segments will be identically sized. PCR amplification of the VDJ gene segment will yield a single-sized product *(see lower panel)*. All the principles illustrated here apply to T-cell receptor (TCR) genes. For the clonality assay, the T-cell receptor γ-chain is amplified, although in theory the TCR β-chain could also be used.

Clonality assays are accomplished by isolating DNA from cells suspected to be neoplastic. PCR primers directed at the conserved regions of T-cell receptor or immunoglobulin genes are used to amplify the variable regions, and the PCR products are separated by size using a variety of methods. The presence of a single-sized PCR product indicates clonality, whereas the presence of multiple PCR products supports a reactive process.[27] This assay has been reported by a number of laboratories for both dogs and cats[27]; it is termed the *PCR for antigen receptor rearrangements* (PARR) assay to distinguish it from other types of clonality assays.[28] It should be noted, however, that the term "PARR" is not used in the human literature, where the assay instead is referred to as a *clonality assay.*

The PARR assay can detect approximately 1:100 neoplastic cells. The sensitivity and specificity of the assay differ between laboratories; however, because the results are significantly affected by the conditions under which the assay is run and the technique used to separate the PCR products, clinicians must consult the laboratory providing the testing about the sensitivity and specificity of the assay as performed under their conditions.

The main application of the PARR assay is to establish clonality in a sample that is cytologically or histologically ambiguous. Another application is to compare two neoplasms arising at different times to determine whether they have the same clonal origin.[29] The PARR assay increasingly is used to distinguish

VetBooks.ir

inflammatory bowel disease from gastrointestinal (GI) lymphoma in dogs[30,31] and cats[32,33] and to aid in the diagnosis of nodular splenic lymphoma, which can be difficult to distinguish from nodular hyperplasia.[34]

Clonality assays sometimes can be useful for establishing the lineage (B cell vs. T cell) in cytologically unambiguous lymphomas if additional case material is not obtainable from the patient. However, flow cytometry or immunohistochemistry generally is preferable for this purpose, for several reasons: first, aberrant rearrangements occasionally can be seen in nonlymphoid tumors, such as myelogenous leukemias.[35] Second, simply knowing whether a neoplasm is derived from a B cell or a T cell may not be clinically useful. Both lineages can give rise to markedly different tumor types with significantly different outcomes. For example, the two most common forms of T-cell lymphoma (peripheral T-cell lymphoma and T-zone lymphoma) both have clonally rearranged T-cell receptor genes. Peripheral T-cell lymphoma, however, has a median survival time of 150 days,[36] whereas T-zone lymphoma is indolent and may not require treatment at all.[37]

The principle of the clonality assay also can be used to quantify tumor cells in blood, bone marrow, or node and to monitor minimum residual disease. For this type of analysis PCR primers specific for the immunoglobulin or T-cell receptor gene carried by the tumor are used instead of the broadly reactive primers used to screen samples. In this way the investigator is certain that only tumor DNA is amplified, and not nonneoplastic lymphocytes. The specificity of this reaction permits determination of the number of tumor cells in a sample of blood, even when those cells are as rare as $1:10^4$ cells. Yamazaki et al demonstrated that with current chemotherapy protocols, all seven dogs they examined had at least $1:10^4$ cells in their peripheral blood, even though the dogs achieved clinical remission.[5] Although this kind of analysis may not be practical for routine diagnostics, it is a powerful research tool to compare the efficacy of novel chemotherapy regimens, and it also can be used to refine current protocols. Indeed, this method subsequently was used by Sato et al to evaluate the responsiveness of B-cell lymphoma to individual components of the *c*yclophosphamide, *h*ydroxydaunorubicin, *O*ncovin and *p*rednisone or prednisolone (CHOP) chemotherapy protocol.[38]

Assessment of Clonality in Nonlymphoid Neoplasms

Nonlymphoid cells do not have unique DNA sequences that differ from cell to cell, so other methods must be used for clonality assessment. The question of whether a collection of cells is neoplastic arises in a variety of circumstances—eosinophilia in the cat, for example, or pleural effusion in a dog, which is dominated by cells that could be either reactive or neoplastic mesothelium. One way to determine whether the cells in these cases are derived from the same clone is to examine the pattern of X chromosome inactivation. One copy of the X chromosome in the cells of female animals is inactivated by DNA methylation. The purpose of the inactivation is to ensure that both male and female animals have the same "dosage" of genes found on the X chromosome. Inactivation is thought to be random, so in a nonneoplastic collection of cells, any given cell would have an equal chance of either the maternal or paternal X chromosome being inactivated. If the cells are all derived from the same clone, however, the same X chromosome would be inactivated in each cell.

In female animals, X chromosome inactivation can be measured using the androgen receptor gene. This gene contains repeated DNA elements (CAG repeats), the number of which varies. If an animal is heterozygous for the number of repeats, it is possible to determine whether the same X chromosome is inactivated in all the cells in a particular sample. Because not all animals will be heterozygous, the assay is useful only in a subset of female animals—68% of cats[39] and 50% of dogs.[40] The assay has been used for canine patients with possible chronic myelogenous leukemia[40] and for cats with possible myelodysplastic syndrome.[39] In dogs this assay has been named the *canine androgen receptor assay* (CANARA assay).[41]

Whole Genome and Whole Exome Sequencing—Next Generation Sequencing

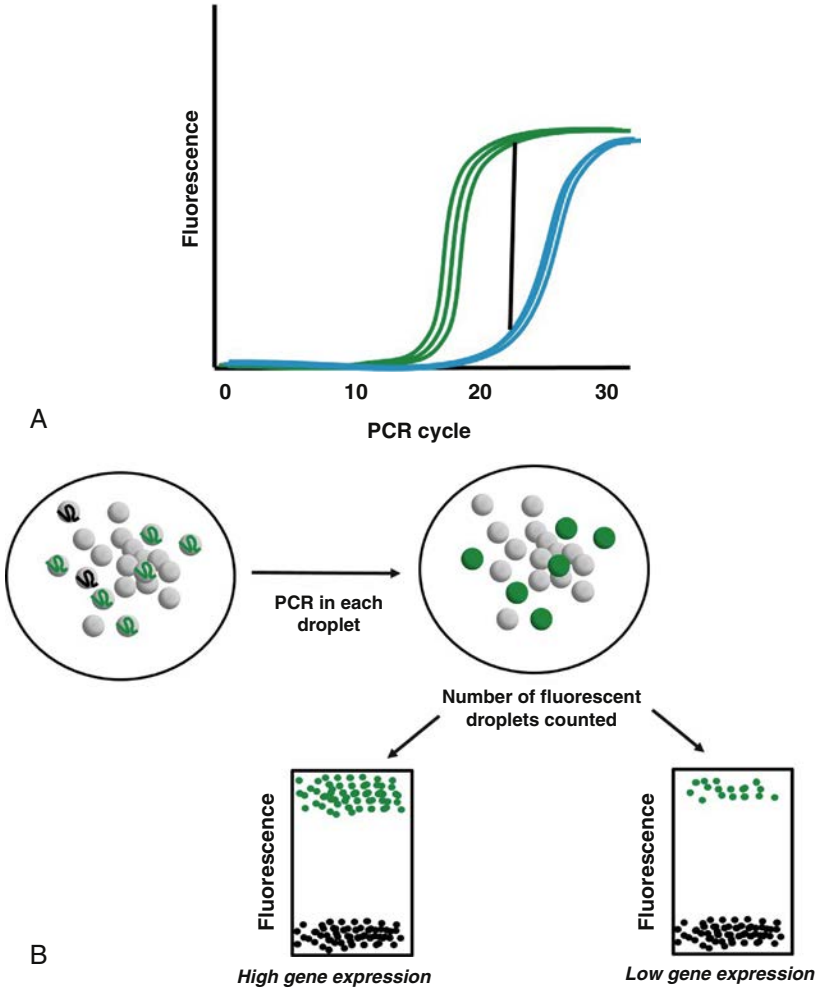
Next generation sequencing (also known as *massively parallel sequencing*) is a technology that allows investigators to sequence the entire genome of an individual (or an individual's tumor). Sequencing an entire genome was considered an enormous and expensive endeavor not many years ago, but it is now a routine part of investigating the biology of cancer. Thousands of human cancers have been fully sequenced, and the cost and efficiency of this process means that individual tumors can be sequenced to aid clinical decision making. The main types of information that can be obtained from whole genome sequencing of a tumor include (1) mutations in potential oncogenes or tumor suppressor genes, including single nucleotide variants (SNVs) and insertions and deletions (indels); (2) structural changes in chromosomes, including fustion genes and copy number variations (CNVs), in which whole genetic regions may be duplicated; and (3) the mutational load of a particular tumor, which may predict responsiveness to checkpoint inhibitor therapy and also identify potential neoantigens that may be targeted in immunotherapy strategies. The principles of next generation sequencing are described in the next section.

Quantifying Genes and Gene Expression

The complete genetic code, or DNA sequence, is present within every cell in the body. The effective genetic information that uniquely defines each cell type within the body is defined by the genes expressed (transcribed) as messenger RNA (mRNA). The complete profile of mRNA expression is more responsible for the phenotype of a cancer than the individual genes, although mutations in a gene often are individual drivers of a cancer phenotype. To assess the level of expression of one or a few genes, three methods could be used: (1) real-time quantitative PCR (RT-qPCR), which has been used for many years; (2) ddPCR, which is a more recent development that has many advantages over RT-qPCR and which probably will replace RT-qPCR for most applications; and (3) non-PCR–based gene counting methods, such as Nanostring.

If the goal is to measure expression of all the genes in a tumor, microarrays and, more recently, RNA sequencing (RNA seq) methods have been used. Assessment of the global level of gene expression is called *gene expression profiling*.

Real-Time PCR and Droplet Digital PCR



RT-qPCR refers to the quantitative (Q) measurement of DNA—either genes or, more commonly, RNA that has be reversed transcribed to cDNA.[42] The principle of RT-qPCR is that DNA is amplified using primers, just as in a routine PCR reaction, but at each round of amplification, the amount of PCR product is quantified. Unlike endpoint PCR, in which the reaction runs to completion and the product is separated by size, real-time PCR is quantitative and relies on the change in the amount of PCR product, as measured by fluorescence, as the reaction progresses.

VetBooks.ir

Real-time PCR typically uses fluorescently labeled DNA probes. These are short segments of DNA complementary to the target sequence between the two primer sites. A fluorescent molecule attached to the probe is quenched (no fluorescence detectable) until the 5′ to 3′ exonuclease activity of the Taq polymerase releases the fluorescent molecule. As the amount of PCR product increases proportional to the starting material, the amount of fluorescence increases (Fig. 8.4A). The expression level of a gene of interest is normalized to housekeeping genes and can be compared between samples.

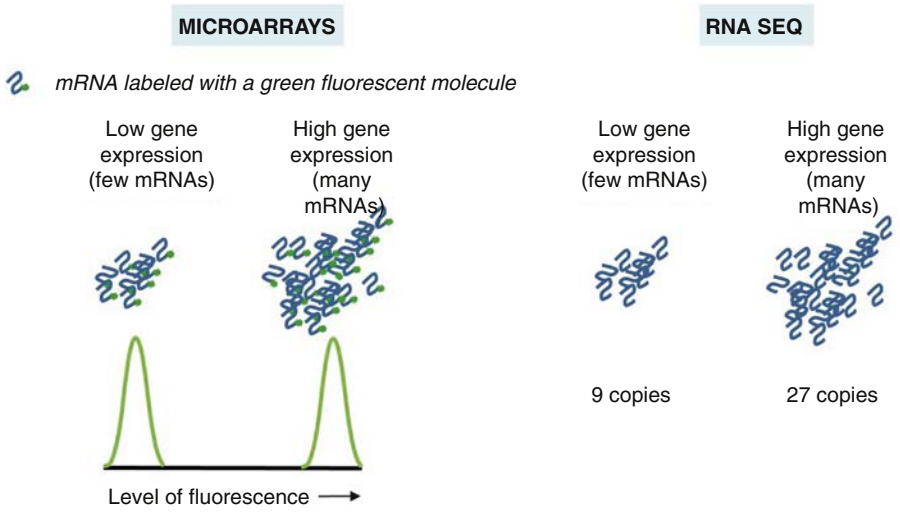
ddPCR rapidly is replacing RT-qPCR because it has a number of distinct advantages.[43] In this method, RNA is reverse transcribed into cDNA and then the cDNA is dispersed into thousands of oil droplets, in such a proportion that the oil droplet will have either one copy of the gene of interest or no copies (see Fig. 8.4B). Also in the oil droplet is the other material for a PCR reaction (primers, fluorescent probes as described previously, and polymerase). An endpoint PCR reaction is performed in each droplet (all droplets are amplified simultaneously), and the number of fluorescent droplets is counted. This is called "digital" PCR because the level of gene expression is correlated with the count of positive droplets. By contrast, RT-qPCR measures the level of gene by the cumulative fluorescence of all the cDNA in the sample.

The reason ddPCR is an improvement on RT-qPCR is that for the latter, scrupulous attention must be paid to primer efficiency, and the range of gene expression over which it is useful is limited.

• **Fig. 8.4** Comparison of a real-time quantitative polymerase chain reaction (RT-qPCR) assay and a droplet digital PCR (ddPCR) assay. (A) An RT-qPCR assay shows different levels of expression of a gene in two different tumors. The green lines are from a tumor (performed in triplicate) that expresses high levels of the gene being measured; the blue lines are from a tumor that expresses lower levels of the gene being measured. At the end of the reaction (cycle 40 in this example), the two samples have almost the same level of fluorescence. In RT-qPCR, gene expression is assessed by measuring the difference in fluorescence in the early cycles. The difference in fluorescence at cycle 22 is significant. The same curves are generated for a housekeeping gene (not shown) to normalize the amount of input complementary DNA (cDNA) for both samples. (B) In ddPCR, RNA is reverse transcribed into cDNA, and the cDNA (which includes all genes) then is partitioned into thousands of oil droplets, using special instrumentation, together with the other materials for a PCR reaction (primers, polymerase, fluorescent probes). Many droplets will be empty; some will have cDNA but not the gene of interest *(black)*; and some will have the gene of interest. The PCR reaction is performed to endpoint (e.g., 30 cycles). The amount of RNA of the gene of interest is reflected by the number of fluorescent droplets. As with RT-qPCR, a similar reaction using a housekeeping gene is performed to normalize input cDNA levels.

VetBooks.ir

With ddPCR, as long as the PCR reaction produces a fluorescent signal, the efficiency with which the reaction achieves that signal is not as relevant to the results. The technology is also less limited by the amount of sample available.



Gene Expression Profiling

Gene expression profiling refers to the quantification of thousands of mRNAs simultaneously, to create a picture of global gene expression in the cell population. The pattern of gene expression is called a *gene expression profile.* In most cases gene expression profiling is comparative. Investigators can compare expression profiles of tumor cells to the normal cellular counterpart, to similar tumors with different clinical outcomes, to tumor cells from the same patient before and after therapy, or between primary and metastatic lesions, to determine how different pathways have changed. Such information has proven invaluable in a variety of settings. For example, in a study of cervical cancer in people, investigators analyzed gene expression profiles of tumors that responded to chemotherapy and radiation and compared those with tumors that did not. Their study revealed that activation of the PI3K/Akt signaling pathway was associated with a poor response, suggesting one potential therapeutic target.[44] It is important to note that the collective signature of an expression profile can be an informative predictor of disease biology or response to therapy; however, alterations in the expression of a single gene are rarely informative and require extensive post hoc validation.

Another example of how gene expression profiling has advanced oncology is the studies of B-cell lymphoma by Staudt and colleagues. Noting that diffuse large B-cell lymphoma (DLBCL) has a heterogeneous outcome in people, this group compared the gene expression profiles of 96 DLBCLs with B cells derived from different stages of normal B-cell development.[45] They found that the gene expression profile of DLBCL could be categorized either as similar to germinal center B cells or similar to activated B cells. Importantly, these two categories had prognostic significance; germinal center–like DLBCL patients have a better prognosis. The distinction between germinal center DLBCL and activated B-cell DLBCL is now well established as a prognostic indicator in people. Studies of canine lymphoma have offered conflicting data with regard to subclassification of canine DLBCL into germinal center and activated B-cell subtypes based on gene expression profiling, so additional study is necessary.[46,47] Staudt et al made another important discovery about human B-cell lymphoma, using gene expression profiling, that provided insights into immunity to cancer. Expression profiles of lymph nodes from patients with follicular B-cell lymphoma demonstrated that the type of immune response signature was prognostic in this disease. Patients whose lymph node gene expression patterns exhibited evidence of T-cell activation had a better overall survival than patients whose gene expression patterns resembled activated macrophages.[48] The expression profile of the tumor cells themselves was not predictive. This finding suggests that the immune response contributes to survival in patients with follicular B-cell lymphoma, a result corroborated in other types of B-cell lymphoma.[49,50]

Microarrays

Microarrays are solid chips on which DNA probes that are complementary to thousands of different genes are imprinted. [51] Such platforms expand the study of expression of single genes to a larger scale needed for an expression signature to be defined. RNA from a tumor is transcribed into cDNA and labeled with a fluorescent molecule. The labeled cDNA is then hybridized with the probes on the chip, and the level of fluorescence is proportional to the number of copies of RNA molecules in the sample (Fig. 8.5). A microarray experiment can be performed in a large variety of ways, but ultimately the goal is to measure expression of all the genes in the sample.

• **Fig. 8.5** Comparison of the measurement of gene expression using microarrays and RNA seq. Microarrays are carried out by labeling all the messenger RNAs *(mRNAs)* (reverse transcribed into cDNAs) in a sample with a fluorescent molecule, and then allowing that molecule to anneal to a chip coated with thousands of DNA probes complementary to each cDNA. The level of fluorescence at each position on the chip (corresponding to an individual gene) reflects the total number of mRNA molecules in the sample, but the number of mRNA molecules is not counted. RNA seq, on the other hand, uses technology that allows every single expressed gene to be sequenced. Because the sequence of every gene is known, the absolute number of mRNAs for each gene in the sample can be counted.

VetBooks.ir

RNA seq

As does a microarray, RNA seq measures global gene expression.[52] In microarrays the amount of mRNA from an individual gene is measured by the cumulative fluorescence contributed by all copies of the mRNA transcribed from a given gene (see Fig. 8.5). RNA seq, however, uses massively parallel sequencing, also known as Next Gen sequencing, to sequence every mRNA in a sample. The sequence allows for identification of the gene from which it was derived. Because all mRNAs are sequenced, this methodology allows the investigator to count the number of individual mRNAs. Genes that are highly expressed will have high numbers of mRNAs.

Although RNA seq experiments involve a great deal more bioinformatic complexity, they also can provide information not obtainable using microarrays. This includes the ability to identify potential mutations in coding regions because sequence information is being obtained, and the ability to identify some fusion genes that create fusion transcripts.

Personalized Medicine in Cancer

Foundations of Precision Medicine: the Genetic Basis of Cancer

Cancer is a genetic disease that arises as a consequence of the stepwise accumulation of disruptive mutations in genes that regulate cell life and death. Clonal expansion of cell populations bearing cancer gene mutations fuels the formation of malignant tumors. This genetic model of cancer emerged in the latter 20th century as a product of advances in genetics, evolution, and cancer medicine. Through this mutational process, cancers acquire specific key properties, including self-sufficient growth signaling, resistance to growth inhibitory signaling, invasion and metastasis, unlimited replication potential, angiogenic signaling, immune modulation, DNA instability, metabolic dysregulation, and immune evasion.[53]

The genetic model and its downstream phenotypes have since been validated in many cancer types and provide a framework for our growing genomic understanding of cancer. The concept of personalized or precision medicine stems from the previously described genomic underpinning of cancer and its nascent and emerging complexity. Indeed, truly personalized and genomic medicine now seeks to define the genomic drivers of a particular patient's cancer and match these alterations to specific therapeutics. PMED is ushering in a new era in cancer therapy in which clinical and translational value are applied to advances in the genomic analysis of cancer. The discoveries and tools described previously have provided new opportunities to tailor cancer therapy to the individual molecular characteristics of a specific cancer, in a specific patient, to guide diagnosis, prognosis, and treatment selection. In many cases these genetic alterations can be matched to specific therapeutic agents as a means to uniquely improve outcomes for patients. Tumor samples and matched germline samples (from peripheral blood or cheek swabs) may be collected, preserved, and then analyzed for genetic alterations in a core set of cancer genes, which ultimately are matched to an individualized therapeutic prescription.

How Precision Medicine Differs from the Current Practice of Oncology

The use of patient-specific information as a means to deliver PMED is not new to the treatment of cancer patients. Through the history of cancer medicine, treatments have been administered in a patient-specific and personalized manner. Even in the modern era, the use of molecular data to guide the therapy of specific individuals with cancer is not entirely novel. The use of specific immunohistochemical or cytogenetic markers to guide the diagnosis and prognosis has been a critical and routine practice in pathology laboratories for many decades. Furthermore, in some cancers molecular markers have been used to guide treatment selection. For example, in human breast cancer a long-standing practice has been to define the expression of hormone receptors as a means to deliver specific therapeutics that alter downstream signaling pathways.[54] *C-kit* mutation status has been used in veterinary medicine to direct therapy for mast cell tumors,[2,55] but conflicting data in the literature raise questions about this approach, and more investigation is needed.[16]

Although genomic data is expected to affect patient outcomes dramatically, genomic data has been slow to enter the clinic. One of the first pilot studies incorporating molecular profiling to guide therapy in advanced cancers was published in 2010.[56] This study faced considerable challenges, but the researchers found that 27% of 68 patients treated according to molecular profiling recommendations (i.e., PMED) experienced a longer progression-free survival than during the most recent treatment on which they had progressed. Although it is perhaps intuitively beneficial to incorporate precise target identification into patient treatment, this approach still faces significant hurdles, and it remains to be proven through prospective trials that treatment based on PMED outperforms a physician's choice of treatment. Now, multiple clinical trials incorporating genomics-guided therapy selection are underway to test this very hypothesis. In one such trial, the Stand Up To Cancer and Melanoma Research Alliance Dream Team Clinical Trial, molecularly guided therapy in non-V600E mutant BRAF metastatic melanoma is being assessed. This is now an ongoing randomized clinical trial.

Returning clinically relevant and actionable information based on genomic analysis within a window that enables effective treatment selection is a substantial challenge. Notable hurdles include those associated with tumor biopsy; sample preservation and transport; nucleic acid extraction and quality control; genomic sequencing infrastructure and platform; data analysis and integration; generation of digestible genomic reports for physicians, veterinarians, and scientists alike; and performance of tumor board reviews to provide a treatment recommendation. Additional hurdles involve the implementation of precision medicine in the clinic.

In the broadest sense, the clinician seeking a PMED approach for a patient must first ask what data would be most helpful.

"I need new treatment options." In the setting of a rare tumor or a patient with unusual tumor biology, new ideas for therapy may be needed. In this setting an optimal PMED platform will identify specific drivers of this patient's cancer biology and propose new treatments. For such a clinical question, an optimal PMED platform likely will include an analysis of mutations in cancer-associated genes, with drug matching to target the presumed aberrant mutational targets of the individual cancer. The validation of the value of this approach has been difficult using conventional clinical trial designs and may demand novel perspectives on evidence for clinical validation. Because many solid tumors are clinical problems as a result of metastatic progression (e.g., canine osteosarcoma), the optimal PMED platform will derive a list of "shed" mutational targets from circulating biofluids (i.e., so-called liquid biopsy) alone or in combination with tumor analysis.

VetBooks.ir

"I have some idea on treatments but want to prioritize the best therapy." It is not uncommon that the selection of the best treatment for a cancer histology is unclear and often defaults to the clinician's preference (e.g., selection of a specific cytotoxic chemotherapy for canine bladder carcinoma). A distinct PMED approach may provide assistance in known drug selection. The theoretical value of selecting the best drug, based on intrinsic resistance and sensitivity signatures, may be effectively provided through transcriptomic, proteomic, and cell-based PMED platforms. The validation of these drug selection strategies will require prospective validation in specific cancers in which cohorts of individuals may receive a PMED-described medication compared with clinician's best choice. Such transcriptomic, proteomic, and cell-based PMED platforms are less likely to identify specific drivers of cancer biology and generate new options for therapy.

An ever-growing array of tests designed to inform diagnostic and treatment decisions in the human clinic is available from more than 100 academic and 50 commercial laboratories. These tests range in scope from single genes to gene panels, exomes, and even whole genomes. Indeed, the multiomic analysis of cancer (multiple modalities used in a single cancer) is now common and has reulted in a need to display and share such multiomic data. In everyday clinical practice the cost is still prohibitive, and the expertise and infrastructure required to bring them to bear on patient care are also largely lacking. Finally, more comprehensive data showing improvements in genomics-correlated clinical outcomes is needed to support the use of these tests.

The Path to PMED for Veterinary Cancer Patients

Although much work remains to be done to chart the genomic landscapes of companion animal cancers, the PMED approach nonetheless is poised to have a dramatic effect on the care of canine cancer patients. Indeed, we have published on the clinical feasibility of this approach in dogs.[57] PMED now represents a cutting edge opportunity in veterinary cancer care and is the subject of ongoing prospective clinical trials. In fact, not only would this approach make great headway in the care of canine cancer patients, but also, given the unique aspects of naturally occurring cancer in pet dogs and the forward-thinking perspectives of the veterinary profession on the whole, veterinary oncology may be able to provide key data validating this model and refining its implementation for human medicine. As a means to change the biology of an important canine cancer problem, we have initiated a research agenda that will deliver personalized medicine for the canine cancer hemangiosarcoma through clinical trials that have recently launched.

Using Molecular Diagnostics as a Clinician

It has been historically acceptable for one laboratory to describe the performance of a specific assay in their hands and for clinicians to expect similar if not identical results from the same analysis performed by a distinct laboratory. Indeed, based on this expected consistency of analysis among laboratories, there was little need for distinct laboratories performing the same assay to publish their own independent results and experiences. Standardization has yet to come to the field of molecular diagnostics, and clinicians should expect the publication of a laboratory experience with a given assay and should not expect the performance of the assay to be the same across laboratories. Further complicating the issue of assay performance, characterized by sensitivity, specificity, and positive and negative predictive values, is the need to understand carefully the relevance of the patient populations used in manuscripts that describe assay performance. Assay performance is closely regulated in the human molecular diagnostics field (e.g., Clinical Laboratory Improvement Amendments [CLIA] laboratory certification), but such regulation is absent in the veterinary reference laboratory diagnostic model. Therefore rigor and the requirement of transparency appropriately become the responsibility of the diagnostic scientist and must be demanded and understood by the attending clinician.

Summary

Molecular diagnostics is becoming more integrated into veterinary medicine and at the same time becoming more affordable. One important feature of such advanced diagnostics is that many of these techniques save money for owners and eliminate the need for invasive procedures for their pets. For example, sensitive methods for detecting lymphoma through a combination of cytology, flow cytometry, and PARR assays can mean that a diagnosis of splenic lymphoma can be made without splenectomy. Detection of the *c-kit* mutation can guide therapy so that the most efficacious (and therefore cost-effective) drugs are used. More expensive exploratory techniques, such as whole genome sequencing and proteomic analysis of tumors, will almost certainly lead to discovery of new testing that can further simplify diagnoses. Veterinarians are encouraged to participate in these developmental studies when they can, by providing biologic materials and clinical data to researchers, because ultimately patients and their owners will derive great benefit from current research.

Biopsy and Sentinel Lymph Node Mapping Principles

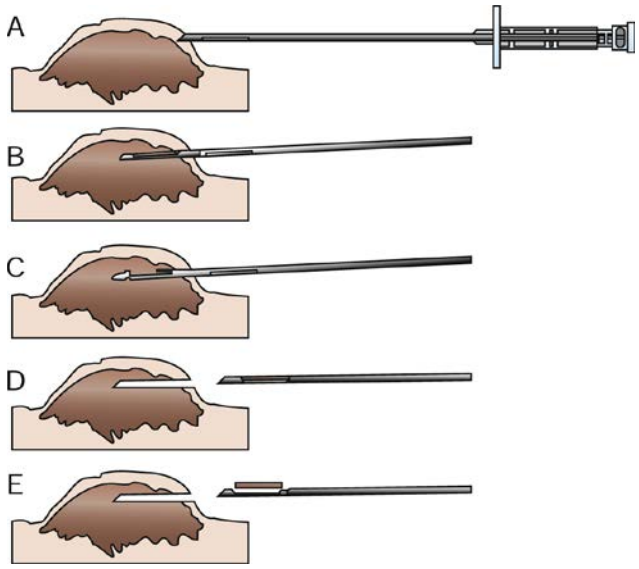
NICOLE P. EHRHART

A biopsy refers to a procedure that involves obtaining a tissue specimen for microscopic (i.e., histopathologic) analysis to establish a precise diagnosis. Histopathologic interpretation of tissue removed from a tumor is not foolproof and is highly dependent on the quality of the biopsy sample submitted. Therefore it is important to understand basic principles of biopsy procurement and submission to obtain an accurate diagnosis. If the tissue diagnosis is incorrect, every subsequent step in the treatment of the patient may also be incorrect.

Fine-needle aspiration cytology (FNAC) is a simple and rapid way to obtain information about a tumor and is often the first step in the diagnostic workup. Results of FNAC help guide the diagnostic tests for staging. Studies have shown that FNAC is a reliable and useful method to guide further workup when neoplasia is suspected or to rule out neoplasia.[1,2] Nonetheless, FNAC gives limited information and may be nondiagnostic or equivocal. Inflammation, necrosis, and hemorrhage may result in cytopathologic changes that do not accurately represent the underlying disease process. Histologic confirmation may be necessary for definitive diagnosis of neoplasia.

There are many available techniques for obtaining tissue specimens, ranging from needle-core techniques to complete surgical excision. The choice of technique depends on the anatomic location of the tumor, the overall health of the patient, suspected tumor type, and clinician preference. Biopsy techniques can be grouped under one of two major categories: pretreatment biopsy (e.g., needle-core biopsy, punch biopsy, wedge biopsy, etc.) or excisional biopsy. Pretreatment biopsy is performed to obtain additional information about the tumor before definitive treatment. Posttreatment (i.e., excisional) biopsy refers to the process of obtaining histopathologic information after surgical removal of the tumor. Excisional biopsy is best used to obtain a more complete picture of the disease process (e.g., histologic grade, histologic subtype, degree of invasion into regional vasculature and lymphatics, etc.) and provides an opportunity to evaluate completeness of excision. It is rarely ever the best first step in obtaining a tissue diagnosis. Although excisional biopsy is attractive to many clinicians because it allows for definitive treatment and diagnosis in one step, it is often used inappropriately in the management of a cancer patient, resulting in incomplete surgical margins. Incomplete surgical margins can result in local tumor recurrence and the need for radiation therapy or a wider, more extensive surgery. All of these sequelae compromise the optimum treatment pathway for the patient and will involve more morbidity and expense than a properly performed first excision. The issue to be determined before surgery then is: how aggressive should the surgery to remove the tumor be? It is intuitive that wide, ablative surgery (e.g., body wall resection) would be inappropriate for a simple lipoma. It also follows that marginal excision (shell out) is inappropriate for definitive treatment of an aggressive infiltrative tumor such as a soft tissue sarcoma. Thus thorough knowledge of the tumor type is imperative before attempting surgical excision. The best way to obtain this information is often via biopsy.

Specific indications for pretreatment biopsy are as follows:



1. When FNAC is nondiagnostic or equivocal
2. When the type of recommended treatment (radiation, chemotherapy, surgery) would be altered by knowledge of the tumor type or grade
3. When the extent of recommended treatment (ablative surgery, wide excision, marginal excision) would be altered by knowledge of the tumor type or grade
4. When the tumor is in a difficult area to reconstruct (maxillectomy, locations requiring extensive flaps, head and neck, etc.) and planning is needed to prepare the patient and client appropriately
5. When knowledge of the tumor type or histologic grade would change the willingness of the client to proceed with curative-intent treatment

If any one of the listed criteria is met, a pretreatment biopsy should be pursued.

There are occasions when pretreatment biopsy would be contraindicated. These include cases when the type of treatment or extent of surgery would not be changed by knowing the tumor type (e.g., testicular mass, solitary splenic mass) or when the surgical procedure to obtain the biopsy is as risky as definitive removal (e.g., spinal cord biopsy). In these cases, the patient would best be served by excisional biopsy of the tumor if staging results support this choice.

Biopsy Methods

The more commonly used methods of tissue procurement are needle-core biopsy, punch biopsy, incisional (wedge) biopsy, and excisional biopsy.

• **Fig. 9.1** Mechanism of action of needle-core biopsy for typical solid tumor. (A) A small stab incision is made with a scalpel blade to allow for insertion of the instrument. With the instrument closed, the needle is advanced into the tumor, taking care to ensure the capsule is penetrated. (B) The outer canula is fixed in place while the inner canula with the specimen notch is advanced into the mass. This allows the tumor tissue to protrude into the specimen notch. (C) The inner canula is held steady while the outer canula is advanced. This traps the tumor specimen in the notch. (D) The instrument is removed. (E) The inner canula is advanced again to allow access to the tissue within the specimen notch.

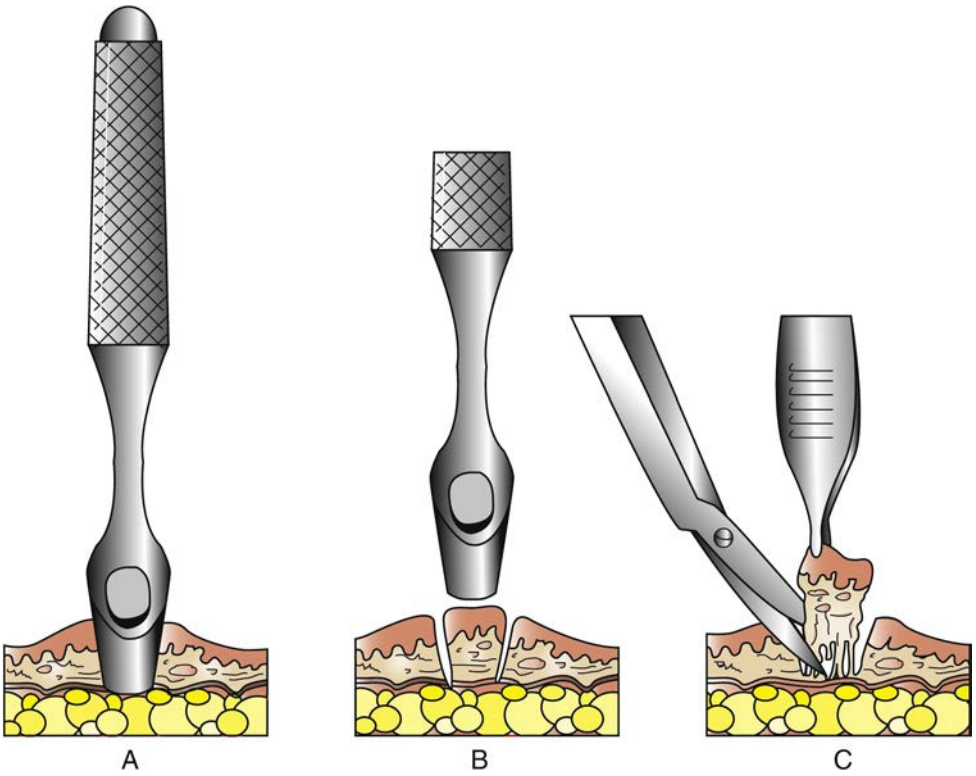
Needle-Core Biopsy

Needle-core biopsy utilizes various types of needle core instruments (Tru-Cut, etc.) to obtain soft tissue (Fig. 9.1). Most of these needles use spring or pneumatically powered needles, although manually operated devices are still available as well. Specialized core instruments are used for bone biopsies and will be covered in Chapter 25. These instruments are generally 14-gauge in diameter and procure a piece of tissue that is about 1 mm wide and 1.0 to 1.5 cm long. In spite of this small sample size, the structural relationship of the tissue and tumor cells can usually be visualized by the pathologist. Virtually any accessible mass can be sampled by this method. It may be used for externally located lesions or for deeply seated lesions (kidney, liver, prostate, etc.) with image-guidance via closed methods or at the time of open surgery.

The most common use of the needle-core biopsy is for externally palpable masses. Except for highly inflamed and necrotic cancers (especially in the oral cavity), where incisional biopsy is preferred, needle-core biopsies can be done on an outpatient basis with local anesthesia and sedation. The area to be biopsied is clipped and cleaned. The skin or overlying tissue is aseptically prepared as for minor surgery. If the overlying tissue (usually skin and muscle) is intact, it is blocked with local anesthetic in the region that the biopsy needle will penetrate. Tumor tissue itself is very poorly innervated and generally does not require local anesthesia. The mass is then fixed in place with one hand or by an assistant. A small 1- to 2-mm stab incision is made in the overlying skin with a scalpel blade to allow insertion of the biopsy instrument. The stab incision is necessary to prevent dulling of the needle tip and allow better penetration into the underlying tissue. Through the same skin incision, several needle cores are removed from different sites to get a "cross section" of tissue types within the mass. The stab incision can be sutured with a single interrupted suture. The tissue is gently removed from the instrument with a scalpel blade or hypodermic needle and placed in formalin and/or alternative media (e.g., culture media) or snap frozen as necessary. For smaller-gauge needle-core biopsy instruments, the tissue may be flushed off the needle with saline. Samples may be gently rolled on a glass slide for cytologic preparations before fixation. With experience, the operator can generally tell from the appearance of the core sample whether diagnostic material has been attained. Small, discontinuous segments of tissue and fluid within the trough will only rarely be diagnostic and usually imply the need for incisional biopsy. Soft tissue sarcomas in particular may not yield good tissue cores because of necrosis and fibrous septa that often permeate the mass. Cystic masses are also problematic.

Needle biopsy tracts are probably a minimal risk for local tumor seeding but should be removed en bloc with the tumor at subsequent resection. Therefore it is important to plan where the stab incision and needle biopsy tract should be placed to make subsequent excision simpler. Avoid excessive tunneling through uninvolved tissues by choosing the most direct path from the skin to the tumor to obtain a representative sample.

Many of these needles are "disposable" with plastic casings and therefore cannot be steam sterilized. It is not uncommon, however, for veterinary practices to resterilize these instruments (using ethylene oxide or hydrogen peroxide gas) and use them repeatedly until they become dull.



Needle-core biopsy instruments are inexpensive, easy to use, and needle-core biopsy procedures can be performed as outpatient procedures. They are generally more accurate than cytology but likely have lower accuracy than incisional or excisional biopsies, especially when a tumor is heterogeneous, inflamed, cystic, or contains a large amount of necrosis. It is important to understand that for a 5-cm diameter mass, one needle-core biopsy sample represents less than 1% of the tumor tissue. The smaller the biopsy specimen, the less representative it may be for the entire tumor.

Needle-core biopsy can be performed with the aid of image-guidance. Utilization of image-guidance for needle-core biopsy is very helpful for obtaining tissue from deeply seated lesions. Ultrasound-, fluoroscopic-, and computed tomographic-assistance may be used to obtain samples from tumors located in areas where percutaneous biopsy would be risky or unlikely to yield a representative sample. In situations in which the lesion is located within a body cavity, the risk of tumor seeding from uncontrolled hemorrhage or fluid leakage as a result of image-guided biopsy must be taken into account before deciding if image-guided needle-core biopsy techniques will hold an advantage over more direct access in a given patient.

Punch Biopsy

Punch biopsy tools were originally designed for biopsy of the skin (Fig. 9.2). They deliver a shorter and wider (2–8 mm) biopsy than does a needle core. They can be used on any external tumor (skin, oral, perianal) or tumors where there is direct access (e.g., liver biopsy during laparotomy). They do not work as well for tumors located under intact skin unless the skin is incised first. Preparation of the site is the same as for needle-core biopsy. If the lesion is cutaneous, the punch biopsy instrument is placed on the surface of the area of interest and rotated back and forth using pressure to penetrate the involved tissue. If the skin is intact over the tumor, the skin is first incised using a scalpel. The punch is then introduced through the skin incision to the surface of the tumor. Once

VetBooks.ir

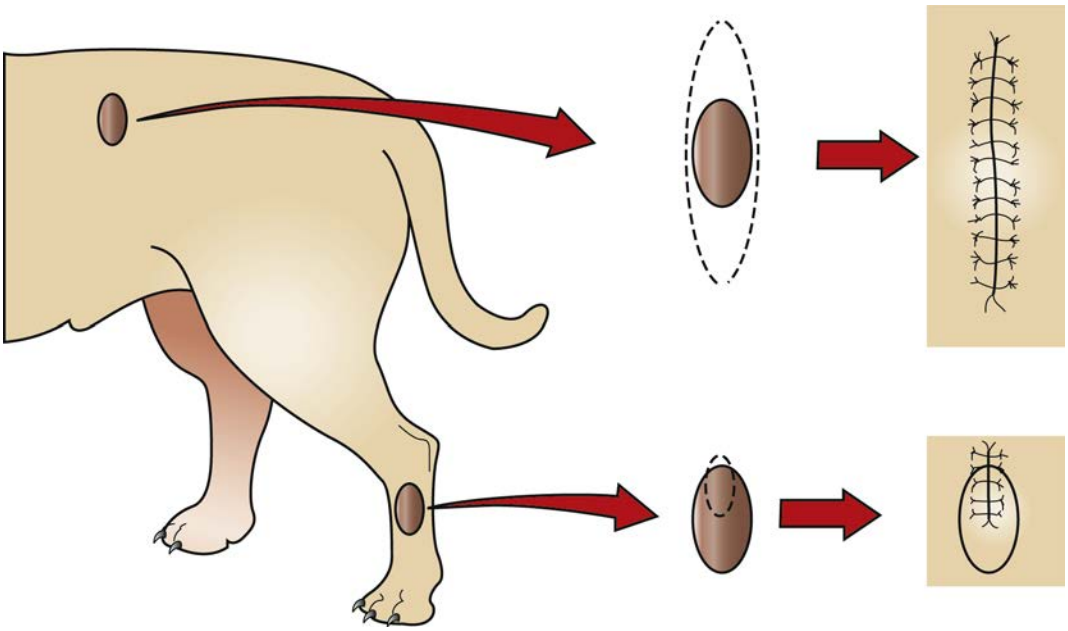
• **Fig. 9.2** Mechanism of action of punch biopsy. (A) The instrument is applied with pressure and back and forth rotation to allow the instrument to penetrate the mass. (B) The punch is removed or angled across the base to sever the deep attachment. (C) If needed, the specimen can be gently grasped with forceps and cut at the base with metzenbaum scissors.

the punch has cut into the tumor, the core is gently lifted, and the base of the core is cut off with scissors. One or two sutures may be placed to close the incision and tamponade bleeding.

Incisional Biopsy

Incisional biopsy is utilized when neither cytology nor needle-core biopsy has yielded diagnostic material (Fig. 9.3). Incisional biopsy is also preferred for ulcerated and necrotic lesions because larger samples can be obtained, making it more likely for the surgeon to sample representative areas. Most tumors are very poorly innervated and may be biopsied without the need for local anesthesia or sedation as long as the overlying normal skin and tissue has been anesthetized. Preparation involves clipping the hair over the incision site. After an aseptic preparation is made, surgical drapes are used to protect the field from the surrounding environment. Under aseptic conditions, the skin, if intact over the tumor, is incised and a wedge of tumor tissue is removed from the mass. It is not necessary to remove a wedge of intact skin overlying the tumor if it appears to be normal and not fixed to the underlying tumor. It is important for the surgeon to confirm at the time of the biopsy that he or she has not simply removed a small section of the reactive tissue surrounding the tumor. This can be difficult in some cases; however, most tumors have coloration and texture that is distinct from that of the surrounding normal and reactive tissue. If needed, cytologic assessment of touch impressions can be made using the resected tissue to confirm that neoplastic cells are present in the removed tissue.

Many authors have recommended that the surgeon acquire a composite biopsy of normal and abnormal tissue to assure accuracy in diagnosis on histopathologic examination. Although this may be helpful to the pathologist in benign skin disease and subtle lesions, it is not recommended in cases in which neoplasia is suspected, as this may result in extending the biopsy incision into previously uninvolved tissues. This can compromise the surgical margins needed to remove the mass entirely at the time of definitive surgery and exposes previously uninvolved tissues to freshly incised tumor. Instead, a representative sample of the tumor itself should be submitted. This may require obtaining multiple samples via the same incision to ensure that a representative sample has been achieved. Care must be taken to ensure that any biopsy tract (incisional or other) will not compromise subsequent curative-intent resection, contaminate uninvolved tissue needed for reconstruction, or compromise subsequent radiation therapy. The surgeon should avoid widely opening uninvolved tissue planes that could become contaminated with released tumor cells. Small incisions, even through expendable muscle bellies, are preferred to contaminating an entire intramuscular compartment. The incisional biopsy tract is always removed in continuity with the tumor at the time of curative-intent resection.



Specialized Biopsy Techniques

Specialized biopsy techniques will generally be covered under specific individual tumors. However, some general comments follow.

Endoscopic Biopsies

These techniques use flexible or occasionally rigid scopes that allow visualized or blind biopsy of hollow lumens, especially gastrointestinal, respiratory, and urogenital systems. Although these

VetBooks.ir

• **Fig. 9.3** Excisional *(top)* contrasted with incisional *(bottom)* biopsy. The top tumor should be small enough that excisional biopsy will not negatively influence other possible treatments. The bottom tumor, however, requires knowledge of the tumor type before excision to ensure appropriate surgical "dose" is used at the time of definitive removal. Note that the biopsy incision is oriented in such a way to make it easiest to include during wide excision and minimize difficulty with closure.

techniques are convenient, cost effective, and generally safe, they may suffer from inadequate visualization and limited biopsy sample size compared with other techniques. For example, an endoscopic biopsy result of ulcerative gastritis in a dog with a firm, infiltrative mass of the lesser curvature of the stomach does not rule out gastric adenocarcinoma.

Laparoscopy and Thoracoscopy

Evaluation of the abdomen and thorax via minimally invasive techniques, when performed by an experienced operator, can yield important information regarding stage of disease and can procure tissue for biopsy. In addition, laparoscopic- and thoracoscopic-assisted removal results in smaller incisions and more rapid recovery times compared with open procedures. The option to convert to an open procedure should be available if problems are encountered that cannot be adequately addressed using minimally invasive methods. As specialists become more proficient at these techniques, more and more options are becoming available for tumor removal.

Image-Guided Biopsy

Diagnostic imaging has greatly expanded the ability to stage various neoplasias. The use of positron emission tomography–computed tomography (PET–CT) in veterinary medicine has also led to significant advances in sentinel node mapping, novel staging methods, and the ability to assess response to treatment. In addition, the use of radiographic-, fluoroscopic-, ultrasonographic-, CT-, and magnetic resonance imaging (MRI)-guided needle aspirates or core biopsies can prevent the need for more invasive diagnostic procedures. Commonly biopsied tissue includes lung, kidney, liver, spleen, prostate, and, more recently, brain.

Excisional Biopsy

This method is utilized when the treatment would not be altered by knowledge of tumor type (e.g., "benign" skin tumors, solitary splenic mass, testicular tumor, etc.). It is more frequently performed than indicated but when used on properly selected cases, it can be both diagnostic and therapeutic as well as cost effective.

Sentinel Lymph Node Mapping and Biopsy

In veterinary medicine, assessment of nodal metastasis has been largely predicated on palpation or imaging of nodal size and architecture with cytologic sampling when abnormal. Sentinel lymph node (SLN) mapping and subsequent biopsy are performed to identify the first lymph node (LN) to which a cancer is likely to spread from a primary tumor and to sample that LN for evidence of metastasis. If the SLN is free of metastasis, subsequent LNs in the drainage pattern are also likely to be negative. This method was initially studied in human cutaneous melanoma to detect lymphatic drainage patterns before surgery. It is now a widely utilized staging procedure in many human cancers, but the evidence for its usefulness in staging has been primarily from the application of this technique in human breast cancer patients. The SLN has been classically defined as the first node detectable after peritumoral injection of a radioactive marker and subsequent scintigraphy. Visual identification in surgery is typically aided by the use of vital dye injection (e.g., methylene blue) in conjunction with use of a portable gamma probe in the operating room to detect the LN with the greatest radioactivity. In one study of 19 dogs with cutaneous mast cell tumors,[3] the SLN was different from the regional anatomic LN in eight (42%) of these dogs. SLN mapping and biopsy identified LN metastasis in these eight dogs and clients were offered adjunctive therapy that otherwise would not have been considered.[3]

Indirect lymphography is an alternative to scintigraphic SLN mapping. This procedure involves injection of a contrast agent in the periphery of the tumor and serial or real-time imaging to follow contrast uptake in the draining lymphatic basin. This method uses contrast enhancement of nearby LNs and lymphatic channels

VetBooks.ir

to identify the SLN. In this technique, the contrast medium is injected in four quadrants around or within the tumor. The first contrasting node(s) is identified via imaging providing a surgical target (as opposed to extensive dissection within the lymphatic basin to find a lymph node with vital dye). A vital dye, such as methylene blue, is injected intraoperatively in the same locations as the contrast agent. The use of the vital dye provides the surgeon with visual confirmation of the SLN. Some authors have advocated using lipid-based contrast medium because it slows clearance and therefore may permit imaging for longer periods compared with water-soluble contrast agents. In a recent study, this method was successful at identifying the sentinel lymph node in 96.6% of veterinary patients with solid tumors of various histologies.[4]

General Guidelines for Tissue Procurement and Fixation

1. When properly performed, a pretreatment biopsy will *not* negatively influence survival. The metastatic cascade involves a series of complex events that are not dependent on the number of neoplastic cells in circulation (see Chapter 2). On the other hand, neoplastic cells contaminate the *local* tissues surrounding the mass and, in some cases, successfully attach and grow within these normal tissues. Careful hemostasis, obliteration of dead space, and avoidance of seromas or hematomas will minimize local contamination of the incisional biopsy site. Definitive surgery to remove the tumor along with the associated biopsy tract should take place as soon as possible after the biopsy procedure. Surgical drains should not be placed in biopsy sites, if possible, because the drain tract can become contaminated with tumor cells and seed tumor cells through uninvolved tissue planes. In particular, care should be taken during biopsy not to "spill" cancer cells within the thoracic or abdominal cavities, where they may seed pleural or peritoneal surfaces.
2. When biopsies are performed on the limbs or the tail, the incision should be made along the long axis of the limb or tail rather than transversely. Transverse incisions are much more difficult to resect completely. If a biopsy is near the midline, the incision should be oriented parallel to the midline.
3. Avoid taking the junction of normal and abnormal tissue for pretreatment biopsy. Care should be taken not to incise normal tissue that cannot be resected or would be used in reconstructing the surgical defect. Avoid biopsies that contain only ulcerated or inflamed tissues.
4. The larger the sample, the more likely it is to be diagnostic. Tumors are not homogeneous and usually contain areas of necrosis, inflammation, and reactive tissue. Several samples from one mass are more likely to yield an accurate diagnosis than a single sample.
5. Biopsies should not be obtained with electrocautery or laser, as it can deform (autolysis or polarization) the cellular architecture of the tissue sample. Electrocautery is better utilized for hemostasis after blade removal of a diagnostic specimen.
6. Care should be taken not to unduly deform the specimen with forceps, suction, or other handling methods before fixation.
7. Intraoperative diagnosis of disease by frozen sections, although not routinely available in veterinary medicine, is used widely in human hospitals. Special equipment and training are required for this technique to be fully utilized. One study in veterinary medicine revealed an accurate and specific diagnosis rate of 83%.[5]
8. If evaluation of margins of excision is desired, it is best if the surgeon indicates the surgical margin on the specimen using tissue ink. Several commercial inking systems are available for this use. The resected tissue should be blotted with a paper towel, as the dyes will adhere better to the tissue when the tissue is slightly tacky. The tissue ink is "painted" on the surgical margins using a cotton swab. The dye should then be allowed to dry for up to 20 minutes before the tissue is placed in formalin. Tissue already fixed in formalin can be marked, but the dyes may not adhere as well and drying time is extended. When the pathologist reads the slides and sees tumor cells at the inked edge, you can be certain tumor cells have been left in the patient. Different colored ink can also be used to denote different sites on the tumor, such as proximal margin or deep margin. Even with inking, proper fixation, and processing, the clinician must realize the entire margin will not be examined by the pathologist. Rather, representative sections will be obtained from the inked margin. Therefore any guidance that the clinician can give to the pathologist as to the most important sections to assess for tumor cells will help the pathologist pay particular attention to such areas. It is essential that both the pathologist and the clinician communicate if the pathology report is confusing or does not match the clinical picture. Of course, margin evaluation is necessary only for excisional biopsy or after curative-intent surgery and does not apply to needle-core or incisional biopsies, which by definition will have inadequate margins.
9. Stainless steel vascular clips or staples in the resected specimen will damage the microtomes used by the pathology laboratory. Remove them before the tissue is submitted.
10. Proper fixation is essential. Tissue is generally fixed in 10% buffered neutral formalin with 1 part tissue to 10 parts fixative. If more than one lesion has been biopsied, they should each be placed in a separate well identified container. Certain tissues such as eye, nerve, and muscle may require special fixation techniques. The clinician may want to call and consult with the pathologist on how to submit tissue for special circumstances.
11. Tissue should not be thicker than 1 cm or it will not fix properly. Masses greater than 1 cm in diameter can be sliced like a loaf of bread, leaving the deep inked margin intact, to allow fixation. Extremely large masses can be incompletely sliced as described earlier, fixed in a large bucket of formalin for 2 to 3 days, and then shipped in a container with 1 part tissue to 1 part formalin. A less ideal but alternative approach is to have the surgeon take representative smaller samples from the mass (e.g., soft and hard pieces, red and pale pieces, deep and superficial pieces, etc.) and the lateral and deep margins in the hope that they are representative. The rest of the mass can be saved in the clinic in formalin in case more tissue needs to be evaluated. This extra tissue should never be frozen. Freezing causes severe artifact in the tissue.
12. A *detailed* history should accompany all biopsy requests. Interpretation of surgical biopsies is a combination of art and science. Without all of the essential diagnostic information (e.g., signalment, history of recurrences, invasion into bone, rate of growth, etc.), the pathologist will be significantly compromised in his or her ability to deliver accurate and clinically useful information.

VetBooks.ir

13. A veterinary-trained pathologist is preferred over a pathologist trained in human diseases. Although many cancers are histologically similar across species lines, enough differences exist to result in interpretive errors.

In 2011 the American College of Veterinary Pathologists, along with several medical and surgical oncologists, published a comprehensive set of recommendations and guidelines for submission, trimming, margin evaluation, and reporting of tumor biopsy specimens.[6] This landmark paper was the first collaborative attempt to standardize pathology reporting in veterinary oncology and has been endorsed by a large international group of veterinary pathologists and oncology specialists. It is recommended that clinicians utilize diagnostic laboratories that adhere to these guidelines so that results are standardized and easier to interpret.

Interpretation of Results

The job of the pathologist is to determine (1) tumor versus no tumor, (2) benign versus malignant, (3) histologic type, (4) histologic grade (if available clinically), and to (5) assess surgical margins (if excisional biopsy). Making an accurate diagnosis is not as simple as putting a piece of tissue in formalin and waiting for results. Many pitfalls can occur to render the end result inaccurate. Potential errors can take place at any level of diagnosis and it is up to the clinician in charge of the case to interpret the full meaning of the biopsy result. In cases in which the biopsy result does not correlate with the clinical behavior of the tumor, a second opinion should be requested. A study published in 2009 reviewed first- and second-opinion histopathology reports.[7] There was diagnostic agreement between first and second opinions in 70% of cases. In 20% of cases, there was partial agreement, where the diagnosis did not change but information such as grade or presence of lymphatic or vascular invasion was disparate. In 10% of cases, there was complete diagnostic disagreement. Of these, 7% were a disagreement between malignant versus nonmalignant disease and 3% were disagreements about the cell of origin of the tumor. If the biopsy result does not correlate with the biologic behavior of the tumor, several options are possible:

1. Call the pathologist and express your concern over the biopsy result. This exchange of information should be helpful for both parties and not looked upon as an affront to the pathologist's authority or expertise. It may lead to
   a. Resectioning of available tissue or paraffin blocks
   b. Special stains for certain possible tumor types (e.g., toluidine blue for mast cells)
   c. A second opinion by another pathologist
2. If the tumor is still present in the patient, and particularly if widely varied options exist for therapy, a second (or third) biopsy should be performed.

A carefully performed, submitted, and interpreted biopsy is the most important step in management and subsequent prognosis of the patient with cancer. The biopsy report is key in decision making regarding therapeutic options, prognosis, and overall case management. All too often tumors are not submitted for histologic evaluation after removal because "the owner didn't want to pay for it." Histopathology interpretation should not be an elective decision. Instead, it should be as automatic as closing the skin after surgery. The charge for submission and interpretation of the biopsy should be included in the surgery fee, but histopathology interpretation is not optional. Because of increasing medicolegal concerns, it is not medical curiosity alone that mandates knowledge of tumor type. Understanding how and when to perform a biopsy, how to submit a biopsy specimen for histopathologic interpretation, and how to interpret the report are of paramount importance in the treatment of veterinary cancer patients.

10 Surgical Oncology

JAMES P. FARESE, JULIUS M. LIPTAK, AND STEPHEN J. WITHROW

Complete surgical removal of localized cancer cures more cancer patients than any other form of treatment,[1] in part because this modality is generally applied as the sole treatment for local disease, early stage disease, and tumors with limited potential to metastasize. In humans, 60% of patients who are cured of cancer are cured by surgery alone.[2] Before this hope for cure can be realized in veterinary medicine, surgeons must have a thorough understanding of anatomy, physiology, resection, and reconstruction options for all organs; expected tumor behavior; and the various alternatives or adjuvants to surgery. Surgical oncologists should not only be good technical surgeons, but also dedicated tumor biologists. Surgery will likely play a role at one point or another in the management of most cancer patients.

Surgical procedures may include any of the following: diagnosis (biopsy), resection for cure, resection for palliation of symptoms, and a wide variety of ancillary procedures to enhance and complement other forms of treatment.

Surgical resection of cancer was introduced in the 16th century BC and remained relatively underutilized until the development of general anesthesia (1840s), antisepsis (1860s), and effective analgesia, which made aggressive resection safer and more tolerable for the patient. Dr. William Halstead developed the basic principles of surgical oncology in the 1890s. In the 21st century, radical resection has increasingly been customized to meet the needs of the patient. Further refinements in surgery have been made possible with newer equipment, advanced imaging, modifications in analgesic drugs and techniques, use of blood products, and advancements in critical care medicine.

Most dogs and cats with cancerous conditions are geriatric; however, with normal major organ function, dogs and cats at an advanced age can still be good candidates for surgery, and age has not been shown to affect the tumor-related prognosis for tumor types. In fact, dogs with osteosarcoma that are younger than 2 years of age have a worse prognosis than dogs that are older than 2 years of age after amputation alone.[3] In most instances older animals will tolerate aggressive surgical intervention as well as younger patients do. Screening for comorbidities (e.g., thoracic radiographs and abdominal ultrasound) is recommended before major surgical procedures, especially in older dogs and cats.

Surgery for Diagnosis

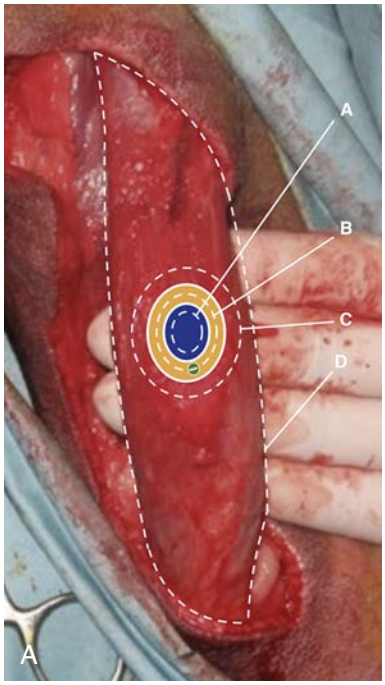
Although biopsy principles are covered in Chapter 9, it is worth emphasizing that properly timed, performed, and interpreted biopsies are one of the most crucial steps in the management of the cancer patient. Not only does the surgeon need to procure adequate and representative tissue to establish a diagnosis, but also the biopsy must not compromise subsequent curative surgical resection or radiation field planning.

Levels of Tumor Excision

The aggressiveness of surgical resection, or surgical dose, is categorized as intralesional (or debulking), marginal, wide, and radical (Fig. 10.1). These categories were first proposed for musculoskeletal tumors by Dr. William Enneking, but they have since gained wide acceptance for all solid tumors.[4] The most common mistake in surgical oncology is to use too low a surgical dose, particularly because of the fear of being unable to close the resultant defect. In human medicine, two surgical teams are sometimes involved in the excision of tumors, one team for surgical resection and another team for subsequent reconstruction, to avoid this situation. Because this is unrealistic in veterinary medicine, the use of sterile surgical markers to delineate margins before incision assists in orientating the surgeon and overcoming the subconscious concerns of wound closure.

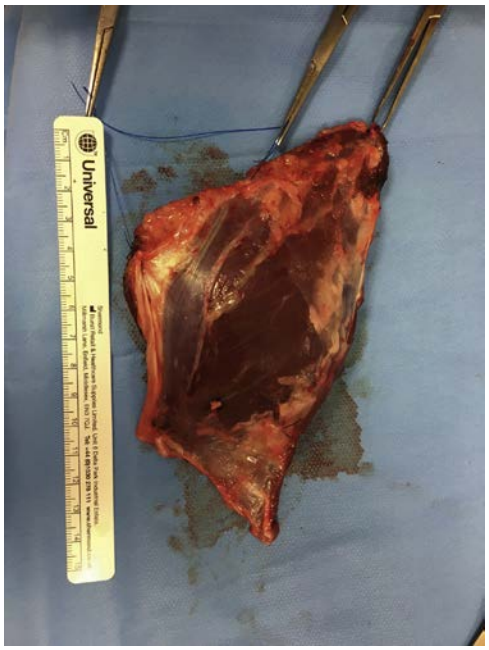
Surgery for Cure

Before a surgeon can provide the optimal operation for the patient with cancer, the following questions need to be considered:



1. What is the histologic type, histologic grade, and clinical stage of the cancer to be treated?
2. What are the expected local and systemic effects of this tumor?
3. Is a cure possible and at what price in terms of function and cosmetics?
4. Is an operation indicated at all?
5. Are there alternative options to surgery, or does surgery need to be combined with other modalities?

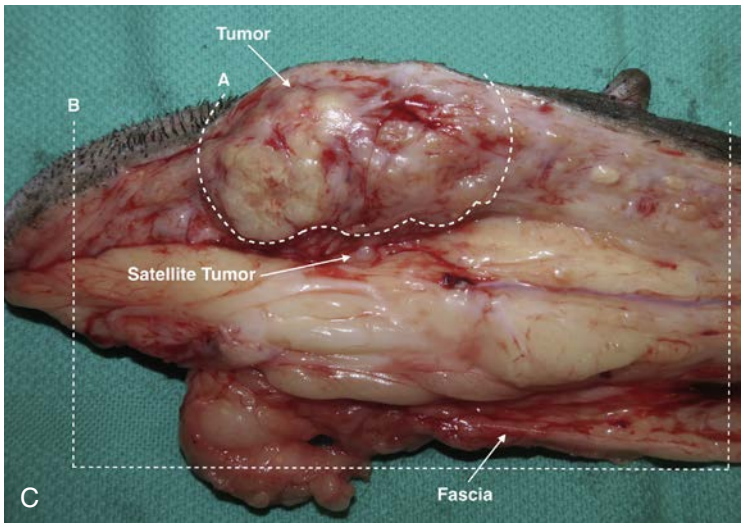
A recurring theme in surgical management of cancer is that the first surgery has the best chance of cure. Several reasons for this improvement in survival have been proposed. Untreated tumors often have had less chronologic time to metastasize and acquire more biologically aggressive phenotypes than recurrent cancers. Untreated tumors and adjacent normal tissues have near normal anatomy, which facilitates surgical dissection and resection. Recurrent tumors may contaminate previously uninvolved tissue planes, thereby requiring wider resection than otherwise would have been needed on the initial tumor excision.



VetBooks.ir

If one thinks about a given cancer as resembling a crab, incomplete surgery removes the body of the crab but leaves the legs behind. The "body" of most tumors is often quiescent and hypoxic, whereas the leading edge of the tumor (legs) is the most invasive and well vascularized. Thus subtotal removal may selectively leave behind the most aggressive components of the tumor. Patients with recurrent cancer often have less normal tissue for closure. Furthermore, changes in vascularity and local immune responses may accompany local tumor recurrence.

Curative-intent surgery is best performed at the first surgery, and the surgeon should have all the necessary diagnostic information to develop an appropriate treatment plan. Radiographs and



• **Fig. 10.1** (A) The four levels of tumor excision proposed by Dr. William Enneking for resection of human musculoskeletal tumors. A tumor is seen within the semitendinosus muscle belly *(blue)*, and the tumor pseudocapsule is surrounded by a reactive zone *(yellow)*. Note the satellite tumor in the reactive zone *(green),* and the levels of surgical excision: intracapsular *(A),* marginal *(B),* wide *(C),* and radical *(D) (dotted lines).* (B) *1,* Intraoperative image of a radical excision of a biceps muscle sarcoma completely contained within the muscle fascia. The biopsy tract is excised en bloc with the tumor. With this plan the entire tissue compartment (i.e., the entire biceps femoris muscle belly) is removed to ensure complete removal. *2,* The excised specimen as seen from the medial aspect.

VetBooks.ir

• **Fig. 10.1, cont'd** (C) Wide resection of tumor involves adequate lateral and deep margins. The width of lateral margins is determined by the tumor type and ranges from 1 cm for benign tumors and carcinomas to 3 cm for soft tissue sarcomas and up to 5 cm for vaccine-associated sarcomas. Malignant tumors may have satellite tumor cells outside the tumor pseudocapsule *(arrow)*. Deep margins are not determined by depth but, rather, by tumor-resistant fascial layers. A minimum of one fascial layer should be included in the resection. The deep margin is the most common site of failure. Dotted lines show the dissection planes for marginal *(A)* and wide *(B)* excisions. Note how a marginal dissection in this example leads to residual tumor cells in the surgical field. (D) Planned marginal resection of a soft tissue sarcoma on the distal limb of a dog. Marginal resection results in removal of the measurable tumor burden, but microscopic tumor cells may remain in the surgical wound. (A Photo courtesy of Dr. Paolo Buracco, University of Torino. D from Johnston SA, Tobias KM: *Veterinary surgery: small animal,* ed 2, St Louis, 2018, Elsevier.)

ultrasonography have been used routinely for many years, and the increased availability of computed tomography (CT) and magnetic resonance imaging (MRI) has added greatly to our ability to determine the extent of a solid tumor and optimize the surgical approach. CT is now readily available at most specialty hospitals and allows good visualization of neoplastic tissue (particularly when it enhances well with an intravenously administered contrast agent), adjacent muscle bellies and fascial planes, intraabdominal and intrathoracic organs, regional lymph nodes (LNs), and bone (Fig. 10.2). CT is commonly used for imaging thoracic wall tumors to determine which ribs need to be resected, oral tumors to assess the degree of bone involvement, adrenal tumors to assess caudal vena caval or renal involvement, and cutaneous or subcutaneous masses to better assess local tumor invasion and extent of disease. Reconstructed CT images allow the surgeon to choose the orientation in which to visualize a mass in relation to adjacent tissues, and multiplanar views and three-dimensional (3D) reconstructions can be manipulated at a computer workstation to help the surgeon envision a surgical plan before the time of surgery with complicated cases (e.g., large skull tumors). Furthermore, for more complex surgeries, CT images can be used to print 3D models to further assist the surgeon in preoperative planning and intraoperative decision making.[5] MRI is preferred for tumors of the central and peripheral nervous system and perhaps tumors of the intraabdominal organs and cutaneous and subcutaneous tissues. MRI is useful for determining the proximity of tumors to important neurovascular structures and for assessing soft tissue components and intramedullary involvement of canine osteosarcoma before limb-sparing surgery is performed.

Advanced imaging has greatly enhanced the surgeon's ability to assess the anatomic location and extent of various cancers; however, imaging needs to be interpreted in conjunction with

• **Fig. 10.2** Computed tomography of a dog with suspected multilobular osteochondrosarcoma of the inferior orbit is used to provide three-dimensional reconstructed images. This enables the surgeon to determine the size and extent of the tumor and to plan the surgical margins and approach accurately. Computed tomography is preferred for imaging of bone and intrathoracic masses. (From Johnston SA, Tobias KM: *Veterinary surgery: small animal,* ed 2, St Louis, 2018, Elsevier.)

TABLE 10.1 Classification and Resection of Wound Margins

Type	Plane of Dissection	Result
Intracapsular	Tumor removed piecemeal or curetted, "debulking"	Residual macroscopic disease
Marginal	Tumor removed on or adjacent to the tumor pseudocapsule, "shelled out"	Usually leaves microscopic disease
Wide	Tumor removed with margins of normal tissue lateral and deep to the tumor; tumor capsule is not compromised	Possible skip lesions
Radical	Tumor removed with an entire compartment or structure (e.g., amputation)	No local residual cancer

clinical palpation, assessment of mobility, and expected biologic behavior. Some cancers deemed inoperable by imaging are in fact mobile and operable. Leading edges of some cancers are compressed against adjacent tissue and can appear more invasive. Before declaring a mass inoperable, surgeons should always take the opportunity to palpate the local tumor with the patient under heavy sedation or anesthesia before or after imaging, explore the history of the tumor's growth pattern and, in many cases, obtain a tissue sample. Positive prognostic factors typically include a slow growth rate, mobility within adjacent tissues, no previous surgery, discrete tumor borders, small tumor size, and a low-grade nature. Conversely, surgery may be less effective for the same tumor type and grade if the mass is ill defined, recurrent, or has a recent history of rapid growth.

The surgical oncologist must be able to assimilate all of the information and make an informed decision. We must also remind ourselves and our clients that there is much we do not know (e.g., incomplete margins do not necessarily ensure local tumor recurrence[6]) and that surgical judgment regarding expected local behavior and likely resection is often qualitative and is an imperfect "science."

The actual surgical technique will vary with the site, size, and stage of the tumor, in addition to the skill and experience of the surgeon. The same tumor type in dogs and cats may vary with regard to the required surgical approach and technique and the prognosis. The following are some general statements that need to be emphasized with surgical oncology.

1. All incisional biopsy tracts should be excised en bloc with the primary tumor because tumor cells are capable of growth within the biopsy incisions. Fine-needle aspiration (FNA) cytology tracts are of minor, but not zero, concern, whereas punch biopsy tracts are of intermediate concern.[7] With this in mind, the surgeon should keep all biopsy incisions to a minimal length and should position and orient them such that they can be easily removed with the definitive resection.
2. Early vascular ligation (especially venous) should be attempted to diminish release of large tumor emboli into the systemic circulation. This is probably only clinically meaningful for tumors with a well-defined venous supply, such as splenic and lung tumors. Small numbers of cancer cells are constantly being released into the venous (and lymphatic) circulation by most tumors. Larger, macroscopic cell aggregates may be a greater concern, however, and these may be prevented from vascular escape with early venous ligation.
3. Local control of malignant cancer requires that a margin of normal tissue be removed around the tumor. Resection of the "bad from the good" can and should be classified in more detail than radical versus conservative (Table 10.1; also, see Fig. 10.1).[8] Tumors with a high probability of local recurrence (e.g., high-grade soft tissue sarcoma, high-grade mast cell tumors, feline injection-site sarcomas, feline mammary carcinoma) should have 2 to 3 cm margins laterally and at least one uninvolved fascial layer for deep margins. Tumors are not flat, and wide removal in one plane does not ensure complete excision. Fixation of cancer to adjacent structures mandates removal of the adherent area en bloc with the tumor. Invasive cancer should not be "shelled out" if a cure is expected. Many cancers are surrounded by a pseudocapsule. This pseudocapsule is almost invariably composed of compressed and viable tumor cells, not healthy, reactive host cells. If a malignant tumor is entered at the time of resection or if the margins are incomplete, that procedure is often no better therapeutically than a large incisional biopsy. When possible, resection of the previous scar and the entire wound bed with "new" margins (never entering the previous surgical field) is indicated, including a minimum of one tissue plane away from or deep to the mass. For example, invasion of cancer into the medullary cavity of a bone requires subtotal or total bone resection, not curettage. The width of surgical margins necessary for complete excision of a given tumor type is an ongoing debate, and our current practices are based on minimal objective data. As a community we have answered most of the questions about how much tissue we can safely remove, but it will serve our patients well to determine how little extra tissue is necessary to excise and consistently achieve the same success. We must challenge recommendations that are reported in the literature if they are based solely on a surgeon's personal experience or opinion, in the absence of objective findings.

VetBooks.ir

4. Tumors should be handled gently to avoid the risk of seeding tumor cells into the surgical wound.[9] Copious lavage of all cancer wound beds helps mechanically remove small numbers of exfoliated tumor cells; however, it should not replace gentle tissue handling and the careful technique required to avoid entering the tumor bed.
5. If more than one malignant mass is being removed, separate surgical packs should be used for each site to avoid iatrogenic tumor cell implantation from one site to a second site. In addition, gloves and instruments should be changed before closure to minimize the possibility of seeding of tumor cells in the incision.

The aggressiveness of resection should be tempered only rarely by fears of wound closure. It is better to leave a wound partially or even in some cases completely open with no cancer cells than to close it and have residual cancer. Numerous innovative reconstructive techniques are available for closure of cancer wounds, and the surgeon is limited only by his or her ingenuity and willingness to try new reconstructive techniques.[10] Practice on a cadaveric specimen is recommended before unfamiliar reconstructive surgical techniques are performed. Reliable microvascular-free composite transfers of muscle and skin are hampered because of the unique canine skin and muscle anatomy, but they are being developed.[11]

Marginal Excision

Aggressive surgical excision may not be recommended in some cases because of the tumor's type, size, and location; the patient's age (i.e., recurrence with a less aggressive surgery may not be expected to occur within the expected life span of the patient); and other factors. In such cases marginal excision may be performed (see Fig. 10.1D). The surgeon should tailor the level of excision to the needs of the patient and client, and the expectations and goals of the procedure must be clearly established and explained to the client before surgery.

Lymph Node Removal

Controversy surrounds the surgical management of regional LNs draining the primary tumor site.[12,13] As a general rule, epithelial cancers are more likely to metastasize to LNs than are mesenchymal cancers. However, any enlarged LN requires investigation for complete staging. Lymphadenomegaly may develop secondary to metastasis (firm, irregular, and sometimes fixed to surrounding tissue) or hyperplasia, or to reactivity to various tumor factors, infection, or inflammation. Metastasis is often a poor prognostic sign, and a reactive LN may represent a beneficial host response. Enlarged LNs as a result of cancer metastasis and invasion are generally effaced by tumor cells; although these can often be diagnosed with FNA cytology, histopathology is superior to cytology for the diagnosis of LN metastasis.[14] LN extirpation should be considered under a number of circumstances:

1. If the LN is positive for cancer and not fixed to surrounding normal tissues, it may be possible to remove it with some therapeutic intent. Frequently, however, multiple LNs drain a primary tumor site (e.g., mandibular, medial retropharyngeal, and parotid LNs for oral tumors), and lymphadenectomy is incomplete. LN metastasis at the time of initial diagnosis is often a poor prognostic sign; however, patients that develop metastasis after local tumor control may benefit from lymphadenectomy. Although it usually is not practical, removal of the primary tumor, intervening lymphatic ducts, and draining LN has been recommended (en bloc resection). Limb amputation for excision of a malignant digit tumor with metastasis to the popliteal LN and mastectomy procedures that include the regional LN are examples of en bloc resections. Few other anatomic sites are amenable to this approach. Lymphadenectomy can have a beneficial effect on survival with specific tumor types, such as dogs with apocrine gland anal sac adenocarcinomas (AGASACs) metastatic to the sacral or sublumbar LNs,[15] dogs with cutaneous mast cell tumors and LN metastasis,[16] and cats with mammary carcinoma and LN metastasis.[17] Lymphadenectomy may also provide a palliative benefit for dogs with metastatic AGASAC LNs causing tenesmus.
2. Normal-sized LNs can be metastatic.[18] Normal-sized LNs that are known to drain a primary tumor site may be randomly sampled (biopsy or cytology) to gain further staging information. This is particularly important if adjuvant therapy decisions (radiation therapy [RT] or chemotherapy) would be predicated on confirmation of residual or metastatic cancer. Intrathoracic or intraabdominal LNs are perhaps most crucial because they are not readily or safely accessible for histologic or cytologic examination (e.g., sublumbar LNs at the aortic trifurcation), even under ultrasound guidance. In such cases the surgeon must educate the owner about the situation and either remove the primary tumor without further knowledge of LN involvement or recommend removal of the normal-sized LNs concurrently, for staging and possibly therapeutic purposes.
3. LNs identified as sentinel LNs using various mapping procedures (see Chapter 9 for more details).

LN removal is generally *not* performed under the following circumstances:

1. LNs in critical areas (e.g., some mesenteric LNs) or in cases in which the tumor cells have eroded through the capsule and become adherent (fixed) to surrounding tissues. In this scenario, LNs may not be resectable without leaving residual disease in the wound bed (necessitating adjuvant therapy to achieve local tumor control), or an attempt at removal may cause serious harm to the patient by injuring important adjacent structures. In such instances the prudent course usually is to aspirate or biopsy the LN for diagnostic purposes and leave it in situ, or to treat the LN with other modalities, such as RT.
2. Prophylactic removal of normal LNs or chains of LNs is not beneficial and may be harmful.[12] Regional LNs may in fact be the initiator of favorable local and systemic immune responses, and elective removal has been associated with poor survival in certain human cancers.[12,19,20]

Surgery for Distant Disease

Metastasectomy for pulmonary metastasis has been described in dogs.[21] Resection of liver metastasis for carcinomas (especially gastrointestinal cancers) increasingly is being performed in human oncology. As more effective adjuvant therapies evolve and minimally invasive techniques are further developed, the need for cytoreductive metastasectomy will likely increase.

Palliative Surgery

Palliative surgery is an attempt to improve the quality of the patient's life (pain relief or improved function), but not necessarily survival time.[22] This type of surgery requires careful consideration of the expected morbidity of the procedure versus the expected gain for the patient and owner. In essence it comes down to a

VetBooks.ir

decision of when to discontinue therapy. One of the most difficult decisions in surgical oncology is the decision not to operate. Treatment of any kind should never be worse than no treatment.

However, in many situations palliative surgery may be beneficial. Examples include mastectomy for infected, metastatic mammary tumors; anal sacculectomy for dogs with a large local AGASAC causing tenesmus and distant metastasis; and splenectomy for a dog with a ruptured splenic tumor.

Cytoreductive Surgery

Incomplete removal of a tumor (planned or unplanned), in which gross tumor is left behind, is referred to as *intralesional, debulking,* or *cytoreductive surgery*. It is commonly performed but rarely indicated.[23] A theoretical indication is to enhance the efficacy of other treatment modalities; for example, debulking an infiltrative lipoma in a swollen limb before RT. Debulking is a practical consideration before cryosurgery to reduce the amount of tissue to freeze and the duration of the cryotherapy. Cytoreduction may also help with treatment planning and dosimetry for certain types of RT. However, the improved tumor control achieved is more a result of geometric and dosimetry considerations than intentional and incomplete removal of tumor cells. Removing 99.9% of a 1 cm tumor (1×10^9, or 1 billion cells) still leaves a million residual cancer cells. Immunotherapy and chemotherapy theoretically could be helped by reducing tumor volume (e.g., LN removal for oral melanoma with the use of a melanoma vaccine),[24,25] but to date few well-controlled clinical trials have shown a benefit in veterinary medicine. If tumors are debulked with the anticipation of postoperative RT, the margins of debulked tumor should be marked with radiopaque metal clips to allow proper treatment planning based on radiographs or CT of the surgical site. The orientation of the incision should be considered carefully if RT is possible postoperatively.

Nonsurgical Locally Ablative Procedures

Ablative techniques to eradicate local (or metastatic) disease have a place in oncology, but they are based only rarely on evidence of outcomes.[26] Indications for the use of local ablative therapy vary, but they generally are limited to small, discrete lesions <2 cm. A limitation of all these techniques is that completeness of cell kill and margin analysis cannot be determined after treatment. If the operator picked the correct tumor, site, and dose delivery, then local control may be achieved; however, monitoring for regrowth is the only way to ensure that treatment has been adequate. As a general rule, recurrent disease tends to be more invasive and difficult to control than primary disease, so the first ablative procedure should be well planned and executed. All of the local ablative treatments require special equipment and training to be performed properly. Selective tumor cell kill that spares adjacent normal tissue is often claimed for these techniques, but it is unlikely to be consistently true.

Radiofrequency Ablation

The most common nonsurgical locally ablative procedures in human medicine include radiofrequency (RF) ablation, microwave ablation, and cryoablation. RF ablation involves delivery of a high-frequency (300–500 KHz) alternating current via a needle-like probe. The procedure typically is performed with either ultrasound or CT guidance and is commonly used to treat primary and secondary hepatic tumors. The minimally invasive nature of this technique makes it ideal for the treatment of metastatic liver lesions. For the treatment of metastatic colorectal cancer to the liver, RF has 5-year survival rates similar to those for surgery. Microwave ablation is similar to RF, but higher frequency currents (900–2459 MHz) are delivered. Microwave ablation is a newer technology with less evidence supporting its use, but it is often used for the same indications as RF ablation. RF and microwave ablation have been reported in dogs as experimental models.[27,28]

Cryoablation

Cryosurgery, or cryoablation, is a much older form of local therapy that has local anticancer effects by means of direct cell kill and vascular collapse. It has been used extensively in veterinary medicine, most commonly for skin, nasal planum, eyelid, perianal, and oral cavity tumors.[29–31] Cryotherapy continues to be an attractive treatment option for owners not interested in invasive procedures and for palliation of advanced (i.e., nonresectable or metastatic) oral tumors. Cryotherapy can be used as an adjunct to cytoreductive surgery. There is one report of image-guided cryoablation of a nasal mass in a dog that recurred after intensity-modulated RT (IMRT).[32] In humans laparoscopic and percutaneous cryoablation of select neoplasms (e.g., breast and renal tumors) has become an attractive, minimally invasive treatment option.[33,34]

Hyperthermia

Hyperthermia is the elevation of tissue temperature above normal physiologic levels. The term *hyperthermia* encompasses a wide range of temperatures and modalities. A variety of methods and devices are used clinically to induce hyperthermia in tissues. Noninvasive methods using RF currents, microwaves, or ultrasound are the most common. Heating of solid tumors typically is nonuniform because of the heating devices available, nonuniform distribution of blood flow in the tumor, and heat-dissipating activity of adjacent normal tissue. A number of studies demonstrated an improved outcome when hyperthermia was combined with RT for the treatment of solid tumors in dogs.[35–38] The ideal strategy for clinical hyperthermia treatment, including thermal dose, fractionation, and time and temperature goals, has yet to be identified.

Photodynamic Therapy

The practice of using sunlight to treat disease is ancient, but modern refinements have allowed the interactions between light and drugs to evolve into a highly effective cancer treatment called *photodynamic therapy* (PDT). PDT relies on light of an appropriate activating wavelength, oxygen, and a photosensitizer (PS) that accumulates within a tumor. The excited PS interacts with molecular oxygen, creating reactive oxygen species that are responsible for causing vascular stasis and necrosis, membrane damage, and apoptosis, and for initiating a signaling cascade resulting in an influx of inflammatory cells. Although initially studied as a single modality, PDT may also be useful when combined with other cancer treatments. Early studies show that a combination of PDT and low-dose cisplatin increased efficacy in both *in vitro* and murine models, and similar synergy has been observed when doxorubicin is combined with PDT.[39,40] In veterinary medicine PDT most commonly has been used in the treatment of feline squamous cell carcinoma (SCC). Most SCCs are superficial, localized, and rarely metastasize, making them well suited for

VetBooks.ir

treatment with PDT. An early description of chloro-aluminum sulfonated phthalocyanine–based PDT in 10 cats with superficial SCC or carcinoma in situ reported a 70% complete response rate, demonstrating the potential for PDT as a skin cancer treatment.[41] With a number of recent technologic improvements, PDT has the potential to become integrated into the mainstream of cancer treatment.[42]

Electrochemotherapy

Electrochemotherapy (ECT) is the use of chemotherapeutic drugs, most typically bleomycin or cisplatin, in combination with electric pulses that cause reversible permeabilization of the cell membrane, enabling the entry of drugs into the cells (or electroporation).[43,44] The antitumor effects of ECT are multiple[45] and include immunogenic cell death, resulting in eradication of clonogenic tumor cells. More recently ECT has been combined with different immunotherapies, especially gene electrotransfer of interleukin-12, to enhance the systemic antitumor effects of ECT.[46–49] Treatment-related adverse effects are usually mild and include wound dehiscence.

ECT is indicated primarily for the treatment of incompletely excised cutaneous and subcutaneous tumors, but also for the sole treatment of small primary tumors. Most published studies are uncontrolled and retrospective in design; however, ECT has shown some efficacy in the treatment of canine mast cell tumors (MCTs),[48–53] canine perianal adenomas and adenocarcinomas,[54,55] canine nasal tumors,[56] canine and feline localized lymphoma,[57] and canine and feline spontaneous soft tissue sarcomas.[58,59]

In one study 37 dogs with incompletely excised cutaneous MCTs were treated with cisplatin ECT; the local recurrence rate was 16%, with a median time to local recurrence of 1200 days.[52] In another study 28 dogs with incompletely excised cutaneous MCTs were treated with bleomycin ECT; the local recurrence rate was 18%, with a median time to local recurrence of 52.8 days.[50] In a retrospective comparative study 51 dogs with cutaneous MCTs were divided into four groups: ECT only, ECT applied intraoperatively, ECT applied postoperatively, and ECT applied for recurrent MCTs.[53] Objective responses were reported in all dogs with complete responses (CRs) recorded in 93%, 90%, 80%, and 64% of dogs treated with ECT postoperatively, intraoperatively, alone, and for recurrent disease, respectively.

In one study, of 21 dogs with primary nasal tumors, 11 dogs were treated with minimally invasive ECT and 10 dogs were treated with cytoreductive surgery and chemotherapy.[56] Partial and CRs were reported in 64% and 27% of dogs treated with ECT, respectively. Dogs treated with ECT had significantly better 12- and 32-month survival rates (60% and 30%, respectively) than dogs treated with surgery and chemotherapy (10% and 0%, respectively).

Surgery and Chemotherapy

The combined use of chemotherapy and surgery is becoming more commonplace in veterinary oncology, and the knowledge an oncologic surgeon must possess to master the use of combination therapy is ever expanding.[60,61] Many chemotherapeutic agents impede wound healing to some extent. In spite of this risk, few clinically relevant problems occur when surgery is performed on a patient receiving chemotherapy.[62,63] General recommendations are to wait 7 to 10 days after surgery to begin chemotherapy, especially for high-risk procedures such as intestinal anastomosis.[64] The use of intraoperative[65] or perioperative chemotherapy[66,67] is receiving increased attention and could have greater implications for wound healing. Neoadjuvant chemotherapy is also becoming more popular and in some instances may greatly facilitate excision of a solid tumor.[68]

Surgery and Radiation Therapy

Theoretically both preoperative and postoperative RT have advantages.[61,69] Regardless, RT results in some impairment of wound healing potential, and the timing of surgery and RT must be considered.[70] Radiation damage to normal tissues (stem cells, blood vessels, lymphatics) may be progressive and potentially permanent as the total radiation dose, dose per fraction, and field size increase; therefore close collaboration between the radiation oncologist and the surgeon is critical in designing the most effective regimen. If RT is given preoperatively, surgery can be performed after any acute radiation effects have resolved (generally 3–4 weeks). Postoperative RT is recommended 7 to 14 days after surgery to allow adequate wound healing. In spite of the theoretical problems, surgery can often be safely performed on irradiated tissues and complications are not prohibitive.

The benefit of surgery and RT is clear for some tumor types; however, in some instances the improvement in outcome over single-modality therapy is controversial. Canine nasal tumors are one example of this controversy.[71,72] Early reports showed no benefit of surgery and postoperative RT over RT alone; however, a recent study demonstrated that preoperative RT was beneficial when exenteration of the nasal cavity was performed 6 to 10 weeks after completion of RT.[72] With the advent of stereotactic radiation therapy (SRT) and IMRT (see Chapter 13), such approaches are even more attractive because the overlying skin or underlying mucosa can be spared the full effects of radiation, thereby diminishing concerns about incisional healing after RT. In the past surgeons were reluctant to operate in a radiation field; these more focused forms of RT hopefully will allow the surgeon to operate with fewer wound healing complications and to create novel treatment plans that combine RT and surgery for select tumors. Radiation side effects are greatly diminished with a more conformal approach, and this in turn makes owners more willing to have their pets undergo RT.

Access to more sophisticated radiation techniques, such as SRT and IMRT, is rapidly increasing, and with these developments a new paradigm is emerging in veterinary radiation oncology. For example, bone sarcomas in locations not amenable to limb-sparing surgery now can be treated with curative-intent therapy,[73] and treatment protocols for large solid tumors previously deemed nonresectable are being investigated. Combinations of SRT and surgery also are being explored.

Although these new treatment options represent great advances, familiar challenges remain. In the case of dogs with appendicular osteosarcoma, fracture may occur after SRT. In addition, although some of these cases are amenable to surgical stabilization, postoperative infection rates are very high with the presence of orthopedic implants, and healing of the fracture does not occur because of the effects of RT on bone healing. Thus the role of the surgeon continues to evolve in the management of cases treated with RT.

Prevention of Cancer

Certain common cancers in dogs and cats can be prevented. The recent elucidation of the canine genome as it relates to genetic

VetBooks.ir

susceptibility to certain cancers likely will increase the surgical indications for prevention. It is well known that early (<1 year) oophorectomy reduces the risk of mammary cancer in the dog by 200-fold compared with intact dogs (and to a lesser degree in cats). Castration of the male dog helps prevent perianal adenomas and, obviously, testicular cancer. Removal of in situ SCC (precancerous) from the skin of white cats or removal of in situ adenomatous polyps from the rectum of dogs may also prevent malignant transformation of these tumors. Elective removal of cryptorchid testes, which are at high risk for tumor development, is another example of preventive surgery.

Miscellaneous Oncologic Surgery

Veterinary surgeons are being called on increasingly to facilitate the medical management of cancer patients. The placement of long-term vascular access catheters for delivery of fluids, chemotherapy, or anesthetic and analgesic agents has become commonplace, and ports are routinely placed to aid in the evacuation of malignant thoracic effusions (e.g., mesothelioma). Operative placement of various enteral and parenteral feeding tubes also is common.

Surgeons and radiation oncologists may work together to treat large cancers or tumor beds after excision with intraoperative RT. Surgical intervention for oncologic emergencies is not infrequent; such emergencies include intractable pain, bleeding, pathologic fracture, infection, and bowel perforation or obstruction.

The comprehensive veterinary oncology team also now includes the discipline of interventional radiology to help manage or palliate certain malignancies. Examples include the use of self-expanding nitinol stents to treat dogs with malignant urethral obstruction[74] and double pigtail stents for the treatment of malignant ureteral obstructions resulting from trigonal transitional cell carcinoma of the urinary bladder.[75]

Equipment advances also are facilitating tumor excisions (e.g., harmonic scalpel[76] and LigaSure), and laparoscopic and thoracoscopic evaluation of body cavities for clinical staging purposes increasingly is performed. Minimally invasive approaches for excision of cancers within body cavities are becoming more commonplace, and given the potential for reduced morbidity, veterinary surgeons may feel more comfortable performing surgery in the face of advanced disease for certain solid cancers (e.g., thoracoscopic partial lung lobectomy of a solitary metastatic lung nodule at the time of amputation for an appendicular osteosarcoma). A few other examples of minimally invasive surgery performed in companion animals for cancerous diseases include thoracoscopic pericardiectomy for heart-based tumors[77,78]; thoracoscopic right atrial mass resection[78]; thoracoscopic and thoracoscopic-assisted lung lobectomy[79,80]; laparoscopic-assisted intestinal surgery[81]; laparoscopic liver, pancreatic, and prostatic biopsy[82]; laparoscopic and laparoscopic-assisted splenectomy[83–85]; and laparoscopic adrenalectomy.[86,87]

Discussion

Surgery is the principal treatment for local or regionally confined cancer; however, just because a surgical procedure is possible does not mean that surgery is justified. Surgical resection of the external genitalia used to be routine treatment for dogs with transmissible venereal tumors, but now chemotherapy alone is curative in more than 90% of dogs. Radical mastectomy does not affect survival in most dogs with mammary gland tumors, but more aggressive surgery is beneficial in cats with mammary carcinomas.[17,88–90] More surgery is not always better surgery. Long-term follow-up of well-staged and graded tumors with defined surgical technique and margins is necessary to demonstrate the true value of any operation. A great deal of progress in surgical technique and surgical thinking needs to take place before the use of surgery can be optimized.

A better understanding of expected tumor biology and more precise staging methods (e.g., molecular diagnostics, angiograms, ultrasound, CT, MRI, positron emission tomography/CT) will facilitate more precise surgical operations. Surgical techniques will continue to improve and undergo refinement,[75,91–93] but until surgeons become biologists, the big breakthroughs will be slow in coming. Surgeons should be investigating the influence of anesthesia, infection, immune function, blood transfusions, growth factors, oncogenes, and cytokines, to name a few factors, on the outcome of our patients.[94–100]

In spite of these anticipated advances in technology and biology, the most difficult aspect to learn is surgical judgment. As Cady has said, "Biology is king; selection of cases is queen; and the technical details of surgical procedures are the princes and princesses of the realm, who frequently try to overthrow the powerful forces of the king or queen, usually to no long-term avail, although with some temporary apparent victories."[101]

Interventional Oncology

WILLIAM T.N. CULP

The field of interventional radiology has grown dramatically over the past decade and has expanded the available diagnostic and treatment options for veterinary patients. Similarly, the field of interventional oncology (IO), with a focus on image-guided therapies for neoplasia, has quickly joined surgery, chemotherapy, and radiation therapy as a 4th pillar of treatment options for oncologic disease in companion animals. IO combines the use of minimally invasive techniques, advanced instrumentation, image guidance, and creative thinking to allow clinicians to offer treatments that can improve pain control, increase quality of life, and potentially alter prognosis favorably. Although this discipline is expanding rapidly, the available scientific evidence is limited. However, significant work into the evaluation of these procedures is underway.

Principles of Interventional Oncology

Imaging

Image guidance allows those individuals performing IO procedures to do so in a minimally invasive fashion. It is required for clinicians performing IO procedures to have a strong understanding of anatomy and anatomic assessment with various imaging modalities. Although there are numerous anatomic descriptions of normal anatomy in dogs and cats, very limited data are available for the description of anatomic changes associated with pathologic conditions that may commonly be treated with IO techniques. However, some basic imaging concepts are applicable in most situations, as the goals of many IO techniques are to either close down a lumen that is naturally open (e.g., embolization) or open a lumen that is obstructed by a malignancy (e.g., stenting).

The most commonly used imaging modality in veterinary medicine for the performance of IO techniques is fluoroscopy. Fluoroscopy provides a real-time assessment of anatomic structures and allows clinicians performing these procedures to use radiopaque instrumentation and contrast medium. Basic fluoroscopic equipment and techniques can be used for most stenting procedures, but advanced capabilities such as digital subtraction angiography and road-mapping are recommended when performing assessments of tumoral blood supply or vascular obstructions. It is important to be cognizant of the potential for increased exposure to radiation when performing these procedures, and appropriate training in management of radiation exposure should be a priority for those performing IO procedures.

As stated previously, fluoroscopic vascular guides for performing IO procedures are limited. The fluoroscopic abdominal anatomy has recently been described and can be used to assist with intravascular locoregional therapies in the abdomen.[1] In this study, the branching patterns of the major abdominal arteries and associated anatomic landmarks (generally vertebral bodies) were described to assist with vascular access and instrument positioning during abdominal IO procedures. Consistency in the location of many of the major abdominal arteries was noted, which will hopefully decrease anesthesia time and improve understanding of the normal anatomy, so that abnormal or altered anatomy can be appreciated when it is encountered.[1]

Recently ultrasound has been used more commonly during veterinary IO procedures. The main indications for ultrasound usage are to guide access to fluid-filled organs for implant placement or drainage or to access tumors for ablation. Ultrasound is an excellent imaging modality for these procedures, as it allows for rapid manipulation of images and real-time assessment of implant positioning. In veterinary patients, percutaneous access to the renal pelvis during antegrade ureteral stent placement is a common indication for the use of ultrasound guidance. In human IO procedures, ultrasound is commonly used to obtain vascular access as well.

Computed tomography (CT) is a crucial component of the preprocedural assessment of many cases undergoing an IO procedure. At the author's clinic, in veterinary IO cases being treated with an intravascular technique a contrast-enhanced CT is generally performed before the IO procedure to allow for assessment both of the vascular supply to a tumor and the extent of the tumor. CT is also being utilized more commonly as a tool for the assessment of tumor response. This modality is excellent for assessing tumor size and generating tumor volumes both pre- and postprocedure.

Instrumentation

Although IO incorporates certain equipment commonly used in veterinary practices, much of the instrumentation and devices used are specific to this discipline. To facilitate the minimally invasive nature that is desired to perform IO techniques, access to organs is obtained and maintained through the use of access needles and catheters and the placement of sheaths. Needles and catheters are often similar to what is regularly used in veterinary practices, but variations in diameter, length, and shape are available for different indications.

Sheaths can be used multifunctionally and are also available in different variations. Some of the more popular sheaths used during veterinary IO procedures include those equipped with a hemostatic valve and sidearm to allow for contrast injection. These

VetBooks.ir

sheaths are often placed intravascularly to allow for serial insertion of instrumentation into a blood vessel without concern for losing access. Sheaths can also be created with a "peel-away" design. This type of sheath allows for instrumentation that may have a sizeable external attachment piece to be introduced into a lumen or cavity.

One of the main workhorses of most IO procedures is the guide wire. The guide wire demonstrates much of its utility as a means of getting into a location in the least invasive way possible and in a relatively safe fashion. The guide wire also acts as means of placement of specialized catheters, sheaths, stents, and balloons, as these devices very commonly are designed with an inner cannula that allows them to slide over a guide wire into position. Guide wires are available in a variety of lengths, diameters, shapes, and stiffness; these variations are particularly important to consider when attempting to gain access through a severely obstructed lumen.

Specialized catheters are generally used to gain or maintain access in a luminal structure (including blood vessel) or for establishing a coaxial system, by which a smaller catheter or other device can also be placed. Specialized catheters are often used to generate contrast studies when planning ballooning and stenting procedures. In companion animals, the catheters used for contrast studies and vascular procedures are generally 4 to 5 French in diameter, although larger catheters may be used to allow for easier drainage of an obstructed organ. In addition, much smaller catheters (microcatheters) can be used to access smaller caliber vessels during intraarterial chemotherapy delivery or embolization; as an example, the author commonly uses microcatheters that are 1.7 to 2.4 French in diameter for prostatic embolization procedures.

Stents are devices placed into a luminal structure or passage to counteract a disease-induced stricture. The use of stents is commonplace in medicine, and the disease processes treated by stenting are constantly expanding. There are descriptions of stents used to treat malignant obstructions in the urethra, ureter, trachea, esophagus, colon, and blood vessels in companion animals.[2–10] In addition, stents have been used to treat malignant obstructions of the biliary tract and nasopharynx in the author's clinic.

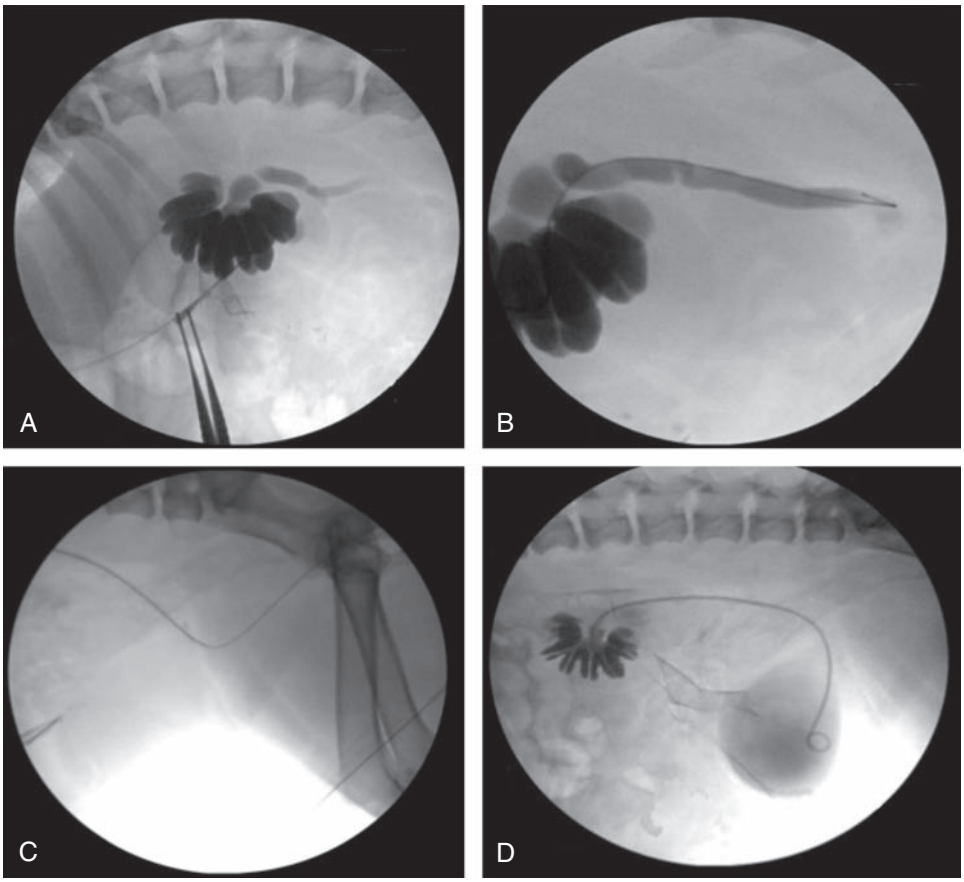
Stents can be simple catheters or other tube-like devices that are placed to simply allow for a lumen to be open, or specially designed with varying metals in a variety of configurations and sizes. Stents that contain interstices can be covered or uncovered, and can be delivered with a balloon (balloon-expandable stents) or be self-expanding. If stents are covered, they can be impregnated with antineoplastic substances such as chemotherapy or radiation beads.

An embolic agent is a substance placed into a blood vessel to cause temporary or permanent occlusion of blood flow. This alteration of blood flow could be a partial or total occlusion of the blood supply depending on the eventual goal. Many different embolic agents have been described, and advances in these products are continuing on a regular basis. Currently, major embolic agents commonly used during the treatment of neoplasia include particles and liquid embolics such as cyanoacrylate or ethylene–vinyl alcohol copolymer, although many other agents may be considered.

Interventional Oncology Treatment Categories

Stenting of Malignant Strictures

The use of stents in the treatment of companion animals has become commonplace over the past decade. Increased availability of specialized equipment and imaging modalities has improved the ability of veterinarians to be able to offer advanced procedures such as stenting. Although stenting procedures are now considered an important component of oncologic therapy, research is still limited.



Most of the available literature describing stenting in companion animals is focused on the description of the procedure and initial outcomes in a small cohort of animals; however, experience is growing, and our assessment of these procedures should expand with that growth. Stenting should be evaluated both from a procedural and clinical outcome standpoint. In many human trials, the technical success of a stenting procedure is determined and generally focuses on whether an obstruction could be bypassed and whether a stent could be successfully placed. Clinical success is often defined as stent patency at a defined period of time after the procedure.

Intraluminal stent placement for the treatment of malignant urethral obstruction is likely the most commonly performed veterinary IO technique. Urethral stent placement is generally considered an attractive option for the relief of malignant obstruction, as the procedure can be performed with minimal invasion and often rapidly relieves obstruction. In dogs, female cats, and male cats that have had a perineal urethrostomy, urethral stents can be placed via the distal urethra without need for an incision.

Several studies have described outcomes in dogs and cats undergoing urethral stenting. In four canine urethral stent studies, 95 dogs undergoing stent placement to treat malignant urethral obstructions have been reported.[2–4] In the first study, both self-expanding and balloon-expandable stents were utilized to relieve obstruction, and stent placement was found to be rapid, safe, and effective at restoring luminal patency.[4] Stent placement was successful in relieving urinary obstruction in 97% of cases in the four published studies.[2–4,11] Reported major complications of urethral stenting have included incontinence (26%–37%), reobstruction (16%), and stent migration (11%)[2,3]; in addition, stranguria poststent placement is also a common finding.[2,4] Of 19 owners surveyed in one study, 16 were satisfied with the outcome and felt that they would recommend urethral stent placement to other owners.[3] When treatment with nonsteroidal antiinflammatory drugs (NSAIDs) before or chemotherapy after stent placement was pursued, median survival times were significantly increased versus when medical therapy was not pursued.[2] Urethral stent placement has been shown to be successful in relieving malignant obstructions in cats as well.[12,13]

Ureteral stenting to relieve a malignant obstruction is generally required when a lower urinary tract carcinoma grows from the bladder, urethra, and/or prostate to obstruct the ureteral orifice in the bladder. This procedure can be performed with minimal invasion using ultrasound and fluoroscopic guidance (Fig. 11.1). As the ureteral orifice is generally obscured by the tumor, it is usually recommended to percutaneously gain access into the renal pelvis and place a guide wire across the obstruction in an antegrade fashion. Dilation of a tract through the tumor then occurs from retrograde placement of a sheath and dilator. The ureteral stent is also passed retrograde through the stent and positioned with its pigtails in the renal pelvis and bladder. In one study evaluating 12 dogs undergoing ureteral stent placement via percutaneous access, stents were successfully placed in all dogs.[5] In dogs with azotemia before stent placement, improvements in blood urea nitrogen (BUN) and serum creatinine concentrations were noted in all dogs.[8] In addition, all dogs with follow-up ultrasonography demonstrated improved hydronephrosis and hydroureter.[5]

VetBooks.ir

• **Fig. 11.1** Fluoroscopic images during a percutaneous ureteral stenting procedure in a 5-year-old male castrated pit bull terrier. (A) An over-the-needle catheter has been placed in the renal pelvis and a contrast nephroureterogram has been performed. (B) A guide wire is being passed down the ureter to the point of the ureteral obstruction. (C) The guide wire can be seen extending through the ureter, through the bladder and out the urethra in this male dog. (D) Final placement of the ureteral stent with a pigtail in the renal pelvis and a pigtail in the bladder.

Whenever possible, surgical resection of gastrointestinal tumors should be pursued. However, tumors occasionally grow undetected in companion animals for extended periods of time, resulting in large and/or invasive tumors that may be considered poor surgical candidates. Stenting of malignant obstructions in the gastrointestinal tract has been described for the esophagus and colon in companion animals.[7,9,10] These procedures can be performed using a natural orifice; the author prefers to use a combination of endoscopic and fluoroscopic guidance during the procedure to improve precision of stent placement. In a case report of a dog with an esophageal squamous cell carcinoma, stent placement resulted in an improvement in clinical signs for 12 weeks until euthanasia for unrelated reasons.[9] Colonic stenting has been reported in two cats and one dog.[7,10] All cases demonstrated clinical improvement after stenting.

Stents have also been used to treat malignant obstruction of the trachea and extraluminal compression of blood vessels.[6,8] A cat with a tracheal carcinoma was evaluated for respiratory distress and noted to have near complete obstruction of the tracheal lumen. Intraluminal tracheal stenting relieved the clinical signs and no complications were noted.[8] Endovascular stenting was used to relieve Budd–Chiari syndrome in three dogs with confirmed or suspected neoplastic obstructions. All three dogs demonstrated resolution of clinical sings and extended survival times ranging from 7 to 20 months.[6]

Intraarterial Chemotherapy

The use of intraarterial (IA) delivery of chemotherapy has long been considered in oncology.[14] The proposed theoretical advantages of IA drug delivery are that local drug concentration is increased (i.e., at the level of the tumoral blood supply), tumor toxicity is not cell cycle specific because of high drug concentrations, and the decrease in systemic exposure to drugs leads to a decrease in potential systemic side effects.[14,15] Several studies have demonstrated that IA infusion of drugs increases the concentration of drug in the target organ.[16,17] In one study, IA drug delivery resulted in greater target organ concentrations of drugs compared with intravenous (IV) administration.[16] Studies have further shown that drug concentration was influenced by blood flow rate, i.e., vessels with a low arterial blood flow will have a higher local concentration of drug[16,18]; however, many questions still remain about the magnitude of these proposed advantages (i.e., if these advantages do exist, do they exist at a level that makes IA delivery a reasonable alternative to IV delivery?) and the pharmacologic activity of a drug in a higher concentration in the tumor.

The IA delivery of drugs comes with certain challenges, many of which are magnified in a veterinary patient. Obtaining vascular access in an artery requires a small incision or ultrasound-guided intravascular access. When the artery used for access is not ligated but instead repaired, the access site needs to be monitored closely

VetBooks.ir

postprocedure for bleeding. In addition, as opposed to humans, dogs and cats require anesthesia during IA procedures. IA delivery also exposes the treating clinician and patient to radiation during the fluoroscopic procedure. Lastly, because of anesthesia and equipment costs, IA procedures are more expensive than traditional drug delivery via an IV route.

IA chemotherapy can be used as a sole therapy, but in humans this technique is often employed in a neoadjuvant setting as a means of margin sterilization or downstaging, or in combination with radiation therapy as a radiation sensitizer.[19–24] Cisplatin is well established as a radiosensitizing agent, although the exact mechanisms of this are still being elucidated.[22,25] Several human studies have demonstrated improvements in both local tumor control rates and survival times when IA chemotherapy is combined with radiation therapy.[21,23,25] In a study evaluating the combination of IA cisplatin with radiation therapy for the treatment of canine bladder cancer, two dogs demonstrated an objective reduction in tumor size.[26] Side effects and toxicity were minimal in these two dogs.[26]

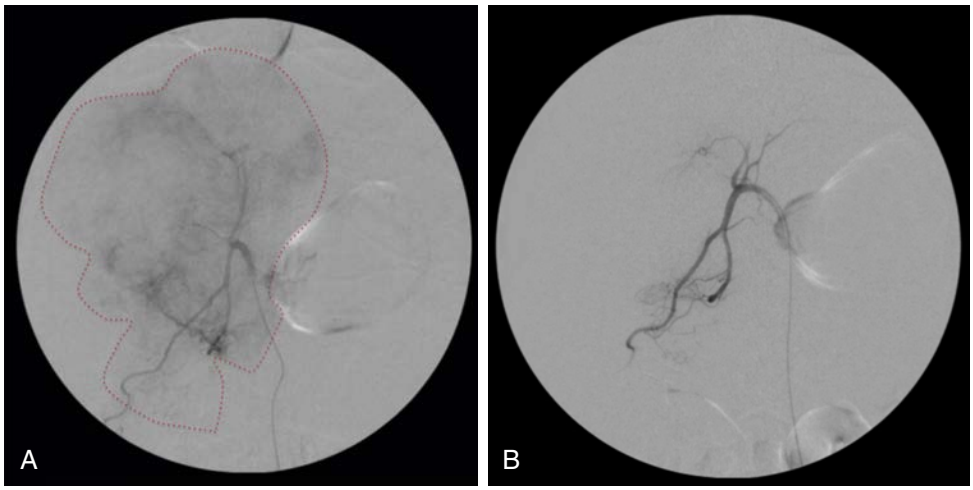
IA chemotherapy has been described in the treatment regimen of canine appendicular osteosarcoma in a few studies.[27–29] In one study,[27] dogs with extremity osteosarcoma were divided into six groups: untreated, radiation alone, IA cisplatin alone, IV cisplatin alone, radiation therapy plus IA cisplatin, and radiation therapy plus IV cisplatin. After treatment, the tumors were resected and evaluated. In all radiation therapy groups, radiation was delivered in different doses. There was a direct relationship between the number of radiation doses (whether given with or without cisplatin) on percent necrosis of the tumor. The radiation doses predicted to result in 80% or 90% tumor necrosis when radiation therapy was the sole treatment were approximately 42 and 50 Gy, respectively. The radiation doses decreased to approximately 28 and 36 Gy, respectively, when combined with IA cisplatin.[27]

In a second osteosarcoma study,[28] IA cisplatin was administered in two doses on days 1 and 21. Dogs in this study were randomized to receive IA cisplatin alone or IA cisplatin plus radiation therapy. Three weeks after treatment, a limb-sparing surgery was performed. This study demonstrated the when IA cisplatin is administered with moderate doses of radiation, a high percent tumor necrosis was achieved. Dogs with less than 75% necrosis had a significantly greater local tumor recurrence rate at 1 year, of approximately 65%, compared with a 15% local tumor recurrence rate in dogs with greater than 75% necrosis.[28]

More recently, the early tumor response of IA chemotherapy was described in the treatment of lower urinary tract neoplasia in dogs.[30] In this study, two treatment groups were established: (1) NSAID and IA carboplatin and (2) NSAID and IV carboplatin. Arterial access was obtained through either the carotid or femoral artery. Complications in the IA chemotherapy group were minor, and adverse events such as anemia, lethargy, and anorexia were significantly less likely in the group receiving IA chemotherapy compared with that receiving IV chemotherapy. The dogs in the IA chemotherapy group had a significantly greater decrease in tumor length, length percentage, width percentage, longest unidimensional measurement, and longest unidimensional measurement percentage after treatment compared with the IV chemotherapy group.[30] It is important to note that this study evaluated only short-term outcome, and larger scale studies are needed to further evaluate the use of IA chemotherapy for lower urinary tract neoplasia.[30]

Embolization and Chemoembolization

Embolization was first described in the early 1970s when autologous blood clot was used as an embolic agent.[31] Currently, embolic agents are generally categorized into permanent and temporary, with temporary agents such as gelatin sponge, collagen, and thrombin rarely used to treat neoplastic disease. More commonly, permanent embolic agents such as particles (e.g., polyvinyl alcohol beads) and liquid agents (e.g., cyanoacrylate, alcohol, and ethylene vinyl alcohol copolymer) are used, although there are also indications for the use of other permanent agents such as coils, plugs, and balloons.



Embolization is focused on the principle of directly targeting the specific blood supply of the tumor with the purpose of slowing or eliminating blood flow to that tumor. Pursuing embolization often stems from the desire to achieve one of two goals: (1) treating a tumor primarily by diminishing the blood supply so that tumor death occurs, or (2) preoperatively treating a tumor to decrease blood loss during a major surgical resection. In veterinary patients, the second reason is rarely used; however, further consideration for this option should be given, especially in tumors that are at particular risk for experiencing blood loss such as liver, nasal, and thyroid tumors. The main reason for embolization currently in companion animals is as a primary treatment in cases that are deemed to be nonresectable or patients considered to be poor surgical candidates.

The concept of embolization has been most evaluated in the treatment of liver neoplasia in humans, with the publication of hundreds of scientific articles. The liver has a unique dual blood supply, as it receives a large portion of normal blood flow from the portal vein as opposed to the hepatic artery.[32] Interestingly, much of hepatic tumoral blood supply is arterial in origin, thus allowing the hepatic arterial branches and their subsequent downstream branches to be catheterized and treated. The outcomes associated with transarterial embolization of liver masses in humans have been favorable, with randomized clinical trials demonstrating a survival benefit.[33]

Many other organs can also be considered for targeting with embolization despite not having a dual blood supply like the liver. In humans, embolization has been described in many different organs, and the literature evaluating embolization in other locations is growing. The concept for treatment in many of these organs is to specifically select the blood supply to the tumor while avoiding normal blood supply to the remainder of the organ. Tumors often stimulate neovascularization, and these abnormal new blood vessels can be targeted by superselective catheterization. In addition, some organs may not be needed (e.g., prostate), allowing these tumors to be targeted with embolization without major concern for loss of function.

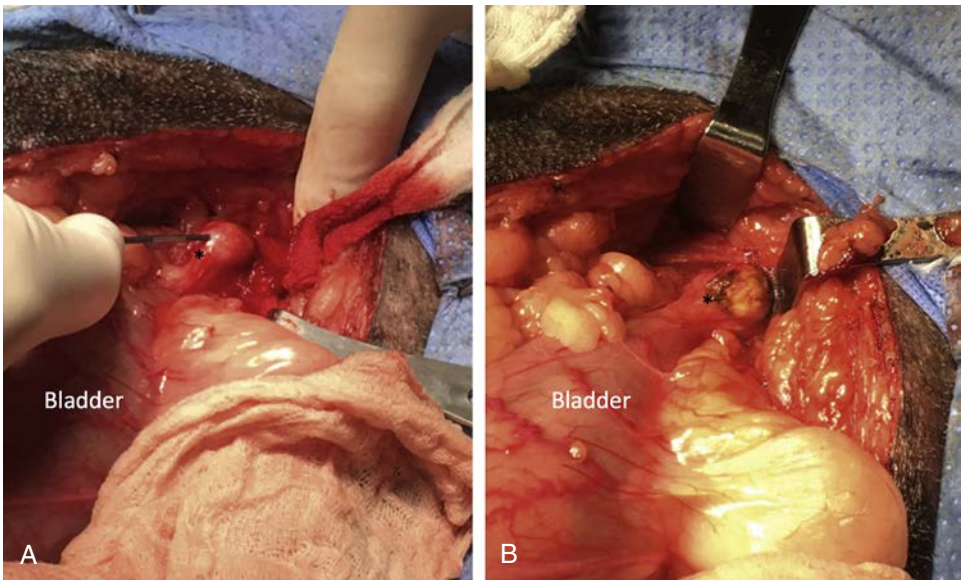
Chemoembolization differs from embolization in that chemotherapy is simultaneously delivered to a tumor at the time of embolization. This provides the theoretical advantages of IA chemotherapy, as described earlier, with the additional aspect that chemotherapy elimination from the target organ/tumor is altered as a result of diminished blood flow.[34,35] After embolization, hypoxia within tumor cells increases vessel permeability, and these factors alter cell membrane function and cause chemotherapy to be sequestered in higher concentrations within tumor cells.[34] This likely plays a major role in reduction of systemic drug exposure and a reported decrease in side effects and toxicity.[34]

VetBooks.ir

• **Fig. 11.2** Fluoroscopic images preembolization (A) and postembolization (B) of a liver tumor in an 11-year-old male castrated mixed breed dog. Note the outline of the tumor marked by the dashes (A), and the lack of tumor opacification postembolization (B).

Traditional chemoembolization involves the administration of a slurry containing a contrast medium, embolic agent, and a chemotherapy agent. Many chemotherapy agents have been described in humans including doxorubicin, epirubicin, cisplatin, and mitomycin C.[33,36] Much research is being invested into the evaluation of other means of delivering chemotherapy to tumors in combination with embolization. Drug-eluting beads (DEBs) have now been evaluated in several human studies and have demonstrated some promise.[33,37] These beads are generally made of a biocompatible polymer that can bind chemotherapeutic agents.[35,37] The drug can be released in the tumoral blood supply in a controlled and sustained manner; consequently, the chance of systemic side effects from the chemotherapy may be decreased.[35] Further evaluation of the efficacy of DEBs compared with traditional transarterial chemoembolization needs to be performed to determine whether there is a benefit of one delivery agent over the other.[33]

An additional agent, called lipiodol, is also often used during chemoembolization. Lipiodol is an iodinated poppy seed lipid–based medium that has several proposed benefits: (1) it is radiopaque and can be used in the slurry to replace contrast medium, (2) it acts as an embolic agent on its own, and (3) it preferentially concentrates in tumor tissue longer than in nontumor tissue.[35,38] Most descriptions of liver chemoembolization include lipiodol in the injected embolic slurry.



The superiority of embolization and chemoembolization to each other remains controversial.[34,35] Embolization (also called bland embolization) has an established antitumor effect, with the rationale being that embolization results in ischemic tumor cell death.[35] Proponents of embolization also highlight the prevention of chemotherapy toxicity. However, investigators who prefer chemoembolization cite the added benefit of chemotherapy-induced cytotoxicity.[35]

Liver embolization (Fig. 11.2) has been described in a few case series in dogs, and is currently the most evaluated embolization technique in companion animals.[39,40] Recently, in an experimental model, temporary hepatic arterial embolization was performed using gelatin sponge particles in five dogs with normal livers and no complications were encountered.[41] In one study describing embolization in dogs with large hepatic masses, one dog was treated with bland embolization and one dog was treated with chemoembolization.[40] Clinical improvement was noted in the dog treated with bland embolization, but the dog died at home approximately 4 months posttreatment.[40] Doxorubicin was administered with polyvinyl alcohol particles and lipiodol in the dog treated with chemoembolization; however, the dog died approximately 3 weeks after treatment as a consequence of an unrelated traumatic event.[40] In another study, superselective catheterization of the hepatic arterial branch was not achieved in two dogs.[39] Both dogs underwent transarterial chemotherapy and lipiodol administration, and one dog also received an additional embolic agent. When hepatic tumor size was evaluated after treatment, both dogs demonstrated stable disease at 1 month, but progressive disease at 3 months after treatment.[39] A hepatocellular carcinoma in a cat treated with bland embolization has also been reported.[42] In this cat, CT revealed a decrease in tumor size at 71 days posttreatment. Surgical resection was pursued 231 days after embolization and no recurrence was noted at 481 days after tumor removal.[42]

Prostatic artery embolization (PAE) is a growing field in both human and veterinary medicine. In humans, PAE has been used mostly as a treatment for benign prostatic hyperplasia (BPH) or to treat prostate-induced hematuria.[43] Experimentally, dogs have undergone PAE in a model of BPH.[44] In this study, four of seven dogs with induced BPH had reduction of prostate size after embolization.[44] The use of PAE to treat prostatic neoplasia has also recently been reported in dogs.[45] Ten dogs with confirmed prostatic carcinoma underwent PAE via a vascular approach in the left carotid artery. Tumor size was evaluated preembolization and approximately 1 month postembolization. In all dogs, prostatic tumor size decreased after embolization, and an improvement in clinical signs was noted based on an owner questionnaire.[45]

Other reported cases of embolization include a metastatic bone lesion treated with bland arterial embolization[40] and a cystic nasal adenocarcinoma in a cat. In the nasal adenocarcinoma case, chemoembolization using a combination of carboplatin, polyvinyl alcohol beads, and contrast was performed.[46] Nasal embolization is regularly performed in the author's practice as a primary treatment for nasal tumors. A femoral vascular approach is used,

• **Fig. 11.3** Intraprocedural images during radiofrequency ablation (RFA) of a prostatic carcinoma in 15-year-old male castrated mixed breed dog. (A) The RFA electrode has been introduced into the prostate *(*)* and ultrasound will be used to determine location and depth. (B) After RFA, the ablation zone can be visually seen by the alteration in color of the prostate.

because this allows for selection of both carotid arteries and subsequent bilateral treatment. A coaxial catheterization system is used to allow for superselection of the nasal blood supply.

Ablation

Ablation is a mainstay of IO treatments in humans, and the applications in veterinary patients are expanding. General categories of ablation are chemical and thermal ablation. Chemical ablation usually focuses on the intralesional injection of liquid agents, with ethanol being the most common. Thermal ablation is often subdivided into hyperthermic and hypothermic therapies. The hyperthermic ablative techniques include radiofrequency ablation (RFA), microwave ablation (MWA), high-intensity focused ultrasound (HIFU), and laser ablation, whereas cryoablation is the major hypothermic ablation technique.

Most ablation procedures are performed percutaneously with image guidance, although these procedures can also be performed with minimally invasive or open surgical approaches. For chemical ablation, a needle is usually placed intralesionally and a liquid ablation agent (most commonly ethanol) is injected to cause tissue destruction. Thermal ablation techniques such as RFA, MWA, and cryoablation are performed after the introduction of a probe into the tumor.

After introduction of an RFA electrode into a tumor, the electrode is connected to a generator that produces an electrical current that is transmitted through the electrode into the tumor; the circuit is completed through grounding pads attached to the patient. The electrical current causes ionic agitation of the tissue, which generates heat resulting in coagulation and cellular necrosis.[47] Electrode tips come in a variety of lengths and may be just a single tip or an array of expandable tines. The goal of RFA is to treat a margin of grossly normal tissue beyond the tumor to limit the potential for local recurrence.[48]

RFA is the most studied thermal ablation technique in humans and has been shown to be an excellent treatment option in several studies.[48,49] Most of the work with RFA in veterinary patients has been in the treatment of parathyroid masses in an effort to control hypercalcemia.[50–52] Recently, the treatment of a prostatic carcinoma in a dog using RFA was described (Fig. 11.3); as the dog was undergoing surgery for removal of metastatic lymph nodes, the RFA procedure was performed via a celiotomy.[53] At surgery, the electrode was placed into the prostatic tumor using ultrasound-guidance and RFA was successfully performed. No signs of residual disease were noted at 8 months post-RFA.

MWA uses electromagnetic energy to cause friction and heat, also resulting in coagulative necrosis.[48] MWA is a more recently described option for tumor ablation and there is significant promise with this modality, especially for veterinary patients. Higher intratumoral temperatures and faster ablations with less char and less pain are often achievable with MWA compared with RFA.[54,55] In addition, this modality does not require grounding pads on the patient, which is beneficial in smaller animals or animals in which grounding pad placement is difficult and may lead to burn injury.

The use of MWA has recently been evaluated in a few veterinary clinical cases.[53,56,57] To date, MWA has been reported to treat liver neoplasia in five dogs, a metastatic pulmonary lesion in one dog, and renal carcinoma in one dog.[53,56,57] In the dogs with liver tumors,[57] a ventral celiotomy was performed and MWA was used to treat hepatic lesions directly. No procedural complications were encountered. A dog with suspected radiation-induced scapular and humeral osteosarcoma was diagnosed with hypertrophic osteopathy after developing a pulmonary metastatic lesion. The metastatic nodule was treated with thoracoscopically guided MWA. Post-MWA evaluation demonstrated resolution of the clinical signs associated with hypertrophic osteopathy.[56] Lastly, a dog with a solitary left renal carcinoma was treated with percutaneous MWA via ultrasound guidance.[53] No complications were reported and the dog is currently 32 months post-MWA with no evidence of disease.[53]

Cryoablation causes cell death by forming ice crystals within cells, through the use of alternating freeze–thaw cycles.[47] Tumors of the head have received the most attention in companion animals when considering cryoablation. Long-term control of a nasal

VetBooks.ir

adenocarcinoma was achieved in one dog,[58] and a combination of transarterial embolization, systemic chemotherapy, and cryoablation resulted in partial tumor remission in a dog with a maxillary fibrosarcoma.[59]

Other thermal ablation techniques demonstrating promise and being used more regularly in human patients include HIFU and laser ablation.[60] The use of HIFU for the treatment of a hepatocellular adenoma has been reported in one dog,[61] and investigation into other options is currently ongoing. Laser ablation performed with ultrasound guidance has been described for the palliative treatment of lower urinary tract transitional cell carcinoma in dogs.[62] In a series of dogs undergoing this procedure, the median survival time was 380 days.[62]

Irreversible electroporation (IRE) is another promising ablation technique. For this technique, high-frequency electrical energy is applied to tumor tissue and causes electroporation with increased permeability of cell membranes.[63] The damage results in cellular apoptosis. Although this technique has not been used in companion animals with spontaneous tumors, the potential is tremendous, as the nonthermal electrical characteristic of IRE prevents damage to adjacent structures, such as vessels and nerves, and a higher specificity in tumor targeting.[63]

Drainage

IO techniques provide minimally invasive options for establishing drainage secondary to malignant obstructive disease. The drainage can occur from organs that should normally be able to drain independently (e.g., gallbladder, renal pelvis, and bladder) and body cavities containing malignant effusions. Access to these organs is often possible with ultrasound guidance.

Drainage catheters are generally designed with several features that assist in catheter placement and enhance maintenance of the catheter when in position, including a stiffening cannula, insertion needle, and pigtail (often with a lock). A modified Seldinger technique can often be used for placement of a drainage catheter. Using ultrasound guidance, an over-the-needle catheter is introduced into the organ or cavity in which the drainage catheter will be placed; alternatively, the insertion needle within the drainage catheter can just be directly inserted. If an over-the-needle catheter is used, a guide wire can be inserted through the catheter into the organ or cavity. The over-the-needle catheter is then removed, and the drainage catheter (with stiffening cannula) is passed over the guide wire into the drainage site. Once appropriately positioned, the stiffening cannula can be removed and the drainage catheter advanced over the guide wire, if required. Once the drainage catheter is properly positioned, the guide wire can be removed, and the pigtail loop can be locked.

Veterinary IO has a promising future. Currently, IO techniques are offered in many specialty practices. As knowledge of the options and exposure to the instrumentation increases, so will the experience with these cases and critical evaluation in the veterinary literature. It is likely that advances in IO diagnostics and treatments will mirror what is seen in human medicine and the translational potential is outstanding.

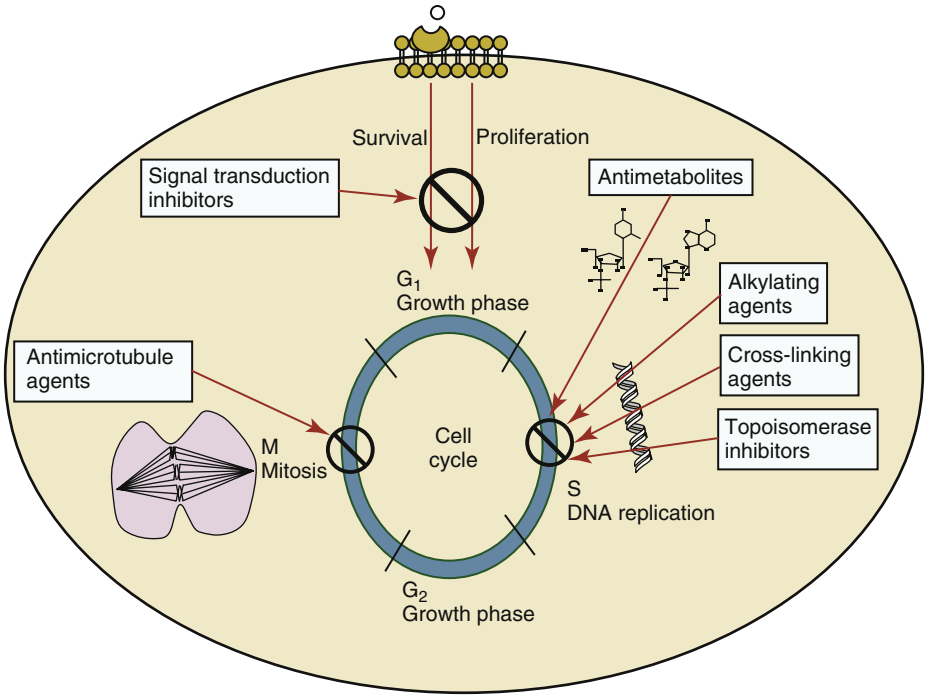
Cancer Chemotherapy

DANIEL L. GUSTAFSON AND DENNIS B. BAILEY

General Principles of Cancer Chemotherapy

Mechanism of Cancer Therapy



The use of chemical elixirs for the treatment of cancer can be traced through the medicinal customs and practices of multiple cultures. The modern use of pharmacologic agents to treat cancer began in the mid-1940s when Alfred Gilman and Louis Goodman showed the efficacy of nitrogen mustard in tumor-bearing mice, and these results were quickly translated and verified in human patients. These results and the efforts of others such as Sydney Farber with antifolates and George Hitchings and Gertrude Elion with purine analogs rapidly advanced the growing interest of treating cancer with drugs. The beginning of a systematic screening program for anticancer drugs at the National Cancer Institute (NCI) in 1955 set the framework for cancer chemotherapy development in both the public and private sectors and led to the characterization of many of the agents still in clinical use today.[1,2]

The basis of anticancer drug activity is the targeting of dividing cells through interference with processes involved in progression through the cell cycle. As shown in Fig. 12.1, the major classes of drugs used to treat cancer work at various steps in the processes of DNA replication (S phase) and subsequent cell division (M phase). Another set of therapeutic agents, the signal transduction inhibitors, work by interfering with the signaling processes that trigger entry into the cell cycle and continuing cellular proliferation. This newer class of agents is discussed in Chapter 15, Section B. DNA synthesis is a complicated process involving anabolic processes to create the purine and pyrimidine nucleotide triphosphates required for replication, unwinding of the template DNA to provide access to the replication machinery, and the high-fidelity process of creating complementary strands. Anticancer drugs may work at any of these steps, including the antimetabolites that inhibit anabolic processes required for providing the nucleotide building blocks, topoisomerase inhibitors that interfere with the enzymatic process of DNA unwinding, and alkylating/DNA binding agents that can either act in a bifunctional manner to cross-link DNA through either interstrand or intrastrand interactions blocking strand separation and template processing, or in a monofunctional manner interfering with the replication machinery through multiple mechanisms of altered binding and base recognition. The resulting effects of interacting at these levels of DNA replication can include the generation of DNA strand breaks, incomplete replication, and triggering of apoptotic signaling such that cell death is the ultimate result.

Processes in cell division not involving DNA replication are also targets for anticancer agents. The most prominent of these targets is tubulin, with several classes of drugs having antitubulin activity. The mechanism of action of these agents involves either inhibiting the polymerization of tubulin or stabilizing the polymerized form so that depolymerization is blocked. The result of blocking either of these processes is the inhibition of microtubule function in the dividing cell. Microtubule function is critical to progression through mitosis via spindle fiber formation and the separation of chromosome pairs into daughter cells. Blockade of this process by antitubulin agents has proved to be an effective strategy because cells blocked in this part of the cell cycle (M phase) can undergo apoptosis, other mechanisms of cell death and loss of viability.

Terminology and Concepts

Terms that are related to the efficacy and toxicity of cancer chemotherapy are important concepts for understanding their pharmacologic activity. The *therapeutic index* for a given chemotherapeutic agent is the ratio between the toxic dose and the therapeutic dose for that drug. For most cytotoxic drugs used to treat cancer, the therapeutic index is an abstract parameter because the administered dose is based on the *maximum tolerated dose* (MTD) rather than dose response. The MTD is an empirically derived value that represents the highest dose of a given drug that can be administered with few patients experiencing unacceptable or irreversible adverse effects (AEs). MTD is initially derived from a limited population sample and then refined with additional clinical experience. This is an important concept in cancer drug administration in that drug doses are generally based on this value rather than assessments of efficacy. A newer concept for drugs used to treat cancer is the *biologically effective dose* (BED), based on a measured response at a putative target or surrogate that is related to the mechanism of action of the agent. Determination of the BED is currently more related to the use of signal transduction inhibitors and molecularly targeted agents; however, the concept is not exclusive to these agents and this approach may be useful when applied to cytotoxic chemotherapy using dosing protocols not based on the MTD. *Dose intensity* (DI) is a measure of dose per unit of time and thus allows comparisons between protracted and compacted dosing schedules. Comparisons of DI between, for example, every 3 weeks and every week dosing allows for determining whether the total dose of the drug or the DI relates to toxicity or therapeutic outcome and the effect that altering dosing

• **Fig. 12.1** Cell cycle specificity of the major classes of drugs used in cancer chemotherapy. Although agents may have effects throughout the cell cycle, the phase where the major effect is realized is highlighted.

schedules can have on outcome. *Therapeutic gain* is often evaluated when combining two drugs or a drug with radiation therapy, and quantitatively describes any improved tumor response relative to increased normal tissue toxicity when agents are used in a planned schedule. The basis for a positive therapeutic gain is the additive or synergistic tumor effects that exceed any summative toxicity patterns in normal tissues accomplished with combination therapy.

Indications and Goals of Therapy

The therapeutic intent and goals of a given chemotherapeutic regimen are important contributors to how a given drug is selected or assessed. *Primary induction chemotherapy* refers to drug therapy administered as the first treatment for patients with hematopoietic cancers and advanced cancers for which no alternative treatment exists. *Primary neoadjuvant chemotherapy* is the utilization of chemotherapeutic drugs before treatment with other modalities, primarily surgical removal of the primary tumor, with the intent of decreasing tumor size and/or clinical stage (*downstaging*) for improved control and preventing possible postoperative growth of micrometastasis. *Adjuvant chemotherapy* is the treatment with chemotherapeutic drugs after the surgical removal or radiation control of the primary tumor. The purpose is to treat occult disease, residual tumor cells after incomplete excision of the primary tumor, and/or micrometastases. In general, chemotherapy is most effective in the adjuvant setting potentially owing to factors associated with the smaller size of residual disease and developing metastases, leading to enhanced drug delivery and more favorable growth kinetics associated with a larger dividing fraction of cells.

Consolidation therapy, used most commonly with hematopoietic cancers, is the reintensification of therapy after remission is attained to further reduce the likelihood of relapse. *Maintenance therapy* is also used after remission is attained but involves low-intensity therapy given over a protracted period of time. *Rescue* or *salvage therapy* is the use of chemotherapy after a tumor fails to respond to a previous therapy or after tumor recurrence. *Palliative chemotherapy* is delivered to decrease clinical signs in the case of unresectable or disseminated disease that is associated with functional disturbances or pain. The outcome of this therapy is based more on quality of life issues as opposed to other metrics of tumor response. The more subjective nature of assessing the effect of palliative chemotherapy, especially in terms of pain control, makes systematic testing of protocols difficult and treatment recommendations more at the discretion of the clinician and client. In cases in which organ function is affected by tumor growth, more objective endpoints may exist in terms of functional improvements after treatment. Doses and scheduling of palliative intent therapies may also differ, as strict adherence to schedules originating from trials where objective responses were measured may not be relevant and more patient-based endpoints may be employed. *Radiosensitization* is the enhancement of cytotoxicity when irradiation and chemotherapeutic agents are combined such that a therapeutic gain is obtained. The basis for chemotherapeutic exposure leading to enhanced radiosensitivity can be multifaceted and involve (1) the enrichment of the tumor cell population in a more sensitive phase of the cell cycle, (2) increased tumor oxygenation through cytoreduction or alterations in tumor vascularization, and (3) selective killing of inherently radioresistant hypoxic cell fractions.

As a preliminary metric, the clinical measurements of the tumor response to cancer chemotherapy are useful for predicting the effect of treatment on the extent of disease or time interval of tumor control. Table 12.1 describes conventional measures of treatment response.

Tumor Susceptibility and Resistance

Tumor Cell Sensitivity

Individual cell sensitivity to anticancer agents has been addressed empirically through the screening of tumor cell panels associated

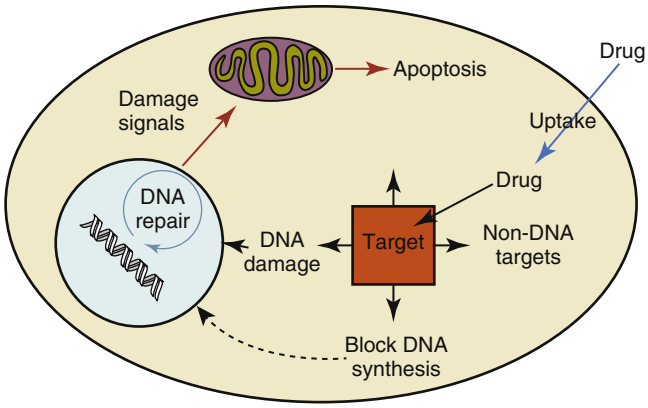


TABLE 12.1 Measures of Response in Cancer Therapy and Treatment

Response Term	Abbreviation	Description
Complete remission/response	CR	Complete disappearance of tumor(s) and symptoms of disease.
Partial remission/response	PR	Decrease in tumor volume of ≥50% or decrease in tumor maximum diameter of >30%.
Stable disease	SD	Neither an increase nor a decrease in tumor size (e.g., <30% reduction or <20% increase in tumor maximum diameter).
Progressive disease	PD	Increase in tumor volume of >25% or increase of tumor maximum diameter of >20%; appearance of new lesions.
Median response duration/median survival time	MRD/MST	The median value for a group of individuals treated with a given therapy in terms of the length of time they achieved a complete or partial remission (MRD) or length of survival after implementation of therapy (MST).
Progression-free interval/progression-free survival	PFI/PFS	The amount of time elapsed without evidence of progressive tumor growth (PFI) or survival without progressive growth of the tumor from treatment start (PFS).
Disease-free interval/disease-free survival	DFI/DFS	The amount of time that elapses without disease recurrence (DFI) or survival (DFS) of the patient after therapy.

with a given histotype. Human cancer cell line databases that include both genomic and drug response data are publicly available and include the NCI60 (https://dtp.cancer.gov), Cancer Cell Line Encyclopedia (CCLE) (https://portals.broadinstitute.org/ccle), and Genomics of Drug Sensitivity in Cancer (CCSG) (https://www.cancerrxgene.org). The rich gene expression and other features of these cell lines allow for drug sensitivity and genotypic characteristics to be explored.[3] The use of canine tumor cell line panels to screen drug sensitivity is becoming established as a viable way to identify potential drug combinations for further testing as well.[4]

Chemosensitivity depends on a number of factors, including drug uptake into the cell, interaction with a cellular target, generation of lethal damage to important cellular macromolecules, repair of potentially lethal damage, and the cell's response to generated damage as depicted in Fig. 12.2. Uptake of some cancer chemotherapeutic agents occurs via passive diffusion because of their lipid-soluble properties, whereas other compounds are actively transported into tumor cells. Melphalan is actively transported into cells by two amino acid transporters,[5] and blocking transport with amino acid substrates or analogs can significantly affect cytotoxicity.[6] Other examples include nucleoside transporters used by Ara-C [7] and gemcitabine[8] and the reduced folate carrier system involved in methotrexate uptake.[9] The intracellular target(s) for specific chemotherapeutic agents can play a role in determining sensitivity based on their levels and the nature of the interaction. For example, topoisomerase IIα levels can play a role in the sensitivity of tumor cells to doxorubicin (DOX),[10,11] as altered levels via decreased gene copy or transcriptional downregulation leads to a decrease in sensitivity (resistance). The opposite is true for thymidylate synthetase levels and 5-fluorouracil (5-FU) toxicity, where increased levels of enzyme correlate with a decrease in sensitivity to 5-FU.[12] Although the nature of the interaction with the target is different for DOX and 5-FU, the fact that altered target levels can modulate response show how quantitative interactions with the target can alter drug sensitivity.

The extent of cellular damage, potential repair of that damage, and the cellular response occur in a tightly knit continuum that

• **Fig. 12.2** Processes involved in the pharmacologic activity and associated chemosensitivity of chemotherapeutic agents in tumor cells. Associated processes include drug uptake, interaction with drug target, effect on DNA and associated DNA repair, and the cellular response to these effects.

determines cellular fate. The generation of cellular damage is a consequence of interaction with a cellular target and can be either a primary or a secondary event. In general, for DNA-damaging agents, the resulting DNA lesions are a result of the interplay of DNA binding and DNA repair. For example, DNA strand breaks that result from O^6-methyl guanine lesions are because of aberrant mismatch repair processes and subsequent replication.[13] DNA damage also triggers response pathways that can result in cell cycle arrest to allow for repair and subsequent survival, or the triggering of apoptotic machinery that ultimately results in cell death. The definition of cellular response, be it mitotic catastrophe, apoptosis, necrosis, autophagy, or cellular stasis, is dependent on an intricate interplay of survival and death signaling and is often specific to the agent, the dose at the critical target, and the cell lineage.[14] Alterations in pro- and antiapoptotic signaling clearly play a role in tumorigenesis and response to therapy,[15] and the effect of antiapoptotic signaling in lymphoma by the mediators bcl-2 and survivin seem the most clear both in regard to chemosensitivity[16–18]

VetBooks.ir

and response to therapy in humans and dogs[19–21]; however, a clear understanding of the role of damage response and active cell death pathways in chemosensitivity and response in solid tumors is still lacking.

Tumor Cell Resistance

Acquired resistance, or selection of resistant cells, during the treatment process is thought to be one of the major mechanisms of therapeutic failure during cancer drug therapy. Resistance of tumor cells to chemotherapeutic agents can be drug and mechanism dependent or can occur through a multidrug mechanism. In general, acquired resistance to a specific agent can develop via a variety of mechanisms associated with drug uptake, drug metabolism/detoxification, target modification, damage repair, or damage recognition and response. Changes in intracellular drug concentrations can come about either because of a decrease in drug uptake or through increased efflux. Decreased expression of transporters known to play a role in drug uptake has been observed in resistance to treatment with melphalan in human breast cancer cells,[22] and acquired resistance to methotrexate in KB carcinoma cells.[23] The induction of drug efflux pumps in response to drug treatment is a primary mechanism for multidrug resistance and will be discussed later in this section.

Alterations in metabolic or detoxification pathways within tumor cells are another mechanism by which acquired resistance may be acquired. As many chemotherapeutic agents are electrophilic based on their DNA-binding properties, enhancement of conjugation reactions with nucleophiles such as glutathione is a plausible mechanism of resistance.[24] Induction of glutathione-*S*-transferases has been shown to be a mechanism by which tumor cells can acquire resistance to nitrogen mustards.[25,26] Although tumor cells themselves generally have limited drug metabolism capabilities, some metabolic pathways can play a role in the resistance phenotype. For example, the sensitivity of tumor cells to 5-FU is inversely correlated with the expression of dihydropyrimidine dehydrogenase,[27–29] the enzyme predominantly responsible for the metabolism of 5-FU to the inactive 5-FUH_2 metabolite.[30] For the prodrug gemcitabine, which must be phosphorylated to the di- and triphosphate forms before eliciting an inhibitory effect on DNA synthesis,[31,32] the enzyme responsible for this metabolic activation, deoxycytidine kinase,[33,34] is decreased in pancreatic tumor cells made resistant to this drug.[35] This interplay between metabolic detoxification and activation, predominantly with nucleotide analogs, leads to complex scenarios involving upregulation of catabolic processes and the downregulation of anabolic processes influencing the cellular pharmacology of these agents.

Modifications in the cellular target of a given drug usually pertain to mutations in the target protein leading to a decrease in affinity or absence of drug interaction. These modifications can include a decrease in the levels of a specific target responsible for the generation of a toxic product, increases in target levels to ameliorate the effect of target inhibition, or target mutations such that the drug can no longer interact in a manner detrimental to the tumor cell. Decreased topoisomerase II gene expression and activity has been observed in human lung and colon cells with acquired resistance to the epipodophyllotoxins etoposide and teniposide,[36] whose antitumor activity involves topoisomerase II–dependent DNA strand break formation.[37] Target amplification as a mechanism of acquired resistance has been observed in methotrexate resistance, where gene amplification and increased dihydrofolate reductase (DHFR) levels allow for cells to overcome DHFR inhibition.[38] Mutations in targets such as β-tubulin in the case of paclitaxel[39] and topoisomerase I for camptothecin[40] affect binding of drug and interaction with the target, thus conferring resistance.

Damage repair in cancer cells treated with chemotherapy commonly refers to DNA repair processes, as a majority of chemotherapy agents work at the level of the DNA. Resistance conferred through alteration in DNA repair includes not only the induction of specific processes to repair discrete lesions but also more global DNA repair processes such as postreplication and mismatch repair.[41] Multiple studies have shown that enhanced removal of platinum adducts from tumor cell DNA correlates with acquired resistance to cisplatin,[42–44] although the exact mechanism(s) and protein(s) responsible for repair of these lesions are unknown. The bulky DNA adducts generated by many cancer chemotherapeutic agents can cause replicative gaps in DNA that require postreplication surveillance and repair. The ability of cells to bypass these bulky lesions and interstrand cross-links during DNA replication is important in tolerance to agents causing these types of DNA damage (cisplatin, mitomycin C, melphalan), and multiple DNA repair pathways can account for this release from the DNA replication block.[45] The fact that DNA repair pathways and processes are redundant and nondiscrete and that both lesion-specific and global processes seem to play a role in determining drug resistance highlights the problems associated with attributing specific resistance phenotypes to specific proteins or pathways. This problem may be addressed with unbiased genomic or proteomic approaches that profile multiple factors.

Tumor cell drug resistance associated with alterations in cellular damage recognition and response is generally associated with defects in apoptosis.[15] Generally, these alterations in apoptosis signaling are not a response to therapy but rather are preexisting and play a role in initial sensitivity. This is exemplified in a study showing that although survivin expression was shown to be predictive for response to CHOP (*C*yclophosphamide, *H*ydroxydaunorubicin, *O*ncovin [vincristine], and *P*rednisone) therapy in canine lymphoma, survivin expression in patient-matched samples pretreatment and at relapse showed no significant difference.[21] This suggests that the role of antiapoptotic, prosurvival signaling diminishes the initial response to drug therapy as opposed to facilitating survival of initially drug-sensitive clones through an acquired mechanism.

Some mechanisms of acquired resistance result in a phenotype in which the tumor is resistant to multiple chemotherapeutic agents, or multidrug resistant (MDR). Some of the mechanisms discussed earlier, including DNA repair, enhanced metabolism or detoxification, and resistance to apoptosis can result in resistance to multiple agents; however, the "MDR phenotype" generally refers to tumor cells expressing individual or multiple members of the ATP-binding cassette (ABC) transporter family, which plays a primary role in active efflux of drugs from cells. Forty-eight ABC genes have been identified in the human genome,[46] and currently 15 members of the ABC transporter family have been recognized that include a cancer drug as a substrate for transport.[47] These include the well-studied and well-characterized PGP/MDR1 (ABCB1), MXR/BCRP (ABCG2), MRP1 (ABCC1), and MRP2 (ABCC2). The basic function of the ABC transporters is conserved across the family and involves the ATP-dependent transport of xenobiotics and endogenous substrates from the inside of the cell to the extracellular space. The role of ABC transporters in multidrug resistance of canine and feline cancers is poorly explored; however, ABCB1 is expressed in canine lymphoma,[48] mammary tumors,[49] and canine and feline primary pulmonary carcinomas.[50] ABCC1, ABCC2, ABCC5, ABCC10, and ABCG2

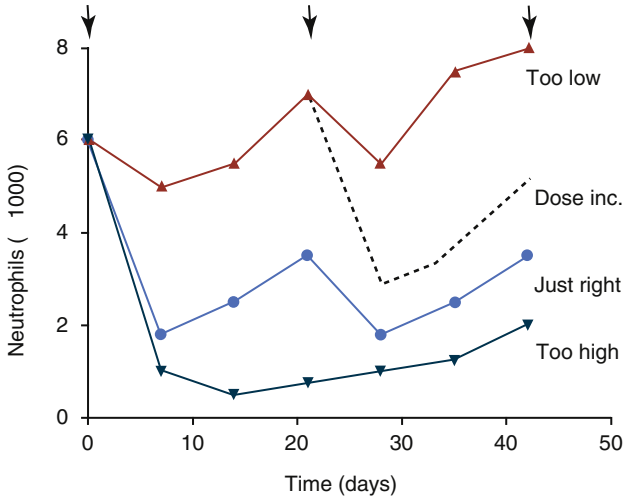
VetBooks.ir

are expressed in canine mammary tumors as well.[49,51] The normal tissue distribution of the ABC transporters is also beginning to be investigated in dogs, with initial studies showing relatively similar tissue distributions and presumed function.[52,53] Feline ABCG2 has specific amino acid changes that lead to transporter dysfunction with regard to a number of substrates, suggesting that cats may have altered pharmacokinetic disposition for drugs that are ABCG2 substrates.[54]

Combination Therapies

The success of combination chemotherapy compared with single-agent treatment is attributed to providing maximal cell kill within the range of tolerable host toxicity, providing a broader range of interactions between the drugs and the heterogeneous tumor cell population, and slowing the development of cellular drug resistance. However, certain guidelines should be followed when designing a combination protocol.[55] Only drugs with known efficacy as single agents against the cancer of interest should be included, with preference for drugs that can induce a complete remission in at least some patients. Whenever possible, drugs with nonoverlapping toxicities should be used. This potentially will result in a wider range of AEs, but a lower risk of a severe or life-threatening episode. Lastly, drugs should be used at their optimal dose and schedule, and drug combinations should be given at consistent intervals.

The success of combination therapies as opposed to single-agent therapy is best illustrated in veterinary oncology by treatment protocols for canine lymphoma. DOX is the most active single-agent therapy tested, and the addition of DOX to other active protocols (i.e., cyclophosphamide [CP], vincristine, and prednisone) empirically increases median remission duration and median survival time compared with either DOX alone or combinations without DOX (see Chapter 33, Table 33.4).[56–72] In contrast, in dogs with appendicular osteosarcoma (OSA), adjuvant treatment with combinations of platinum and DOX empirically does not show any improvement in disease-free interval or survival over those treated with single-agent DOX or platinum protocols (see Chapter 25, Table 25.2).[73]



The concept of summation dose-intensity (SDI) can be used to compare different combination chemotherapy protocols.[74,75] The contribution of each drug is based on its fractional dose-intensity (DI) (relative to maximum DI when the drug is used as a single agent) and its relative antitumor potency compared with the other drugs included in the protocol. The individual contributions of each drug are then added together. SDI > 1 implies a benefit over monotherapy using the single-most active drug at its MTD and optimum dosing schedule. SDI = 1 implies equality, and SDI < 1 implies diminished efficacy.

Toxicities Associated with Drug Therapy of Cancer

Chemotherapy may fail to produce a positive clinical benefit for the reasons described earlier but may also fail because of unacceptable toxicity. Anticipating and managing AEs requires a thorough understanding of drug activity profiles and clinical experience modifying chemotherapeutic administration. The first step in the process of successfully managing cancer in companion animals is always a clear and frank discussion with the owner regarding the potential for benefit, toxicity, cost, and time commitment. A common understanding about the goals of therapy, and committing to a continuing dialog as needs may change throughout treatment, cannot be underestimated.

Dosing conventions have been developed from formal phase I studies for an increasing number of agents investigated specifically in companion animals. Nonetheless, suggested starting doses represent an estimate of the MTD from a small population of animals, and safe individual patient dosing may vary substantially. There are numerous reasons for pharmacokinetic variability in cancer drugs among a population of patients.[76] Concurrent illness or organ dysfunction, extreme tumor burden, specific breed sensitivities (e.g., Collies with ABCB1 *mut*/*mut*), or idiosyncratic considerations (anticipated drug–drug interactions or drug allergies) will mandate modifications of the protocol and dosing. Concurrent illness and organ dysfunction can have profound effects on selection of anticancer agents and dosing. In general, predictable dose adjustments for pets with renal or hepatic disease have not been developed and treatment should be approached conservatively. Interestingly, in cats, the glomerular filtration rate (GFR) can be used to define an individual dose for carboplatin that will permit some patients with renal disease to be safely dosed that would not have been safe if dosed by conventional methods.[77] Chemotherapeutic dosing in obese patients often raises questions about drug partitioning in lipid storage sites around the body. Distribution of many pharmaceutical agents may be affected in obese patients; however, there is no accepted scale for empiric dose adjustments in humans. Individual factors such as the specific drug, degree of obesity, and other comorbidities may convince a clinician to dose reduce or cap the dose of a chemotherapeutic agent.[78] Some reviews suggest that dose reductions based on body mass may ultimately be detrimental to outcomes in obese patients.[79] It is the initial chemotherapeutic intervention that is expected to result in the greatest opportunity to benefit the patient and, therefore, thoroughly assessing the patient's specific medical limitations and then proceeding with thoughtfully designing, administering, and completing a therapeutically robust protocol is highly desirable.

As individual patient tolerance and response to each compound in a multiagent protocol is observed, future modifications may be anticipated more accurately. The greatest benefit achievable with anticancer cytotoxic therapy requires a commitment to dose intensity. Optimal dose intensity demands therapeutic monitoring to either reduce *or* increase the dose based on the patient's capacity to maintain an acceptable quality of life during effective therapy. The decision to increase the dose of an agent is conceptually challenging but important. To make a recommendation to increase dosing of a cytotoxic compound, owner understanding and monitoring of the patient's hematologic values and clinical events during the first treatment cycle are critical. A dose of a cytotoxic agent that does not result in any change in the target normal tissue (e.g., blood neutrophil count) is likely ineffective and could potentially be increased at the next infusion with continued follow-up to determine adequacy of dose adjustments (Fig. 12.3). Dose reductions are deleterious to the optimum delivery of chemotherapy but are to be anticipated. Specific guidelines for dose adjustments of antineoplastic agents are not standardized and are done empirically with a 10% to 25% reduction in dose generally considered for patients experiencing severe or unacceptable hematologic or gastrointestinal AEs. Close monitoring and preemptive management of signs may permit successful management of any potential future clinical signs, and clinical management is based on the extent and severity of the resulting signs as described in Table 12.2.

• **Fig. 12.3** Blood neutrophil patterns after chemotherapy treatments *(arrows)*. The appropriate dose *(circles)* results in noticeable nadirs with return to normal before the next dose. Doses that are too high or too low should prompt dose adjustments, including potential dose increases *(dashed line)*.

The AEs for anticancer agents may be categorized into acute toxicities (at the time or within 24–48 hours after treatment), acute delayed effects (2–14 days), or cumulative/chronic toxicity (weeks, months, or years). Acute toxicity may include infusion hypersensitivities because of histamine release associated with allergic (L-asparaginase) or allergic-like (DOX) reactions, or vehicle-induced mast cell degranulation (e.g., paclitaxel, etoposide). Routine management of these events with antihistamines and corticosteroids may significantly mitigate this problem. Acute nausea and vomiting may occur with specific agents (e.g., cisplatin, dacarbazine, streptozotocin) or when the infusion is too rapid (e.g., DOX). Preemptive antiemetic management often manages these AEs. Drugs with vesicant properties can cause moderate or severe tissue necrosis if not administered safely through a suitable catheter. Vinca alkaloid, DOX, mechlorethamine, and actinomycin D extravasations can be very severe situations that should be avoided, even if sedation is required or rescheduling is required for safe catheter placement. Owners need to be informed about this possibility before treatment and a management plan for this situation should be developed. Management recommendations for extravasations are included in the individual drug descriptions in the text that follows.

TABLE 12.2 Guidelines for Common Chemotherapy-Induced Toxicity

	Prophylaxis	Grade 2/Mild Toxicity	Grade 3/Moderate Toxicity	Grade 4/Severe Toxicity
Neutropenia		**1000–1500/ μL**	**500–999/μL**	**<500/μL, with or without fever**
Broad-spectrum antibiotics	Not recommended	No	Oral.[a] If fever, then hospitalize and IV.[b] CBC in 2–5 days.	Oral.[a] If fever, then hospitalize and IV.[b] CBC in 24 hours.
Parenteral fluids (SQ or IV) and supportive care	No	No	Not routine unless febrile.	Not routine unless febrile.
Nausea/vomiting		**<3 vomiting episodes**	**3–5 episodes/day for 2–4 days**	**>5 episodes/24 hours or >4 days**
Antiemetics[c]	Oral, if prior experience warrants.	Oral or IV as indicated.	IV	IV
H_2 blocker,[d] proton pump inhibitor[e]	Oral, if prior experience warrants.	Oral or IV as indicated.	IV	IV
Parenteral fluids (SQ or IV) and supportive care	No	As indicated.	Yes	Yes, hospitalize.
Diarrhea		**2 stools/day over baseline**	**3–6 stools/day over baseline**	**>6 stools/day**
Diet adjustment	Yes	Yes	Yes	Yes
Antidiarrheals[f]	Yes	Yes	Yes	Yes
Parenteral fluids (SQ or IV) and supportive care	No	No	Yes	Yes, hospitalize.

CBC, Complete blood count; *IV*, intravenous; *SQ*, subcutaneous.

[a]Enrofloxacin (dog: 10 mg/kg PO q24h, cat: 2.5–5 mg/kg PO q24h) or Clavamox (13.75 mg/kg PO q12h).

[b]Ampicillin (20 mg/kg IV q8h) or ampicillin/sulbactam (30 mg/kg IV q8h) and enrofloxacin (dog: 10 mg/kg IV q24h, cat: 2.5–5 mg/kg IV q24h).

[c]Maropitant (dogs: 1 mg/kg IV or SC, 2 mg/kg PO, once daily, cats: 1 mg/kg PO, SC, or IV). Ondansetron (0.5–1.0 mg/kg IV or PO, q12–24h).

[d]Famotidine (0.5–1.0 mg/kg PO, SQ, or IV).

[e]Pantoprazole (1 mg/kg IV or SQ as needed).

[f]Loperamide (0.08 mg/kg PO q8h); tylosin (10 mg/kg PO q12h); metronidazole 15 to 25 mg/kg PO q12h).

VetBooks.ir

Delayed acute effects from chemotherapy often include bone marrow suppression and nausea, vomiting, and diarrhea. In the majority of instances these effects are self-limiting, and the incidence of hospitalization is low. Table 12.2 reviews the general therapeutic strategies for management of the most common types of AEs experienced in companion animals after chemotherapy.[80]

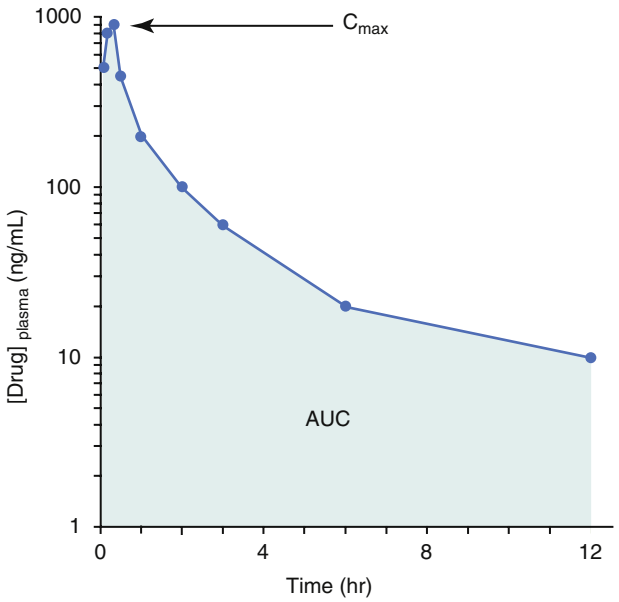
Examples of potential cumulative and/or chronic toxicity include hepatic dysfunction after multiple doses of lomustine (CCNU), cardiac abnormalities after exceeding a safe cumulative dose of DOX (dogs), and renal disease after cisplatin (dogs) or DOX (cats) use. Screening recommendations and strategies to reduce the risks of such chronic effects have been developed and are incorporated into standard protocol procedures. It is critical to the success of treatment that owners be thoroughly informed about monitoring guidelines for the signs of chemotherapy-induced toxicity. Owner online educational resources are readily available at www.csuanimalcancercenter.org. It is advisable to instruct the owner regarding monitoring and early responses when his or her pet experiences nausea and vomiting, diarrhea, or hematuria and it is important to inform the owner about how to obtain an accurate body temperature. These "at home" aids will allow the clinician to assess the management options should a concern arise.

Safety Concerns of Cancer Drug Therapy

Handling cytotoxic chemotherapy drugs is classified as an occupational health hazard by the National Institute for Occupational Safety and Health (www.cdc.gov/niosh/topics/hazdrug/). Cytotoxic chemotherapy drugs are mutagenic, carcinogenic, teratogenic, abortifacient, and increase the risk of stillbirth.[81–84] Veterinary hospitals that handle chemotherapy drugs must be aware of and comply with evolving federal and state guidelines, and only trained personnel should be involved with handling these drugs or the patients that receive them. Clients must also be informed about potential hazards, particularly for women who are pregnant or breastfeeding, and for young children.

Chemotherapy should be stored, prepared, and used in designated areas that are clearly labeled. Ideally, these areas should be dedicated solely for these tasks, with access restricted for unauthorized personnel. Eating, drinking, smoking, chewing gum, using tobacco, applying cosmetics, or storing food or drinks must be prohibited in these areas. Chemotherapy ideally should be prepared in a class II, type B2 biologic safety cabinet (BSC). This type of BSC provides inward airflow, downward HEPA-filtered laminal airflow, and HEPA-filtered exhausted air that is 100% ventilated outside. The use of a closed-system transfer device (CSTD) such as PhaSeal, Equashield, Chemoclave, or Onguard is recommended as well. A CSTD mechanically prevents the escape of drug or vapor out of the system into the environment and reduces the risk of accidental needle puncture.[85] These precautions reduce environmental contamination, but do not obviate the need for personal protective equipment (PPE). Double-gloving is recommended using powder-free latex or nitrile gloves that are chemotherapy rated by ASTM International standards. Gowns should be disposable, impermeable, closed-front style, and long-sleeved with elastic or knit cuffs. Eye and face protection should be used when there is a high risk for splashes or aerosols, such as with intralesional chemotherapy injections. Respiratory protection using a fitted respirator with an N95 rating is required when engineering mechanisms cannot control exposure of an aerosolized drug (e.g., a drug spill). Guidelines for limiting exposure to hazardous drugs in the workplace has been addressed through the United States Department of Labor.[86]

Chemotherapy must be administered in a quiet location without distraction. Oral chemotherapy drugs should be intact; tablets should never be split or crushed, and capsules should never be opened. Oral liquid preparations are not recommended because of a risk of inaccurate dosing and environmental contamination if some of the medication is spit out. For intravenous (IV) chemotherapy, the smallest gauge and shortest length of catheter to accommodate therapy should be used, and it must be placed via a "clean stick." Only nonheparinized saline flushes should be used. IV pumps should be avoided, except for multihour infusions (e.g., cytosine arabinoside, dacarbazine). Chemical restraint should be considered as-needed to ensure the safety of the patient and treating personnel.



When dealing with chemotherapy spills, there is no universal cleaning agent; however, use of a sodium hypochlorite (bleach) solution, a strong detergent, and water will deactivate and remove most hazardous drug residues.[86] Alcohol will not deactivate chemotherapy drugs and can spread contamination. Chemotherapy drugs and their metabolites can be excreted in urine, feces, saliva, and vomitus. Urinary levels of some active drugs may remain high for days after treatment,[87] and fecal excretion may also be expected. Contaminated excreta should be handled like a chemotherapy spill.

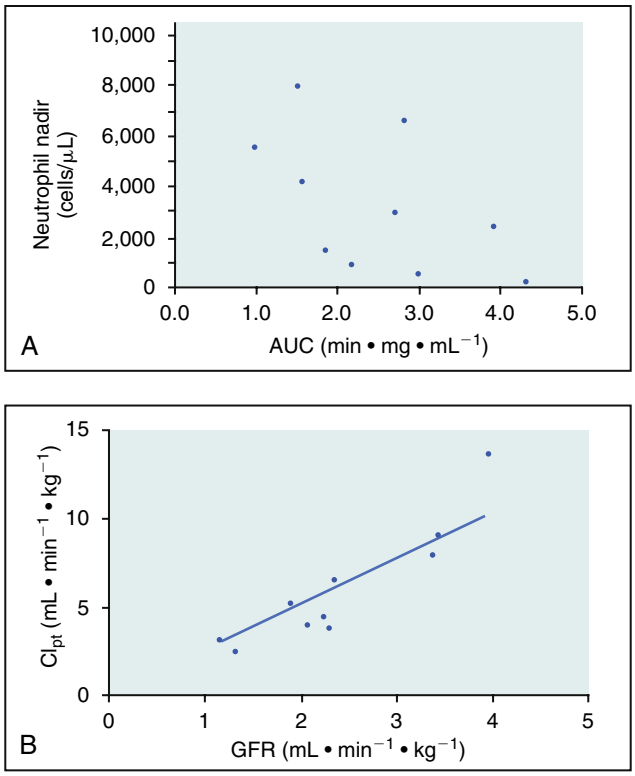
Pharmacologic Principles in Cancer Therapy

Pharmacokinetics

Pharmacokinetic (PK) considerations in cancer drug therapy are important because of the relationship between drug exposure and pharmacodynamic (PD) response, be it efficacy or toxicity, that is more exact than the relationship between drug dose and PD response.[88] PK considerations are also important with regard to interactions with other drugs,[89] herbal products,[90,91] and genetic differences among breeds and individuals that can cause changes in drug exposure at a given dose.[92] Cytotoxic chemotherapy is usually dosed on an MTD-based schedule reflecting only acceptable toxicity and thus limits any informative role of drug half-life and effective therapeutic concentrations from initial dosing considerations. The most important PK parameters are those that have a relationship with either a response to therapy (efficacy) or toxicity, which is most often either the area under the plasma/serum concentration versus time curve (AUC) or the maximum drug concentration achieved (C_{max}), illustrated in Fig. 12.4. The relationships of AUC and C_{max} in the clinical pharmacology of DOX illustrate the complex associations with PK considerations. The C_{max} during DOX infusion in humans is related to the incidence of cardiotoxicity both in adult[93] and pediatric[94] patients, but is also associated with longer remissions in leukemia patients.[95] A relationship between AUC values and decreased white blood cells has also been established with DOX[96]; however, no clear relationships between AUC and efficacy exist.[97] These data have allowed for adjustments in DOX dosing protocols such that intermediate infusion times (10–30 minutes) are utilized to decrease the C_{max} and thus cardiotoxicity, while still maintaining peak levels associated with effective therapy.

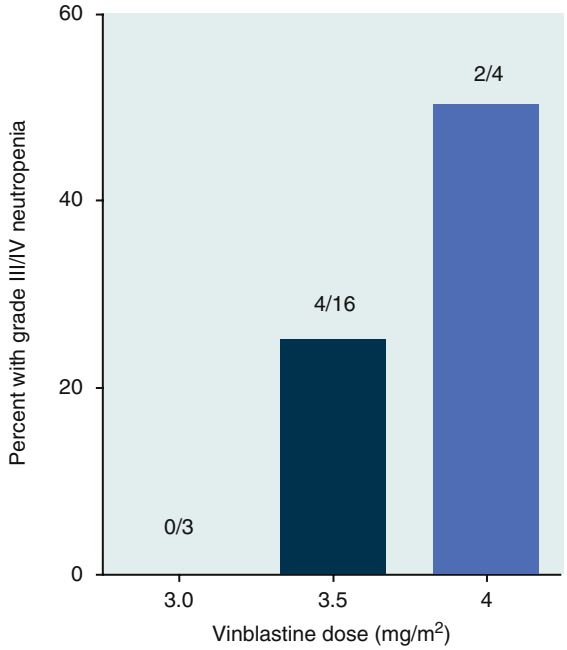
PK studies that relate drug exposure to responses are an important first step in establishing relationships that may be exploited for dose modification based on patient characteristics or therapeutic drug monitoring. These data are generally lacking for the drugs

• **Fig. 12.4** Illustration of pharmacokinetic parameters C_{max} and area under the curve *(AUC)* in a theoretical drug plasma concentration versus time plot.



used to treat cancer in companion animals, with a few exceptions. Studies on the PK and myelotoxicity of carboplatin in cats have shown a clear relationship between drug exposure and the neutrophil nadir and also drug clearance and GFR (Fig. 12.5). The fact that PK parameters can be correlated both with a toxic endpoint and a physiologic function allows for the calculation of a dosing metric relating the GFR of an individual cat to a dose that produces a drug exposure (AUC) that results in acceptable toxicity.[77] It remains to be determined whether such individualized dosing results in improved outcome in a heterogeneous population. The current drug-dosing convention for cancer drugs is the use of body surface area (BSA) for dose normalization (mg/m^2). Exceptions to this paradigm are the use of body weight (mg/kg) for dogs that weigh less than 15 kg and for cats with DOX dosing, based on empiric evidence showing a better toxicity profile for smaller animals when mg/kg dosing is used.[98] The approximate calculation for BSA in dogs and cats based on weight is as follows:

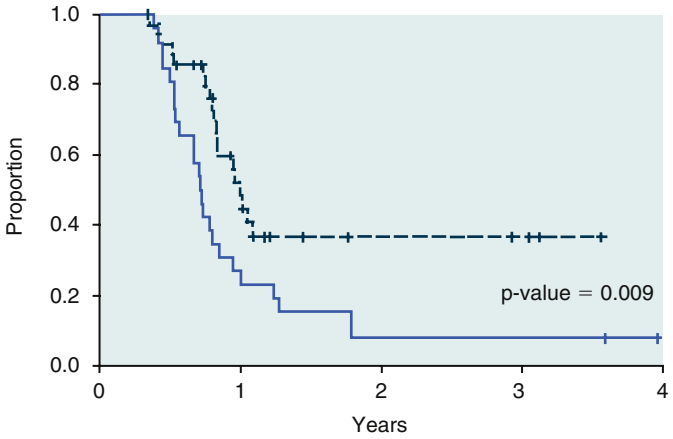
$$m^2 = \frac{A \times (\text{weight in grams})^{\frac{2}{3}}}{10{,}000}$$



where A is equal to 10.1 for dogs and 10.0 for cats.

Pharmacodynamics

Pharmacodynamic (PD) considerations for cytotoxic chemotherapy are generally related to standard measures of response (i.e., CR, PR, SD, etc.) and AEs.[99] A majority of the literature in veterinary oncology relates PD responses to specific drugs or combinations, doses, or schedules. Fig. 12.6 shows the relationships between vinblastine dose and the incidence of grade III or IV neutropenia observed in a Phase I cohort of dogs.[100] These results relate a dose to a PD response with the absence of exposure PK data. PD endpoints can also be used as indicators of efficacy and potentially as targets of therapy. The proportion of dogs in remission after treatment for lymphoma is increased in the group that experienced grade III or IV neutropenia compared with the group that did not (Fig. 12.7).[101] In this example, outcome was related to overall drug effects on normal



• **Fig. 12.5** Relationship between (A) neutrophil nadir and carboplatin exposure and (B) platinum clearance and glomerular filtration rate *(GFR)* in cats being treated for cancer. *AUC*; Area under the curve. (From Bailey DB, Rassnick KM, Erb HN, et al: Effect of glomerular filtration rate on clearance and myelotoxicity of carboplatin in cats with tumors, *Am J Vet Res* 65:1502, 2004.)

• **Fig. 12.6** Relationship of prevalence of grade III/IV neutropenia with vinblastine dose in dogs being treated for cancer. (Data from Bailey DB, Rassnick KM, Kristal O, et al: Phase I dose escalation of single-agent vinblastine in dogs, *J Vet Intern Med* 22:1397, 2008.)

tissues as indicated by the degree of neutropenia (PD response), whereas dose intensity did not have a significant effect. Again, these data did not include exposure (PK) assessment and in this case only

• **Fig. 12.7** Proportion of dogs in remission after chemotherapy treatment for lymphoma. The *dashed line* represents those animals experiencing grade III/IV neutropenia, whereas the *solid line* represents those animals that did not show that level of toxicity. (From Ghan A, Johnson JL, Williams LE: Impact of chemotherapeutic dose intensity and hematologic toxicity on first remission duration in dogs with lymphoma treated with a chemoradiotherapy protocol, *J Vet Intern Med* 21:1332, 2007.)

relates the therapeutic outcome to an observed drug response. A lack of complete PK/PD data relationships in veterinary medicine reduces the opportunities for therapeutic drug monitoring and the potential for optimizing efficacy.

Pharmaceutics

Pharmaceutics is the science associated with dosage form design with regard to formulation and optimizing drug delivery via a specific route. For example, improved formulations of clinical agents such as paclitaxel have made these compounds available for use in veterinary patients. The excipient (drug carrier) used in the original clinical formulation of paclitaxel (Taxol®) was cremaphor-EL, which causes hypersensitivity reactions when used in dogs.[102,103] A new water-soluble micellar formulation of paclitaxel (Paccal® Vet) appears effective without associated hypersensitivity reactions in dogs with mast cell tumors (MCTs).[103,104] (This preparation was not commercially available at the time this chapter was written.) The ability of new formulations and delivery methods to alter the efficacy and toxicity profile of agents is a rapidly expanding field. It is expected that new technologies in drug formulation and targeting will be incorporated into veterinary medicine to alter drug delivery and distribution in a more favorable manner.

Specific Chemotherapeutic Agents

Alkylating Agents

The alkylating agents comprise antitumor drugs whose mechanism of action involves the covalent binding of alkyl groups to cellular macromolecules. The cellular target of these agents is DNA, where they form monofunctional or bifunctional adducts that generate inter- or intrastrand cross-links.

Nitrogen Mustards

Mechlorethamine (Mustargen)

Basic Pharmacology. Mechlorethamine is frequently referred to as "nitrogen mustard" and was the first cytotoxic agent to show antineoplastic activity.[105–107] Mechlorethamine undergoes spontaneous hydrolysis to 2-hydroxyethyl-2-chloroethylmethylamine and bis-2-hydroxyethylmethylamine, yielding nucleophilic reactive centers capable of forming DNA cross-links.[108]

Clinical Pharmacology. Mechlorethamine rapidly disappears from the plasma after administration, primarily through spontaneous degradation, although some percentage of the drug is enzymatically metabolized.[109] Mechlorethamine uptake into cells seems to be carrier mediated, with decreased uptake as a mechanism for resistance.[110]

Experience with mechlorethamine as a single agent is not reported, although gastrointestinal (GI) and bone marrow toxicities are dose-limiting toxicities (DLTs) of conventional mechlorethamine-containing protocols. This drug is a strong vesicant and can cause severe tissue necrosis if extravasated. In case of extravasation, sodium thiosulfate (0.17 mmol/L, or 2.5%) should be administered through the catheter before it is removed, or it can be injected directly into the affected site after the catheter has been removed. The volume injected should be equal to that of the intended mechlorethamine dose.

Clinical Use. Mechlorethamine is used predominantly in multiagent protocols for lymphoma in dogs and cats.[111–113,114] Dosing of mechlorethamine in these protocols is reported as 3 mg/m^2 IV on days 0 and 7 of a 21- or 28-day cycle.

Melphalan

Basic Pharmacology. Melphalan (L-phenylalanine mustard) is a nitrogen mustard containing DNA cross-linking agent with a similar structure and pharmacology to chlorambucil. The major difference is that melphalan is actively transported into tumor cells by amino acid transporters,[5] and its uptake can be blocked by the amino acid leucine. Melphalan has direct alkylating activity and does not require metabolic activation.

Clinical Pharmacology. Melphalan can be given orally, with an oral bioavailability of approximately 30%. A relatively high percentage of melphalan (20%–35%) is excreted unchanged in the urine, with a majority of the remainder of the dose undergoing spontaneous chemical decomposition to inert products.[115] The primary toxicity is myelosuppression—neutropenia and thrombocytopenia.

Clinical Use. The primary indication for melphalan in companion animals is for management of multiple myeloma. The initial dose of 0.1 mg/kg daily for 10 to 14 days should be reduced to 0.05 mg/kg daily based on control of the paraproteinemia and hematologic screening for both dogs and cats. Alternate dosing regimens have also been used for dogs: 7 mg/m^2 daily for 5 days every 3 weeks or 2 mg/m^2 daily for 10 days with a 10-day off cycle and repeated as needed.[116]

Cyclophosphamide

Basic Pharmacology. CP is a nitrogen mustard–containing prodrug that is inactive in the absence of metabolic activation, which occurs via microsomal mixed function oxidases predominantly in the liver.[117] The activation of CP involves ring oxidation to 4-hydroxycyclophosphamide (4-OHCP), spontaneous and reversible ring opening to the amino aldehyde aldophosphamide, and the subsequent irreversible breakdown of aldophosphamide to phosphoramide mustard and acrolein. Phosphoramide mustard is considered the most active CP metabolite and is capable of bifunctional alkylation and cross-linking.[118]

Clinical Pharmacology. In dogs and cats, PO and IV administration are equally effective, and this has been verified by PK

VetBooks.ir

studies showing similar exposure to the active 4-OHCP metabolite.[119,120] The major DLT of CP is neutropenia. GI toxicity (nausea and vomiting) is not common but has been observed.[121] In dogs, sterile hemorrhagic cystitis (SHC) can result from the metabolite acrolein.[122] It is uncommon with conventional IV dosing, but there are reports after even just a single IV administration.[123,124] The incidence is higher with chronic oral dosing, and a cumulative dose is a risk factor.[125,126] Concurrent treatment with furosemide (1–2 mg/kg PO or IV) significantly reduces the risk of SHC.[123,125] CP should be discontinued permanently in patients that develop SHC. Chlorambucil is often a suitable replacement. Treatment for SHC is largely symptomatic with nonsteroidal antiinflammatory drugs (NSAIDs), oxybutynin (0.2–0.3 mg/kg PO q8–12 h), and/or pentosan polysulfate sodium (20 mg/kg PO twice weekly for 5 weeks, then once weekly for 12 weeks). In extreme cases, intravesicular dimethyl sulfoxide (DMSO) or dilute formalin, or surgery can be considered.[127,128]

Clinical Use. CP is commonly included in multiagent protocols for lymphoma in both dogs and cats. Standard bolus dosages are 200 to 250 mg/m^2 in both dogs and cats. Bone marrow ablation protocols in dogs have used doses in the range of 500 to 750 mg/m^2 before hematopoietic cell transplantation.[129–131] CP has also been dosed using a fractionated schedule (50–75 mg/m^2 PO for 3–4 consecutive days) in both dogs and cats in combination protocols for sarcomas and mammary carcinoma.[132–136] The use of CP in low-dose continuous (metronomic) chemotherapy protocols is discussed in detail in Chapter 15, Section C of this text.

Ifosfamide

Basic Pharmacology. Ifosfamide is a nitrogen mustard–containing prodrug that, like CP, requires metabolic activation by microsomal mixed function oxidases before generating the isofosforamide mustard metabolite capable of bifunctional alkylation.[137]

Clinical Pharmacology. The major difference between the clinical use of ifosfamide and CP is a result of differences in the relative metabolism of the parent drugs, with dechloroethylation accounting for up to 25% of the metabolism of ifosfamide,[138] whereas this number is much smaller for CP. This difference in metabolism accounts for an increase in the formation of the neurotoxic metabolite chloracetaldehyde after ifosfamide dosing and potentially for the less favorable metabolism profile observed with ifosfamide after oral dosing.[139] The primary DLT associated with ifosfamide treatment is a dose-related myelosuppression, but nephrotoxicity and damage to the bladder epithelium are not uncommon. Vigorous hydration is required with ifosfamide administration, and mesna, a urinary epithelial protectant, must be administered to avoid severe cystitis.

Clinical Use. Ifosfamide has been evaluated in dogs and cats with cancer and is recommended primarily for management of sarcomas. The recommended dose for dogs is 375 mg/m^2 IV and for cats is 900 mg/m^2 IV, both as slow infusions and saline diuresis, every 3 weeks.[140,141] The basis for such discrepancies in the MTD between species is not understood but reflects profound and interesting differences in metabolism pathways and most likely reduced generation of bioactive metabolites. A phase II study in feline injection site sarcomas (ISSs) reported moderate objective response rates.[142]

Chlorambucil

Basic Pharmacology. Chlorambucil (*p*-bis[chloro-2-ethyl] aminophenyl-4-butanoic acid) is a nitrogen mustard derivative that enters cells via passive diffusion[143] and has direct bifunctional alkylating ability responsible for the cytotoxic activity.[144]

Clinical Pharmacology. Chlorambucil is orally bioavailable with rapid absorption. Hepatic metabolism is extensive, with the pharmacologically active phenylacetic acid being the primary metabolite and presumably responsible for much of the clinical activity.[145,146] The major DLT is myelosuppression, including granulocytopenia and thrombocytopenia.

Clinical Use. Chlorambucil is used primarily for chronic lymphocytic leukemia, Waldenström's macroglobulinemia and feline low-grade (small cell) GI lymphoma. It also is used as part of metronomic therapy for a variety of cancers, including bladder transitional cell carcinoma (TCC) (see Chapter 15, Section C).[147] Chronic oral dosing typically begins at 3 to 6 mg/m^2 once daily. Doses as high as 4 mg/m^2/d are well tolerated long term in dogs, but often the dose can be lowered based on control of cancer.[148] In cats, to maintain dose intensity without splitting tablets, a dosage of 2 mg every-other-day or Monday–Wednesday–Friday is commonly used. An oral bolus dose of 20 mg/m^2 every 2 weeks also has been reported with excellent response in feline low-grade GI lymphoma.[149]

Nitrosoureas

Lomustine (Cyclohexylchloroethylnitrosurea)

Basic Pharmacology. Cyclohexylchloroethylnitrosurea (CCNU, CeeNU) is a nitrosourea-based agent that is highly lipid soluble and enters cells by passive diffusion.[150] Under aqueous conditions and at physiologic pH, CCNU will spontaneously decompose to a reactive center capable of DNA alkylation [151,152] and DNA–DNA and DNA–protein cross-links.[153]

Clinical Pharmacology. The highly lipophilic properties of CCNU allows for rapid crossing of biologic membranes including the blood–brain barrier. CCNU undergoes extensive hepatic metabolism,[154] predominantly by hydroxylation of the cyclohexyl ring, to metabolites with at least equivalent alkylating activity that presumably play an important role in the cytotoxic activity.[155] This extensive hepatic metabolism is presumably responsible for the lack of oral bioavailability of the parent compound but rapid appearance of metabolites after oral dosing.[156] The major DLT is myelosuppression with acute neutropenia followed by cumulative and potentially irreversible thrombocytopenia.[157] In cats, the neutrophil nadir can occur anywhere from 1 to 4 weeks posttreatment.[158] In dogs, and much less commonly in cats, chronic administration may result in hepatic enzyme elevations and possible hepatic dysfunction requiring discontinuation of the drug temporarily (i.e., drug holiday) or permanently.[159–161] The most consistent and dramatic hematologic abnormality is a marked elevation in alanine aminotransferase (ALT). Concurrent administration with Denamarin^{TM}, a product that increases glutathione levels and provides antioxidant properties, reduces the risk of ALT elevation, and decreases the magnitude of elevations in ALT, aspartate aminotransferase (AST), alkaline phosphatase (ALKP), and bilirubin.[162] Pulmonary fibrosis has been reported rarely in cats.[163]

Clinical Use. CCNU (70–90 mg/m^2 PO every 3 weeks) is most often used alone or in multiagent protocols for canine lymphoma, MCTs, and histiocytic sarcoma. In cats, CCNU (40–60 mg/m^2 PO or 10 mg per cat every 4–6 weeks) is used primarily for MCTs and lymphoproliferative disorders.

Streptozotocin

Basic Pharmacology. Streptozotocin is a naturally occurring nitrosourea capable of DNA alkylation and inhibition of DNA synthesis in both bacteria and mammalian cells.[164,165] Cellular

uptake of streptozotocin is dependent on the GLUT2 transporter and expression of this transporter determines sensitivity of both insulinoma[166] and pancreatic beta cells.[167]

Clinical Pharmacology. Streptozotocin is rapidly cleared from the blood after IV administration with a reported half-life of 15 to 40 minutes in humans.[168] Streptozotocin has unique activities, including inducing diabetes in animals[169,170] and lack of significant bone marrow toxicity.[171,172]

Clinical Use. Streptozotocin is used to manage insulinoma. Limited reports of efficacy have appeared in the literature, although transient normoglycemia occurred in the experience of the authors.[173] The drug is dosed at 500 mg/m^2 as an IV infusion every 2 weeks with saline diuresis to avoid renal toxicity.

Other Alkylating Agents

Dacarbazine

Basic Pharmacology. Dacarbazine (DTIC) is a prodrug that requires metabolic activation by the hepatic cytochrome P450 system[174,175] to the resulting 5-aminoimidazole carboxamide and the active methylating intermediate methyldiazonium ion.[176] Resulting DNA methylation products are 3-methyl adenine, 7-methyl guanine, and *O*^{6}-methyl guanine,[177] which are presumably responsible for the cytotoxic activity.

Clinical Pharmacology. DTIC has poor oral bioavailability and is administered intravenously. Use in cats is not recommended because of a lack of information regarding their ability to convert the parent drug to the active form. DTIC is extensively metabolized in the liver and excreted in the urine. The major DLT is GI toxicity, although occasional severe myelosuppression can be observed.

Clinical Use. In dogs, DTIC is used as a single agent, or in combination with DOX or CCNU, for lymphoproliferative diseases in a relapse setting.[178–181] It also has been used in combination with DOX, with or without vincristine, for hemangiosarcoma.[182,183] As a single agent, an IV infusion dose of 800 to 1000 mg/m^2 every 3 weeks has been used.[178] When combined with other cytotoxics, the dose must be reduced (600–800 mg/m^2 IV)[179,181,183] or spread out over several days (200 mg/m^2/d IV for 5 days).[180,182]

Procarbazine

Basic Pharmacology. Procarbazine (PCB), like DTIC, is a prodrug requiring chemical or metabolic alteration for the generation of active metabolites.[184,185] The mechanism of action of PCB could involve multiple interactions, including inhibition of DNA and RNA synthesis, but a predominant role for DNA methylation to form *O*^{6}-methyl guanine seems likely.[186]

Clinical Pharmacology. PCB is rapidly and completely absorbed after oral administration followed by rapid disappearance of the parent compound and subsequent appearance of metabolites.[187] PCB and/or metabolites equilibrate rapidly between the blood and cerebrospinal fluid.[188] IV delivery has been tested in humans with the appearance of neurotoxicity not seen with oral delivery, suggesting that first-pass metabolism associated with oral dosing significantly alters the spectrum of exposure to parent drug versus metabolites.[189]

Clinical Use. PCB most frequently is used in combination with mechlorethamine or CCNU, vincristine, and prednisone for lymphoma.[111–113,190,191] It is dosed at 50 mg/m^2/d PO for 14 days of a 21- or 28-day cycle. Every other day dosing or use of reformulated capsules is required for smaller dogs and cats owing to the limitations of available capsule sizes.

Antitumor Antibiotics

The antitumor antibiotics consist of natural products from microbial fermentation including the anthracyclines, mitomycins, and actinomycins that have yielded clinically useful compounds with diverse mechanisms of action. Included in the discussion here are the anthracycline DOX, the anthracenedione (synthetic analog) mitoxantrone (MTO), and actinomycin D.

Doxorubicin

Basic Pharmacology. The cellular pharmacology of DOX is dominated by its ability to react with a number of cellular components and a multimodal mechanism of cellular toxicity. Its activities include DNA intercalation and inhibition of RNA and DNA polymerases[192] and topoisomerase II,[193] alkylation of DNA,[194] reactive oxygen species (ROS) generation,[195,196] perturbation of cellular Ca^{2+} homeostasis,[197,198] inhibition of thioredoxin reductase,[199] and interaction with plasma membrane components.[200] These processes are involved in both the antitumor effects and AEs of DOX, with their relative contributions still open to some debate.

Clinical Pharmacology. After intravenous dosing, DOX is extensively distributed to tissues, with binding to cellular DNA[201] and anionic lipids[202,203] determining the magnitude of tissue uptake.[204] Elimination occurs through renal and biliary elimination of parent drug and metabolism to doxorubicinol and the 7-hydroxy aglycone. Metabolism to doxorubicinol is via side chain reduction mediated by aldo-keto reductases[205] and 7-hydroxy aglycone by reductive cleavage of the sugar moiety both by the liver and extrahepatic tissues.[206]

Rapid administration of DOX can cause an anaphylactoid-like reaction associated with increased plasma histamine levels.[207] Routine pretreatment with diphenhydramine typically is not needed as long as DOX is administered over 15 to 30 minutes. DOX is a vesicant and in the event of an extravasation, cold compresses should be applied. Dexrazoxane (Zinecard, 10 mg per 1 mg DOX IV) has been shown to substantially reduce the extent of tissue damage and should be given IV (different vein from site of extravasation) immediately after extravasation, and ideally again 24 and 48 hours later.[208]

The acute DLTs associated with DOX are myelosuppression and GI toxicity. In dogs, cardiotoxicity is well established.[209,210] Acute cardiotoxicity manifests as transient arrhythmias associated with transient increases in circulating histamine and catecholamines and is usually of little clinical significance. Cumulative cardiotoxicity manifests as a decrease in myocardial contractility and/or arrhythmias, which often leads to congestive heart failure. The damage is irreversible and carries a grave prognosis. The mechanism of cumulative cardiotoxicity by DOX is complicated,[211] and may involve ROS generation,[212] altered calcium homeostasis,[213] topoisomerase-IIβ–mediated DNA double-strand breaks,[214] or upregulation of death receptors on cardiomyocytes.[215] It is controversial whether or not every dog should have cardiac evaluation with echocardiogram and electrocardiography before receiving DOX, but evaluation should be considered in dogs with known heart disease and breeds predisposed to dilated cardiomyopathy (e.g., Boxer, Doberman Pinscher). Dogs with normal baseline myocardial function should be able to safely receive a cumulative DOX dose of 150 to 240 mg/m^2. For dogs with impaired systolic function or dogs in which the cumulative dose has reached this maximum, dexrazoxane can be administered immediately before DOX to help prevent cardiotoxicity.[216] In cats, DOX can cause

VetBooks.ir

cumulative nephrotoxicity[217] and should be used cautiously in cats with underlying renal disease, with close monitoring of renal function parameters.

Clinical Use. DOX is the most active single agent available for a wide variety of cancers in companion animals. The drug may be used alone or in combination protocols for a variety of cancers including lymphoma, HSA, OSA, histiocytic sarcoma, feline ISS, mammary carcinoma, thyroid carcinoma, and colonic adenocarcinoma. Conventional dosing regimens are 30 mg/m^2 via IV infusion (15–30 minutes) every 3 weeks in dogs larger than 15 kg, and either 25 mg/m^2 or 1 mg/kg for dogs smaller than 15 kg and all cats.

Mitoxantrone

Basic Pharmacology. Mitoxantrone (MTO) is a synthetic DOX analog and maintains similar activity as DOX in terms of DNA intercalation and the inhibition of RNA and DNA polymerases and topoisomerase II.[218,219] However, MTO does not cause oxidative damage to cells[220] and has a reduced potential to undergo one-electron reduction and generate ROS.[221]

Clinical Pharmacology. After IV administration, MTO is extensively distributed to tissues, with residual levels being long lasting. MTO is not extensively metabolized and a fraction of the drug (<30%) is excreted unchanged in the urine and feces.[222–224] The DLT is myelosuppression. Cardiotoxicity has not been reported in dogs and only rarely in humans.

Clinical Use. MTO is administered at a dose of 5.0 to 5.5 mg/m^2 in dogs and 6 mg/m^2 in cats as a slow IV bolus every 3 weeks. It is considered a front-line drug for treating canine TCC and anal sac adenocarcinoma.[225,226] MTO has been used as a cardiac-sparing alternative to DOX in dogs with underlying myocardial dysfunction or that have reached their maximum cumulative dose of DOX with the potential for similar outcomes,[227] and as a rescue agent in relapsed canine lymphoma with mixed results.[228]

Actinomycin D (Dactinomycin)

Basic Pharmacology. Actinomycin D, or dactinomycin (DACT), consists of two symmetric polypeptide chains attached to a central phenoxazone ring. DACT has been shown to interact with double-stranded DNA in multiple ways in a sequence-dependent manner,[229–231] and also bind to single-stranded DNA.[232] The resulting interactions of DACT with both double- and single-stranded DNA results in a potent inhibition of transcription, thus inhibiting RNA and protein synthesis.[233,234] DACT is taken up into cells by passive diffusion,[235] and the sensitivity of cells may depend on uptake and retention,[236] with ABCB1 playing a role in DACT efflux.[237]

Clinical Pharmacology. After IV administration, DACT is rapidly distributed to tissues and then slowly eliminated from tissues. Metabolism is minimal, with 20% of DACT excreted unchanged in the urine and 14% in the feces.[238] The major DLTs of DACT are myelosuppression and GI toxicity.[238] It is a vesicant and can cause severe tissue damage if extravasated.

Clinical Use. DACT is used in multiagent protocols for dogs with lymphoproliferative diseases in the relapse setting or as a DOX substitute in dogs with cardiac abnormalities. It is administered IV at 0.5–0.75 mg/m^2 every 1–3 weeks.

Antimetabolites

The antimetabolites comprise agents that inhibit the use of cellular metabolites in the course of cell growth and division. Therefore these agents are generally analogs of compounds used in the normal course of metabolism and in the case of cancer chemotherapeutics, specifically anabolic processes associated with DNA replication.

Cytosine Arabinoside

Basic Pharmacology. Cytosine arabinoside (cytarabine, Ara-C) acts as an analog to deoxycitidine and is phosphorylated in cells to generate arabinosylcytosine triphosphate (ara-CTP), which acts as a competitive inhibitor of DNA polymerase α.[239] Ara-CTP is also incorporated into DNA, which correlates with cytotoxicity,[240] and thus presumably is the primary mechanism of action. Incorporation into DNA cannot be excised[241] and inhibits both the function of the DNA template and subsequent synthesis.[242] Ara-C has also been reported to have a differentiating function in leukemic cells through decreased c-*myc* expression.[243] Ara-C is actively transported into tumor cells via nucleoside transporters [244] and phosphorylated sequentially by deoxycytidine kinase, dCMP kinase, and nucleoside diphosphate kinase.[245]

Clinical Pharmacology. Ara-C is water-soluble and dosed by intravenous infusion. It distributes rapidly in total body water and crosses into the central nervous system (CNS) with cerebrospinal fluid concentrations reaching approximately 60% of plasma levels at steady-state.[246] The primary mode of metabolism is deamination by the liver and extrahepatic tissues. Observed DLTs are myelosuppression and occasionally GI signs.

Clinical Use. Ara-C is administered at a dose of 600 mg/m^2, ideally as a CRI over a 2- to 5-day duration. However, a more convenient method of administration in dogs and cats is to divide that dose into 4 SC injections given twice daily for 2 consecutive days. Ara-C was not effective as a single agent at inducing remission in naïve canine lymphoma,[247] but is a component of the rescue protocol DMAC (dexamethasone, melphalan, actinomycin-D, Ara-C).[248] However, results of a recent small study suggest improved responses in dogs with naïve, stage V multicentric lymphoma when Ara-C (150 mg/m^2/day as a continuous rate infusion) was infused over 5 days after the first and second cycle of a conventional CHOP-based protocol compared with the CHOP protocol alone.[249] Bone marrow support with human granulocyte colony stimulating factor and erythropoietin were coadministered with Ara-C and patients in this treatment group did not experience increased AEs. Low-dose subcutaneous Ara-C (50 mg/m^2 BID for 2 days or 100 mg/m^2 as a constant rate infusion for 1 day) has been reported to improve clinical signs in dogs with meningoencephalitis of unknown origin when combined with prednisone.[250,251]

Methotrexate

Basic Pharmacology. Methotrexate (MTX) is a folate analog that inhibits the enzyme dihydrofolate reductase, thus depleting reduced folate pools required for purine and thymidylate biosynthesis.[252] MTX is also converted to polyglutamates that act as direct inhibitors of folate-dependent enzymes that play a role in de novo purine and thymidylate synthesis.[253,254] MTX enters cells via active transport through the reduced folate carrier.[9]

Clinical Pharmacology. The oral bioavailability of MTX is high at lower doses but becomes variable as doses increase,[255] and thus is usually dosed orally at lower doses and intravenously at higher doses. The PK of MTX is well understood across species[256] and is dominated by enterohepatic recycling that accounts for the observed GI side effects at doses that do not cause hematopoietic toxicities. At higher doses, both GI toxicity and myelosuppression are observed. MTX does not undergo substantial hepatic

metabolism except when administered at high doses and is primarily excreted unchanged in the urine.[256]

Clinical Use. MTX was used in original multiagent protocols for treatment of lymphoproliferative disorders in dogs and cats. With the development of other less toxic and more potent agents, MTX has been eliminated from conventional treatment regimens and is rarely used in veterinary oncology.

Gemcitabine

Basic Pharmacology. Gemcitabine (GCB), or 2,2-difluorodeoxy−cytidine (dFdC), is actively transported into cells by nucleoside transporters[257] and metabolized by phosphorylation to mono- (dFdCMP), di- (dFdCDP), and triphosphorylated (dFdCTP) species.[245] The effect of dFdC treatment on cells is the inhibition of DNA synthesis through dFdCTP inhibition of DNA polymerase,[258] dFdCDP inhibition of ribonucleotide reductase and subsequent depletion of deoxyribonucleotide pools,[31] and dFdCTP incorporation into DNA leading to strand termination.[32] The dFdCTP incorporated into newly synthesized DNA appears resistant to normal DNA repair[259] and its presence is critical for triggering apoptosis by this agent.[260] Recent studies suggest that the primary deamination metabolite of dFdC, dFdU, may also play a role in cytotoxicity.[261]

Clinical Pharmacology. GCB is dosed intravenously because oral dosing leads to low systemic exposure,[262] presumably because of extensive first-pass metabolism in the liver through deamination to the dFdU metabolite.[263] Infusion length also seems to be a potentially important variable as longer, constant rate infusions have been shown to lead to increased intracellular dFdCTP levels and enhanced response as opposed to shorter infusions.[264] The DLT of GCB is hematologic in both humans and dogs.[245,265]

Clinical Use. The role of GCB in veterinary oncology is still being defined. A preliminary study indicated efficacy when GCB (800 mg/m^2 IV over 30–60 minutes, once a week) was used in combination with piroxicam for canine TCC[266]; however, no benefit has been demonstrated for canine lymphoma, OSA, mammary carcinoma, or hepatocellular carcinoma.[265,267–269] Single-agent doses have ranged from 400 to 800 mg/m^2 IV over 30 to 60 minutes, once a week, but standardized dosing regimens need to be established before clinically relevant phase II efficacy studies can be done. Low-dose GCB has been shown to be tolerated well in combination with carboplatin in dogs and cats.[270–272] GCB was not well tolerated as a radiosensitizer for head and neck carcinomas in dogs and cats owing to unacceptable hematologic and local tissue toxicity.[273]

5-Fluorouracil

Basic Pharmacology. 5-Fluorouracil (5-FU) is a halogenated analog of uracil that enters cells using a facilitated-transport system shared by adenine, uracil, and hypoxanthine.[274] 5-FU is converted to active nucleotide forms intracellularly by a series of phosphorylase and kinase reactions to yield mono-, di-, and triphosphate forms of both fluorouridine and fluorodeoxyuridine,[275,276] which are incorporated into RNA and DNA interfering with synthesis and function.[277–279] The 5-FU metabolite FdUMP is an inhibitor of thymidylate synthetase, leading to depletion of thymidine 5′-monophosphate and thymidine 5′-triphosphate.[280] The alterations in thymidine and deoxyuridine phosphate pools caused by thymidylate synthetase inhibition, effects on DNA synthesis and integrity, and effects on RNA synthesis and processing are all thought to play a role in cytotoxicity induced by 5-FU.

Clinical Pharmacology. 5-FU is dosed IV and is extensively metabolized in many tissues by dihydropyrimidine dehydrogenase to dihydrofluorouracil, which is further catabolized to α-fluoro-β-alanine, ammonia and CO_2.[281,282] Approximately 90% of an administered dose is metabolized, and both 5-FU and its catabolites undergo biliary excretion with <5% of the parent drug renally excreted. 5-FU causes a dose-dependent myelosuppression, GI toxicity, and neurotoxicity in dogs. Inadvertent ingestion of a topical 5-FU cream is toxic and/or fatal.[283] 5-FU is **contraindicated** in cats because of severe CNS toxicity.

Clinical Use. 5-FU is infrequently used for management of organ epithelial tumors (hepatic, pancreatic, renal, mammary). The reported dose is 150 mg/m^2 IV weekly. It also may be administered topically and intralesionally to dogs, although convincing reports of efficacy are not available.

Rabacfosadine (Tanovea)

Basic Pharmacology. Rabacfosadine (RFD) is a multiactivation-step prodrug that results in the intracellular generation of the nucleotide analog 9-(2-phosphonylmethoxyethyl)guanine (PMEG).[284] The metabolic sequelae of RFD involve cellular uptake of the parent compound and subsequent hydrolysis by cathepsin A to cPrPMEDAP and deamination by N^6-methyl-AMP aminohydrolase to generate intracellular PMEG.[285–287] PMEG is then phosphorylated to the diphosphate form (PMEGpp) that competes with dGTP as a substrate for DNA polymerases with resulting incorporation into DNA resulting in chain termination.[288,289] Distribution studies of RFD have shown preferential uptake into PBMCs and lymphoid tissue and selective metabolism of cPrPMEDAP in liver and kidney via dealkylation to the less toxic PMEDAP metabolite, presumably leading to selective toxicity in target as opposed to normal tissue.[285]

Clinical Pharmacology. The most common AEs observed with RFD are GI. Neutropenia, thrombocytopenia, elevated liver enzymes, and proteinuria are also reported. RFD can cause dermatologic toxicity, characterized by otitis externa or focal pruritic, alopecic, and erythematous lesions adjacent to the pinna, on the dorsum, or in the inguinal areas. The underlying mechanism is unknown, but it has been proposed that it is secondary to drug distribution to the skin. Anecdotally, concurrent treatment with antiinflammatory doses of prednisone may reduce the frequency of dermatologic changes. Although uncommon, the most severe and irreversible toxicity associated with RFD is idiosyncratic pulmonary fibrosis.[285,290–294]

Clinical Use. The standard dose of RFD in dogs is 1 mg/kg IV every 21 days as a single agent[294] or every 42 days when alternated with DOX.[292] RFD has been evaluated as a single agent in dogs for cutaneous T-cell lymphoma,[290] multiple myeloma,[291] relapsed B-cell lymphoma,[294] and in naïve canine multicentric lymphoma in combination with DOX.[292] The established efficacy of RFD in relapsed lymphoma makes it a reasonable choice in the salvage setting.[294] Efficacy of RFD in combination with DOX in the treatment of naïve lymphoma also establishes this protocol as an option for first-line therapy.[292] As of the time this chapter was written, RFD has conditional licensure by the FDA and can be used only for canine lymphoma.

Antimicrotubule Agents

The antimicrotubule agents currently used in veterinary medicine are structurally complex agents belonging to the taxane or vinca alkaloid class of compounds. These agents have a mechanism of

VetBooks.ir

action involving interference with the polymerization or depolymerization of the microtubules that play critical roles in cell function and division.

Taxanes (Paclitaxel and Docetaxel)

Basic Pharmacology. The clinically used taxanes (paclitaxel [PTX] and docetaxel [DTX]) both act by stabilizing microtubules against depolymerization and thus inhibit reorganization dynamics required for carrying out cellular functions.[295–297] This alteration in microtubule function causes an abnormal organization of spindle microtubules involved in chromosome segregation during mitosis, leading to mitotic arrest.[298] PTX and DTX share identical mechanisms with the increased potency of DTX [299] attributable to an approximately 2-fold higher affinity for tubulin binding compared with PTX.[300]

Clinical Pharmacology. The clinical use of the taxanes is complicated by their poor solubility and the use of excipients including cremophor EL (PTX) and polysorbate 80 (DTX) to allow for intravenous administration. Both PTX and DTX are rapidly distributed throughout the body and eliminated slowly, primarily by hepatic metabolism and biliary excretion. Renal elimination is 10% or less for both compounds. Toxicities associated with taxanes include hypersensitivity reactions that are attributable to the cremophor EL and polysorbate 80 utilized in formulation. Diarrhea and neutropenia are the major dose-limiting taxane-specific toxicities observed.

Clinical Use. The use of PTX has not been frequently described in either dogs or cats. This is likely because of the requirement for significant pretreatment with antihistamines and corticosteroids followed by a prolonged infusion that must be monitored for acute hypersensitivity. One report evaluated dogs treated with PTX at a dose of 165 mg/m^2 slow IV infusion every 3 weeks.[103] Although a few measurable responses were identified for various tumor types, hypersensitivity was frequent (64%) despite pretreatment, and significant bone marrow toxicity was observed, leading to the conclusion that the recommended dose for further evaluation is 132 mg/m^2 as a slow IV infusion every 3 weeks. As discussed earlier in the section on pharmaceutics, a water-soluble micellar preparation is effective for nonresectable MCT, but at the time this chapter was written it was no longer commercially available.[301] PTX in cats has been used at 80 mg/m^2 slow IV infusion every 3 weeks with similar need for pretreatment.[302]

Hypersensitivity is more manageable with DTX as opposed to PTX. In a small group of dogs with mammary carcinoma, DTX was administered at a dosage of 30 mg/m^2 IV over 30 minutes with routine pretreatment (steroids, diphenhydramine).[303] Low-grade cutaneous hypersensitivities were reported but easily managed. Similarly, cats were successfully treated at a dosage of 2.25 mg/kg IV over 1 hour with pretreatment.[304] To overcome hypersensitivity reactions a strategy was developed to administer DTX orally with cyclosporine as an absorption aid. This strategy was investigated in phase I studies in dogs and cats with cancer where the MTD of DTX was 1.63 mg/kg and 1.75 mg/kg PO (by gavage) every 2 to 3 weeks, respectively, when combined with cyclosporine (5 mg/kg PO).[305,306] Although no hypersensitivity reactions were reported, diarrhea was the DLT. Subsequent phase II evaluation of this dosing strategy in dogs demonstrated modest activity against oral squamous cell carcinoma (SCC).[307]

Vinca Alkaloids (Vinblastine, Vincristine, Vindesine, Vinorelbine)

The vinca alkaloids as a class of antitumor agents consist of the naturally occurring vincristine (VCR) and vinblastine (VBL) and a semisynthetic derivative and metabolite of VBL, vindesine, and the semisynthetic derivative of VBL, vinorelbine. These agents all share a similar mechanism of action and focus will be on VCR and VBL in this section because of their use in veterinary medicine.

Basic Pharmacology. The vinca alkaloids bind to a distinct site on tubulin[308] and inhibit microtubule assembly.[309] This inhibition of microtubule function leads to a disruption in the mitotic spindle apparatus resulting in metaphase arrest and cytotoxicity.[310,311] The vinca alkaloids enter cells by a simple diffusion process. Exposure time and concentration seem to be important variables in determining cytotoxicity.

Clinical Pharmacology. The vinca alkaloids are administered by IV infusion, rapidly distribute to tissues, and are slowly eliminated primarily by hepatic metabolism and biliary excretion of parent drug and metabolites. Urinary excretion of parent drug and metabolites is relatively low: 10% to 20%. One of the metabolites of VBL is desacetylvinblastine (vindesine), which is active and has been identified in dogs.[312] VBL and VCR differ in their respective toxicities, with VCR being less myelosuppressive than VBL but causing more peripheral neurotoxic and GI effects, including significant ileus. All vinca alkaloids are vesicants. If extravasated, 5 to 10 mL saline can be infused around the affected area. The addition of hyaluronidase (150 U/1 mL extravasated drug) to the saline has been reported but is not widely available. Warm compresses should be applied as well. A solution of DMSO and flucinolone acetonide (Synotic) mixed with 10 mg of flunixin meglumine should be applied topically after each heat application.

Clinical Use. VCR is used predominantly as a component in multiagent protocols for dogs and cats with lymphoma. It is also used as a single agent for dogs with transmissible venereal tumor. The dose for VCR is 0.5 to 0.75 mg/m^2 IV bolus weekly in both dogs and cats, or as defined in the protocol.

VBL is most often used to manage canine MCT either as a single agent or in combination with other agents. It also is used to treat canine bladder TCC,[313] as a rescue for lymphoma,[314] and in place of VCR in multiagent protocols to help minimize adverse GI AEs.[315] Several dose-schedule variations exist in dogs. When given weekly, starting dosages of 2.0 to 2.67 mg/m^2 IV are used most commonly, but dosage escalations up to 3.0 mg/m^2 have been reported.[316,317] Doses as high as 3.0 to 3.5 mg/m^2 IV are well tolerated when the dose interval is extended to q2 weeks.[100,313] In cats, VBL has been administered at a dosage of 1.5 mg/m^2 IV as part of a COP-based protocol.[315]

Vinorelbine is administered at a starting dosage of 15 mg/m^2 IV over 5 minutes once weekly in dogs, and 11.5 mg/m^2 in cats.[318–321] There is preliminary evidence to support activity against primary lung tumors, histiocytic sarcoma, and MCTs, but insufficient numbers of patients have been evaluated to accurately quantify tumor response at this time.

Topoisomerase Inhibitors

The topoisomerase inhibitors represent classes of drugs that inhibit either the type I or type II topoisomerase enzymes that are involved in the unlinking and unwinding of the DNA strand for replication and transcription. The major classes of topoisomerase II inhibitors used in veterinary oncology are the anthracyclines, which have already been discussed, and the epipodophyllotoxins of which etoposide and teniposide are the clinically relevant members. The major class of topoisomerase I inhibitors used in human oncology are the camptothecins, which have found little use so far in veterinary medicine and will not be discussed here.

VetBooks.ir

Epipodophyllotoxins (Etoposide and Teniposide)

BasicPharmacology. Etoposide (VP-16) and teniposide (VM-26) both inhibit the catalytic activity of topoisomerase II[322] by stabilizing a protein–DNA cleavage complex[323] that ultimately results in the generation of single- and double-strand DNA breaks.[324] These compounds enter tumor cells by simple diffusion across the cell membrane, and increased levels of topoisomerase II in proliferating tumor cells increases selectivity.[325]

Clinical Pharmacology. Etoposide has been evaluated in dogs both IV and orally. Etoposide administered IV is associated with severe histamine release in dogs associated with the polysorbate 80 vehicle as described earlier with the use of IV DTX. Oral dosing has shown low and highly variable bioavailability in dogs, making this route of delivery difficult to use.[326] Etoposide is eliminated after dosing by hepatic metabolism, and renal elimination of both parent drug (30%–40% of the dose) and glucoronide metabolites. The major DLT of IV etoposide in the dog is hypersensitivity.[327]

Clinical Use. Based on the hypersensitivity reactions experienced in dogs after IV etoposide and the low bioavailability of orally administered etoposide, it is not recommended for use. Strategies to overcome the vehicle induced hypersensitivity by reformulation or to improve bioavailability are required to continue evaluating etoposide. No studies have been reported in cats.

Corticosteroids

Prednisone

Basic Pharmacology. Prednisone and prednisolone are corticosteroids that presumably induce killing of hematopoietic cancer cells through interaction with the glucocorticoid receptor[328] and the induction of apoptosis.[329] Mechanisms of apoptosis induction by corticosteroids in hematologic cancers is still not completely understood and multiple mechanisms exist whereby tumor cells of hematopoietic origin resist steroid-induced killing.[330]

Clinical Pharmacology. Prednisone is generally well tolerated in dogs over short time periods (weeks) when administered as a tapering schedule to a tolerable baseline dose dependent on the response of the patient and the cancer. The adrenal–pituitary axis can become suppressed with, signs of iatrogenic hyperadrenocorticism causing severe disease in dogs if prednisone is continued at immunosuppressive doses. Cats tolerate exogenous steroids well for prolonged periods.

Clinical Use. Prednisone is widely used for management of lymphoid malignancies, MCTs, insulinoma, and brain tumors in dogs and cats. It is also useful for the management of paraneoplastic hypercalcemia. Dogs are often dosed at 2 mg/kg (or 40 mg/m^2) PO daily at the beginning of multiagent protocols for lymphoma and are weaned off the drug over 3 to 4 weeks. Cats are tolerant of prednisone or prednisolone and are maintained at 5 mg PO q24h or BID as needed. Prednisone is also used to manage signs and side effects of chemotherapy-induced toxicity such as hypersensitivities or hemorrhagic cystitis. Antiinflammatory doses are used in dogs (0.5–1.0 mg/kg) PO once daily and reduced as indicated by signs.

Others

Platinum (Carboplatin and Cisplatin)

Basic Pharmacology. The activity of platinum containing antitumor agents is through covalent binding to DNA through displacement reactions resulting in bifunctional lesions and interor intrastrand cross-links.[331] Intrastrand adducts, in particular N^7-d(GpG) and N^7-d(ApG) account for the majority of platinum-DNA damage and are highly correlated with drug-induced cell killing.[332] Reactions with water are an important component of the pharmacology of cisplatin (CDDP) owing to some of the aquated species potentially crossing cell membranes more rapidly.[333]

Clinical Pharmacology. Both CDDP and carboplatin are administered intravenously. Metabolism of both CDDP and carboplatin occurs primarily through reactions with water and elimination by binding to plasma and tissue proteins. Urinary elimination of unbound and bound forms accounts for nearly 50% of the cisplatin dose 5 days after administration. Carboplatin is predominantly excreted in the urine with approximately 65% of the dose recovered in the urine 24 hours after administration.[333] Strong correlations exist between carboplatin exposure and renal function such that simple formulas have been derived in both humans[334] and cats[335] for dosing calculations based on renal function. The DLTs associated with CDDP are GI (nausea and vomiting) and renal. Pretreatment with antiemetics, and vigorous saline diuresis is required. CDDP is **contraindicated** in cats because of fatal pulmonary vasculitis and edema.[336] In contrast, the DLT associated with carboplatin is myelosuppression. GI AEs are less common and less severe, the drug is not nephrotoxic, and it can be safely administered to cats.

Clinical Use. CDDP (50–70 mg/m^2 IV infusion administered with saline diuresis and antiemetics every 3 weeks) is indicated primarily for canine OSA. It also has activity against bladder TCC, mesothelioma, carcinomatosis, and germinal cell tumors.[337,338] A variety of other tumor types have been reported to be marginally sensitive to CDDP.

In dogs, carboplatin (300 mg/m^2 or 10 mg/kg IV as a slow bolus every 3 weeks) often is preferred to CDDP because of its more favorable toxicity profile and ease of delivery. Although no formal comparisons exist, carboplatin appears to have similar efficacy to CDDP for canine OSA but is inferior for TCC.[73,339] Carboplatin also is used for anal sac adenocarcinoma, SCC, intestinal carcinoma, prostatic carcinoma, mesothelioma, and carcinomatosis.[271,340–342]

The traditional dose of carboplatin in cats is 200 to 240 mg/m^2 IV as a slow bolus every 3 weeks.[343] A significant proportion of cats require every 4 week regimens owing to prolonged neutropenia. As in humans, an individualized dose of carboplatin may be calculated based on GFR and a targeted area under the concentration versus time curve (AUC_{Target}).[77,344] When GFR is measured using serum iohexol clearance (commercially available through Michigan State University), the dosing equation is:

$$\text{Carboplatin dose} = AUC_{Target} \times [(1.3 \times \text{GFR}) + 1.4] \times \text{Body weight(kg)}$$

Based on a phase I study, the maximum tolerated AUC_{Target} is 2.75 min × mg/mL.[345] Limited efficacy information is available with either dosing strategy, but clinical responses have been reported in cats with injection site sarcoma, HSA, colonic adenocarcinoma, and oral SCC.[77,343,346]

Hydroxyurea

Basic Pharmacology. Hydroxyurea (HU) enters cells via passive diffusion[347] and is an inhibitor of ribonucleotide reductase,[348] resulting in depletion of deoxyribonucleotide pools.[349]

VetBooks.ir

This interaction with ribonucleotide reductase can also lead to the allosteric inhibition of other enzymes in the DNA precursor synthesis pathway that make up the replitase complex.[350] The magnitude of decrease in cellular deoxyribonucleotide pools induced by hydroxyurea treatment correlates with inhibition of DNA synthesis observed.[351]

Clinical Pharmacology. HU is dosed orally and distributes rapidly to all tissues. Elimination is through hepatic metabolism and urinary elimination of the parent compound. AEs associated with HU treatment include GI effects, myelosuppression (including anemia), and rarely pulmonary fibrosis, with cats being more susceptible to myelosuppressive effects and potentially methemoglobinemia at higher doses. In dogs, a painful detachment of the claw (nail) from the quick (onycholysis) is often observed after chronic HU treatment.

Clinical Use. HU is used primarily for management of bone marrow disorders such as polycythemia vera and granulocytic leukemias. It also has been used to treat canine MCT.[352] HU is safe to use at 50 to 60 mg/kg orally once daily initially for 2 weeks followed by 30 mg/kg/d to lessen myelosuppressive and onycholytic effects.

L-Asparaginase

Basic Pharmacology. The enzymatic function of L-asparaginase is the hydrolysis of L-asparagine to L-aspartic acid. This depletion of circulating L-asparagine leads to inhibition of protein synthesis in tumor cells lacking L-asparagine synthetase, causing induction of apoptosis.[353]

Clinical Pharmacology. L-Asparaginase can be dosed subcutaneously, intramuscularly, or intraperitoneally and blood levels of the protein remain for weeks. Hypersensitivity reactions can lead to a shorter half-life through enhanced clearance. The AEs associated with L-asparaginase treatment are a result of either hypersensitivity reactions, which may be accentuated after repeated exposures, or to decreased protein synthesis from depleted L-asparagine pools.[354] Furthermore, neutralizing antibodies may be produced to this foreign protein that can result in limited effectiveness after repeated dosing. Hypersensitivity may be managed using pretreatment antihistamines and occasionally dexamethasone if allergic reactions are severe enough to warrant its use. Patients receiving multiple doses should remain under observation for at least 30 minutes after treatment before being discharged, and owners should be advised to observe their pet for 1 to 4 hours after treatment for signs of hypersensitivity.

Clinical Use. L-Asparaginase (400 IU/kg IM or SQ or 10,000 IU/m^2 IM or SQ) is used exclusively for lymphoproliferative disorders. To avoid development of resistance to L-asparginase, it is often used only in patients at the time of initial induction (especially if clinically ill) or at the time or relapse. A polyethylene glycol (PEG)ylated form of L-asparaginase is available to mitigate neutralizing antibody production; however, its use in veterinary medicine is limited because of cost.

Targeted Agents

Tyrosine Kinase Inhibitors

Tyrosine kinase inhibitors (TKIs) are small-molecule inhibitors that block, with varying specificity, receptor tyrosine kinases (RTKs) expressed on the cell surface by acting as competitive inhibitors of adenosine triphosphate (ATP) binding. ATP binding is required for RTK autophosphorylation and subsequent downstream signaling. Toceranib (TOC) phosphate (Palladia), masitinib (MAS, Kinavet, Masivet), and imatinib mesylate (Gleevec) have been used most commonly in veterinary oncology. At the time of writing, MAS no longer has Food and Drug Administration (FDA) approval in the United States, but it remains available in Europe.

Basic Pharmacology. The TKIs used in veterinary oncology inhibit RTKs in the split kinase family. The primary targets of TOC are KIT (stem cell factor receptor, CD117), vascular endothelial growth factor receptor 2 (VEGFR2), platelet-derived growth factor receptor β (PDGFRβ), and FMS-like tyrosine kinase-3 (Flt-3).[355–357] However, TOC is structurally very similar to the human TKI sunitinib, which has been shown to in addition block VEGFR3, PDGFRα, RET, and colony-stimulating factor receptor (CSF1R).[358] MAS targets KIT, PDGFR, and Lyn (an intracellular kinase in the Src family).[359] Imatinib targets KIT, Abl, and PDGFR.[360]

TOC has a reported oral bioavailability of approximately 80% in dogs and feeding does not affect absorption characteristics.[361] TOC is highly protein bound in the plasma (>90%) and undergoes hepatic metabolism to a single alicyclic *N*-oxide metabolite.[362] The half-life of TOC ranges between 13 and 17 hours, and it is estimated that approximately 90% of TOC and its metabolite are excreted in feces and 10% in urine.[361,362]

Clinical Pharmacology. TKIs can target tumor cells directly by inhibiting normal or mutated RTKs expressed on their surface that promote cell division and survival. They also can have an antiangiogenic effect through inhibition of VEGFR and PDGFR on endothelial cells and pericytes, respectively.[355,356]

AEs likely result from chronic inhibition of RTKs on normal cells that require these pathways for cell survival and proliferation. As to be expected, TKIs that target multiple RTKs often have more toxic effects. In both dogs and cats, the most common AEs associated with TOC and MAS are diarrhea, vomiting, hyporexia, and less commonly, GI bleeding.[357,363–366] Neutropenia has been reported with both drugs, but it is relatively uncommon and usually mild. Hemolytic anemia has been reported in dogs receiving MAS.[363] Protein-losing nephropathies have been reported in dogs receiving TOC or MAS, and in cats receiving MAS.[363,366,367] TOC has also been associated with hypertension in dogs; this AE is generally controllable with standard hypertension medications. TOC can cause muscle cramping, which usually resolves with NSAIDs and/or a short drug holiday.[356,357] Imatinib has been observed to cause idiosyncratic hepatotoxicity in dogs.[356]

Clinical Use. The label dose for TOC in dogs is 3.25 mg/kg PO q48h. However, subsequent use has shown doses of 2.5 to 2.75 mg/kg either every-other-day or Monday–Wednesday–Friday to be effective and better tolerated.[356,368,369] TOC is approved for canine MCT. It also has activity against anal sac adenocarcinoma, gastrointestinal stromal tumor, thyroid carcinoma, and nasal adenocarcinoma.[368,370] In dogs with OSA, the addition of TOC-based maintenance protocols after amputation and conventional chemotherapy did not improve DFI or survival, although a small percentage of dogs with gross metastatic OSA do experience short-term benefit.[371,372] TOC has been used in cats with a recommended starting dosage of 2.7 mg/kg Monday, Wednesday, and Friday, with biologic responses being reported in cats with mast cell disease.[364,365]

The recommended dosage for MAS in dogs is 12.5 mg/kg PO q24h, with a standard dosage reduction to 9.0 mg/kg q24h in the event of unacceptable toxicity.[363] It is indicated primarily for nonresectable or recurrent MCT. In healthy cats, MAS was well tolerated at a dosage of 50 mg (10.9–14.8 mg/kg) PO q48h,[366]

but data supporting efficacy are lacking. The recommended dosage for imatinib in dogs and cats is 10 mg/kg PO q24h, but caution should be used because this is based on small numbers of patients, with most treated for less than 1 month,[356,373,374] with the primary indication being mast cell neoplasia.

Future Directions in Drug Therapies for Cancer

Individualized Dosing

Population Pharmacokinetics

The convention for drug dosing is to normalize the dose to the weight or surface area of the patient. This is done even though there are often no data to support a relationship between a given drug's exposure in the patient and either of these parameters. These conventions are based on the idea that body weight or BSA is related to drug distribution and/or elimination in a manner that allows for consistent drug exposure in treated individuals. Dosing in mg/kg or mg/m^2 is a crude attempt at individualized dosing, and for some drugs, substantial variability is expected. Studies specifically aimed at determining what demographic characteristics in the patient population determine variability in drug exposure are termed *population pharmacokinetic studies.*

Molecular Profiling

Tumor Sensitivity

Tumors have traditionally been classified by descriptive characteristics such as organ of origin, histology, aggressiveness, and extent of spread. That empiric rubric is being challenged, as molecular classifications made possible by microarrays and other profiling technologies become increasingly common and persuasive.[375,376] The reductionist program would suggest that, eventually, all differences among traditional tumor types will be reduced to statements about molecules in the tumors and about the interactions among those molecules; hence it might then be possible to study physiologic processes in one type of cancer and extrapolate the results in a predictive manner to another type through commonalities in their molecular constitutions. But what if we want to do the same thing at the pharmacologic level-to extrapolate and predict drug sensitivity based on molecular characteristics of the tumor? These types of decisions are already being used in human medicine at a discrete level for the use of antiestrogens in estrogen receptor–positive breast cancers,[377] and the use of select molecularly targeted agents based on the mutation/expression status of target molecules[378,379]; however, responses to traditional chemotherapy agents, which still make up the backbone of available therapies both in human and veterinary medicine, are more complex and do not generally sort as responders and nonresponders based on single, or even a few, molecular characteristics. Examples do exist in which this is the case, such as overexpression of ABCB1 and the multidrug resistance phenotype,[380] but generally a multitude of genes involved in drug activation, detoxification, DNA repair, stress responses, and a myriad of other known and unknown pathways play a role in determining tumor cell chemosensitivity. Therefore a mechanism that can evaluate multiple factors in a tumor indiscriminately and determine whether it is sensitive or insensitive to a given chemotherapeutic agent would be an invaluable adjunct in determining which drugs to use for which individual tumor.

Predictive Evaluations

Current clinical practice in both human and veterinary oncology bases the choice of cytotoxic chemotherapy on descriptive histopathology characteristics. For example, a diagnosis of OSA in a veterinary patient would lead to the use of adjuvant DOX and/or a platinum-based drug (carboplatin or CDDP) after surgical resection of the tumor. Why are these drugs used? The easy answer is that studies have shown that dogs receiving either of these drugs after surgery live significantly longer than dogs receiving surgery alone.[381] Studies in human patients have shown in a variety of tumor types that in vitro chemosensitivity testing of tumor biopsies and tailoring therapy can lead to increases in antitumor response.[382–385] Therefore basing therapy on an empirical assessment of drug sensitivity rather than on tumor type alone is a strategy that could lead to preferred outcomes. Issues with the use of chemosensitivity assessment in clinical practice are the technical difficulties associated with tissue procurement and culturing and measures of drug response. Another approach to predicting the chemosensitivity of tumors has evolved around gene expression profiling and an informatics approach.[386,387] Although much attention has been focused on recent evidence of research impropriety and improper validation of predictors used for clinical trials in human lung and breast cancer,[388,389] and this has dampened some enthusiasm for using genomic predictors in chemosensitivity profiling, it should be noted that extensive review of these data by statisticians[390] and NCI review panels has found that the errors made were in data handling and consistency in analysis. Thus these unfortunate events should not be an indictment of "omics" approaches in making clinical decisions but rather a stark reminder that correct and careful research approaches and data analysis must be adhered to.

Novel Combinations

The approval of the first targeted agent for veterinary applications in the United States (TOC) has provided access to a multitargeted TKI. Biologic agents, including species-specific cytokines, peptides, monoclonal antibodies, chimeric molecules, and targeted toxins will also invariably become more prevalent as experimental therapies in veterinary medicine. The use of these novel agents in combination with traditional cytotoxic chemotherapy will likely follow the development pathway seen in human oncology, which includes adding these agents to standard protocols in a disease-specific manner. Thus changes to current standards of practice and care should be expected as these newer agents are incorporated and tested.

13 Radiation Oncology

SUSAN M. LARUE AND IRA K. GORDON

Radiation therapy (RT) has been used to treat cancers in both veterinary and human medicine since shortly after the discovery of x-rays by Roentgen in 1895, and the fields have followed similar paths. Dr. Henri Coutard, a radiation oncologist at the Curie Institute in Paris, carefully evaluated the effect of dose per fraction, total dose, overall treatment time, field size, and tumor size on tumor control and adverse radiation effects.[1] Alois Pommer, an Austrian veterinarian, published extensively starting in the 1930s on fractionated irradiation of benign and malignant diseases and established an RT protocol widely used for many years.[2] It was not until the 1970s and 1980s that scientists acquired a broader understanding of radiation biology, rationally explaining the benefit of dividing dose into smaller fractions.[3] Close to 60% of human patients with serious cancers undergo RT at some point during treatment.[4] Over the past 20 years, major technological advances have improved tumor control and reduced adverse effects from irradiation. RT has also proven to be an effective treatment modality for solid tumors in animal cancer patients; however, early use of the newer modalities was limited due to the paucity of veterinary treatment centers. The past decade has been marked by the opening of numerous veterinary RT centers and the commissioning of more advanced RT technologies. Modalities, such as stereotactic RT (SRT), image-guided RT, and intensity-modulated RT (IMRT) have allowed more targeted treatment, decreasing adverse radiation effects and providing improved radiation options for tumors in a variety of locations.[5] More than 70 facilities in North America are actively treating animals with RT and 27 of those reporting SRT capabilities.[6] The American College of Veterinary Radiology (specialty in radiation oncology) has residency training programs at 13 treatment centers.[7] International expansion has included Europe, Asia, Australia, and South America.[6]

The management of cancer patients is complex, and determining the best treatment modality or combination of modalities can be challenging. In most instances, when local control of a solid tumor cannot be obtained surgically without excessively compromising function, appearance, or quality of life, consultation with a radiation oncologist is advised. Surgery followed or preceded by fractionated RT may allow a more conservative surgery and yield comparable or better tumor control and/or functional outcome than either surgery or RT alone. RT alone is indicated in areas where surgical options are limited, such as nasal tumors, heart-based tumors, and some brain tumors.[8–10] SRT has provided treatment alternatives in patients where surgery is not an option and in locations that were not previously amenable to unmodulated RT, such as abdominal tumors.[11] In addition to treating serious cancers with what is referred to as "curative intent," RT also plays an important role in the palliative management of advanced cancers, the treatment of endocrinopathies associated with endocrine adenomas, as an adjuvant treatment for lymphoma, and for certain benign conditions.[12–19] New technology and treatment approaches have led to an unwieldy collection of acronyms, the most common of which are listed in Table 13.1.

Principles of Radiation Biology

Radiation dose is described by the amount of energy absorbed by the tissue. The unit of absorbed dose is the Gray (Gy); 1 Gy equals one joule absorbed per kilogram of tissue. Ionizing radiation kills cells by damaging critical molecules in the cell, primarily deoxyribonucleic acid (DNA), which eventually leads to cell death.[20] Megavoltage photons, the predominant form of radiation used in veterinary medicine, interact with tissue primarily by the Compton effect, producing high energy electrons that cause ionization events either to critical molecules (direct action) or from water molecules located within nanometers of critical molecules (indirect action).[21–25] These events produce highly reactive free radicals that result in biologic damage that may kill the cell or render it incapable of reproducing.[20,25] This type of cell death, referred to as mitotic catastrophe, is due to chromosomal aberrations, primarily from double strand breaks.[20,26] Although mitotic death is still the primary mode of radiation-associated cell death, other mechanisms have been recognized, including apoptosis, radiation bystander effect, radiation abscopal effect, autophagy, and senescence.

Repair of Radiation-Induced DNA Damage

A critical determinant of a cell population's sensitivity to radiation is the ability of cells to repair DNA damage caused by radiation. 1 Gy of radiation from photons causes approximately 2500 base damages, 1000 single strand breaks, and 40 double strand breaks in DNA in each cell.[20] Mammals have developed highly conserved pathways to sense and repair single and double strand breaks as well as other forms of DNA damage.[27,28] The double strand breaks are the most lethal as they may lead to severe chromosomal aberrations.[20,28] Most of this damage is repaired by cells within 6 to 24 hours.[29,30] Genes involved in control of intrinsic radiosensitivity are primarily genes involved in cell-cycle progression and DNA repair.[31,32] A given dose of radiation is preferentially cytotoxic to proliferating cells, including tumor cells and renewing cell

VetBooks.ir

TABLE 13.1 Acronyms Commonly Used in Radiation Oncology

GTV	Gross tumor volume	The extent of gross disease as determined by palpation, direct visualization, or indirectly through imaging techniques. (GTV cannot be defined after a tumor has been surgically excised.)
CTV	Clinical target volume	The region of suspected subclinical tumor involvement, including normal tissue with presumed microscopic extension. Additional volumes such as lymph nodes may be included in the CTV.
PTV	Planning target volume	The volume including the CTV and an additional margin to account for variations in size, shape, and position of the CTV during therapy. The PTV margin also accounts for setup and physical uncertainties.
SIB	Simultaneous integrated boost	A portion of the tumor, generally central, that is prescribed a higher dose than the rest of the tumor. Allows for high-dose delivery to the central core of the tumor and a dose fall-off toward the periphery.
OAR	Organ at risk	Normal organs/tissues in proximity to a target structure that may influence prescribed dose or treatment plan parameters.
MLC	Multileaf collimator	A beam-shaping device made up of individual independently moving "leaves" of shielding material (usually tungsten).
OBI	On-board imaging	An imaging system and tool on a radiation delivery device used to confirm the match of treatment setup to the planned setup.
PRT	Palliative radiation therapy	A radiation treatment course delivered with the intent to minimize tumor-related symptoms and improve quality of life with few short-term side effects.
DRT	Definitive radiation therapy	A radiation treatment course delivered with the intent of achieving long-term tumor control or durable tumor response.
3DCRT	Three-dimensional conformal radiation therapy	Radiation planning technique utilizing cross-sectional imaging (i.e., computed tomography scan) and treatment-planning software to optimize radiation beam angles, blocks, and beam-shaping devices (i.e., wedges) with the goal of maximizing doses to targets and minimizing doses to organs at risk. Typically involves static blocks and gantry angles.
IMRT	Intensity modulated radiation therapy	Radiation planning technique and delivery technique by modulating fluence within each of multiple radiation fields. Requires "inverse" treatment planning.
SRT	Stereotactic radiation therapy	Radiation-planning technique involving minimal margins applied to the target and maximizing dose fall-off outside of target and near OARs. Most commonly used in high dose-per-fraction protocols.
SRS	Stereotactic radiosurgery	Generally implies a single fraction, high-dose radiation treatment course involving minimal margins applied to the target and maximizing dose fall-off outside of target and near OARs.
VMAT	Volumetric modulated arc therapy	A radiation delivery technique involving the radiation gantry rotating about the patient while delivering IMRT.
QA	Quality assurance	Processes that insure all aspects of radiation treatment quality and safety. These processes frequently involve independent measurements that verify radiation dose delivered for comparison to expected values or values calculated by a treatment planning system.

populations (e.g., epithelial stem cells), although slowly dividing and nondividing cells (e.g., bone and cells of the nervous system) are also affected by radiation and often limit the dose deliverable during RT.[3,33] Tumor cells are also capable of DNA repair, although DNA mutations may alter repair capabilities.[23]

Cell Cycle Effects

The period of the cell cycle in which DNA undergoes synthesis is known as S-phase. Before and after S-phase are periods without overt activity by the DNA; these periods are called the G1 phase and the G2 phase. The G2 phase is followed by mitosis (M phase). Cells are distributed throughout the cell cycle in a tumor or tissue at a given time. Individual cell sensitivity to irradiation varies depending on the phase of the cell cycle at the time of irradiation. Cells in late S-phase are most resistant to irradiation, and cells in late G2 or M phase are most sensitive.[29,30] Cells with a long G1 period may be resistant early in that phase.[34]

Oxygen Effects

Because of their rapid growth and abnormal vasculature, tumors often become hypoxic.[35,36] Oxygen is a critical factor in the response to irradiation, because reactive oxygen species generate much of the damage from radiation.[20] As a result, normoxic cells are up to three-fold more sensitive to radiation than hypoxic cells.[20] Additionally, tumor hypoxia is associated with the upregulation of hypoxia-inducible proteins that may prepare the tumor cells to handle stresses and can also affect tumor metabolism and metastatic potential.[36,37]

Relative Biologic Effectiveness

Although this chapter primarily discusses the effects of photons (x-rays and gamma rays) and electrons, other forms of radiation can be used for treatment, including protons, neutrons, and carbon particles. The relative biologic effectiveness (RBE) is not a

VetBooks.ir

physical measurelike the linear energy transfer (LET), which measures the amount of energy transferred per unit path length. LET is a factor in RBE, but RBE also considers factors such as biologic endpoint, fractionation, radiation dose rate, and dose. The RBE of 1 Gy of electrons and photons is the same, but 1 Gy of neutrons or heavy charged particles such as carbon causes substantially more damage.[38,39] RBE essentially compares the biologic difference between specific types of radiation relative to the effect of photons. Protons, which are commonly used in human radiation facilities, have a slightly higher RBE than photons and electrons.[40] Protons and heavy charged particles also share unique properties in dose distribution that can be beneficial in treatment planning.[41,42]

Alternative Methods of Radiation Cell Death

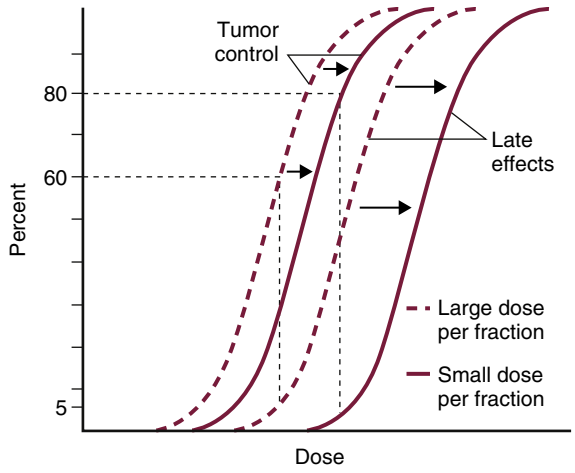
Radiation-induced apoptosis is the second most common form of cell death after irradiation, but it is highly cell-type dependent.[43] Lymphoid tissues are particularly prone to apoptosis, which may be the dominant form of cell death in these tissues.[43] Apoptosis can occur spontaneously in tumors, although the degree of occurrence can vary even within the same tumor type.[44] Radiation responsive tumors may undergo greater levels of radiation-induced apoptosis than more radioresistant tumors.[45] Apoptosis of endothelial cells may indirectly affect tumor cell kill by leading to vascular collapse. Vascular collapse has been recognized to play a role in the overall response to radiation therapy.[46] Apoptosis of endothelium primarily occurs when high-dose fractions are administered and may play a more important role when hypofractionated radiation is delivered.[47–49]

The bystander effect, defined as biologic effects observed in cells not traversed by radiation but in proximity, may affect some cells, but this has not been well quantified in vivo.[50] Autophagy, cell senescence, oxidative stress, and immune response may also play roles.[50,51] Abscopal effects refer to distant sites, such as when a tumor irradiated in one part of the body affects tumors in other locations.[50] Abscopal effects may be associated with an enhanced immune response.[50]

Tumor Stem Cells

As early as 1973, it was recognized that the number of injected tumor cells from a variety of spontaneous cell lines to induce tumor formation in 50% of recipients varied from 21 to 24,000 cells.[52,53] This tumor-forming ability in vivo appears to correlate in many cases with the percentage of cells within the tumor bulk possessing a stem-cell-like phenotype. Cancer stem cell markers, such as CD24 and CD44, have been identified, but the relationship between the markers and stem cell characteristics remains under investigation.[54,55] It is hypothesized that the number or percentage of tumor stem cells and their intrinsic radiation sensitivity predict radiocurability.[55] Tumor stem cells are being intensively investigated as a potential target for therapy.

Principles of Fractionated Radiation Therapy



Time, Dose, and Fraction Size

Early radiation oncologists found that higher total doses could be given if the doses were divided into smaller doses, known as fractions. Coutard, a radiation oncologist at the Curie Institute in Paris, observed that tumor response was improved and less injury of normal tissue occurred when radiation was fractionated.[1] Coutard's recommendations were 2 Gy fractions delivered Monday through Friday for 6 to 8 weeks with a total dose of 60 to 80 Gy. In veterinary medicine, standard fractionation denotes a regimen delivering 2.7 to 4.0 Gy per fraction, three to five times per week, to a total dose of 42 to 57 Gy. Hyperfractionation refers to schedules in which the dose per fraction is reduced and the total dose is increased. In human radiation oncology, this approach has been associated with improved outcome for a number of tumor types, including oropharyngeal carcinoma.[56] Accelerated RT describes a treatment regimen in which the overall time of treatment is reduced.[57] Hypofractionation describes the administration of higher doses per fraction given in a smaller number of fractions. Compared with most conventional human protocols, the protocols used in veterinary medicine would be considered hypofractionated and accelerated. The response of tumor and normal tissues to conventionally fractionated RT (regardless of human or veterinary oncologist prescribed) has been described by Withers as the "Four Rs" of RT: repair of DNA damage, redistribution of cells in the cell cycle, reoxygenation of tumor cells, and repopulation of tumor and normal tissues.[3]

Division of the total radiation dose into fractions is important for a number of reasons. The first reason is to exploit potential differences in repair capabilities between tumors and normal tissues. Slowly dividing cells are somewhat less sensitive to small doses of radiation than more rapidly dividing cells; however, they appear to become relatively more sensitive if radiation is delivered in larger doses per fraction. If smaller doses per fraction are used, normal tissues with slowly dividing cells can be spared relative to tumor tissues with rapidly dividing cells.[58]

Other events that occur between radiation fractions are cell cycle redistribution and reoxygenation. When a fraction of RT is administered, many of the cells in the sensitive portions of the cell cycle are killed. During the interval between fractions, cells from the late S-phase, which are more likely to be alive than other cells, progress to more sensitive parts of the cell cycle. This is known as redistribution.[29,30] Tumor hypoxia is a common feature occurring in many solid tumors due to decreased vascular density and malformed tumor vessels. Chronic hypoxia, also known as diffusion-limited hypoxia, is caused by limitation in oxygen diffusion to cells further away from tumor vessels.[36,37,59] Perfusion-limited related hypoxia is due to temporary closing or blockage of malformed blood vessels. The tumor microenvironment is constantly changing and is itself affected by radiation.[36] After a fraction of radiation, oxygenated cells die, allowing hypoxic cells closer access to vessels. The location of acutely hypoxic cells varies based on the opening and closing of vessels and is transient. Tumor hypoxia cannot be predicted by tumor size or histologic type but is thought to contribute to treatment failure. In experimental models, the pattern for reoxygenation and the extent of the reoxygenation varies.[60,61]

The length of time over which RT is administered is important primarily because of tumor repopulation but also because of rapidly proliferating normal tissues, such as mucosa and skin. Tumor cells that have not been destroyed by irradiation continue to replicate during the course of therapy. This process is exacerbated by a phenomenon known as accelerated repopulation.[3,62,63] It is believed that after approximately 4 weeks of therapy, tumors repopulate more rapidly than initially.[3,63] The reason for this is not clear, but the phenomenon could be related to (1) a reduction in the cell cycle time, (2) an increase in the number of tumor cells that are actively dividing (growth fraction),

• **Fig. 13.1** Radiotherapy delivered in small fractions *(solid lines)* can produce a higher probability of tumor control with the small level of late effects as radiotherapy delivered in large fractions *(broken lines)*.

(3) a reduction in the number of tumor cells that normally die (cell loss factor), or (4) an increase in the number of tumor stem cells. Regardless of the cause, when treatment lasts longer than 4 weeks, repopulation may affect the outcome unless total dose is increased to account for this phenomenon. Repopulation may have a greater adverse effect on rapidly dividing tumors than on slowly dividing tumors.

Repopulation of rapidly proliferating (also known as acutely responding) normal tissues is also affected by time. The same total dose of radiation administered over a short period results in somewhat more severe acute effects than if administered over a longer course.[3,64–66] Nonproliferating (late responding) normal tissues are not significantly affected by the length of time over which therapy is administered;[33,64–65] they are more affected by dose per fraction and total dose.[3,33] Additionally, fractions should be separated by at least 6 hours to allow repair of DNA damage to normal tissues.[66] Cells of the brain and spinal cord may require additional time for complete repair.[66]

The total dose administered to a patient should have a low probability for causing significant late normal tissue reactions in the region of therapy; however, the response of tissues also depends on the fraction size. For example, 48 Gy administered in 4 Gy fractions has a higher probability of causing late effects than 48 Gy administered in 3 Gy fractions (Fig. 13.1). The probability of tumor control is minimally affected because rapidly proliferating tissues, including tumors, are not as sensitive to the change in dose per fraction. The benefits of protocols that use small doses per fraction are clear: they allow a higher total dose to be administered without increasing the probability of damage to late-responding normal tissues. Conversely, extending overall treatment time may allow for greater accelerated repopulation.[3,62,67–68]

Radiation Effects to Normal Tissues

Reactions from RT are classified as acute, late, consequential, and early delayed. Acute effects occur during or shortly after RT. Acute effects involve rapidly proliferating tissues, such as the oral mucosa, intestinal epithelium, and epithelial structures of the eyes and skin. Concurrent chemotherapy can exacerbate acute radiation effects.[69] Although the severity of acute effects may vary between patients, these effects generally are self-limiting and recovery is rapid; however, acute effects can be unpleasant for the patient and distressing to the owner, and in rare instances they can be life-threatening if proper care is not given. Acute effects will heal with modest pain management in the vast majority of cases over the course of weeks or occasionally months. In veterinary patients, the most important provision to allow healing during this time is prevention of self-trauma of the irradiated site. Pain management plays an important role and should be addressed. Pain management for cancer patients is discussed in Chapter 16A of this text and specific protocols have been published.[70] Additional treatment is based on common sense, supportive care, and the knowledge that the signs will resolve with time.

Early delayed radiation effects have been recognized only in neurologic tissues. Occurring between 2 weeks and 4 months after treatment, they may take several forms.[71] Somnolence may develop in patients receiving whole brain irradiation.[72] Early delayed effects may simulate tumor recurrence or may cause neurologic signs not previously associated with the tumor, and so careful imaging evaluation is necessary. Early delayed effects may be due to demyelination or from cerebral edema–associated cytokine release with tumor cell death. Early delayed effects will generally respond to corticosteroid administration and supportive care.[71]

Late effects are mechanistically more complex than acute effects and involve more slowly proliferating tissues, such as bone, lung, heart, kidneys, and nervous system. The dose of radiation administered to the patient is limited by the tolerance of these normal tissue structures in the field. Late reactions can be difficult to treat; it is the radiation oncologist's obligation to minimize the incidence of late effects with appropriate dose prescriptions and careful radiation planning and treatment. When late effects occur, they may be quite severe, resulting in fibrosis, necrosis, loss of function, and even death.[73] Late effects occur from the loss of normal tissue stem cells with concurrent radiation-induced vascular changes and inflammation. These changes are multifactorial, but the cytokine transforming growth factor beta (TGFβ) is believed to play a critical role in radiation fibrosis.[74] Strategies attempted in human radiation oncology to mitigate late radiation effects include the use of antioxidants and free radical scavengers (e.g., superoxide dismutase, vitamin E, thiol radioprotectors), vascular directed therapies (e.g., clopidogrel, statins, pentoxifylline), antiinflammatory agents (corticosteroids), inhibitors of the renin-angiotensin system (e.g., ACE inhibitors), and stem cell therapies.[73] Consequential late effects, the result of extensive damage to stem cells of acutely responding tissues such as colon, are indistinguishable clinically and histologically from late effects and should be managed in a similar fashion.[75]

An unusual late effect associated with RT is the occurrence of radiation-associated secondary tumors. Ionizing radiation is a complete carcinogen, capable of initiating, promoting, and progressing cellular changes that lead to cancer. Therefore it is possible to see radiation-induced neoplasia develop in an RT field. It appears that radiation with high LET such as neutrons result in carcinogenesis at a higher frequency than the megavoltage photons typically used in veterinary RT.[76] Age influences the risk of radiation carcinogenesis because younger patients have the potential to live longer after radiation, and information from nuclear accidents suggest that they are more likely to develop secondary tumors.[76,77] Certain tissues such as the thyroid gland are also more prone to development of radiation-induced tumors.[78] Secondary tumors have been reported in dogs in both clinical and research settings.[79,80]

VetBooks.ir

For a tumor to be considered radiation induced, the following criteria must be met:

1. The malignancy must arise within the irradiated field.
2. Sufficient latency must have elapsed between the time of irradiation and development of the tumor (typically at least 1 year).
3. The original tumor and the new tumor must have different histologic diagnoses.
4. The tissue in which the new tumor forms must have been previously normal before radiation exposure.

The overall incidence of radiation-induced tumors in patients treated with RT is thought to be extremely low (up to 2% of patients treated).[78]

In veterinary patients, severe late reactions such as fibrosis and tissue necrosis should be managed under the guidance of an oncologic surgeon and/or radiation oncologist experienced in dealing with radiation injury.

Chemical Modifiers of Radiation

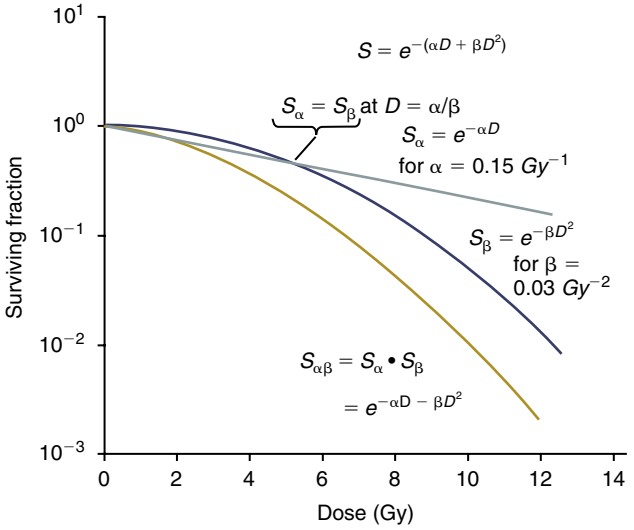
Although rarely used clinically in veterinary medicine, many drugs can modify the cellular and tissue response to radiation.[81] Radioprotectors (e.g., amifostine/WR-2721) are compounds that decrease the amount of radiation damage to targeted normal cells without providing similar protection to tumor cells.[82,83] Radiosensitizers are chemicals that achieve greater tumor inactivation than would be expected from the additive effect of treatment with either radiation or the chemical alone and have included common chemotherapeutic agents such as carboplatin and gemcitabine.[82] Mechanisms of action also include targeting hypoxic cells by increasing sensitivity, increasing oxygen delivery, decreasing oxygen consumption, and the use of hypoxia molecular target inhibitors.[84] Newer concepts include employing gold nanoparticles and targeted therapies, including immune checkpoint inhibitors.[85,86]

STEREOTACTIC RADIATION THERAPY: BIOLOGIC AND ONCOLOGIC PRINCIPLES

Although time, dose, and fraction size are still the underpinnings of SRT, some of the biologic mechanisms appear to be different from conventionally fractionated RT. It can be confusing, because the term "stereotactic RT technology" describes the physical equipment and software required to deliver focal treatment with location confirmation. Although generally associated with hypofractionated protocols, the technology can be used for administration of traditionally fractionated RT. For instance, the use of image-guided and intensity-modulated RT has been described for the treatment of urinary tract tumors in dogs.[87] For purposes of this chapter, the term SRT will refer to the use of high doses per fraction (hypofractionation) using SRT technology and techniques.

Unlike conventionally fractionated RT, which spares normal tissues by improved repair, SRT overcomes the radiobiologic limitations by stereotactically verified positioning and treatment delivery techniques that leave a minimal volume of normal tissue in the high dose area. SRT, by definition, requires: (1) a tumor for targeting (not microscopic disease); (2) treatment planning and administration that will provide a dramatic dose drop off between the tumor and the surrounding normal tissue structures; and (3) a method of stereotactically verifying patient positioning.[88,89] The result is that normal late-responding tissue structures are spared through dose avoidance rather than by administering small doses per fraction. The normal tissue structures still receive the dose, and the dose per fraction is higher than for traditional RT; however, the total dose to normal tissue structures is lower than what is typical for fractionated RT because of the steep dose drop-off between tumor and critical normal tissue structures. Normal tissue tolerance data are just evolving for SRT, as are reports of long-term outcome, in both human and veterinary medicine. Estimates of tolerance have been based on limited clinical data, toxicity observation, and educated guessing.[90] It is inappropriate to extrapolate dose constraints from fractionated protocols. An additional clinical difference between SRT and fractionated RT is that with SRT, acutely responding normal tissues in the surrounding region, such as skin, esophagus, and colon, are susceptible to consequential late effects due to the short overall treatment time.[91,92] Dose constraints therefore must also be applied to these tissues. SRT is generally hypofractionated and delivered in one to five fractions over a period of 1 to 2 weeks, minimizing the effect of accelerated repopulation. Early stereotactic treatment using a gamma-knife necessitated delivery in a single fraction (referred to as stereotactic radiosurgery [SRS]). Current technology allowing precise repositioning makes limited fractionation feasible. Even this minimal fractionation should allow higher total doses to be administered safely to late-responding tissues in the region and presumably take advantage of tumor reoxygenation and redistribution. Biologic response after SRT has not been conclusively evaluated. Experimental data imply that direct tumor cell death cannot account for the efficacy of SRT and SRS. Tumor cell death will be discussed later, but based on cell culture and rodent experiments, which suggest that 10^{8-9} tumor cells must die to eradicate a 1-gram tumor, the doses used to obtain tumor control in human tumors treated with SRS or SRT are far lower.[93–97] High dose, hypofractionated RT has been shown to cause vascular damage in mouse tumor models, which leads to greater-than-expected tumor control, leading to the conclusion that tumor vascular injury leads to indirect tumor cell death.[46,49]

From a practical standpoint, SRT minimizes the number of anesthesia episodes required in older and sometimes debilitated patients and is also generally more convenient for the owner; however, these factors should not be the overarching rationale for prescribing SRT. Although acute effects are minimal and tumor-associated signs, such as discomfort or dysfunction, often improve rapidly, the ultimate decision should be based on choosing the modality that provides the best long-term tumor control and/or best quality of life. Long-term tumor control and late effects are still being quantified, but recent publications demonstrate comparable survival times (STs) in nasal and brain tumors and improved outcome in the treatment of feline acromegaly when compared with conventionally fractionated protocols.[8,9,98] SRT technology has also resulted in the improved treatment of tumor sites infrequently previously irradiated in veterinary medicine, including the adrenal gland, brachial plexus, and trigeminal nerve.[11,99,100]



No all-embracing RT protocol exists. With increased understanding of underlying biology, protocols continue to be manipulated to exploit tumor characteristics for improved control or to increase sparing of normal tissues. Regardless of whether using finely fractionated RT or SRT, the protocol should be chosen based on the specific normal tissues present in the irradiated field. For example, brain and spinal cord are less tolerant to the effects of irradiation than muscle or bone. Another factor that must be considered when selecting the appropriate dose is the volume of tissue in the field. Large volumes of normal tissues are more susceptible to damage from irradiation than smaller volumes. For many tumor locations, a 5% probability for late effects is

tolerated, because without the treatment, patients may not live long enough to develop late effects; however, for structures such as the spinal cord, where a late effect such as paralysis is viewed as unacceptable, a 1% probability of effects is used. Conversely, for procedures like SRT limb-sparing for canine osteosarcoma (OSA), the risk of fracture is affected by the region and condition of lytic bone at the time of treatment. Owners may choose to accept a higher risk of fracture to maintain limb function, because a future amputation can be used as a salvage procedure.[101]

It is not within the scope of this chapter to prescribe specific radiation doses or fractionation schedules, because many factors must be considered. Rather, referring veterinarians must know what to expect when sending patients to a radiation oncology center and should be able to explain the fundamental principles to clients. The radiation oncologist should inform the referring veterinarian and owner of the probabilities of tumor control, acute effects, and late effects expected with a specific protocol. The goal of RT is to destroy the reproductive capacity of the tumor without excessive damage to surrounding normal tissues. The relationship of three parameters (overall treatment time, total dose, and fraction size) as well as other factors, such as chemotherapy, previous surgery, and underlying medical conditions such as diabetes, must be carefully considered in the development of an RT plan.

THE LINEAR QUADRATIC FORMALISM AND BIOLOGIC EFFECTIVE DOSE

Many mathematical models have been used to describe or predict the effect of radiation on cells and tissues. The linear quadratic formalism has been useful for evaluating the effect of radiation in fraction sizes commonly used in RT and has been a tool for modifying radiation protocols based on projected effect on late-responding tissues.[102–105] Mechanistically, this model corresponds radiation injury to chromosome aberrations.[106–108] After a tissue or population of cells is exposed to any dose of radiation, a fraction of the cells will be killed. The proportion of remaining cells is known as the surviving fraction (S). The sensitivity of a tumor or tissue to radiation can be shown as a graph of the radiation dose (D) versus the surviving fraction (Fig. 13.2).[109] The relationship between a dose of radiation and the surviving fraction of cells is commonly described by the linear quadratic equation: $S(D) = e^{-(\alpha D + \beta D^2)}$, where S is the surviving fraction at a dose (D).[103] Alpha (α) and beta (β) are constants that vary according to the tissue, with α corresponding to the cell death that increases linearly with dose, and β corresponding to the cell death that increases in proportion to the square of the dose (also known as the quadratic component). The α/β ratio is a useful number that is the dose in Gy when cell kill from the linear and quadratic components of the cell survival curve are equal. Cells with a higher α/β ratio have a more linear appearance when plotted on a log scale, and cells with a low α/β ratio have a parabolic shape. The α/β ratio is also an important description of the radiosensitivity of a cell. At low dose fractions, tissues or cells with low α/β ratio are relatively radiation resistant compared with tissues or cells with high α/β ratio. It has been suggested that tissues and cells with low α/β ratios have a greater capacity for repair of sublethal radiation damage.[110] Sublethal radiation damage is defined as damage that can become lethal if it interacts with additional damage.[29,30] Sublethal damage repair is the reason that cell survival increases when a radiation dose is split into two fractions separated by a time interval.[29,30]

• **Fig. 13.2** Illustration of the alpha/beta model in which cell killing occurs by either a single-event process or a double-event process such that the overall killing by either process is the product of the two, and the alpha/beta ratio is the dose at which both processes contribute equally to the total killing. Note that the upper curve is survival for the alpha component only, the middle curve is for the beta component only, and the lower curve is for both components. (From Wilson PF, Bedford JS. Radiobiological principles. In: Hoppe RT, Phillips TL, Roach M, III, eds. *Leibel and Phillips Textbook of Radiation Oncology.* 3rd ed. St. Louis: Elsevier; 2010:3–30.)

Most early-responding tissues and tumors have a high α/β ratio, whereas late-responding tissues have a low α/β ratio.[103] Tumors that may have a low α/β ratio can influence the optimal radiation prescription in terms of total dose, time, and fraction size. Tumors that may have lower α/β ratios include melanoma, prostatic tumors, soft tissue sarcomas, transitional cell carcinomas, and OSA, but these are generalities and the α/β ratio may differ from tumor to tumor.[110–112]

The concept of biologic effective dose (BED) is used to predict how changes in dose prescription may preferentially affect different cells or tissues based on their α/β ratio in the linear quadratic model of survival. The formula for BED is as follows: $BED = nd[1 + d/(\alpha/\beta)]$, where n is the number of fractions and d is the dose per fraction. If the α/β ratio of a tissue is known or can be estimated, the BED can be calculated for any dose prescription. It is possible to use this formula to assess how dosimetry changes or errors alter the effective dose of a protocol. It is important to note that there are several limitations to the use of this equation, including that it does not account for differences in the overall length of time of the radiation protocol or accelerated repopulation. More complicated additions to the formula can be used to take overall treatment time into account.[105] Although experimental and clinical data provide confirmation of α/β ratios for most tissues, linear quadratic parameters for tumors are uncertain; therefore calculations made with this model for tumor control prediction may not be valid.[113] Nevertheless, this formula is a useful tool when considering hyperfractionating a standard radiation protocol to create a new protocol that increases normal tissue tolerance, which could allow increased total dose, or to adjust a protocol when there has been an extensive delay in treatment. The validity of BED for SRT is unclear. It has been useful for estimating late effects based on data from conventionally fractionated RT; however, BED-derived constraints for acutely responding tissues may overestimate tolerance of acutely

responding tissues because of the shortened overall treatment time in SRT. Work is ongoing to establish SRT constraints for acutely responding tissues.[91,92]

PALLIATIVE RADIATION THERAPY

Palliative RT (PRT) is an important tool in cancer treatment, and its use in veterinary medicine for a wide variety of tumor types is increasing. PRT is not ideally intended to provide long-term or definitive tumor control; rather, it is intended to relieve pain or improve function or quality of life in patients in which other factors (e.g., advanced metastatic disease, comorbidities) are likely to lead to early demise. Because curing the patient is no longer the goal, the treatment should not negatively affect quality of life by causing acute radiation effects. Radiation protocols used for palliation are far less aggressive and more flexible than when treating with curative intent. PRT is most often hypofractionated compared with curative-intent protocols, often administered in 6 to 10 Gy per fraction, in one to six total fractions once or twice weekly. Conversely, PRT can be delivered in conventional or modestly hypofractionated schedules once or twice daily for a shorter treatment regimen. Most publications have focused on metastatic or primary bone tumors, principally canine OSA (see Chapter 25), but it is also reported for nasal tumors, hemangiosarcoma, soft tissue sarcoma, mast cell tumors, GI lymphomas, and oral tumors.[114–117] Palliative RT is more convenient and less expensive for the owner than fractionated RT or SRT with curative intent. It is, however, important to remember that palliative RT is not a substitute for curative-intent protocols despite the convenience. Some palliative RT protocols may have an increased probability of causing late radiation effects based on biologic effective dose calculations[102,103]; however, because they are prescribed to patients that have a poor long-term prognosis, these late effects generally do not have time to manifest. Curative-intent RT protocols require strict adherence to radiation biologic principles; palliative RT protocols, on the other hand, are far more flexible. As in human hospital settings, the protocols may vary dramatically between centers and, regardless of the protocol, most palliative RT patients receive some level of benefit. Because the duration of response after palliation is limited, some owners elect pursuing a second course.[118] PRT is not restricted to specific modalities of radiation administration. SRT is also an option for palliative treatment. It may provide quicker and more durable response for the primary or metastatic lesion being treated and ideally maintain quality of life until death from disseminated disease.

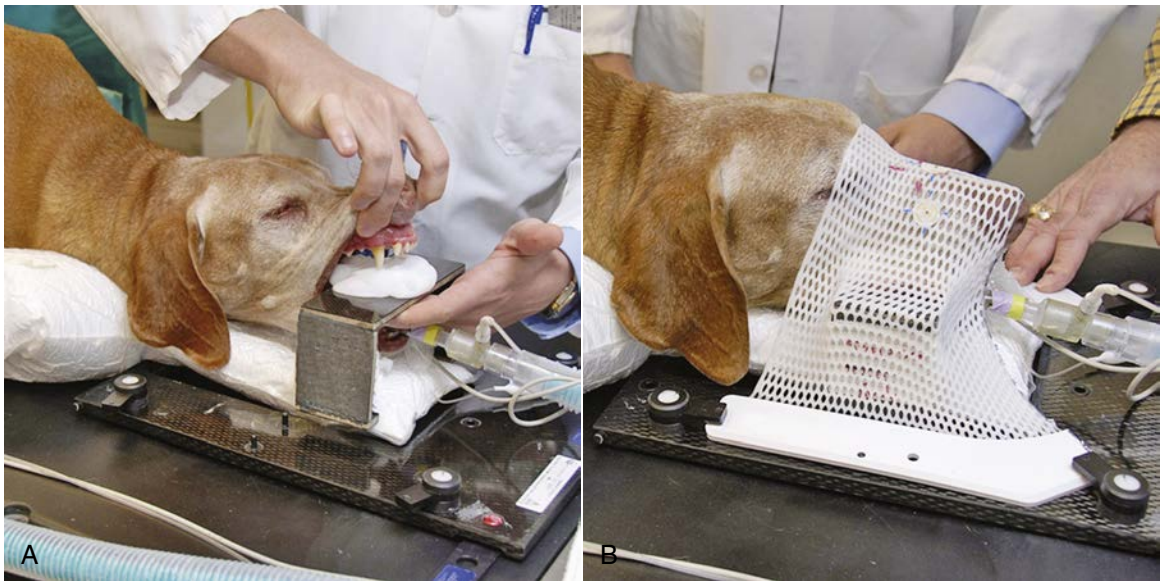
Radiation Therapy Equipment

Ionizing radiation can be administered by an external source (teletherapy) through placement of radioactive isotopes interstitially (brachytherapy) or by systemic or cavitary injection of radioisotopes, such as iodine-131 (^{131}I). Teletherapy, also referred to as external beam RT, is the most commonly used method of RT in veterinary medicine. External beam RT usually is classified as orthovoltage or megavoltage radiotherapy, based on the energy of the photon. Orthovoltage machines produce x-rays with an energy of 150 to 500 kVp; megavoltage radiation emits photons with an average energy greater than 1 million electron volts (1 MeV). Although some veterinary radiation oncology centers continue to treat with orthovoltage machines, megavoltage radiation is the most commonly used type of external beam RT. Megavoltage radiation for therapy can be obtained from cobalt machines or linear accelerators.[6] Because megavoltage radiation has excellent tissue-penetrating capabilities, RT can be performed on deeply seated tumors for which orthovoltage therapy would not be an option.

Orthovoltage x-rays, which have low energy, distribute maximum doses to the skin surface. Acute effects to the skin can be quite severe, causing discomfort to the patient, and late effects to the skin and subcutaneous tissues can be dose limiting. Megavoltage radiation has a higher energy than orthovoltage, and the photons must interact with tissues, allowing the dose to build up before the maximum dose can be achieved. The skin therefore can receive a significantly lower dose than the underlying tumor. This skin-sparing effect of megavoltage radiation allows the optimal dose to be administered to a more deeply seated tumor without causing severe reactions to the skin. When the tumor involves or is in close proximity to the skin, megavoltage radiation can be used successfully by placing a sheet of tissue-equivalent material, called a bolus, over the tumor. This allows the dose buildup to occur before reaching the skin so that the skin and associated tumor can receive the maximum dose of radiation.

The absorption of megavoltage radiation, unlike that of orthovoltage radiation, is minimally dependent on the composition of the tissue. This characteristic permits even distribution of the dose throughout the tissues in the field. Orthovoltage radiation is preferentially absorbed by bone.[119] If a tumor adjacent to or overlying bone is administered a meaningful dose of orthovoltage radiation, the probability that late effects to the bone (bone necrosis) will develop is quite high.[119,120] Treatment with orthovoltage should be limited to small, superficial tumors, such as nasal planum tumors, or to superficial tumor beds after surgical excision.

Interaction of megavoltage radiation with tissues is quite predictable; this has allowed the development of accurate computerized treatment planning systems. These planning systems allow treatment of the tumor with multiple beams administered from different angles. The goal of computerized treatment planning is to ensure a desired minimum tumor dose to a region specified by the radiation oncologist and to spare normal tissue structures when possible. Three-dimensional conformal RT uses CT or MRI images, which are imported or contoured using a tablet. The summation of multiple beams coming from different directions provides a higher dose to the tumor than surrounding tissues.



In addition to photons, radiation treatments in veterinary medicine also include electron-beam therapy. Various energies of electrons are commonly incorporated in the capabilities of modern linear accelerators. Electron beam therapy is most favorable for superficial targets, because electrons do not penetrate to nearly the depth of a photon beam, which can allow for sparing of deep structures.

Although not yet commonly utilized in veterinary medicine due to the technical demands and cost, proton beam radiation equipment is becoming widely available in human treatment facilities and offers dosimetric benefits that photons cannot. A machine called a cyclotron speeds up protons, imparting high energy that determines the travel depth of the proton. Unlike photon therapy, protons deposit radiation dose in the targeted range and minimal dose exits the tumor.[42]

Radiation Planning and Delivery Techniques

Advances in treatment planning and imaging over the past decade have led to the development of image-based, 3D conformal RT (3D-CRT), which permits better conformity between

VetBooks.ir

the irradiated high-dose volume and the geometric shape of the tumor. 3D-CRT requires importation of CT images into a treatment planning system. The animal must be positioned for the imaging in a fashion that can be closely replicated on a day-to-day basis for treatment. Acrylic face masks and Vac-Lok Cushions are commonly used for positioning (Fig. 13.3). The radiation oncologist identifies important normal tissue structures known as organs at risk, gross tumor volume (GTV), clinical target volume (CTV), and planning target volume (PTV) on these images. By definition, the GTV only includes gross tumor whereas the CTV includes the GTV plus an expansion based on the known clinical behavior of the specific tumor to account for regional microscopic disease.[121] For example, the CTV expansions for a sarcoma are generally larger than for a carcinoma. If the patient has had cytoreductive surgery and only microscopic tumor remains, there is no GTV and the CTV is based on the scar, regions of surgical disruption, and an expansion for microscopic disease beyond the surgical site.[121] In addition to the GTV and CTV, the PTV includes expansion for an internal margin that accounts for variations in size and shape relative to anatomic landmarks (e.g., filling of bladder, respiratory movements) and set-up margin (SM). The SM accounts for uncertainties in patient positioning and alignment during planning imaging and subsequent treatments.[121] The better the immobilization device, the smaller the SM expansion can be. SM expansions will vary based on the location of the tumor because some sites, such as the head, are more amenable to rigid immobilization devices, such as bite blocks, which provide better replicability. Decreasing the PTV expansion by using good immobilization and available imaging affects the volume of normal tissue treated, is a key component to successful 3D-CRT, and is critical to other advanced treatment modalities. PTV expansions are both facility and region specific and ideally are determined with input by both the medical radiation physicist and the radiation oncologist. Somewhat more sophisticated beam shaping is performed by taking advantage of fixed multileaf collimators. The major advantage of 3D-CRT is that dose-volume histograms can be obtained for the tumor and normal tissue structures. This provides a quantitative method of evaluating treatment plans and enhances quality assurance.

IMRT and related modalities, such as TomoTherapy, allow even greater sculpting of the radiation dose. IMRT requires a treatment planning system that uses inverse treatment planning. Inverse planning requires that the various tumor structures (GTV, CTV, and PTV) as well as critical normal tissue structures be identified and contoured into the planning system. Optimization objectives for each structure are entered, and a sophisticated algorithm attempts to meet all objectives. This is standard of care for the treatment of prostate tumors, head and neck cancers, vertebral cancers, some brain cancers, and pelvic cancers in humans. A major benefit associated with IMRT is that dose to adjacent normal tissue structures can be minimized, dramatically reducing acute effects. Patients are more comfortable and require less pain medication.[122] The tumor dose can be increased without exceeding normal tissue tolerance, presumably leading to improved tumor control. Fractionation schedules and other factors, such as immobilization, margins, and CTV expansions, are similar to 3D-CRT. TomoTherapy, a form of IMRT that uses a helical delivery system to sculpt the beam, and volumetric-modulated arc RT are also being used in veterinary medicine.[11,123] IMRT is proving useful for the treatment of tumors or tumor beds with complex geometry located near important normal tissues, such as nasal tumors, oral tumors, and urogenital tumors.[123,124]

SRT is a treatment technique made possible by highly conformal radiation treatment techniques, such as IMRT and proton therapy, in combination with precise positioning devices and localization methods, such as cone-beam computed tomography (CBCT). In SRT, the usual wide margins (CTV) to account for microscopic disease extension are not applied, and PTV expansion may be decreased to spare important adjacent normal tissues (Fig. 13.4). Highly conformal radiation is applied to a specific gross (tumor) target with rapid dose fall-off within a small margin. This technique minimizes the radiation dose reaching normal structures adjacent to the treated target. Table 13.2 shows a comparison of characteristics of traditionally fractionated RT compared with SRT.

• **Fig. 13.4** A canine nasal tumor with axial (A), dorsal (B), and sagittal (C) sections through a canine nasal tumor. Dose is in color wash with the prescribed dose in orange. (D) The dose volume histogram. Note the high dose to the tumor compared with regional normal tissue structures.

TABLE 13.2 Characteristics of Traditionally (Finely) Fractionated Radiation Therapy vs. Stereotactic Radiation Therapy

General Characteristics	3D/IMRT	SRT
Dose/fraction	2.5–4.2 Gy	6–24 Gy
Number of fractions	10–25	1–5
Target definition	CTV/PTV gross disease and clinical extension Tumors may not have sharp boundaries	GTV/CTV/ITP/PTV Well-defined tumors: GTV = CTV
Margins	cm	mm
Primary imaging modalities for planning	CT	CT/MR/PET-CT
Redundancy in geometric verification	No	Yes
Maintenance of high spatial targeting accuracy for the entire treatment	Moderately enforced, moderate patient position control and monitoring	Strictly enforced (sufficient immobilization and high-frequency position monitoring through integrated image guidance)
Need for respiratory motion management	Minimal, usually managed by increasing ITV	High particularly for tumors thorax and cranial abdomen
Staff training	High	High, plus special SRT training
Radiobiologic understanding	Well understood	Poorly understood
Interaction with systemic therapies	Yes; principles well established	Yes; minimally understood
Immobilization devices	Vac-Lok bags, pillows, and acrylic mesh	Vac-Lok bags, pillows, and acrylic mesh + bite blocks for head and neck tumors
Purpose	Palliative/curative	Palliative/curative

Immobilization and Localization Techniques

As radiation delivery techniques become more conformal and treatment margins are reduced, the importance of precise patient positioning and target localization/verification become increasingly important. A variety of techniques are used to achieve the requisite level of accuracy for any given patient and RT procedure. A port film is a radiograph taken, typically by the treatment beam, at the beginning of an RT and periodically throughout the treatment course to ensure proper radiation positioning and alignment of the treatment beam and patient for 3D-CRT. Commonly obtained as a double exposure from the treatment machine with an initial exposure of the treatment field followed by exposure of a wide field of the surrounding anatomy, it results in a radiographic image with a dark central area indicative of the treatment field with lighter exposure of the surrounding anatomy for reference. Digital radiography technology is now frequently implemented and may be integrated into a linear accelerator. An electronic portal imaging device (EPID) is a digital imaging plate mounted on a linear accelerator with a robotic arm for extending and retracting the plate in precise positions. EPIDs allow for more routine or daily treatment localization/verification, with rapid image acquisition, analysis, and storage of these images. An on-board imager (OBI) is a high-resolution digital imaging system (x-ray source and digital capture system) separate from the primary beam from the treatment machine itself. OBI systems are typically kilovoltage energy systems that provide superior contrast to images generated from a megavoltage linear accelerator beam. CBCT platforms are integrated into linear accelerators whereby a volumetric CT image can be generated by rotating the x-ray source and digital reading plate around the patient during an exposure. CBCT allows for improved localization, particularly for soft tissue structures that are difficult to immobilize relative to cutaneous or bony anatomic landmarks. Surface-guidance RT utilizes 3D camera technology or other means to accurately detect the patient surface, often in real-time during RT.

TUMORS COMMONLY TREATED WITH RADIATION

Oral Tumors

Many oral tumors, such as acanthomatous ameloblastomas (AAs) and rostral squamous cell carcinomas (SCCs), respond well to both complete surgical excision and RT. For less radiation responsive tumors such as fibrosarcomas, complete surgical excision is preferred; however, postoperative RT is recommended after incomplete histologic excision (see Chapter 23, Section A). For large oral tumors, aggressive surgery can lead to functional and/or cosmetic abnormalities. In these cases pretreatment planning for both surgery and RT may be indicated.[125] RT after surgery should start as soon as possible and can start immediately after surgery. However, in the face of excessive tension on the suture line or indication of delayed healing, RT should be postponed until healing has occurred. The therapeutic gain from following surgery with RT will be lost if the radiation is delayed for too long. The introduction of IMRT allows better sparing of important structures in the area and minimizes inadvertent dosing to salivary glands, tongue, lips, and skin, making patients more comfortable during treatment.[122]

Efficacy of Treatment

AAs are very radiation responsive. Tumor control with RT can be close to 90%.[126] A relationship has been demonstrated between tumor (T) stage and local control.[127] The reported 3-year progression-free survival time (PFS) for T1 tumors (less than 2 cm) and T2 tumors (2–4 cm) is 86%; it is only about 30% for T3 tumors (over 4 cm).[127] In a retrospective study of 57 dogs with AAs that were treated with RT reported that the overall median time to first event and median survival time (MST) were 1210 and 1441 days, respectively.[128] Dogs younger than 8.3 years old (the median age in the study) had a significantly longer MST (2322 days) than dogs older than 8.3 years (1106 days). Dogs that received doses higher than 40 Gy had significantly longer MST than dogs that received 40 Gy or less (2994 days vs. 143 days). It was previously suggested that RT could result in transformation of AAs into malignant epithelial tumors, but this possibility has since been refuted.[126,128]

Canine oral SCCs are responsive to radiation, although the prognosis is site dependent, with tumors located more rostrally having better probability of control.[129] Tumors at the base of the tongue or tonsil are highly metastatic and are likely to recur locally or regionally. In one study of oral SCC the reported PFS at 1 and 3 years is 72% and 40%, respectively, for all T stages.[130] Another study of fractionated RT (48–57 Gy in 3–4 Gy fractions) in 14 dogs with oral SCC, the median disease-free interval (DFI), and MST were 365 and 450 days, respectively.[131] In cats, oral SCC has a poor prognosis.[132] Although many cats show an initial response and may even show dramatic reductions in tumor size, tumor recurrence is common. Combining curative-intent RT with etanidazole or mitoxantrone therapy has resulted in MSTs of 116 to 170 days.[81,133] Seven cats with mandibular SCC were treated with hemimandibulectomy and mandibular node excision followed by RT; the MST was 420 days, but some cats do not adapt to bilateral mandibulectomies.[134] Nine cats with oral SCC received accelerated RT (14 fractions of 3.5 Gy in 9 days), which resulted in an MST of 86 days.[135] In a different approach, SRT (20 Gy) was delivered to 18 cats with oral SCC. Acute radiation effects were minimal and initially cats improved clinically, but MST was only 106 days.[136] Although RT is likely to play a role in the treatment of this disease, new approaches are indicated.

Oral fibrosarcomas (FSAs) are unlikely to metastasize but can be difficult to control locally. Oral FSAs are less radiosensitive than AAs and SCCs, although tumor control probabilities ranging from 33% to 67% at 1 year have been reported.[137,138] In one study of oral FSAs treated with RT, the PFS at 1 year and 3 years were 76% and 55%, respectively.[130] Surgical cytoreduction improves the probability of tumor control by RT.[137] This should be taken into consideration during surgical planning with a focus on removing gross disease and obtaining a tension-free closure. An MST of 540 days was reported in eight dogs with oral sarcomas treated with surgery followed by RT.[139] In tumors too large to be surgically resected to a subclinical level, RT alone is indicated; the probability of long-term tumor control is low with conventional RT, but new strategies using IMRT or SRT are currently being evaluated.

Malignant melanoma (MM) is the most common oral tumor in dogs and is associated with a high rate of regional and distant metastasis.[140] Higher doses of radiation per fraction (4 Gy and above) are believed to improve response rates for melanoma.[111] In one study, 38 dogs with nonmetastatic oral MM were treated with 48 Gy delivered in 4 Gy fractions on a Monday-Wednesday-Friday schedule.[130] The overall median PFS was 17.8 months, and the median PFS was 38.0 months, 11.7 months, and 12.0 months for dogs T1, T2, and T3 tumors, respectively. In a retrospective study of 140 dogs, most of which had regional or distant metastasis at presentation,[141] coarsely fractionated (9–10 Gy weekly

fractions to a total dose of 30–36 Gy) and conventionally fractionated (2–4 Gy fractions to as high as 45 Gy or more) protocols were used with or without surgery or chemotherapy. The median times to first event and MST were 5 and 7 months, respectively. Tumor recurrence was the first event in only 27% of the dogs, whereas new metastases or death accounted for the remaining 63%. In a retrospective study of 39 dogs with incompletely resected oral MM treated with coarsely fractionated RT plus platinum-based chemotherapy, the MST was 363 days.[142] The dogs received six weekly fractions of 6 Gy, with cisplatin (10–30 mg/m^2) or carboplatin (90 mg/m^2) administered 1 hour before irradiation. The local recurrence rate was 15% and the median time to metastasis was 311 days.[142] Five cats with oral MM were treated with 8 Gy delivered on days 0, 7, and 21. All died from progressive disease and the MST was 146 days.[143]

Radiation Considerations

Reproducibility of treatment fields for oral tumors can be aided by positioning and immobilization devices. Depending on the size and location of the target, IMRT allows better sparing of surrounding normal structures such as the eyes and salivary glands. MM may have a low α/β ratio, making them more responsive to coarsely fractionated protocols.[144]

Treatment-Related Toxicities

Treatment toxicity depends on the time-dose-fraction size of the protocol and the specific normal structures in the treatment field. For oral tumors, this can include the skin, nasal cavity, and eyes. The major acute complications associated with RT of the oral cavity are mucositis and skin effects. Mucositis always occurs to some degree in patients that have received irradiation to the oral cavity, pharynx, and/or esophagus. Mucositis typically begins during the second week of therapy and reaches a maximum severity during or shortly after the last week of therapy. Clinical signs include thickened saliva and tenderness of the mouth. Patients may be reluctant to eat or drink and require supportive care. Low-salt foods are less irritating to the oral mucosa than regular commercial diets. Infrequently, placement of a gastrostomy or esophagostomy tube may be necessary to facilitate feeding. Oral mucositis should subside within 2 weeks after therapy. The extent of skin effects will vary based on the field size and location. Erythema, hair loss, dry and moist desquamation, and swelling of lips can occur. The effects may start late in the course of treatment or shortly after completion of treatment. Blotting the skin gently with moist towels can help keep the area clean. Never rub or scrub the area, and an E-collar may be useful to keep the patient from rubbing or pawing at the area. Pain management is important for both mucositis and skin effects.

Rarely, animals treated with chemotherapy subsequent to a course of RT can develop a return of radiation side effects such as mucositis or moist desquamation of the skin, a phenomenon known as radiation recall.[145] Radiation recall is a poorly understood phenomenon that can occur with many different antineoplastic drugs, although it is most commonly associated with doxorubicin, taxanes, and gemcitabine.[145] It is drug specific for individual patients and rechallenge does not necessarily induce the reaction.[145]

Late complications of radiation specific to the oral cavity include osteoradionecrosis, xerostomia, and oronasal fistula development. Xerostomia (dryness of the mouth due to salivary dysfunction) is a common complication in human patients undergoing RT of the head and neck region[146,147]; however, clinically significant xerostomia is not commonly recognized in animals. IMRT technology should provide improved sparing of salivary glands and in human patients has resulted in significantly lower proportion of patients with grade II or worse xerostomia.[147] Osteoradionecrosis, or development of nonvital bone susceptible to pathologic fracture after RT, is an uncommon complication that can occur in any bone in a radiation field, typically years after treatment. The mandible is the most susceptible bone to osteoradionecrosis but, as with most late effects, the risk can be minimized by administering radiation in lower doses per fraction.[148] The role of SRT for the treatment of oral tumors is unclear.[149] Human patients who have failed traditional RT regimens are sometimes treated with salvage SRT.[149]

Nasal Tumors

Nasal tumors (see Chapter 24, Section B) in dogs are difficult to control. Surgery, cryosurgery, or immunotherapy alone do not appear to improve survival over no treatment.[150–153] RT provides the best reported tumor control for canine nasal tumors and likely needs to be part of any curative-intent treatment regimen.

Efficacy of Treatment

RT has long been the standard of care for nasal and sinonasal tumors. The location is not generally amenable to complete surgical resection, and although early reports of orthovoltage radiation pulse surgery showed improved outcomes,[154,155] most reports combining RT and surgery have not demonstrated therapeutic gain compared with radiation alone.[156,157] Interestingly, over the past 20 years, advancements in treatment planning technology from point calculations to 2D, 2.5D, and 3D-CRT technologies have not been associated with improved tumor control or survival. Megavoltage RT alone planned with 3D-CRT has been reported to provide an MST of approximately 1 year.[158–160] Histologic subpopulations may be prognostically significant; however, most publications are hampered by inadequate patient numbers. Cribriform erosion has been associated with a poor prognosis with fractionated RT protocols.[161,162]

Two publications have evaluated outcome in dogs with nasal tumors treated with IMRT.[122,123] Thirty-one dogs treated with IMRT were compared with 36 historical controls treated with the same prescription using 2D treatment planning. The MSTs were 420 days and 410 days, respectively.[123] In another report, 12 dogs treated with IMRT to a dose commonly used for 2D or 3D-CRT planning had an MST of 446 days.[122] Patient numbers in both studies were low, and there was no stratification for prognostic factors. Although definitive conclusions cannot be made regarding tumor control, the decrease in acute effects to the region in both studies was profound with minimal grade II and III cutaneous and mucosal toxicity noted. Although the ipsilateral eye could not be spared, minimal side effects to the contralateral eye were noted.[123]

SRT has been investigated in 29 dogs with solid nasal tumors with three daily fractions of 10 Gy.[10] Clinical signs improved in all dogs. Acute effects were minimal; however, approximately 10% of dogs developed significant oronasal or nasocutaneous fistulas. The MST was 586 days with 69% and 22% alive 1 and 2 years post-SRT, respectively.[9] Developing patient selection criteria and modifying normal tissue radiation constraints should be a priority, so late tissue effects can be minimized.

Lymphoproliferative nasal tumors in cats respond well and durably to RT (these are addressed later in the chapter in the section on lymphoma; also see Chapter 33, Section B).[163] Carcinomas

VetBooks.ir

and sarcomas in cats respond comparably to nasal tumors in dogs: 48 Gy administered in 4 Gy fractions over 4 weeks resulted in a 1- and 2-year survival rates of 44.3% and 16.6%, respectively.[164] The histologic type and clinical stage of the tumor did not affect the prognosis.

Nine dogs with recurrent nasal tumors previously treated with 3D-CRT (median 50 Gy) were reirradiated.[165] The overall MST from initial treatment was 31 months with an increased incidence of late effects. Retreatment becomes a more viable option with new modalities, such as IMRT and SRT, that can better spare local normal tissues.

The response to feline nasal planum SCC is affected by the tumor stage.[166] Cats with T1 tumors had 1- and 5-year survival rates of 85% and 56%, respectively, and the mean ST was 53 months (the median was not reached). However, larger, more invasive tumors showed a less favorable response when treated with 40 Gy in 4 Gy fractions over 3.5 weeks.[166] Tumor control should be improved by reducing the dose per fraction and increasing the total dose. For small, superficial SCC lesions of the nasal planum in cats, strontium (Sr)-90 plesiotherapy is a viable option. Because Sr-90 emits a low-energy β-particle, very high doses can be administered to the surface of a lesion without unacceptable complications or damage to underlying tissue. In one study, 49 cats with SCC of the nasal planum were administered a median of 128 Gy in a single fraction with a complete response rate of 88% and median PFI of 1710 days.[167] Larger, invasive SCC lesions are usually not amenable to treatment with Sr-90.[167]

Radiation Considerations

Canine and feline sinonasal tumors are challenging to treat with radiation because they are anatomically complex with frequent involvement of the nasal sinuses, cribriform plate, and nasopharynx. The geometry of the nasal cavity is problematic, because the target is larger caudally than rostrally, making it difficult to achieve even dose distribution. The dose sculpting benefits of inverse treatment planning used for IMRT and SRT make these modalities the treatment of choice for nasal tumors. Regardless of radiation modality used, clients should be advised of the potential for persistent nasal symptoms and long-term radiation effects.

Treatment-Related Toxicities

After treatment with 3D-CRT, radiation toxicities of nasal tumors are similar to those described previously for the oral cavity, with mucositis affecting the oral cavity and tongue, and dry to moist desquamation of skin. Regardless of radiation modality used, the nasal cavity will never be completely normal after turbinate destruction from the tumor and from radiation damage. In dry environments, room humidifiers can make patients more comfortable, and intermittent antibiotics may be necessary to treat periodic bouts of rhinitis. Fungal infections after the treatment of nasal tumors has also been reported.[9] Long-term use of pentoxifylline and vitamin E are recommended to help mitigate radiation effects in patients treated with SRT.[168] Nasal discharge, sneezing, and epistaxis may indicate tumor recurrence and can be challenging to differentiate from posttreatment rhinitis. Deep nasal culture and sensitivity may help direct antibiotic treatment. If there is no durable clinical response from antibiotic treatment, then a CT is recommended to evaluate for recurrence.

Ocular radiation complications are extremely common when 3D-CRT planning is used because of the proximity of the nasal cavity and frontal sinus to the orbit.[169] Effects to the eyes are dose related and vary in severity.[170] Acute effects include blepharitis, blepharospasm, conjunctivitis, and keratoconjunctivitis sicca (KCS).[169,170] KCS may be temporary or permanent, depending on the dose administered and the sensitivity of the patient.[169,171] KCS is treated with artificial tears and steroids to prevent corneal ulceration. If corneal ulceration is present, healing may be delayed as a result of radiation damage to the corneal stem cells.[172] Late effects include vascular changes, which may have subtle effects on vision but in most cases do not result in blindness. Radiation-induced cataracts may occur and the latent period is related to dose.[173] As with other cataracts, these can be removed with phacoemulsification. When treating nasal or facial tumors, it may be necessary for the eye to receive the full treatment dose. At doses above 40 Gy, degenerative angiopathy of retinal vessels can progress over 2 years and result in retinal degeneration.[172] Optic nerve axonal degeneration has been reported to occur secondary to the retinal changes.[172] IMRT and SRT allow greater sparing of ocular tissues, resulting in diminished acute and late toxicities.[9,123]

Tumors in the Cranial Vault

Brain tumors can be treated successfully with RT and/or surgery (see Chapter 31). In the treatment of brain tumors, surgery may be indicated to relieve life-threatening clinical signs. Although appropriate studies are still needed, reported STs after radiation for brain tumors in dogs with less severe neurologic signs are frequently comparable to surgery alone.[174] Adjuvant RT is indicated in patients with incomplete surgical resection; RT alone should be performed in dogs and cats with cancer at surgically inaccessible sites or in locations where surgical morbidity is high.

Efficacy of Treatment

Published STs of canine brain tumors treated with RT compare favorably to surgery, although directly comparable data is lacking and combinations of surgery and RT may be superior to either modality alone. There is little published information on irradiation of nonpituitary feline brain tumors, because most feline meningiomas are effectively treated surgically.[175] Nevertheless, radiation outcomes for cats appear comparable to canine brain tumors, and RT should be considered when the tumor location is not amenable to surgical resection. In one study, 46 dogs with brain tumors associated with neurologic disease were treated with RT alone[176]; the MST was 23.3 months with 1- and 2-year survival rates of 69% and 47%, respectively. No prognostic clinical factors were identified. The outcome in this study was superior to those from previous reports in which the MST was about 1 year.[177–179] Differences may be due to improved treatment planning capabilities, which was supported by a study of 31 dogs treated with 3D-CRT that had an MST of 19 months.[180] In another study also involving 31 dogs with meningioma, postoperative RT improved the MST from 7 months with surgery alone to 16.5 months with surgery followed by RT.[181]

Thirty dogs with image-based diagnoses of intracranial meningiomas were treated with SRT, with most receiving 24 Gy in three fractions. The overall MST for any cause of death was 561 days and treatment was well tolerated.[8] In another study, 39 dogs with image-based meningiomas were treated with stereotactic volume-modulated arc RT (VMAT) receiving 33 Gy in five fractions. The 2-year overall survival rate was 74.3% and treatment was well tolerated.[182]

Forty-two dogs with presumed gliomas were treated with VMAT alone or in combination with temozolomide. The MSTs for RT alone and RT and temozolomide were 383 days and 420

days, respectively; there was no significant difference between the groups. A control arm of 30 dogs with glial tumors was treated medically and their MST was 94 days.[183]

Pituitary tumors in dogs and cats generally are responsive to radiation, and surgical access is limited. Dogs with pituitary tumors treated with fractionated RT have MSTs varying between 1 and 2 years.[184,185] A study comparing 19 dogs with pituitary tumors receiving RT (48 Gy in 16 daily fractions of 3 Gy) to untreated dogs found 1-, 2-, and 3-year survival rates of 93%, 87%, and 55% in the RT group and 45%, 32%, and 25% in the unirradiated group, respectively.[186] Fractionated pituitary irradiation in dogs is more effective at delaying tumor growth than in controlling adrenocorticotropic hormone (ACTH) secretion.[186,187] Eucortisolism is seen in some patients after RT; however, pre-ACTH and post-ACTH cortisol levels should be monitored at regular intervals so that medications can be modified, if indicated.

Cats seem to have marked clinical improvement of associated endocrinopathies when treated with RT.[188] In one study, 53 cats with functional pituitary adenomas associated with feline acromegaly were treated with SRT.[98] Diagnosis was based on history, physical examination, laboratory results, and cross-sectional imaging of the pituitary region. The overall MST was 1072 days. Of the 41 cats where insulin information was available, 95% experienced a decrease in required insulin dose, with 32% achieving diabetic remission. Hypothyroidism developed in 14% of treated cats. Interestingly, three cats with no pituitary enlargement, but who met other criteria, were treated and responded.[98] Previous studies using fractionated RT showed durable response to neurologic disease but limited endocrine responses (Chapter 26).[188,189]

Two recent manuscripts explored the treatment of trigeminal nerve sheath tumors with SRT, with MSTs ranging from 441 to 745 days.[190,191] In both studies, all tumors had an intracranial component. Extension into the cranial nerve can involve one to three of the branches, and administering dose to involved branches could be important for tumor control.[191]

Radiation Considerations

The integration of 3-D imaging, patient positioning devices, and advanced treatment planning techniques have the potential to improve tumor targeting and sparing of normal brain tissue. For many brain tumors, IMRT will not provide an improved dose distribution compared with 3D-CRT; however, dose sculpting may be beneficial for cranial nerve tumors. An additional consideration in patients undergoing RT for a brain tumor is the anesthetic risk associated with increased intracranial pressure or brainstem disease; an appropriate anesthetic regimen should be selected to minimize the risk of complications. Specifically, patients should be ventilated while under anesthesia to decrease blood P_{CO_2}, and anesthetic agents that decrease (or at least do not increase) intracranial pressure should be selected. SRT limits the number of anesthetic episodes, which may be beneficial in unstable patients.

Treatment-Related Toxicities

For most brain tumors, acute effects to the skin can be avoided with megavoltage RT. Occasionally, ocular and otic side effects or mucositis to the caudal oral cavity may be seen if these structures are in or adjacent to the treatment field. The radiation tolerance is lower when the entire brain is treated; this limits prescription of a dose that is adequate for tumor control but still has an acceptable probability of late effects. The radiation tolerance of brain and spinal tissues is generally considered to be less than that of other commonly treated tissues, and volume may be an important factor for brain and spinal lesions. Early delayed effects can occur 1 to 3 months after treatment and may be due to transient demyelination or from edema associated with cytokine release from dying tumor cells. Animals with early delayed effects may have signs similar to or different from those at the initial presentation or they may be stuporous. Early delayed effects occur in up to 40% of humans undergoing brain RT; symptoms include headache, lethargy, and exacerbation of focal neurologic signs.[192] In animals, clinical signs often are transient, but response time can be slow. Early delayed effects are treated with the administration of systemic corticosteroids, and sometimes supportive care is required. MRI may show an apparent increase in tumor size and tumor enhancement during this time. Focal enhancement in a normal brain associated with edema and demyelination may also be present.[193] In a study of SRT for canine meningiomas, 37% of dogs showed mild-to-moderate exacerbation of neurologic signs 3 to 16 weeks after treatment.[8] Most dogs responded to systemic corticosteroids and supportive care, and dosimetric information relating to the toxicity helped establish dose constraints for the brain.[8]

Late effects probably occur in veterinary patients more often than identified. Late effects generally occur at least 6 months after treatment but can also occur years later. Brain necrosis is the most commonly identified effect. The probability of late brain effects depends on the total dose, fraction size, and the volume of brain irradiated. In a study of 83 dogs with brain masses treated with a hypofractionated protocol (38 Gy administered in five weekly fractions), brain necrosis was confirmed or suspected in 14% of dogs.[194] Signs are similar to those associated with early delayed effects, although the response to corticosteroids is limited. Clinically distinguishing between late effects and tumor recurrence can often be difficult. CT or MRI evaluation can be misleading. Not all brain tumors completely regress after treatment, therefore the presence of a mass does not always indicate a recurring tumor. A prudent course is to obtain a CT or MRI evaluation 6 months after treatment to serve as a reference if clinical signs develop in the future.

Superficial Tumors of the Trunk and Extremities

Many tumors involving the trunk or extremities are amenable to treatment by RT. Combining RT and surgery has the potential to enhance tumor control and improve the functional outcome over either modality alone. For many invasive tumors, conservative surgery with adjuvant RT can provide a viable alternative to radical surgery. For tumors in nonresectable locations, SRT alone may provide a good outcome depending on tumor type and volume. The surgeon and radiation oncologist should consult before therapeutic intervention is started to develop an overall treatment approach.

Soft tissue sarcomas (STSs) are common tumors arising in a wide range of locations, most commonly arising as subcutaneous masses. Hemangiopericytomas, FSAs, neurofibrosarcomas, myxosarcomas, and nerve sheath tumors are classified together as STSs because of their similar biologic behavior (see Chapter 22). Metastases are uncommon with grade I and grade II STSs; therefore local tumor control is the primary concern, whereas grade III tumors have more aggressive metastatic potential. STSs are locally invasive, and tumor cells may extend far beyond the bulk of the tumor. Surgery alone can result in long-term tumor control if the tumor can be excised completely.[195] When wide excision is not feasible, recurrence rates after narrow excision are reported to vary

VetBooks.ir

from <10% to >70% depending on histologic grade, completeness of excision, tumor size, tumor invasiveness, and tumor location. Accordingly, risk assessment for local recurrence and the potential recommendation for adjuvant therapy requires consideration of all of these factors. Based on these risks, combining RT and surgery may be beneficial in cases where complete excision may not be possible. RT can be administered first with the hope of converting an inoperable tumor into an operable one. This approach has the benefit of reducing the volume of normal tissues irradiated. More commonly, surgical excision is performed first as a cytoreductive procedure and then followed by RT to eliminate the residual subclinical disease. In one study, 48 dogs with STS were treated with surgical cytoreduction followed by RT; eight dogs (16%) developed tumor recurrence, and the 5-year survival rate was 78%.[196] In another study of 38 dogs with STS of the body and extremities, treatment with surgery followed by RT resulted in an MST of 2270 days.[139] Recent publications indicate that many low-grade STSs may not recur despite incomplete excision[197–199]; however, the level of surgical training can affect outcome.[200]

STS can be treated with RT alone; however, tumor control is not as durable as with a combination of RT and surgery.[137] RT alone is useful for tumors near the paw/pads, where surgical options are limited, and in tumors wrapping around the limbs. Pads in the radiation field initially may slough; however, if appropriate fractionation schemes are used, the pads regrow and can function normally.

Injection site sarcomas (ISSs) are a significant problem in cats (see Chapter 22). These tumors are challenging to control locally and seem unresponsive to aggressive RT or conservative surgery alone. In one study, 33 cats with histologically confirmed ISS were treated with RT followed by surgery.[201] The median DFI and MST were 398 and 600 days, respectively. In another study, 25 cats with subclinical disease after surgery were treated with RT alone (57 Gy delivered in 3 Gy fractions) and, in some cases, with adjuvant chemotherapy.[202] The overall MST was 701 days. Local recurrence was observed in 28.6% of cats. In cats with local recurrence, one tumor developed outside the treatment field, and the remaining tumors recurred in the radiation field. Similar findings were reported in 78 cats treated with surgical cytoreduction followed by RT.[203] In this study, cats that underwent only one surgery before RT had a lower recurrence rate than cats that had more than one surgery. The ST and DFI shortened as the time between surgery and the start of RT lengthened. In a study of 79 cats treated with either pre- or postoperative RT, PCV >25% was associated with better outcome (MST 760 days) than in cats with PCV <25% (MST 306 days).[204]

Cats with surgically nonresectable disease present a greater challenge. Escalation of the radiation dose by delivering the dose in smaller fractions is probably necessary for these patients. IMRT or SRT may be beneficial for obtaining adequate dose to the tumor, because appropriate sparing of the lungs, viscera, and spinal cord is critical in these patients. SRT was used to treat 11 cats with nonresectable ISSs. Acute radiation effects were minimal and cats tolerated the treatment well; however, this modality should be considered palliative as the overall MST was 301 days.[205]

Cutaneous mast cell tumors (MCTs) can be treated successfully with RT (see Chapter 21). The obvious advantage is that greater margins may be obtained with RT than with surgery. The probability of control may be improved if surgical cytoreduction is performed first. In a study of 37 dogs with grade II MCTs treated with cytoreduction and RT, tumor control at 1 and 2 years exceeded 90%.[206] In 56 dogs with incompletely resected MCTs, the median DFI was 32.7 months.[207] Controversy exists regarding whether the addition of RT is necessary after incomplete excision of MCT due to moderate recurrence rates; however, a study of 64 dogs showed lower recurrence rates (8% vs. 38%) and significantly longer MSTs (2930 days vs. 710 days) in dogs receiving adjuvant RT compared with dogs not receiving RT.[208]

RT also is indicated for cutaneous MCT with regional LN metastasis. In one study, 19 dogs with MCT and regional node involvement were treated with surgical cytoreduction of the primary site, radiation to the primary tumor and regional node, and prednisone.[209] The median disease-free ST was 1240 days. In a study of 21 dogs with grade II, stage II MCTs treated with surgical resection and adjuvant chemotherapy, the addition of RT for locoregional control resulted in a longer MST (2056 days) than dogs not treated with adjuvant RT (1103 days).[210] Palliative RT is commonly used to treat symptomatic locoregional MCT in dogs when systemic spread has occurred.

Radiation Considerations

Many tumors of the limbs and trunk extend very close to the skin surface. Point calculations or 3D-CRT modalities are commonly and successfully used. Application of an appropriate thickness of a bolus material over the skin is frequently needed when treating with megavoltage photons to avoid underdosing the superficial region. When an extremity is in a radiation field, a 1- to 2-cm strip of tissue should be shielded to avoid the risk of lymphedema, which can present as painful swelling of the distal limb. For microscopic or macroscopic ISSs in cats, radiation planning is challenging with 3D-CRT. Inverse planning allows better sculpting around body curvatures and allows a higher dose to be delivered to the target structures.

Treatment-Related Toxicities

When treating superficial tumors, early effects to the skin are expected and are restricted to the radiation field. The severity of these effects are dose related. Depilation is common and in some cases may be permanent. The hair may not return for several months and varies in relation to the dose administered to the skin and the individual patient's sensitivity. Damage to the melanocytes may result in hypopigmentation or hyperpigmentation of the skin and/or alteration of the coat color when regrowth occurs, often resulting in whitish-gray fur (leukotrichia). Dry desquamation may accompany epilation; this generally does not cause any problem or discomfort for the patient and usually is not treated. Moist desquamation, which usually appears 3 to 5 weeks after the start of therapy, is associated with pruritus and pain, which can vary in severity. Self-mutilation exacerbates the problem and may lead to ulceration or necrosis. Pain management is an important part of the overall treatment plan. NSAIDs are usually the first line of therapy if there are no contraindications. Tramadol, amantadine, and gabapentin are often added to the regimen. Severe late effects to the skin are rare with fractionated RT but include fibrosis and necrosis.

Bone Tumors

Although OSAs are not considered highly radiation-responsive tumors, RT may be considered as part of a multimodality therapy when surgical excision is not an option (see Chapter 25). RT can be combined with chemotherapy and surgery for limb-sparing protocols.[211,212] SRT is currently being evaluated as a limb-sparing alternative. In one study, SRS was performed on 11 dogs

VetBooks.ir

with appendicular OSA[213]; although radiation dose varied and not all dogs received adjuvant chemotherapy, good limb function and tumor control were observed in some of the patients. A recent study of 46 dogs with OSA treated with SRT showed a median survival of 9.7 months, which is comparable to reports of amputation plus chemotherapy, but a high rate of pathologic fracture.[101]

Treatment of axial OSA has been particularly challenging because of the proximity to important normal tissue structures, particularly when treating vertebral tumors. In a retrospective study of multimodality therapy for axial OSAs, dogs that underwent curative-intent RT protocols had a longer duration of tumor control (265 days) than those treated with a palliative regimen (79 days).[214] SRT was delivered to nine dogs with primary or secondary vertebral OSA.[96] The protocols and doses varied based on proximity to spinal cord. Five of six dogs had improved pain control, but the overall MST was only 139 days.[191] As more information becomes available regarding dose constraints and optimal fractionation, RT may have value, but it should currently be considered a palliative procedure.

The mechanism of the amelioration of pain caused by bony neoplasia is not completely understood, but decreases in intratumoral pressure, local antiinflamatory effects, tumor cell apoptosis, and cytotoxicity to osteoclasts have been proposed.[215] Relief of pain may occur almost immediately or may be delayed, sometimes as long as 2 weeks after the start of RT. Human studies have indicated that a single large dose may be comparable or superior to multifraction protocols using more conventional doses per fraction.[216] In a recent study of 58 dogs, 8 Gy was administered on 2 consecutive days, providing onset of pain relief within 2 days in 91% of patients.[217] Commonly in veterinary medicine, 7 to 10 Gy fractions have been administered on days 0, 7, and 21.[218,219] In one study, 12 of 15 dogs with appendicular bone tumors treated with palliative RT had improved limb function, and the MST was 130 days.[219] In another study, dogs with appendicular OSA were given either three fractions of 10 Gy or two fractions of 8 Gy[118]; 74% of 95 dogs experienced pain relief for a median duration of 73 days. No difference in response was found between the two treatment groups. Sometimes localized pain recurs before metastatic disease becomes life limiting. Palliative RT can be readministered as long as the owners understand that continued administration of large doses per fraction eventually leads to late effects. Clearly, most palliative OSA RT protocols help relieve pain; the preference of the protocol chosen by the attending radiation oncologist will likely be based on the geographic location of the clients and the availability of staffing.

Radiation Considerations

RT is unlikely to have a substantial palliative effect if a displaced pathologic fracture from a bone tumor is already present. Additional monitoring during anesthesia recovery is recommended to prevent the patient from trying to stand prematurely. Nonslick flooring may be helpful in preventing injury to the affected limb while recovering from anesthesia.

Treatment-Related Toxicities

All dogs with bone tumors are at risk of developing pathologic fracture unless the affected limb is amputated. This risk may be increased with radiation therapy due to palliative benefit, resulting in increased weight-bearing load and other potential effects of radiation on bone maintenance. For limb sparing using SRT/SRS, patient selection is crucial. A study of 46 dogs treated with SRT for OSA had pathologic fracture rates of 27%, 56%, and 62% at 3, 6, and 9 months, respectively.[101] Area of bone involvement was prognostic for fracture as dogs with involvement of subchondral bone had a median time to fracture of 4.2 months versus 16.3 months in dogs without.[101] Occasional grade III acute and late skin toxicity was also seen in this study, particularly for tumors involving the radius.[101] Proximity of the tumor to the skin must be considered, particularly in locations such as the distal radius where minimal soft tissue exists between the bone and skin. Bisphosphonates at time of diagnosis or before SRT may be helpful for bone maintenance.[220,221] Prophylactic stabilization with a bone plate or interlocking nail has been investigated, but this was associated with high rates of severe complications.[222,223]

Lymphoma

RT can be important in the treatment of localized lymphoma, and it has an emerging role as an adjuvant therapy in the treatment of systemic lymphoma. Lymphocytes are exquisitely radiation sensitive[224] and may undergo apoptosis in addition to classic mitotic death after exposure to radiation.[225] Humans with non-Hodgkin lymphoma commonly receive combined modality treatment with RT and chemotherapy, primarily for stage I or stage II disease,[226] although this treatment may have a role in more advanced stages as well.[227] Combined modality treatment or RT alone is also beneficial in humans for primary lymphomas of bone, cutaneous B-cell lymphoma, and mycosis fungoides.[228–231]

In one study of 10 cats, extranodal lymphomas (nasal cavity, retrobulbar area, mediastinum, subcutaneous tissue, maxilla, and mandible) were treated with megavoltage RT with or without concurrent chemotherapy.[232] Complete responses were achieved in 80% of cats and partial responses in two cats. The median remission time for the cats that experienced complete responses was 114 weeks, and three cats were alive and disease free at 131 weeks. Three cats developed disease outside the radiation field, which suggests that adjuvant chemotherapy or extending the field for part of the treatment to include additional nodes may improve locoregional control.

RT has also been used to treat cutaneous lymphoma in dogs. RT of localized lymphoma has been reported to result in prolonged remission times.[233] Humans with cutaneous B-cell lymphoma are commonly treated with RT, which generally results in long-term control of disease. The extent of skin involvement and the presence of extracutaneous disease are prognostic.[231] Mycosis fungoides is sometimes treated with total skin electron irradiation in humans. As with cutaneous B-cell lymphoma, the stage of disease is prognostic, but human patients with disease confined to the skin may have prolonged remission times.

Half-body RT has been investigated as an adjuvant multicentric canine lymphoma. An 8 Gy dose to lymphoma cells reduces the surviving fraction to 0.005, which is much greater than the estimated cell kill from one cycle of chemotherapy.[224] In one study, RT was administered at the end of the chemotherapy protocol, whereas another sandwiched the RT after the first chemotherapy cycle.[234,235] Although the protocols were well tolerated, the additional expense was not justified by patient outcome.

Whole abdomen RT has also been used as a salvage technique for feline GI lymphoma.[117] In a study of 11 cats with relapsed or resistant alimentary lymphoma treated with 4 Gy fractions on 2 consecutive days, 10 cats had either partial or complete clinical remission. Acute effects associated with RT were minimal. The post-RT MST was 214 days.[117]

An emerging approach in the management of dogs with hematologic malignancies, such as lymphoma and leukemia, is

VetBooks.ir

total body irradiation (TBI) followed by either autologous or allogeneic transplantation of peripheral blood hematopoietic progenitor cells. After consolidation with a standard CHOP-based chemotherapy protocol, dogs are given a high-dose cyclophosphamide, followed 2 weeks later with progenitor cell mobilization using 5 days of recombinant human granulocyte colony-stimulating factor. Peripheral blood mononuclear cells are then harvested, and the CD34+ cells are enumerated, with the goal of obtaining >2 x 10^6/kg CD34+ cells. The next day, 10 to 12 Gy of TBI is administered over 2 days, and the harvested cells are immediately infused intravenously once RT is completed. In a toxicity study of 10 dogs, all dogs experienced grade IV neutropenia, lymphopenia, and thrombocytopenia.[236,237] Neutrophils recovered to at least 500/uL by day 12; however, thrombocytopenia often persisted for weeks. Using this treatment strategy, the median DFI and MST were 271 days and 463 days, respectively, for 24 dogs with high-grade B-cell lymphoma, with 33% of dogs living >2 years. When using the same protocol to treat 13 dogs with high-grade T-cell lymphoma in first remission, the median DFI and MST were 184 and 240 days, respectively, with 15% of dogs being long-term survivors.[237,238]

Other Tumors

RT is used for a variety of tumors in the thoracic and abdominal cavities. The principles of patient selection for RT with tumors in these regions are the same as for any other region. RT should be considered for any tumor that cannot be excised completely. In one study, dogs with thyroid carcinomas treated with 48 Gy delivered in 4 Gy fractions had PFS rates of 80% at 1 year and 72% at 3 years.[239] Thymomas are radiation responsive in human patients.[240] In a study of seven cats with thymoma treated with RT, the MST was close to 2 years (see Chapter 34, Section B).[241]

Eighteen dogs with primary disease of the urinary bladder (7), urethra (1), or prostate (10) were treated with IMRT assisted by image guidance to verify tumor position.[124] In all dogs, the radiation dose ranged from 54 to 58 Gy, delivered in 20 daily fractions. The majority of patients were treated with adjuvant chemotherapy and non-steroid antiinflammatory drugs (NSAIDs). Acute and late tissue toxicities were limited, and treatment was well tolerated. The overall MST was 654 days. Location of the primary tumor had no effect on either local tumor control or survival. A modified treatment protocol in a larger number of dogs resulted in increased radiation effects such as urinary incontinence (personal communication, B. Clerc-Renaud).

Perianal adenocarcinomas and apocrine gland anal sac adenocarcinomas (AGASACA) (see Chapter 23, Section H) can be difficult to control locally with surgery alone and may metastasize to the regional sublumbar LNs. RT may be used in the adjuvant setting to treat residual microscopic or gross locoregional disease. A study of 28 dogs with locoregionally advanced (stage IIIb) AGASAC treated with either surgery or RT showed a significantly longer median PFS for dogs treated with IMRT (14.7 months) compared with dogs treated surgically (6.0 months).[242] Perianal gland carcinomas are generally slow to disseminate systemically, so full-course RT or SRT of involved regional LNs may be warranted. Mucositis also can occur whenever any portion of the alimentary system is included in the RT field. Colitis is a common acute effect during RT for colorectal tumors. Severe large bowel diarrhea may be seen. Anusitis from irradiation is worsened by the diarrhea, making the patient quite uncomfortable. High-bulk diets and regional hygiene are recommended. Steroid enemas seem beneficial in some patients with colitis.[243] Late effects from RT to the pelvic region can occur, and these can be clinically significant.[75] This can be addressed by administering the radiation in smaller doses per fraction.[75]

Because of the rapid drop-off between tumor dose and regional tissues, SRT has introduced treatment to a much wider variety of tumors in the thorax and abdomen. Nine dogs with canine adrenocortical tumors with vascular invasion were treated with SRT (VMAT). The overall MST was 1030 days with minimal toxicity. The endocrine panels in two of three dogs with cortisol-secreting tumors normalized.[11] SRT has been used to treat extensive abdominal LN involvement in dogs with AGASACA, and this was well tolerated and provided durable palliation in three dogs (personal communication, Dr. Tiffany Martin). SRT was used to treat six dogs with heart base tumors.[244] The MST was not reached, and four dogs were progression free at 408, 451, 751, and 723 days posttreatment. Treatment-related complications included coughing, congestive heart failure, and tachyarrhythmias.[244] Palliative RT can be useful for tumors causing airway, bowel, or urinary tract obstruction or neurologic dysfunction. Mediastinal lymphoma often responds rapidly to irradiation. Relief from respiratory distress can be achieved within hours of a single dose of RT.

Cancer Immunotherapy

STEVEN DOW AND AMANDA GUTH

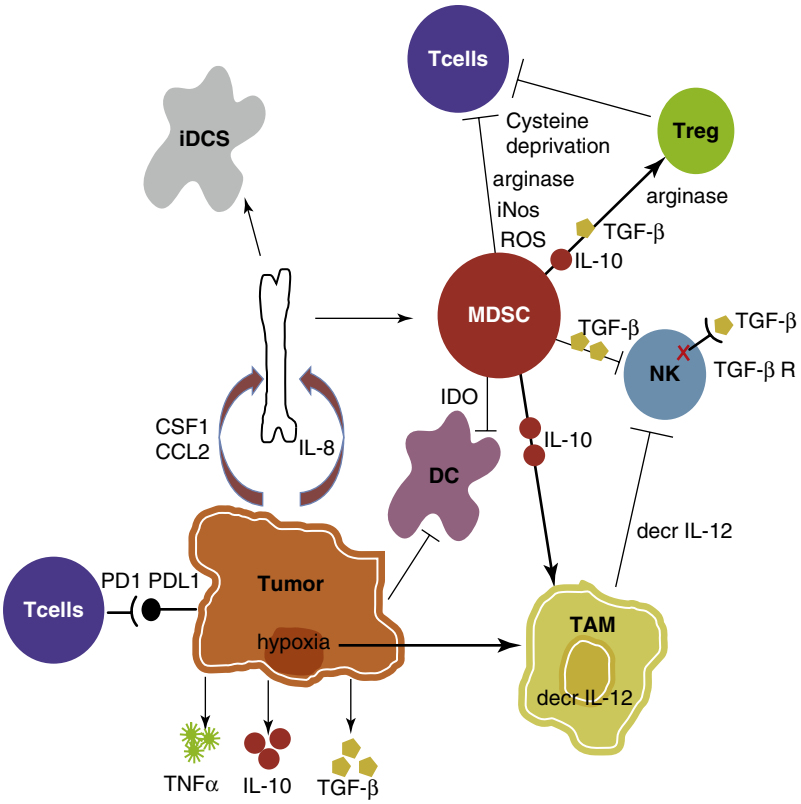
The main role of the immune system is recognition of "foreign" proteins. In the case of cancer, this role includes immune recognition of mutated or altered forms of self-proteins that arise during tumorigenesis (commonly referred to as "tumor antigens" [TAs]). However, it is now apparent that powerful regulatory cells and expression of certain molecules whose main functions are to prevent rampant, uncontrolled immune responses can also serve to block natural development of effective antitumor immune response. Therefore immunotherapy approaches in treatment of various cancers must take into account the ability to overcome these negative regulators of tumor immunity to be successful.

Under appropriate conditions, the immune system is capable of controlling cancer. For example, it is well established that the incidence of virally induced cancers is increased in immunosuppressed individuals. Further, cancer incidence increases in aged individuals and correlates with the progression of immunesenescence (aging and exhaustion of the immune response) that is thought to reduce immunosurveillance of cancer, a topic discussed in the text that follows. Moreover, in some cases, spontaneous remission of tumors is observed without any therapeutic intervention, most likely attributed to a successful immune response. Biologically, tumor-specific T cells are observed in the tumor tissue and tumor-draining lymph nodes, providing evidence that these cells have encountered and recognized the tumor cells as foreign. Finally, in some cases, paraneoplastic autoimmunity develops, suggesting that the antitumor immune response has somehow gone unchecked by regulatory cells.

Recently the field of immunotherapy took an exciting twist with the development in human medicine of therapeutic antibodies designed to target immune suppressive molecules (checkpoint molecules) and/or their ligands expressed on T cells and antigen-presenting cells, such as programmed death molecule-1 (PD-1) and cytotoxic T-lymphocyte antigen-4 (CTLA-4). By using antibodies to block negative signaling by certain checkpoint molecules such as PD-1 and CTLA-4, remarkable, and durable, antitumor responses have been observed in a significant, but minority, subset of patients with advanced tumors such as melanoma, renal cell carcinoma, and non–small cell lung cancer.[1–5] The development of checkpoint targeted immunotherapies has reignited the field of immunotherapy for cancer, and similar antibodies for treatment of cancer in dogs are under development by several different groups, including ours.

Improving knowledge of the immune system and how it is regulated will increase our ability to design better immunotherapies. In addition, immunotherapy has the potential to work in conjunction with chemotherapies, radiation therapy, and surgery. This chapter will first discuss the role of the immune system in regulating tumor development, then the various classes of immunotherapies both currently in use and those under investigation. The biological basis for the therapies, their use in human and companion animals, and their successes and limitations will be discussed.

Immune System Control of Tumor Development and Growth



Immune Surveillance of Cancer

Forty years ago, Thomas and Burnet, while studying how lymphocytes could respond to newly formed antigens on transformed cells, put forth the concept that the immune system could actively respond to and eliminate neoplastic cells, an idea known as immune surveillance.[6] In contrast, later studies showed that genetically manipulated immunodeficient (athymic) mice did not demonstrate an increased incidence of spontaneously or carcinogen-induced cancer.[7,8] Such observations led to the immune surveillance concept falling out of favor.

Since the development of more sensitive and sophisticated technologies, many of the ideas behind the concept of the immune surveillance hypothesis are now again accepted, and currently, this modification of the original hypothesis is referred to as the immunoediting hypothesis,[9] which consists of three phases: (1) "elimination"—removal of the immunogenic tumor cells by the immune system; however, less immunogenic cells can survive; (2) "equilibrium"—tumor growth and immune destruction are equal; and (3) "escape"—tumor growth ensues due to decreased immunogenicity, immune suppression, and rapid tumor cell growth.[9] However, despite recent data, a controversy still remains around the immune surveillance hypothesis, discussed in a review by Schreiber et al.[9]

Mechanisms of Immune Evasion by Tumors

Given the fact that cancer can develop in immunocompetent individuals, clearly tumor cells are able to avoid recognition by the immune system.[10] This is accomplished by various mechanisms discussed in the text that follows, which involve both changes in the tumor cells themselves and ways in which the tumor and the tumor stromal environment can manipulate the immune system and prevent antitumor immunity. These mechanisms of immune evasion pose a significant challenge to the development of effective immunotherapies. Fig. 14.1 demonstrates some of these key mechanisms.

• **Fig. 14.1** Mechanisms of tumor cell evasion via hijacking the immune system. *DC,* Dendritic cell; *iDC,* immature dendritic cell; *MDSC*, myeloid-derived suppressor cell; *TAM*, tumor-associated macrophage; *Treg*, regulatory T-cell.

Failure of Tumor Cells to Activate the Immune System

One of the most exciting achievements in human cancer therapy and immunotherapy has been development of monoclonal antibodies (mAbs) that either block or activate signaling through so-called checkpoint molecules.[11–14] Checkpoint molecules are expressed primarily by T cells, and are divided into two classes, including those that negatively regulate T cells (coinhibitory checkpoint molecules) and those that stimulate T cells (costimulatory checkpoint molecules). At present, there are at least 16 identified checkpoint molecules, which include eight coinhibitory receptors (PD-1, CTLA-4, TIM-3, VISTA, BTLA, B7-H3, B7-H4, and LAG3) and eight costimulatory receptors (CD28, OX40, GITR, ICOS, CD137, CD27, CD40L, and CD122).[15] All of these molecules are potential targets for tumor immunotherapy using antibodies that either activate (costimulatory checkpoint molecules) or inhibit (coinhibitory molecules) signaling. These checkpoint molecules have been evaluated as targets for tumor immunotherapy in rodent models, and most have also been evaluated in human clinical trials.[1–5]At present, PD-1 (and its ligand PD-L1) and CTLA-4 antibodies have been approved for treatment of cancer in humans. Of the costimulatory checkpoint molecule targeted therapeutics, antibodies targeting OX40 and GITR are the most promising and furthest advanced in human trials.[16–18]

In particular, the PD-1/PD-L1 axis has been targeted to reverse immunosuppression in cancer.[11,12,19,20] PD-1 and CTLA-4 are expressed primarily on T cells and NK cells, whereas PD-L1 is expressed by myeloid cells (monocytes, macrophages, and dendritic cells) and by certain tumor cells.[21–23] We and others have reported recently that some tumors in dogs express PD-L1, and we have also shown that macrophages in dogs express PD-L1.[24] We also demonstrated that PD-L1 is regulated by T cell cytokines in dogs.[24] Several new monoclonal antibody therapeutics targeting checkpoint molecules have been approved, including Yervoy (Ipilimumab) targeting CTLA-4 and Keytruda (pembrolizumab) and Opdivo (nivolumab) targeting PD-1, for treatment of four different cancers (melanoma, head and neck cancer, bladder cancer, and Hodgkin lymphoma). In addition, pembrolizumab has recently received expanded approval for treatment of any cancer with high levels of microsatellite instability, which is associated with generation of neoantigens recognized by tumor-infiltrating T cells. An antibody therapeutic targeting PD-L1 (Tecentriq, atezolizumab) was also recently approved in humans. Responses in patients with advanced, heavily pretreated tumors to checkpoint targeted therapies are reported in approximately 20% of patients, and many of these responses are durable and in some cases complete.[25]

Currently, similar therapies are not yet available for veterinary patients. Due to target–antigen specificity, the Food and Drug Administration (FDA)-approved antibodies do not cross-react with canine antigens and the constant domain portion of the antibodies is specific for humans (aka humanized antibodies). However, there is growing interest in developing similar antibodies in a canonized form for use in veterinary medicine. For example, we reported recently the target specificity and functional properties of canine specific PD-1 targeted antibodies.[26] In addition, a clinical trial evaluating a canine version of this antibody is currently in progress in dogs with cancer. Results of the first trial of a canine chimeric antibody targeting canine PD-L1 were also reported recently.[27] Development of checkpoint molecule targeted therapies for dogs is likely to continue rapidly and to eventually exert a tremendous effect on veterinary oncology.

VetBooks.ir

Tumors also can express other immune suppressive molecules that work in modulating the tumor microenvironment. An example would be CD73, an ecto-5′-nucleotidase that catalyzes the breakdown of AMP to the adenosine. When expressed on tumors, this creates a local microenvironment rich in adenosine, which is immunosuppressive.[28] Indoleamine deoxygenase is another highly immune suppressive molecule expressed locally by tumors and tumor-infiltrating myeloid cells.[29,30]

Lastly, tumor cells are also capable of avoiding immune elimination by failing to be recognized by the immune system in the first place. For example, some tumor cells can down-modulate major histocompatibility complex (MHC) surface expression to escape recognition by T cells. MHC Class I expression can be lost on tumor cells due to changes in protein synthesis, structure, or allelic loss.[31,32] Moreover, defects in antigen processing and presentation can occur that can also lead to decreased MHC expression.[31,32] A decrease in MHC class II expression is also observed in certain human hematopoietic cancers, although it should be noted that most tumors are normally MHC class II negative.[33,34] Reduced expression of MHC class II has been recently correlated with poor outcome in dogs with B cell lymphoma.[35] Thus tumor cells themselves can actively and directly suppress antitumor T cell responses through such mechanisms as decreased expression of MHC molecules and increased expression of inhibitory molecules.

Active Immune Suppression by Myeloid-Derived Suppressor Cells

A population of cells in the tumor microenvironment that plays a major role in tumor immunosuppression is myeloid-derived suppressor cells (MDSCs). These cells consist of immature monocytes and granulocytes released from the bone marrow into the blood in response to sustained inflammation, including cancer.[36–44] Sometimes included in the functional description of this group of cells are tumor-associated macrophages (TAMs), which have the same ability, and use similar mechanisms as MDSCs, to induce potent tumor immunosuppression.[45,46] Numerous studies demonstrate increased numbers of MDSCs in humans with cancer[47–49] and in mouse cancer models.[40,50] Furthermore, it has been shown that the presence of these cells correlates with clinical disease stage and metastatic tumor burden in humans with solid tumors.[48] MDSCs are released from the bone marrow in response to cytokines released in inflammation, including granulocyte-macrophage colony stimulating factor (GM-CSF) and interleukin-3 (IL-3).[51] MDSCs can be recruited to the tumor microenvironment by multiple chemokines, many of which are produced by the tumor during times of hypoxia and are regulated by hypoxia-inducible factor 1α (HIF-1α) production.[45,52–60] Once within the tumor microenvironment (TME), MDSCs differentiate into macrophages or neutrophils and actively suppress the local antitumor immune responses and promote tumor invasion and metastasis via the production of matrix metalloproteinases (MMPs).[43,61] Moreover, TAMs stimulate tumor angiogenesis and promote metastasis.[45] Of note, there is still no clear consensus on how to identify MDSC in humans, mice, or dogs, thus making it more difficult to clearly define the role that MDSCs play in cancer.

The ability of MDSCs to suppress the antitumor response is the subject of many recent studies.[42,62,63] Numerous mechanisms of suppression have been reported and MDSCs have the ability to suppress not only T cells, but also natural killer (NK) cells and DCs. They are also able to potentiate T regulatory cells (Tregs, discussed in the text that follows) and differentiate into TAMs in the tumor (see Fig. 14.1). Current known mechanisms of immune suppression by MDSCs include suppression of T cells through production of inducible nitric oxide species (iNOS), reactive oxygen species (ROS), arginase, and cysteine deprivation.[42] MDSCs can produce transforming growth factor-beta(TGF-β) and IL-10, which stimulate Tregs and TAMs, and MDSC can cause down-regulation of the IL-12 production by TAMs, a cytokine involved in T-cell activation.[62] MDSCs cause NK cell anergy (lack of function) also by this decreased IL-12 production and through membrane-bound TGF-β.[62,63] Thus given the ability of these cells to use multiple pathways to induce tumor immunosuppression, the development of effective immunotherapies that can target these cells and either eliminate them or lead to their maturation, rather than ones that target specific pathways of suppression, is critical for that therapy's success.

Induction of Regulatory T Cells by Tumors

Numbers of regulatory T cells (Tregs) are expanded in cancer patients, in tumor tissues, tumor-draining lymph nodes, bone marrow, and blood.[64–66] These cells are phenotypically defined by surface expression of CD4 and CD25 but are most specifically identified by the intracellular transcription factor, forkhead box P3 (FoxP3).[67,68] Other surface markers used to identify Tregs include CTLA-4, GITR, Lag3, and folate receptor 4 (FR-4).[69–72] Tregs are capable of directly suppressing tumor-specific CD4+ and CD8+ T cells and NK cells and are enriched in the tumor microenvironment by conversion of CD4 T cells to Tregs by locally produced factors such as IL-6 and TGF-β.[73–76] Proliferation of tumor-specific Tregs occurs after antigen recognition, or recruitment of these cells via chemokine signaling (i.e., CCR5). [77] Recent work has also suggested a role for the chemokine CCL-1 in specifically converting T cells to Tregs and inducing their suppressive nature.[78]

Many studies demonstrate that increased numbers of Treg cells are correlated with a poor prognosis.[64,79–81] In addition, Tregs present in metastatic lymph nodes inhibit the ability of tumor-infiltrating lymphocytes to mount an effective antitumor response.[82] Work in the author's laboratory demonstrated that canine Treg cells can also be identified via the expression of CD4 and foxp3.[83] Moreover, they reported previously that cancer-bearing dogs had increased numbers of Tregs compared with healthy dogs and that this difference was greater in certain types of canine cancer.[65,83] Therefore current therapies aimed at depleting Treg cells in humans could be applied to veterinary medicine. In particular, many studies have shown that the use of cyclophosphamide or anti-Treg-specific antibodies decreases the numbers of Tregs present in tumors and in circulation of tumor-bearing patients.[84–88] In addition, it was shown that the tyrosine kinase inhibitor drug toceranib (Palladia) can deplete canine Tregs both in vitro and in vivo.[89]

Impaired Dendritic Cell Activation and Function

Another important mechanism of tumor suppression is through impairment of the potent antigen-presenting cells, dendritic cells (DCs). Numerous studies have denoted that overall numbers of DCs are decreased in various human cancers studied, including head and neck squamous cell carcinoma (HNSCC),[90] breast and prostate cancer, and malignant glioma.[91] A recent study showed that indoleamine 1 (IDO1), expression in the tumor microenvironment led to increased DC apoptosis.[28] The aforementioned tumor studies demonstrated fewer circulating myeloid DCs with a concurrent increase in immature DCs (iDCs) with reduced ability to present antigen and stimulate T cells; thus they induce

VetBooks.ir

T-cell tolerance rather than activate T cells.[91–93] The DCs present in the tumor tend to be immature and dysfunctional. Studies of DCs in numerous human cancers demonstrate minimal activation, decreased ability to stimulate in an alloreactive fashion, and decreased expression of costimulatory molecules.[90,91,94–99] A similar study done in dogs with canine transmissible venereal tumors (CTVTs) showed that the tumor environment caused downregulation of DC surface markers of activation and MHC, and decreased endocytic capabilities and decreased allogenic mixed lymphocyte reaction (MLR) responses.[56] Possible mechanisms causing the DC dysfunction include the overexpression of the protein S100A9,[100] accumulation of triglycerides in the DCs which leads to decreased capacity to present antigen,[101] and downregulation of toll-like receptor (TLR)-9 expression.[102] Moreover, factors such as IL-10 and vascular endothelial growth factor (VEGF) can negatively affect DC function and maturation.[103,104] Lastly, some DCs in the tumor are considered to be regulatory based on low expression of surface markers MHC II, CD86, and CD11c with high expression of costimulatory molecules CD80, CD40, CD106, and CD11b. These cells secrete regulatory factors such as IL-10 and nitric oxide (NO) and inhibit proliferation of naïve CD4+ T cells to antigen presented by mature, functional DCs.[105] Overall, the microenvironment of the tumor leads to attraction of immature and regulatory DCs that, due to their decreased activation and function, can potently inhibit the development of antitumor T cell responses even when copious amounts of antigen are present.

Production of Immunosuppressive Cytokines

In addition to the suppressive milieu established by tumor-infiltrating cells, tumor cells themselves are capable of producing immunosuppressive cytokines.[106] A few key immunosuppressive cytokines produced by tumor cells are IL-10, VEGF, and TGF-β.[106,107] These cytokines act to suppress antitumor T cell responses and inhibit DC function. IL-10 promotes Treg production and function[108] and, in an autocrine and/or paracrine fashion, may potentially affect tumor cell proliferation and survival.[109] In human cancer patients, increased levels of serum IL-10 are observed in patients with either pancreatic carcinoma or non-Hodgkin lymphoma (NHL).[110,111] In addition, elevated levels of IL-10 in diffuse large B-cell lymphoma of humans correlate with a poor prognosis.[112] TGF-β acts similarly to IL-10 in that it is a potent immunosuppressive cytokine that can potentiate Treg proliferation and function.[74,113–115] It can also enhance tumor progression; carcinomas can produce excess TGF-β, which in turn increases the epithelial-to-mesenchymal transition, tumor invasion, and metastasis and inhibits tumor-specific CD8+ T cells.[115] Moreover, tumor-produced tumor necrosis factor-alpha (TNF-α) leads to promotion of tumor cell survival via induction of antiapoptotic proteins.[116] Finally, TNF-α has been shown to promote tumor angiogenesis and metastasis and hamper cytotoxic T-cell and macrophage responses.[117]

One study in veterinary medicine examined a lymph node of a dog with metastatic melanoma. This study revealed an overexpression of IL-10 and TGF-β concurrent with a lack of expression of IL-2, IL-4, or interferon-gamma (IFN-γ) cytokines typically associated with antitumor immunity, thus demonstrating that tumor immunosuppression occurs in veterinary patients as well.[118] For a review of cytokines relevant to tumor immunotherapy, see Table 14.1.

TABLE 14.1 Biological Activities of Key Cytokines Relevant to Tumor Immunotherapy

Cytokine	Major Activity
IL-2	Growth factor for T cells, including regulatory T cells; induces proliferation and differentiation of T cells to effector T cells; enhances CTL and NK cell cytotoxicity, production of LAK cells, induces B-cell proliferation. Approved for use clinically by the FDA.
IL-3	Multicolony-stimulating factor, promotes production/differentiation and proliferation of macrophages, monocytes, granulocytes, and dendritic cells; secreted by activated T cells and supports growth and differentiation of T cells.
IL-4	Key Th2 cytokine; induces differentiation of naïve CD4 T cells toward Th2 phenotype, inhibits macrophage activation, induces B cell growth and differentiation, stimulates isotype switching and IgG and IgE production. Up-regulates MHC Class II production.
IL-6	Supports B-cell proliferation and differentiation to plasma cells; proinflammatory, antiapoptotic cytokine that may contribute to tumor development associated with chronic inflammation. Causes upregulation of PD-1 on monocytes that are triggered to produce IL-10 after ligation of this receptor.
IL-8	Chemotactic/activation factor for neutrophils and T cells; induces matrix metalloproteinase-2 activity; plays a role in inflammation and tumor metastasis.
IL-10	Immunosuppressive cytokine produced by activated DCs, macrophages, and T cells; induces regulatory T cell function; also overexpressed by some tumors and tumor-associated leukocytes.
IL-11	Stimulates proliferation of hematopoietic stem cells; induces megakaryocyte maturation resulting in increased platelet production.
IL-12	Key Th1 cytokine produced by DCs, macrophages; stimulates synthesis of IFN-γ and TNF-α by T cells and NKs, thus decreasing angiogenesis, enhances cytotoxicity of CTLs and NK cells, stimulates differentiation of naïve CD4+ T cells to T cells with the Th1 phenotype.
IL-13	Th2 promoting cytokine, produced by NKT cells; inhibits inflammatory cytokine production by macrophages; possible inhibitory role in tumor immunosurveillance.
IL-15	T cell growth factor; supports survival of memory CD8+ T cells; promotes NK cell activation and survival and triggers cytotoxic activity.
IL-17	Induces proinflammatory response. Role in cancer is currently controversial—depending on context, may either promote or inhibit tumor growth.
IL-19	Promotes T-cell differentiation toward the Th2 phenotype.
IL-21	Member of IL-2 cytokine family; enhances cytotoxicity and proliferation of CTL and NK cells.

TABLE 14.1 Biological Activities of Key Cytokines Relevant to Tumor Immunotherapy—cont'd

Cytokine	Major Activity
IL-23	Member of IL-12 cytokine family; upregulates the production of MMP9 in tumors; increases angiogenesis while reducing CD8 TILs. Stimulates CD4+ T cells to become Th17 cells.
GM-CSF	Promotes growth and differentiation of pleuripotent progenitor cells; stimulates growth of cells of the granulocyte, macrophage, and eosinophil lineage.
CSF-1	Promotes differentiation of stem cells into monocytes and macrophages.
G-CSF	Stimulates bone marrow to produce granulocytes and stem cells. Stimulates neutrophil survival, function, and maturation.
IFN-α, β	Induce apoptosis of tumor cells; enhances CTL effector function, activates NK cells, modulates MHC Class I/II expression, inhibits tumor angiogenesis.
IFN-γ	Key Th1 cytokine produced by activated T cells and NK cells; promotes the differentiation of naïve CD4+ T cells to Th1 phenotype; activates macrophages, increases MHC Class I/II expression.
TNF-α	Produced by Th1 T cells, CTLs, activated DCs and macrophages; induces NO production by macrophages, induces tumor apoptosis; important proinflammatory cytokine.
TGF-β	Immunosuppressive cytokine; inhibits macrophage activation and B-cell growth; overexpressed by some tumors.

CSF-1, Colony-stimulating factor-1; *CTL,* cytotoxic T-lymphocyte; *DCs,* dendritic cells; *FDA,* Food and Drug Administration; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony stimulating factor; *IFN,* interferon; *IgE,* immunoglobulin E; *IgG,* immunoglobulin G; *IL,* interleukin; *LAK,* lymphokine-activated killer; *MHC,* major histocompatibility; *MMP,* matrix metalloproteinase; *NK,* natural killer; *NKT,* natural killer T-cell; *NO,* nitric oxide; *PD-1,* programmed death molecule-1; *TGF,* transforming growth factor; *Th1,* T-helper 1; *Th2,* T-helper 2; *TILs,* tumor-infiltrating lymphocytes; *TNF,* tumor necrosis factor.

TABLE 14.2 Ways to Manipulate MDSCs to Decrease Immunosuppression

Depletion/Inhibit Proliferation	Promote Maturation	Inhibit Recruitment	Block Interactions	Block Function
Liposomal clodronate	Zoledronate[263]	cFMS kinase inhibitor (GW2580)[264]	Anti-CD40 Ab[265]	Nitroaspirin[266]
Gemcitabine[267]	ATRA[268]	NSAIDs[269]	Anti-PD-1/PD-L1 Ab[270]	Arginase 1 inhibitor (NOHA)[271]
5-FU[272]	Docetaxel[273]			Triterpenoid[274]
Sunitinib[275]	Sunitinib[275]			Sildenafil[276]
Docetaxel[273]	Decitabine[277]			
Cox 2 inhibitor (SC58236)[269]	Activated NKT cells[278]			
KIT-specific Ab[279]	VSSP vaccine[280]			
25-Hydroxyvitamin D3[281]				
CXCR2 antagonist (S-265610)[55]				
CXCR4 antagonist (AMD3100)[55]				
PROK2-specific Ab[282]				

Ab, Antibody; *ATRA,* all-*trans* retinoic acid; *5-FU,* 5-fluorouracil; *MDSCs,* myeloid-derived suppressor cells; *NKT,* natural killer T cells; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PD-1,* programmed death molecule-1; *PD-L1,* ligand of PD-1; *VSSP,* very small size proteoliposome.

Strategies to Control Tumor Growth Through Immune Activation

Blocking Checkpoint Molecules

With the recent advancements in human immunotherapy, many companies are pursuing development of checkpoint inhibitor antibodies besides ones that block PD-1 and CTLA-4. Antibodies targeting PD-1, CTLA-4, and PD-L1 are now approved for treatment of a variety of different cancers in humans, including the broad category of all tumor cells with high levels of microsatellite instability. Currently, there are clinical trials looking at the use of antibodies targeting the other inhibitory checkpoint molecules Tim-3 and Lag-3, and studies evaluating costimulatory checkpoint molecules such as OX40, CD28, and ICOS. In addition, clinical trials evaluating PD-1 and PD-L1 antibodies in dogs with cancer are currently underway.[27]

Depletion of Immunosuppressive MDSCs

In light of many recent studies, it has become clear that an effective immunotherapy must be able to overcome or be combined with other treatments that can overcome the immunosuppression present in the tumor microenvironment. As mentioned earlier, both checkpoint molecules and myeloid-derived suppressor cells (MDSCs) are a key component of such immunosuppression. Although a few of the human antibodies that target checkpoint molecules were discussed earlier, Table 14.2 lists the various potential ways in which MDSCs may be manipulated to enhance the effectiveness of immunotherapy.

Nonspecific Immune Activation to Generate Antitumor Activity Using Biological Response Modifiers

In the 1900s, William Coley observed that cancer patients who developed bacterial infections survived longer than those who did not (reviewed[119]). Building on these observations, Coley developed "Coley's toxins" consisting of killed cultures of *Streptococcus pyogenes* and *Serratia marcescens* that he gave to patients with inoperable sarcomas. Although with this "vaccine" Coley saw cure rates of approximately 15%, his therapy was discontinued because of its significant failure rate and intolerable side effects. However, this seminal work laid the foundation for further studies aimed at nonspecific, pan immune activation to treat cancer through the use of biological response modifiers (BRMs).

Bacillus of Calmette and Guerin and *Corynebacterium parvum*

One of the most well-known and clinically used BRM is bacillus of Calmette and Guerin (BCG), a live, attenuated strain of *Mycobacterium bovis.* Currently, in human medicine, BCG is intravesically instilled into the bladder, where it is considered to be effective as a means to treat and prevent relapse of noninvasive transitional cell carcinoma.[120,121] One proposed mechanism for its antitumor effects relates to the recruitment of neutrophils and their ability to promote urothelial cell turnover.[122] This recruitment most likely relates to the ability of BCG to elicit Th1 inflammatory cytokines,[123,124] a cytokine profile associated with inducing cytolytic cells to kill the target tumor cells (compared with a Th2-cytokine response, which is typically associated with antiinflammatory immune responses).

BCG immunotherapy has been evaluated in dogs with cancer,[125] but its clinical use as an immunotherapy in dogs is limited. Although BCG can be safely instilled into canine bladders,[126] the rate of true superficial (as opposed to infiltrative) bladder cancers is extremely low in dogs compared with humans.[127] Recent uses of BCG in dogs includes treatment of CTVT in conjunction with vincristine,[128] or in combination with human chorionic gonadotropin (LDI-100), to treat dogs with mast cell tumors.[129] In this study, response rates for grade I and II MCTs were comparable to those for single-agent vinblastine, but without the myelosuppression.

Another BRM studied in human and veterinary medicine is *Corynebacterium parvum.* In human and dog melanoma studies, *C. parvum* displayed antitumor activity as an adjunct to surgery.[130,131] However, the efficacy of *C. parvum* as an immunotherapy in other canine cancers has been disappointing.[132]

Immunotherapy with Live Attenuated *Salmonella*

As a tumor grows, the core may become necrotic as the initial tumor cells are deprived of nutrients. Layered upon the necrotic core are tumor cells that exist in an area of hypoxia—they are out of reach of blood vessels that can supply them with oxygen. These cells remain viable and pose a challenge to most immunotherapies, chemotherapies, and even small-molecule drugs because of their restricted location. Recently researchers have begun to genetically modify facultative anaerobic bacteria that can penetrate and survive in these regions. In fact, it has been shown that several strains of *Salmonella*, including *S. typhimurium* and *S. choleraesuius,* target tumors after systemic administration. These bacteria penetrate the necrotic core and feed on the dead cells while also emitting natural toxins that will destroy surrounding, viable cells. Using a mouse melanoma model, treatment with VNP20009, an attenuated *Salmonella typhimurium*, was able to slow tumor growth and specifically target primary tumor and metastatic lesions.[133] Although this study showed that the effects were independent of B and T cells, possible indirect effects of the *Salmonella* include production of inflammatory cytokines, such as TNF-α.[134] Recently, another proposed mechanism involves the ability of *Salmonella* to induce melanoma cells to express gap junctions that can interact with DCs and cause bits of tumor cell proteins to be loaded and expressed on the surface of these DCs for presentation to T cells.[135] Unfortunately, in human trials, the bacteria failed to colonize some patients and did not provide any antitumor activity.[136]

Administration of VNP20009 in dogs resulted in a more positive outcome than in humans. In a Phase I clinical trial, VNP20009 was administered to dogs with a variety of malignant tumors.[137] In this study, 41 dogs received intravenous infusions of VNP20009 either weekly or biweekly at escalating doses. Fever and vomiting were reported as dose-limiting toxicities. Bacterial colonization was seen in approximately 40% of dogs and significant clinical responses observed in 15% of patients, with an overall rate of 37% of dogs experiencing either a transient response or stable disease. Thus the use of VNP20009 in specific dog tumors should be further investigated, perhaps in combination with modified *Salmonella* engineered to deliver tumor cytotoxic agents.

Liposome-Encapsulated Muramyl Tripeptide

Bacterial cell components, such as peptides derived from mycobacterial cell walls, were evaluated for potential immunogenicity. One such product is muramyl tripeptide-phosphatidylethanolamine (MTP-PE), an NOD2 receptor agonist, that when encapsulated in a liposome (L-MTP-PE) can efficiently activate monocytes and macrophages to produce proinflammatory cytokines, such as IL-1α and -β, IL-6, IL-7, IL-8, IL-12 and TNF-α.[138] L-MTP-PE has been assessed in Phase I and II trials of people with osteosarcoma (OSA), renal carcinoma, and metastatic melanoma.[138–140] Moreover, this drug has been approved for use in treating pediatric osteosarcoma in Europe under the name Mepact (mifamurtide).[141]

L-MTP-PE has been evaluated in veterinary medicine in a variety of studies.[142–146] The survival benefit of L-MTP-PE therapy has been most clearly demonstrated in dogs with appendicular OSA.[147] In this study, dogs receiving L-MTP-PE after limb amputation had a median survival time (MST) of 222 days whereas dogs that received placebo had a MST of 77 days. However, as most of the dogs in both groups developed metastatic disease, further studies evaluated the efficacy of L-MTP-PE in conjunction with chemotherapy.[142] In this study, dogs receiving L-MTP-PE after treatment with cisplatin had a MST of 14.4 months versus 9.8 months in dogs that received cisplatin only. Interestingly, only 73% of dogs receiving L-MTP-PE developed metastatic disease compared with 93% in the cisplatin-only group. However, in a second trial, these investigators saw no significant survival advantage in dogs with OSA that received L-MTP-PE concurrently with cisplatin.The authors postulated that cisplatin attenuated antimetastatic potential of L-MTP-PE because of impaired immune effectors. L-MTP-PE was also evaluated for efficacy in canine hemangiosarcoma (HSA).[144] Dogs that received L-MTP-PE with chemotherapy after splenectomy had a MST of 9 months versus 5.7 months seen with dogs receiving chemotherapy alone. In another study only dogs with stage I oral melanoma that received L-MTP-PE had an increased survival over placebo-treated dogs.[145] No differences were observed in dogs with more advanced disease.

VetBooks.ir

Liposome–DNA Complexes

Bacterial DNA can also stimulate the innate immune system via its CpG oligonucleotides, particularly when complexed with cationic liposomes, in a form known as cationic lipid–DNA complexes (CLDCs).[148] Complexing bacterial plasmid DNA to liposomes allows for more efficient delivery of the CpG DNA to the endosomal compartment of antigen presenting cells, such as DCs, where it is released from the liposomes and binds to its receptor, TLR-9.[149,150] In mouse studies, CLDCs stimulate the immune system largely through induction of NK cell activity and release of IFN-γ.[148] Moreover, CLDCs were also shown to stimulate the production of type I IFN,[151] and thus are potent nonspecific immunostimulants.

The use of CLDCs in dogs has been evaluated in metastatic OSA and in dogs with soft tissue sarcoma (STS).[152,153] Intravenous administration of a modified CLDC that encodes for IL-2 was performed in dogs with stage IV OSA.[152] Dogs that received the CLDC developed fevers and showed changes in their leukogram profile indicative of immune stimulation. Moreover, NK cell activity was observed, as assessed by target cell lysis, and monocytes showed increased expression of B7.2 on their surface, indicating activation. Treatment was associated with a significant increase in survival times compared with historical controls. Another study examined the use of CLDC in canine STS.[153] Administration of CLDC, IV, once weekly for 6 weeks resulted in an objective response in 15% of the dogs and a decrease in tumor microvessel density in half of the dogs receiving the treatment. Thus CLDC has excellent potential to be used as a stand-alone immunotherapeutic in veterinary medicine for a variety of cancer types.

Oncolytic Viruses

Oncolytic viruses are defined as viruses capable of replicating in and lysing tumor cells, thus making them likely candidates for drug or gene delivery to tumors. This section focuses on oncolytic viruses as means of directly killing the cells, and a later section focuses on using viral vectors as a means of gene delivery. A beneficial side effect of these viruses is that they not only kill the tumor cells, but they also cause release of tumor antigens for processing by the immune system. With safety being the main concern, modern genetics has allowed for modifications of the virus to make them less pathogenic and also target tumor cells specifically. A recent review of the use of oncolytic virotherapy for canine cancer describes the biology behind this therapy and recent veterinary studies assessing these therapies.[154] Adenoviruses that have undergone genetic modification of their early genes, 1A (E1A) and 1B (E1B), preferentially target rapidly dividing tumor cells and have been used to target canine OSA cells.[155–157] Canine distemper virus (CDV) has also been investigated as a treatment for B and T cell lymphoma in dogs.[158] In vitro studies using fluorescently labeled, attenuated CDV and canine lymphoma cells demonstrated that CDV infected lymphoid cells via binding of the cell membrane protein CD150, which is overexpressed on malignant B cells, and induced cellular apoptosis.[158] More recently, many groups have begun looking at Pox viruses in oncolytic viral therapy, although this research has been done only in in vitro cultures or xenograft mice.[159–162] There is also a report on the use of an attenuated strain of Newcastle disease virus in in vitro cultures on both human and canine lymphoma cells and compared cell death with peripheral blood mononuclear cells (PBMCs).[163] They reported a 34% increase in cell death in canine lymphoma cells compared with normal PBMCs. Furthermore, this group injected one dog with a T-cell lymphoma and found viral particles in kidney, salivary gland, lung, and stomach. Lastly, a clinical study of dogs with various cancer types were treated with a recombinant form vesicular stomatitis virus (VSV), that expresses IFN-β and the sodium iodide symporter (NIS).[164] This study was designed to assess for safety and efficacy. They determined that there was no viral shedding two of the five dogs (both with T-cell lymphoma) had a transient partial response during the 28-day observation posttreatment time period. Five of the 9 dogs demonstrated stable disease for the same 28-day time period and the remaining two dogs had progressive disease. One of the dogs with stable disease (anal adenocarcinoma) had resection of the tumor after completion of the study and evidence of an uncharacteristic T cell infiltration into the tumor tissue was observed, suggesting a possible immune effect of the VSV therapy.

Toll-Like Receptor and NOD-Like Receptor Agonists

TLRs are part of the innate immune system and are proteins expressed on the surfaces of macrophages and dendritic cells and serve the purpose of recognizing microbial pathogens. As discussed earlier, CLDC contains CpG DNA, which can bind to TLR-9. Lipopolysaccharide (LPS) is a known ligand for TLR-4. Recently the TLR-7 agonist imiquimod was studied as a topical therapy in combination with an autologous cellular vaccine in dogs with invasive meningioma,[165] and as a single therapy in cats with squamous cell carcinoma.[166] As noted earlier, MTP functions as an NOD2 receptor agonist, and can be preferentially targeted to activate macrophages by liposome encapsulation.[167]

Nonspecific Tumor Immunotherapy Using Recombinant Cytokine Therapy

Interleukin-2

IL-2 is a cytokine that is released by T cells after their activation via interactions of antigen-loaded MHC and costimulatory molecules expressed on the surface of antigen presenting cells. Its function is to induce clonal expansion of T cells in an antigen-specific fashion and activate DCs, macrophages, and B cells, which in turn release proinflammatory cytokines. Moreover, IL-2 stimulates NK cells, thus playing an important role in inducing both the innate and adaptive arms of the immune system.

The therapeutic use of IL-2 in humans is fraught with toxicity[168–170]; however, the use of IL-2 therapy in veterinary medicine holds some promise. Helfand et al demonstrated that intravenously injected recombinant human IL-2 (rhIL-2) activates canine lymphocytes, causing only mild gastrointestinal toxicity, even at high doses for 4 consecutive days.[171] Another study demonstrated the ability of rhIL-2 to induce canine lymphokine activated killer (LAK) cells and, incidentally, showed that LAK cells from tumor-bearing dogs did not kill tumor cells as efficiently compared with normal dogs.[172] Further evaluation of toxicity and efficacy of rhIL-2 was done using dogs with primary lung cancer and with lung metastases in an aerosol formulation.[173] In this study, complete regression was seen in two of the four dogs with pulmonary metastases and these dogs remained disease-free for at least 12 months after treatment. One of the two dogs with a primary lung tumor had stabilized disease for more than 8 months, whereas the other dog had progressive disease. Assessment of the lymphocytes obtained from bronchoalveolar lavage showed increased cytolytic activity after 15 days of IL-2 treatment. In addition, minimal toxicity was noted in this study. Finally, IL-2 gene therapy using viral vectors has been examined for treatment

VetBooks.ir

of feline fibrosarcomas and canine melanoma and was shown to be safe and effective.[174–176] Therefore given its comparatively low toxicity and promising effectiveness, rIL-2 therapy is a plausible treatment for canine cancer.

Interleukin 12

IL-12, produced by antigen-stimulated DCs, macrophages, and B cells, plays a role in stimulating the growth and function of T cells and enhances the cytolytic activity of both T cells and NK cells. Similar to IL-2, IL-12 therapy in humans lead to serious side effects, and is thus currently not used clinically. Current investigation into the use of IL-12 in veterinary medicine revolves around recombinant gene therapy for treatment of canine head and neck tumors,[177] with some in vitro work looking at its use in feline hyperthermia-induced gene therapy.[178] More recently, in an experimental model of CTVT, intratumoral delivery of the IL-12 gene resulted in decreased tumor growth and complete tumor remission.[179] Similar studies in dogs using IL-12 electrogene therapy resulted in reduced tumor volume of 9 out of 11 dogs with mast cell tumors[180] and increases in intratumoral IFN-γ and antiangiogenic effects in nine dogs with various cancers,[181] and in six dogs treated with concurrent metronomic chemotherapy.[182] However, no significant clinical responses were observed in these studies. Interestingly, both studies demonstrated increased levels of tumor-infiltrating lymphocytes, suggesting immune specificity of this therapy.

Interleukin-15

IL-15 is structurally similar to and uses similar signaling molecules as IL-2. IL-15 plays a role in stimulation of NK cells and in promoting proliferation of T cells. However, from an immunotherapy standpoint, IL-15 holds more promise than IL-2 in that (1) it does not cause activation-induced cell death of CD4+ T cells after prolonged periods of exposure, but rather sustains T-cell proliferation[183]; (2) it plays a critical role in CD8+ T cell memory formation and maintenance[184]; and (3) unlike IL-2, it does not appear to play a role in the development of Tregs.[185]

Clinical evaluation has been underway now in several trials in human cancer patients. An initial safety study in nonhuman primates was recently conducted.[186] Twelve daily doses of clinical grade human recombinant IL-15 revealed that neutropenia was the dose-limiting and documented an increase in circulating NK cells and memory CD8+ T cells.

In veterinary medicine, one study combined intralesional IL-15 and IL-6 plasmid DNA injections in beagles with CTVT.[187] With this treatment, investigators observed a threefold increase in the proportion of CD8+ T cells that infiltrated the tumors and an enhancement of IFN-γ-producing cells and increased cytolytic activity against the tumor. Lastly, in 2015, one group reported on the generation of recombinant canine IL-15.[188] They demonstrated that *in* vitro, recombinant IL-15 could expand canine NK cells and could cause expansion of lymphocytes in peripheral blood when administered to dogs intravenously. Thus IL-15 therapy shows promise as an effective immunotherapy in both human and veterinary medicine.

Interferons

Interferons (IFNs) are proteins produced by lymphocytes that play an important role in immune responses to pathogens and cancer. Broadly, they can influence cell proliferation, play a role in the induction of apoptosis, upregulate antigen presentation to T cells, and enhance the ability of the adaptive immune system to mount a cytolytic immune response. Moreover, IFNs have antiangiogenic properties. The IFNs are typically classified as either type I (IFN-α, -β, and -ω) or type II (IFN-γ).

Interferon-α, Interferon-β, and Interferon-ω

The type I IFNs can affect cellular proliferation through various mechanisms including interactions with cell cycle proteins (i.e., c-myc and retinoblastoma) and induction of apoptosis via Bcl-2/Bax and TNF/Fas interactions. Their antiangiogenic properties of downregulating VEGF and basic fibroblast growth factor (bFGF)[189] make them attractive as immunotherapies and they have been used successfully to treat pediatric hemangiomas.[190]

Clinical trials using the type I IFNs have met limited success because of the high occurrence of severe toxicity and overall limited response rates. Nonetheless, their effectiveness was assessed in melanoma, multiple myeloma, renal cell carcinoma, leukemia, other cancers, and in conjunction with chemotherapies. The best response, in terms of disease-free survival, was seen in renal cell carcinoma and melanoma when used as single agents.[191,192]

The use of type I IFNs in veterinary medicine is limited and they are used mostly for feline viral diseases.[193] One study showed that recombinant feline IFN-ω was safe and easy to use for treating feline fibrosarcomas. As this was a safety study, the therapeutic effects of this treatment were not evaluated. Another recently published study also used recombinant feline IFN-ω with or without chemotherapy to study its effects in treating mammary tumors in vitro.[194] This study reported that the antitumor cell effects of recombinant IFN-ω and chemotherapy were additive and suggested further investigation into its clinical use as an adjuvant therapy.

Interferon-γ

IFN-γ plays an important role in stimulating the immune system. It is secreted mostly by NK cells, DCs and antigen-activated T cells and counteracts the effects of many of the immunosuppressive cytokines. It is a physiologic activator of macrophages, leading to increased antigen presentation and increased lysosomal function and NO production by macrophages. NO production by macrophages is an efficient mechanism of tumor cytolysis. IFN-γ can also cause increased MHC Class I and II expression on a variety of cells, including tumors. Increased MHC expression has been confirmed to occur on in vitro IFN-γ treated canine tumor cells lines[195] and in vivo after treatment with IFN-γ.[196] Thus its role in antitumor immunity is characterized by increased tumor cell lysis and increased tumor antigen presentation to the adaptive immune response.

The use of IFN-γ in veterinary medicine is currently being investigated. A recently published study examined the use of IFN-γ in combination with a single injection of autologous, ex vivo activated DCs in dogs with various malignant or benign tumors.[197] In the seven dogs enrolled in the study, the investigators noted four complete responses and two partial responses against malignant tumors and saw moderate partial responses against fast-growing benign tumors. Another study looked at the use of adenoviral IFN-γ gene transfer as an adjuvant therapy to treat a dog with astrocytoma.[198] After therapy and surgery, the dog was tumor free for more than 450 days. Finally, a safety study was done in cats with fibrosarcomas using a triple gene therapy that included IFN-γ along with IL-2 and GM-CSF.[176] In this study, cats tolerated the therapy, although six of the eight cats developed local recurrence of disease within 1 year of treatment.

Specific Immunotherapy for Cancer: Tumor Vaccines

The development of a tumor vaccine that is safe, effective, and long-lasting is an ultimate goal of immunotherapy. Whereas the effects of traditional cancer treatments such as chemotherapy, surgery, and radiation therapy typically result in noticeable clinical responses within hours to days after treatment, cancer vaccine therapeutic responses typically take weeks to months to lead to an appreciable clinical response. This difference in response time, coupled with the lack of congruent and objective ways to measure efficacy, make it difficult to develop tumor vaccines.

Nonetheless, despite the challenges to tumor vaccine development, there are many different varieties of tumor vaccines currently in use either clinically or as part of Phase I, II, and III clinical trials. In fact, in April of 2010, the first FDA-approved therapeutic cancer vaccine for human prostate cancer was approved. In the following section, we will discuss only those showing success in human trials and those relevant to veterinary medicine.

Tumor Antigen Targets for Immunization

Tumor antigens (TAs) are proteins are other molecules that are either unique to cancer cells or significantly more abundant in cancer cells compared with normal cells. These proteins include the broad categories of oncogenes, oncofetal proteins, and cancer testes antigens. Although TAs offer potential targets for vaccine development, their downside is that some of them tend to be individual or certain tumor type specific. Nonetheless, much work has been accomplished characterizing TAs for various forms of cancer and a table of currently studied TAs can be found in a 2009 publication by a panel of experts organized by the National Cancer Institute (NCI).[199] Although numerous TAs exist, the use of these TAs in tumor vaccines is not trivial. As mentioned earlier, the tumor is highly capable of inducing a potent, immunosuppressive microenviroment by various mechanisms; thus standard vaccine procedures using TAs can be rendered useless in this powerful environment. In fact, there are little data available showing a clear correlation between in vitro TA responses and prognosis. The success of most tumor vaccines has been limited to animal models of induced disease.[200,201] However, through the use of better vaccine strategies and by combining therapies that can ultimately overcome tumor immunosuppression, more promising specific immunotherapies are being developed. In the text that follows we will discuss the various platforms used to develop tumor vaccines.

Tumor Vaccine Approaches

Whole Tumor Cell and Tumor Cell Lysate Vaccines

One of the more simple approaches to tumor vaccine development is through the use of whole tumor cell or tumor cell lysate vaccines. These can either be made directly from the patient in the form of an autologous vaccine or from cell lines of similar tumor types from the same species as an allogeneic vaccine. Whole cell preparations are most often produced made by lethally irradiating tumor cells and/or tissues. Tumor lysate vaccines, including membrane protein fraction vaccines, are made by mechanically disrupting the tumor cells and/or tissues. Both whole cell and tumor-lysate vaccines are typically administered with some form of adjuvant to enhance the immune response. These polyvalent vaccines may be superior to specific peptide or protein (subunit) vaccines in that they contain a heterogeneous population of TAs.

One study out of our laboratory assessed the use of an allogeneic HSA tumor lysate vaccine in combination with chemotherapy.[202] In this Phase I/II study, 28 dogs were evaluated and received eight immunizations of tumor lysate plus CLDC (see the section "Liposome–DNA Complexes") over a 22-week period while concurrently receiving doxorubicin. The vaccine was well tolerated; adverse effects were limited to moderate diarrhea and anorexia. Tumor-specific antibody responses were detected in four to five of the six dogs tested, depending on which HSA cell-line they were screened against. Moreover, overall survival times of dogs receiving the combination treatment were significantly better than chemotherapy-only treated historical controls.

Whole cell and tumor lysate vaccines can also be modified to enhance their immunogenicity. Aside from different adjuvant strategies, combination of these vaccines with modifiers such as immunostimulatory cytokines has been examined. One clinical trial of 16 dogs with STS or melanoma assessed the use of an autologous, whole cell vaccine transfected with human GM-CSF.[203] Three dogs in the study demonstrated objective tumor responses that included regression of primary and metastatic lesions. On histologic examination of tumor tissue in the dogs that received the vaccine, an impressive inflammatory response was noted. Another recent study using a similar human GM-CSF adjuvanted, autologous vaccine looked at its efficacy in treating dogs with B cell lymphoma.[204] Dogs in remission after a 19-week standard CHOP (*C*yclophosphamide, *H*ydroxydaunorubicin, *O*ncovin [vincristine], and *P*rednisone) protocol were randomized into placebo or vaccine treatment groups. No improvement in median length to remission, nor overall survival, was seen. Another study investigated the use of an allogeneic melanoma vaccine in combination with a xenogeneic melanoma protein, human glycoprotein 100 (hpg100).[205] In this Phase II trial, the vaccine was well tolerated and the researchers observed an overall response rate of 17% and a tumor control rate (including complete and partial responses and stable disease greater than 6 weeks duration) of 35%. Lastly, some positive results have been seen with an autologous B cell lymphoma vaccine where the cells were transfected loaded with tumor RNA and activated through CD40, particularly in prolonging remission duration of salvage therapy.[206]

Immunization Against Defined Tumor Antigens Using Plasmid DNA

Vaccines that use specific gene sequences of TAs encoded in plasmid DNA have shown some clinical promise with their ability to invoke both cellular and humoral immunity. The ease of working with bacterial DNA and the ability to quickly produce large quantities of plasmid DNA make this an attractive vaccine platform. Moreover, the DNA sequences of a majority of TAs are known and can be easily inserted into the plasmid DNA and expressed under the control of a constitutively active bacterial promoter. Typically given intradermally or intramuscularly, the proteins expressed by transcription and translation of the plasmid are readily picked up by DCs, processed and presented in the context of MHC Class I and II, thus providing a more "natural" stimulation of the immune system. Moreover, the unmethylated dinucleotide-CpG residues, or CpG motifs, present in high frequency in the bacterial DNA provide additional stimulation of DCs, triggering them to induce a Th1-type immune response.[207]

No DNA vaccines have been licensed for human use yet. However, many DNA vaccines have been tested in clinical trials and results have thus far been disappointing for various reasons (see review[208]). Nonetheless, the first conditionally licensed veterinary

VetBooks.ir

cancer vaccine is based on the DNA plasmid technology.[209] The ONCEPT Vaccine (Merial, Inc.) for canine malignant melanoma (CMM) uses xenogeneic DNA plasmids that contain the gene encoding human tyrosinase (huTyr). Initial studies showed the development of an antibody-mediated immune response against the huTyr protein that cross-reacted to canine tyrosinase (also see Chapter 19 for more details).[210] Improved survival of dogs treated with this vaccine compared with historical control animals has been reported with no severe side effects noted.[209,211] Further studies of this plasmid DNA technology demonstrated that the vaccine could induce antigen-specific IFN-γ+ T cells in normal beagle dogs.[212] The same group that developed the CMM vaccine has reportedly completed Phase I trials of murine CD20 for treatment of canine B cell lymphoma and is initiating a Phase II trial soon.[213] Lastly, a recently developed vaccine against the dog telomerase reverse transcriptase protein, for use in canine lymphoma patients, has demonstrated positive results, significantly increasing survival in dogs with B-cell lymphoma when added to conventional chemotherapy.[214,215]

Tumor Vaccination Using Viral Vector Vaccines

As discussed earlier (section "Oncolytic Viruses"), viruses have been used to target tumor cells, in particular ones with innate oncolytic properties. However, viruses can also be used as vectors for expression of particular TAs. Typically, attenuated or replication-defective forms of the virus are used to allow for effective stimulation of the innate and adaptive immune responses without the risk of spreading and rapidly dividing within the host. The most commonly used viral platform for both human and veterinary studies is the Poxviridae family. The poxviruses are easy to work with, are amenable to large amounts of foreign DNA, and are highly immunogenic, allowing for strong immune responses against weak TAs, such as carcinoembryonic antigen (CEA).[216] In humans, one of the most commonly used viral vaccine platform is the canarypox virus ALVAC. Recent published human clinical trials using ALVAC include combining CEA-expressing ALVAC with chemotherapy for metastatic colorectal cancer,[217] ALVAC expressing huGM-CSF or IL-2 for treatment of melanoma or leiomyosarcoma,[218] and intranodal injection of ALVAC expressing gp100 in high-risk melanoma patients.[219] Interestingly, although all of these studies reported that the vaccine was safe to use and that immunologic responses were observed, the efficacy of these therapies is limited.[220]

Vaccination Against Tumor Antigens Using Dendritic Cells

DCs possess very potent antigen presenting abilities and are an attractive target for cancer vaccine strategies. Besides their role in vivo in processing and presenting TAs derived either naturally or from tumor vaccines, there are many clinical trials published that examine the use of ex vivo activated and expanded DCs injected back into the donor as a way of activating tumor-specific T cells in vivo. The drawback to this method is that the ex vivo processing of DCs typically is expensive, takes about 7 to 10 days, requires growth in a combination of cytokines, and can be used only autologously. Nonetheless, ex vivo prepared DCs have shown clinical efficacy, particularly in human patients with metastatic disease.[221,222] Recently, it has been determined that the potency of the DCs produced ex vivo depends on the combination of cytokines used.[223] DCs generated with GM-CSF and IFN-α or GM-CSF and IL-15 display potent priming of T-cell–mediated and CD8+ T-cell–mediated immune responses in vitro. Moreover, the use of mature DCs is better than use of immature DCs, as immature DCs actually induce immune tolerance via expansion of IL-10–secreting T cells.[224] However, the methods of maturation matter as well, with studies showing DCs activated with a mixture of IFN-α, polyinosinic-polycytidylic acid, IL-1β, TNF, and IFN-γ elicit many fold more antimelanoma CTLs in vitro than the standard IL-1β, TNF, IL-6, prostaglandin E_2 (PGE_2) cocktail.[225] Finally, new methods of targeting antigens to DCs through anti-DC receptor (i.e., lectin receptors such as DEC-205, DC-SIGN, or DNGR-1) antibody–TA fusions, appropriate selection of adjuvants to deliver antigens to DCs, and combination therapies using chemotherapy and DC activation are being investigated.[221,223]

DC vaccination in veterinary medicine has been and is still currently being explored. An initial study of three dogs with oral melanoma showed that bone marrow derived DCs transduced with an adenovirus expressing human gp100 could safely be used. In this study, dogs received three subcutaneous vaccines over 4 months.[226] One of the dogs, which was disease-free 4 years later, developed a robust CTL response against the gp100. Another dog that relapsed after 22 months had no evidence of antigp100 CTLs. A similar study performed in normal dogs was done to assess the immune response of DCs pulsed with canine melanoma cell (CMM2) lysates, where a good delayed-type hypersensitivity (DTH) response was seen against CMM2 after vaccination.[227]

Another study described earlier (section "Interferon-γ") saw success using ex vivo activated DCs and IFN-γ for treating canine solid tumors. Finally, a very recent study looked at the safety of using a DC–mammary tumor cell fusion hybvrid vaccine.[228] In this case normal dog PBMCs were used to generate DCs that were subsequently fused to canine mammary tumor cells. Injection of normal beagle dogs with this fusion plus CpG adjuvant resulted in a robust antibody response against the fusion partner tumor cell line and three unrelated canine mammary tumor cells. However, no CTL responses were noted. Hence, development of DC vaccines for use in veterinary medicine is currently being explored in various tumor models and using various strategies to optimize the induced antitumor immune response.

Antibody Therapy for Cancer

Monoclonal Antibodies

The use of mAb therapy for cancer has been studied for more than four decades after the development of hybridoma technology by Kohler and Milstein in 1975.[229] This technique consisted of antibody-producing cells fused with mouse myeloma cells, thus becoming immortalized and capable of continuously producing antibody that can be purified out of the culture media. Initially, the use of mAbs clinically was limited because of the responses mounted by the host against the foreign mouse proteins. However, recent technology allowed for "humanizing" these antibodies by genetically grafting the mouse hypervariable region of interest onto the human immunoglobulin, thus resulting in an antibody that is 95% human. Moreover, mice genetically rendered to express human immunoglobulins can successfully generate 100% human antibodies in response to various antigens.[230] Using humanized antibodies improves antibody-dependent cell-mediated cytotoxicity (ADCC), improves antibody stability, and decreases immunogenicity of the antibody itself. The use of mAbs in human medicine has increased over the years. Table 14.3 lists those approved by the FDA for use as human cancer treatments and some recent mAbs tested in human clinical trials.[231] As a general guide, mAb names ending in -omab are murine based, -ximab and -zumab are chimeric, and -umab are humanized versions of the antibodies.

TABLE 14.3 Approved Monoclonal Antibodies

Target	mAb	Indication	Year Approved by the FDA
EpCAM	Edrecolomab	Colorectal	1995
CD20	Rituximab	Non-Hodgkin lymphoma	1997
HER2	Trastuzumab	Breast cancer	1998
CD33	Gemtuzumab	Acute myelogenous leukemia	2000
CD52	Alemtuzumab	Chronic lymphocytic leukemia, T-cell lymphoma	2001
CD20	Ibritumomab tiuxetan[a]	Non-Hodgkin lymphoma	2002
VEGF	Bevacizumab	Colorectal	2004
VEGFR	Cetuximab	Colorectal	2004
EpCAM × CD3	Catumaxomab	Hepatocarcinoma	2005
EGFR	Panitumumab	Colorectal	2006
CD20	Ofatumumab	Chronic lymphocytic leukemia	2009
CTLA-4	Ipilimumab	Melanoma	2011
CD30	Brentuximab vedotin	Lymphoma	2011
HER2	Pertuzumab	Breast cancer	2012
	Ado-trastuzumab	Breast cancer	2013
CD20	Obinutuzumab	Chronic lymphocytic leukemia	2013
VEGFR	Ramucirumab	Gastric cancer	2014
PD-1	Pembrolizumab	Melanoma	2014
CD20	Tositumomab[b]	Acute lymphocytic leukemia	2014
PD-1	Nivolumab	Melanoma	2014
GD2	Dinutuximab	Neuroblastoma	2015
CD38	Daratumumab	Myeloma	2015
EGFR	Necitumumab	Lung cancer	2015
SLAMF7	Elotuzumab	Myeloma	2015
PD-L1	Atezolizumab	Urothelial cancer	2016
CD19/CD3	Blinatumomab	Acute lymphocytic leukemia	2017
PD-L1	Avelumab	Gastric cancer	2017
	Durvalumab	Urothelial cancer	2017

CD, cluster of determination; *CTLA-4*, Cytotoxic T-lymphocyte antigen-4; *EGFR*, epidermal growth factor receptor; *EpCAM*, epithelial cell adhesion molecule; *GD2*, glycolipid antigen disialoganglioside 2; *HER-2*, human epidermal growth factor receptor 2; *PD-1*, programmed death molecule-1; *PD-L1*, ligand of PD-1; *SLAMF*, signaling lymphocytic activation molecule family F; *VEGF*, vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptor.

[a] ^{111}In/^{90}Y-labeled.

[b] ^{131}I-labeled.

With the current excitement surrounding immune checkpoint inhibitor therapy, it is anticipated that fully caninized antibodies may be available for cancer therapy in the near future. In fact, a chimerized anti-PD-L1 antibody was tested in a small clinical trial in Japan with some positive results.[27] There has already been USDA approval of the Cytopoint (Zoetis), a canonized antibody that targets canine IL-31, which is involved in allergic skin disease and pruritus in dogs.

Conjugated Monoclonal Antibodies

Another use of mAbs is linking them to potential toxins, immunocytokines, or radioisotopes. Initial studies involved linking chemical toxins to immunoglobulins to generate molecules called immunotoxins. Such chemicals tested were ricin and diphtheria toxins, but these conjugates were immunogenically and chemically unstable. Development of recombinant immunotoxins helped address this issue, although the current concern with immunotoxins is their ability to nonspecifically kill any cell expressing the antibody-specific receptor.

Recently Paoloni et al developed an "immunocytokine" that targets necrotic areas of the tumor and is linked to IL-12.[232] A dose escalation was performed with this drug, called NHS-IL12, and it was demonstrated that it could be safely administered to dogs with melanoma at the appropriate dose, and that IL-12 could be measured in dog serum postadministration and was correlated with an increase in systemic IL-10 levels. Interestingly, they observed increased IFN-γ levels that correlated with adverse reactions. In five of seven dogs, they observed an increased infiltration of CD8+ T cells. Some partial responses and stable disease were observed in the dogs in the study.

mAbs can also be linked to radionuclides. The concept behind these antibodies is that the antibody targets tumor tissue and the energy released by the radioisotope attached to the antibody can penetrate bulky solid tumors and can also kill surrounding tumor and stromal cells. Examples of radiolabeled mAbs in clinical use in humans are found in Table 14.3. The current use of radiolabeled mAbs in dogs is limited to imaging modalities rather than treatment of cancer.

Cancer Immunotherapy Using Adoptive Transfer of T Cells

Adoptive T-cell transfer (ACT) is a technique whereby cells are collected from a cancer patient, expanded, and activated in culture and then transferred back into the patient. Although this technique allows for the enhancement of tumor-specific T cells, it is labor intensive, expensive, and time-consuming; thus its use is limited in both human and veterinary patients. In the text that follows, we will discuss historical methods to generate these cells and new techniques currently being investigated to improve this form of immunotherapy. As mentioned at the beginning of this chapter, one limitation to most immunotherapies is the fact that tumors can orchestrate an immunosuppressive environment. Thus even if one instilled thousands of activated, tumor-specific T cells into a cancer patient, the majority of these cells will become inactivated on reaching the tumor, particularly when dealing with solid tumors.[233] It is currently being recognized that strategies to overcome immunosuppression must be implemented to enhance the efficiency of tumor-specific T cells in ACT studies. One technique to address this suppression is performing lymphodepletion before ACT.[234–236] Recent studies have also suggested the isolation

VetBooks.ir

of CD4+ T cells for ACT, rather than cytotoxic CD8+ T cells, as CD4+ T cells are capable of activating both innate immune cells and CD8+ T cells.[237,238] However, CD4+ T cells contain Treg cells; thus strategies to block the development of Treg cells during CD4+ T cell ACT have been investigated.[237] In addition, the availability of TAs appears to also play a role in the strength of CD4+ ACT therapy.[239] Similarly, the addition of cytokines and/or blocking antibodies against suppressor cells, along with ACTs, has been shown to enhance the effectiveness of this therapy.[237,240–242]

More recently, there has been interest in developing chimeric antigen receptor (CAR) T cells for canine immunotherapy. CAR-T cells are generated via transfection of antibody genes specific for a tumor target into a T cell.[243–247] This directs the engineered T cells specifically to the tumor tissue. Success with this technology has been seen in humans with chronic lymphocytic leukemia where the T cells target the CD19+ B cells.[244,245] In terms of veterinary use, initial in vitro studies were performed looking at autologous T cells transfected with the *HER2* gene to target canine osteosarcoma cells.[248] More recently, Panjwani et al transfected canine T cells with CD20-targeting RNA for dogs with B cell lymphoma.[249] This was the first study to show that these cells could be made, expanded, and safely administered to dogs.

Transfer of Lymphokine-Activated Killer Cells

Initial T-cell transfer studies involved the generation of lymphokine-activated killer (LAK) cells. This was done by culturing PBMCs in high concentrations of IL-2, thus selecting for a population of cells with potent tumor cell lysis ability. Clinical trials using this technique in humans were disappointing and unfeasible despite promising mouse studies.[250] The use of LAK cells in veterinary medicine is limited to studies of cats with FeLV or FIV.[251]

Transfer of Tumor-Infiltrating Lymphocytes

One source of potent antitumor T cells is in the tumor itself. These cells, called tumor-infiltrating lymphocytes (TILs), when expanded using IL-2, exhibit potent cytolytic activity that is many folds higher than LAK cells against tumors in both a specific and nonspecific way. [252] Although they are considered the best source of T cells for ACT,[253,254] their use in human medicine is limited because of a few variables such as time of isolation, the tumor they were isolated from, and the functional state of the cells when isolated.[250] Nonetheless, limited success has been observed in cases of treating human melanoma with TILs, particularly when combined with nonmyeloablative chemotherapy such as fludarabine and cyclophosphamide, which deplete lymphocytes but spare bone marrow stem cells.[255] In one study, 6 of 13 melanoma patients had significant tumor regression and four had a mixed response including regression of some lesions and growth of others.[255] In a follow-up study involving a larger number of patients (34 in total), tumor regression was seen in 51% of the patients that received chemotherapy before the TIL transfer and IL-2 treatment.[256] In addition to the use of nonmyeloablative treatments, recent studies have investigated the use of other forms of Th1 stimulation along with ACT. One group has investigated the use of adding CpG-ODNs to their TILs to increase their efficacy.[257] In a study using ex vivo isolated human TILs, instillation of the activated TILs with CpG-ODN into athymic nude, tumor-bearing mice, resulted in decreased tumor burden and prolonged survival. Regardless of the human clinical trials' results, the use of TILs in veterinary medicine is absent, perhaps owing to the lack of reliable efficacy across multiple tumor types.

Natural Killer Cell Immunotherapy

Lastly, there is a growing interest in using NK cells for immunotherapy. A recent canine immunotherapy review states that the author's institution is currently conducting a phase II canine clinical trial using autologouse NK cells that were activated ex vivo for treatment of appendicular OSA.[258]

The Future of Cancer Immunotherapy

The use of immunotherapy for the treatment of cancer is an exciting and ever-evolving field of research and application. With the advancement of techniques used to assess immune responses to tumors, better ways of predicting responses, including development of Response Evaluation Criteria in Solid Tumors (RECIST), and an understanding that tumor responses to immunotherapies may be delayed compared with conventional chemotherapy, radiation therapy and surgery, one can more reliably assess the clinical efficacy and safety of novel immunotherapies. Moreover, a better understanding of the disease pathology in our veterinary patients has led to a movement toward using spontaneous canine and feline cancers as models for human disease, thus allowing for testing of novel immunotherapies in our small animal patients that will benefit not only them, but human cancer patients as well.[259,260]

However, the development of a successful immunotherapy protocol is not without limitations. One of the main reasons for failure of many immunotherapies is due to the immunosuppressive microenvironment established by the tumor. Thus immunotherapies that are best able to overcome this suppression will prove the most successful.[261] In addition, the use of certain drugs and/or proteins that can deplete or inactivate the key players in immune suppression, i.e., MDSCs and Tregs, and therapies that target checkpoint molecules may be best used in concert with novel vaccines or other immunotherapies to optimize their effectiveness. Along those lines, the use of newer and more potent adjuvants, such as various preparations of CpG motifs, to stimulate the immune system will be a critical component of newer vaccines. It has now become clear that the most successful adjuvants are ones that not only stimulate a strong primary response against the tumor, but ones that also lead to the development of a robust central memory response.

One of the more successful categories of immunotherapies currently used in human medicine is mAbs. Advances in technology led to the development of humanized, nonimmunogenic forms of antibodies against key cellular receptors, either to activate key antitumor immune cells or lead to cytolytic activity against tumor cells. However, similar advances in treating dogs with mAbs are not currently available, although development of such reagents is underway by many investigators and companies.

It should be understood that many, if not all, immunotherapies developed should work in concert and synergize with current cancer treatment modalities. Given the ability of tumor cells to become resistant to chemotherapy and radiation therapy and their ability to suppress the immune system, one would be naïve to think that a single-modality treatment is the most effective means of tumor control. Although the immune system can be manipulated to mount an effective antitumor immune response, it is best used in cases of residual and metastatic disease, where radiation therapy, chemotherapy, and/or surgery are used to cytoreduce and down-stage large tumors. Moreover, it is becoming very clear that the immune system is a key player involved in the tumor responses to radiation and chemotherapy,

VetBooks.ir

thus finding ways to incorporate immunotherapy into current standard of care may actually enhance the effectiveness of these modalities. For example, we have observed that the use of liposomal clodronate therapy to eliminate MDSCs can enhance the tumor response to chemotherapy in dogs with malignant histiocytosis.[262] We hypothesize that the immunosuppressive cells present in the tumor microenvironment are capable of protecting tumor cells from the effects of chemotherapy, thus by removing these tumor cells, we can enhance the effectiveness of the chemotherapy. We predict that the use of immunotherapy as part of a protocol to treat canine and feline diseases should soon become routine. By understanding the role of the immune system in cancer in our small animal patients, we can develop better immunotherapies that will not only benefit these patients, but also ones that will be applicable to human medicine.

15 Molecular/Targeted Therapy of Cancer

SECTION A: GENE THERAPY FOR CANCER

DAVID J. ARGYLE

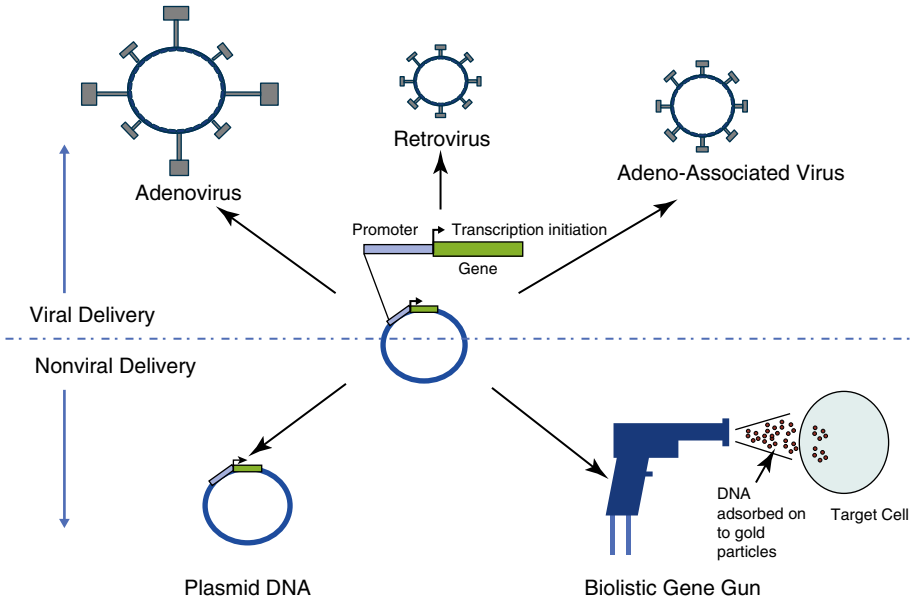
Since its development, recombinant DNA technology has been vigorously applied to the advancement of medicine. New molecular techniques have been used to study the role of specific genes and their products in disease, to improve diagnosis, and to produce novel therapeutics. Gene therapy, in its simplest definition, is the introduction of genes into cells in vivo to treat a disease,[1] and it has been applied to many chronic, intractable diseases such as single gene defects and cancer. This definition could probably now be extended to the delivery of all forms of nucleic acids for treatment. More than 2000 clinical gene therapy trials have been conducted worldwide, and as could be predicted with any developing technology, there have been a litany of disappointments interspersed with a few prominent successes, particularly in ocular and immunodeficiency diseases.[2] Cancer has proved to be an attractive target for gene therapy, with clinical studies that have included delivery of "killing genes," immune-modulating genes, and genes that can alter host tumor microenvironment (e.g., tumor vasculature).[1] Early human cancer trials, including those to deactivate oncogenes or restore tumor suppressor gene function, proved to have little clinical utility, but the past 20 years have seen a growing number of clinical successes in human medicine that have paralleled our increased understanding of and experience with the delivery technology.[2–5] Furthermore, the exponential growth of data around cancer genomes, biology, and immunology is allowing the exploitation of gene therapy technologies to improve patient outcomes and a drive toward precision medicine. The gene therapy field in veterinary oncology has proved to be much slower that in human medicine, hindered by the paucity of biology data, costs of development, and (in some cases), the regulatory environment. However, a number of studies are now emerging that suggest that this technology may prove to be a useful adjunct in veterinary oncology.

Delivery Vehicles for Cancer Gene Therapy

Effective gene therapy relies on our ability to introduce genes efficiently into target cells or tissues in vivo, or the ex vivo delivery of genes to autologous cells and subsequent adoptive transfer back to the patient. It is the efficient and safe transfer of genes that has proved to be the greatest hurdle to clinical development over the past 20 years, and a herculean effort has been placed into developing robust vector systems for clinical use. The major delivery vehicles that have been exploited fall into the two broad categories of viral vectors and nonviral (usually plasmid-based) vectors. Vector systems are summarized in Table 15.1 and Fig. 15.1.

The great advantage to viral vectors for gene delivery is their ability to infect cells and our ability to exploit their replicative machinery. The majority of systems use replication-defective viruses to overcome concerns that recombination within the host may lead to the production of wild-type virus with pathogenic potential. The common systems rely on oncogenic retroviruses (e.g., murine leukemia virus [MuLV]), adenoviruses (e.g., human adenovirus type 5 [AD5]), adeno-associated viruses (AAVs), or lentiviruses. Lentiviral vectors have a better safety profile than retroviral vectors and are more efficient at delivering genes to nondividing cells.[6–11] Among the various viral-based vector systems, the AAVs are proving to have the greatest utility in the treatment of human diseases. Alipogene tiparvovec (marketed as Glybera), an AAV-vector based treatment for lipoprotein lipase deficiency, was one of the first gene therapy products to be licensed by the European Medicines Agency in 2012 and was an important milestone in drug development[2]; however, the drug was withdrawn in 2017 by the parent company because of lack of demand and the 1 million euro price tag.

Most of the viral systems for cancer gene therapy involve the local delivery of virus to tumor deposits (e.g., by intratumoral injection), or ex vivo delivery of transgene to autologous cells. Systemic delivery of virus is hindered by rapid clearance of viruses from the body by the immune and complement systems. To overcome this, work has progressed to explore cellular delivery of viruses by the systemic route. In this delivery system, viral producer cells are delivered to the patient, and virus production is triggered when the cells reach the tumor. Endothelial cells, T cells, macrophages, dendritic cells, and mesenchymal stem cells (MSCs) are also being explored as potential cell delivery systems. The advantage of these systems is that virus could potentially be delivered to metastatic disease and primary tumors.[12–16]



Concerns relating to virus safety, an inability to produce high enough viral titers for clinical trials, and the cost of viral vectors have led to the development of nonviral delivery systems for gene therapy.[17–18] Such methodologies have included the use of cationic liposomes, "naked" (plasmid) DNA, synthetic viruses, transposons, and bacteria (summarized in Table 15.1). Cationic liposomes are microscopic vesicles that enter cells by endocytosis and have been used to safely and efficiently deliver genes to

VetBooks.ir

TABLE 15.1 Gene Therapy Vector Systems

Viral Vectors	
Retroviruses (oncoviruses)	Originally the gold-standard vector. Gene is packaged into replication-defective viral particles using a packaging cell line. The therapeutic gene is integrated into the host cell genome when the virus is delivered to the target cell. Limited by their inability to infect postmitotic cells.
Retroviruses (lentivirus)	Many are based on HIV-1. These vectors have become safer in recent years and have many of the benefits of the oncoviruses and also will infect postmitotic cells. Construction of the vector takes place in a packaging cell line and the therapeutic gene is integrated into the host cell genome.
Adenoviruses	Have become the most popular viral delivery mechanism. Gene is packaged into a replication incompetent adenovirus (usually E1 deleted). Gene expression remains episomal when delivered to the host cell. Concerns have been raised about the safety of adenoviral vectors, in particular potential toxic side effects at high doses. Adenoviruses can infect a wide range of pre- and postmitotic cells. Conditionally replicating adenoviruses are being explored as oncolytic vectors.
Adeno-associated viruses (AAV)	Gaining popularity as a vector as they are potentially safer than adenoviruses. They infect a wide variety of mammalian cell types but are limited by the amount of DNA they can deliver. Gene expression in the host cell is episomal. However, in the natural host, integration is possible.
Nonviral Vectors	
Naked DNA	This is a simple form of gene delivery in which "naked" plasmid DNA is directly injected into the tumor. Vectors are derived from bacterial plasmids and are engineered to express the therapeutic gene under the control of a strong promoter. Naked DNA can be taken up by many tissues, but typically the efficiency for delivery is lower than that for viral gene delivery.
Particle bombardment (gene gun)	This is a more sophisticated approach to the delivery of naked DNA. In this system plasmid DNA is typically adsorbed onto gold particles. Helium is then used as a motive force to fire the gold particles into cells or tissues via a hand-held "gene gun."
Liposome/DNA conjugates	In this system naked DNA is coated with liposomes to improve uptake by endocytosis. This enhances the efficiency of gene delivery.
Ligand/DNA conjugates	Ligands are used to specifically target DNA to tumor tissue.

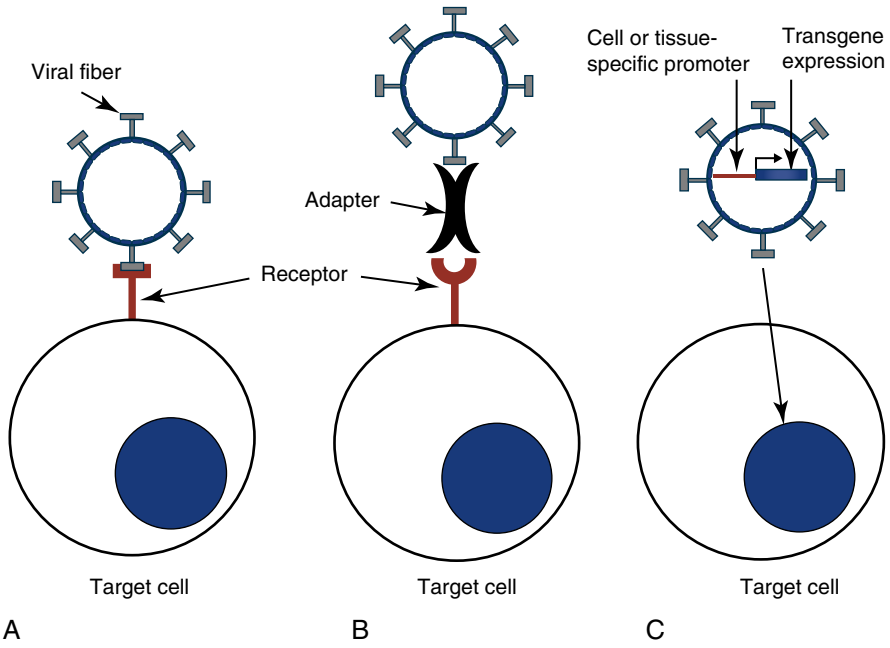
HIV-1, Human immunodeficiency virus-1.

• **Fig. 15.1** Viral and nonviral gene delivery. Adenoviral vectors are produced in "producer cell lines." They enter the cell by transduction and their genetic material is transported to the nucleus. In contrast to retroviruses, the DNA is not integrated into the host genome, but gene expression is achieved episomally. Retroviral vectors are also produced is specialized producer cell lines. They enter the cell by transduction but their RNA genome is reverse transcribed into proviral DNA. This integrates into the host genome, where expression of the transgene takes place. DNA plasmid vectors contain a gene cassette that incorporates the therapeutic transgene under the control of a promoter. The plasmid can be delivered by direct injection as naked or liposome encapsulated DNA, by direct injection or systemically wrapped in nanomedicine particles, or by direct injection utilizing a helium-driven "biolistic" gene gun.

VetBooks.ir

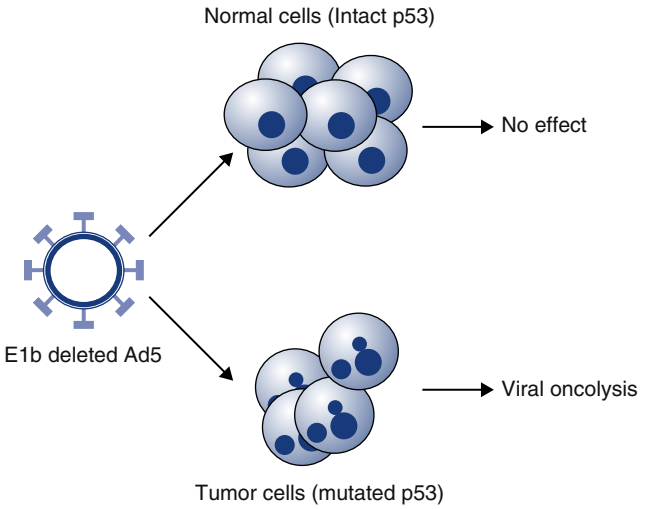
tumor cells through direct injection and systemic delivery.[15,16] They have a selectivity for endothelial cells, are considered efficient gene delivery systems, and are relatively safe. Naked DNA delivery (the delivery of plasmid DNA alone containing the gene of interest) results in uptake by tumor cells and antigen-presenting cells after simple direct injection.[17] A modification of this is particle-mediated gene delivery using a "gene gun." In this approach, DNA is adsorbed onto gold particles and fired into tissues under high pressure (using helium as the motive force).[17,18] However, the majority of these naked DNA approaches are still inefficient and are not able to be given systemically (see Table 15.1).[19–23]

Plasmid vectors for gene therapy have a number of limitations[19–23]:



- Plasmid DNA preparations contain several topological variants of the plasmid, including the unwanted open circular and linear forms of the molecule.
- Plasmids are inefficient at delivering genes compared with viruses, thus requiring vehicles, physical forces, or specialized modifications for uptake and nuclear localization. Some delivery methods lead to breakage of the plasmid DNA backbone, which increases the likelihood of genome integration and/or less efficient expression.
- Plasmids are nonreplicating episomes, so transgene expression is transient and is diluted by cell division.
- Bacterial sequences in plasmids, such as unmethylated cytosine-phosphate-guanine (CpG) dinucleotides, have the potential to be recognized by the mammalian immune system via toll-like receptor (TLR)-9, potentially precipitating not only transgene silencing but also immune response.
- Plasmids typically encode antibiotic resistance-encoding genes for selection of plasmid-harboring bacteria. The use of antibiotics and their resistance genes in the preparation of plasmid vectors, however, is discouraged by regulatory bodies such as the Food and Drug Administration (FDA) and the European Medicines Agency because of the risk of transfer and replication of resistance genes to bacteria in the human microbiome and possibly into the environment.
- Residual antibiotics that remain from vector production may trigger an immune reaction in patients.

In human gene therapy, these issues have led to the development of minimal plasmid vectors, with extensive deletions (minivectors).[17]



Targeting Cancer Gene Therapy

In terms of delivery, one of the major barriers is the ability to give vectors systemically, to target them to cancer tissues, and to ensure that therapeutic transgenes are not expressed in normal cells. Targeting also ensures that enough vector can reach the target of interest, without being dispersed to irrelevant sites. Numerous strategies have been attempted to provide levels of targeting and to spare normal tissue, and many have been explored in isolation or as combination strategies (e.g., dual and triple targeting).

1. **Transductional targeting.** This involves surface modification (usually of virus), to allow delivery and/or entry to cells via specific surface receptor. This approach has largely been applied to adenoviral vectors and has included modifications to the *c*oxsackie and *a*denovirus *r*eceptor (CAR) (which gives adenovirus its normal cellular tropism), and/or the use of "adaptors." An adaptor molecule can ablate native CAR-based tropism and target the virus to an alternate cellular receptor molecule. For example, bispecific fusion proteins (e.g., diabodies, composed of two single-chain antibodies [scFv], with one scFv recognizing the fiber knob and the other a tumor-associated antigen [TAA]) can be used as an adaptor to target adenovirus to a specific tumor type[24,25] (Fig. 15.2).

• **Fig. 15.2** Vector targeting. The specificity of viral vectors can be improved utilizing either transductional targeting (A), where the viral surface proteins are modified so they will only enter the cell of interest; transductional targeting, where the vector is modified using an "adapter" (B); or transcriptional targeting (C), where the expression of the therapeutic transgene is under the control of a tissue or cell-specific promoter. Transcriptional targeting can also be employed in nonviral vectors and directly delivered to the patient.

• **Fig. 15.3** Conditionally replicating adenovirus. The ONYX-015 vector is an E1b-deleted Adenovirus that conditionally replicates in cells with a nonfunctional *p53* gene. p53 protein has the potential to shut down cell cycling when infected with wild-type adenovirus but is prevented from doing so through the actions of the product of viral E1b. E1b-deficient viruses cannot replicate in normal cells with p53 intact. However, in cells that have no functional p53 protein, viral replication can proceed and cause cell lysis.

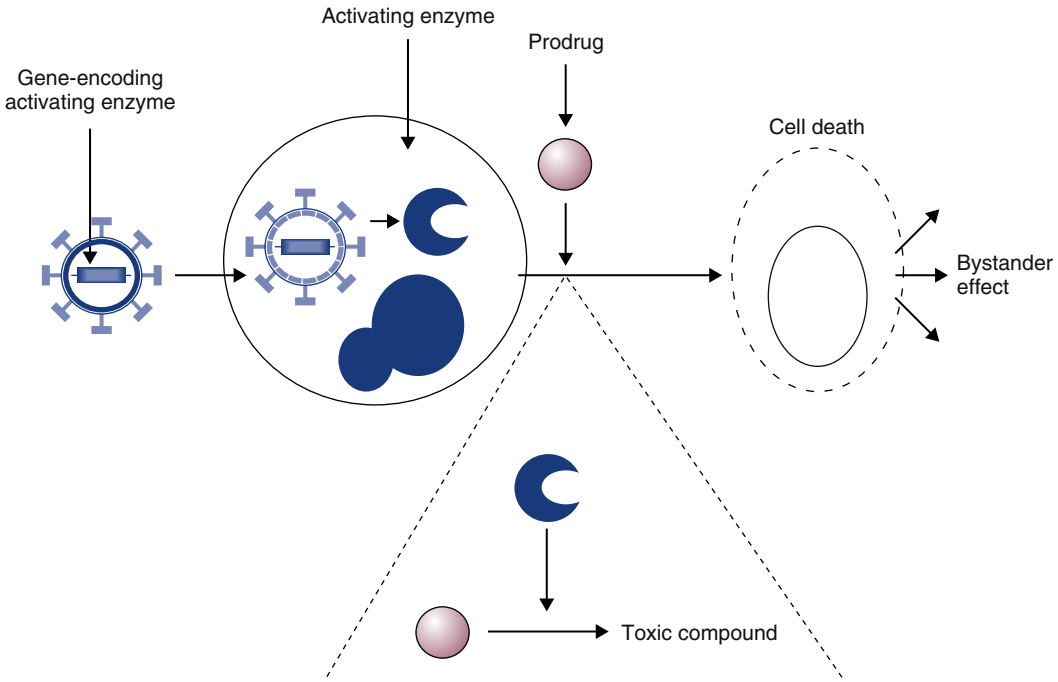
2. **Transcriptional targeting.** This strategy exploits unique gene expression in specific cell types once the vector has entered the cell.[26–30] Although every gene is represented in every cell of the body, expression of any one gene requires specific transcription factors that may be unique to a particular cell or tissue type. Certain genes have been identified that are expressed in cancer cells but are not expressed in normal cells (e.g., telomerase) or are expressed only in a specific tissue type (e.g., prostate-specific antigen [PSA]). By using the promoter sequences for these genes to drive transgene expression, targeted expression in cancer cells only (e.g., using the promoter for telomerase) or to a specific tissue type (e.g., to the prostate using the promoter for PSA) can be achieved (see Fig. 15.2).
3. **Replication-competent oncolytic viruses.** Progress has been made in the development of viruses that conditionally replicate in cancer cells.[31,32] One of the first examples to be used in clinical trials was the ONYX-015 vector, an E1b-deleted adenovirus that conditionally replicates in cells with a nonfunctional *p53* gene. p53 protein has the potential to shut down cell cycling when infected with wild-type adenovirus but is prevented from doing so through the actions of the product of viral E1b. E1b-deficient viruses cannot replicate in normal cells with p53 intact; however, in cells that have no functional p53 protein, viral replication can proceed and cause cell lysis (Fig. 15.3). Many other conditionally replicating viruses are being developed that rely on specific cancer cell defects (e.g., reoviruses that conditionally replicate in cells with intact Ras signaling pathways) or are transcriptionally targeted. Replication-competent viruses are described in more detail in the text that follows.

Gene Therapy Strategies for Cancer

In the following sections, the broad approaches that can be applied to cancer treatments are outlined. In reality, experience tells us that the optimal approach for patients will be a combination of approaches, including a combined approach with more conventional treatments.

Rescue of the Cancer Cell Through Gene Replacement or Repair Technologies

Early cancer gene therapy strategies focused on the ablation of oncogenes or the replacement of defective tumor suppressor genes.[1] One of the most studied genes in cancer development has been the tumor suppressor gene *p53,* acting as a genomic guardian for the cell and being "switched on" when a cell is exposed to DNA damaging agents. The *p53* gene product causes the cell to either stop dividing or undergo apoptosis, depending on the degree of damage. In many cancers (50% of human cancers), this gene is defective and the second allele is missing. Damaged cells fail to stop dividing and can accumulate further damaging events, which can allow selection for a malignant phenotype. A number of studies have addressed this by attempting to replace the defective *p53* gene with its normal counterpart[31]; however, problems associated with this approach include:



- The current technology is unable to efficiently deliver a normal *p53* gene to every cancer cell in a tumor mass.
- Cancer is a multigenetic abnormality, and the delivery of one correct gene to a tumor cell may still not have the desired phenotypic effect.

Gene replacement for cancer therapy proved to be disappointing clinically, but gene repair is possible, at least in the laboratory setting. Gene repair has been achieved using lentiviral-mediated zinc finger nucleases and exploiting endogenous repair mechanisms. In addition, newly developed gene editing approaches such as *T*ranscriptional *A*ctivator-*L*ike *N*ucleases (TALENS), and *C*lustered *R*egularly *I*nterspaced *S*hort *P*alindromic *R*epeats (CRISPR) provide novel ways to manipulate the genome.[33] At present, these technologies are laboratory based and are being used to develop newly engineered cancer models. Their utility in actual "gene repair" treatments is very far from clinical exploitation.

Gene Silencing in Cancer Cells

Gene silencing usually refers to the delivery and use of small interfering double-stranded RNA (siRNA) molecules to cancer cells to ablate the deleterious effects of activated oncogenes. In the cell, exogenously delivered siRNA is directed to the RNA-induced silencing complex (RISC). This complex is then directed to the target mRNA of the offending gene. By degradation of mRNA, expression of the target gene is suppressed, which is known as posttranscriptional gene silencing (PTGS).[34]

Proponents of RNA interference (RNAi)-based cancer therapy have argued a high efficiency and potential low cost compared with the other methods of gene therapy,[34,35] and high specificity compared with other modalities of cancer therapy such as chemotherapy. The major advantage of RNAi is the potential to target multiple genes of various cellular pathways involved in tumor progression.[36] Simultaneous inhibition of multiple genes is an effective approach to treat cancer and to reduce the possibility of multidrug resistance. RNAi suffers from some of the same issues as conventional gene delivery, in that its efficiency is dependent on an efficient delivery system. siRNA can be delivered directly to tumors but systemic delivery is vulnerable to

• **Fig. 15.4** Gene-directed enzyme prodrug therapy. In gene-directed enzyme prodrug therapy (GDEPT), an activating gene is delivered to the cancer cells. A relatively inactive prodrug is then given to the patient systemically. In cells processing the activating gene, the prodrug is converted to a highly toxic drug, which can kill the cancer cell. The advantage of this system is the evidence of bystander effect. In this, only a small proportion of cancer cells need to receive the activating gene, as toxic metabolites leak across gap junctions and kill surrounding cancer cells.

enzymatic inactivation and renal clearance. A number of delivery systems are in clinical trials, including nanoparticles for systemic use. At present, no clinical trials have been performed in veterinary species.

Gene-Directed Enzyme Prodrug Therapy

Gene-directed enzyme prodrug therapy (GDEPT) involves the delivery of a "suicide" gene (usually viral or bacterial enzyme) to cancer cells that has the ability to convert a relatively nontoxic prodrug to an active compound within the cancer cell (Fig. 15.4). At the clinical level, the gene would be delivered to the patient's tumor and the enzyme activity would be confined to the cancer cells.[37] These systems have been combined with transcriptionally targeted vectors (described previously) to improve the targeting and eventual therapeutic index.[32] Once the patient's cells have been transduced, they would then be given a prodrug systemically. In the cancer cells, this novel enzyme can convert the prodrug to a more active compound that has the ability to kill the cancer cell (see Fig. 15.4). A number of successful approaches have been developed in vitro, based on this system. For example, the *Escherchia. coli* nitroreductase gene has been used in preclinical models to cause reduction of an inactive prodrug (CB1954, a weak alkylating agent) to promote cell killing in cancer cells.[37] However, because of the low efficiency of existing vectors, the success of this therapy will largely depend on the extent of the bystander effect. In this, the activation of the prodrug in the cell causes cell death and also leakage of toxic metabolites to neighboring cells. Consequently, it is estimated that only a small fraction of the cells need receive the gene for there to be a dramatic effect on tumor volume. Furthermore, in mouse models, a distant bystander effect on tumor metastases has been demonstrated that is mediated through the patient's immune system.[38] The in situ destruction of tumor cells is mediated through necrosis rather than apoptosis, creating an ideal inflammatory environment for the exposure and presentation of tumor antigens to the immune system. This allows the patient's immune system to recognize tumor metastases and has caused regression in a number of preclinical model systems. Owing to the presence of this phenomenon, complete tumor regression has been reported in model systems, even when only 10% of the tumor cells have been transduced with suicide genes. To date, five basic mechanisms have been proposed as mediators of the bystander effect[38]:

- Release of activated soluble toxic factors as cells die
- Passive diffusion of toxic factors from intact cells
- Transference of toxic compounds through gap junctions
- Phagocytosis of apoptotic bodies released from transduced cells
- Stimulation of host immune response in the tumor microenvironment

It is likely that a combination of these mechanisms operates to support bystander tumor cell killing.

In reality, the use of GDEPT in human clinical trials has been disappointing, with many of the preclinical successes not translated into large-scale clinical successes. Human clinical trials have included colon, liver, lung, prostate, breast, glioma, and ovarian cancers with variable results[38]; however, it should be noted that the apparent safety concerns related to suicide gene therapy have often limited trials to patients with highly aggressive tumors and poor clinical performance scores. This may have significantly limited any potential for clinical success.

VetBooks.ir

Utilizing Stem Cells to Deliver "Suicide Genes"

The attractiveness of enzyme–prodrug cancer gene therapy has been described earlier, but it relies on the ability to specifically target prodrugs to tumors. Prodrug cancer gene therapy driven by MSCs has been suggested as a treatment modality that could achieve this.[39–42] Thanks to their immunosuppressive properties, allogeneic MSCs can substitute for autologous stem cells in delivering the therapeutic agent in targeted tumor therapy, and the tumor-homing ability of MSCs holds therapeutic advantages compared with vehicles such as proteins, antibodies, nanoparticles, and to some extent viruses.

Gene-Directed Immunotherapy

The search for an effective cancer vaccine over the past 150 years has led to extensive studies of the immune response of cancer patients. These studies have suggested that cell-mediated immune responses are important components of the antitumor immune response. Cytokines are small glycoprotein molecules that orchestrate the immune response, tissue repair, and hematopoiesis, and it has been demonstrated that the relative amounts of individual cytokines can direct the immune system toward either a mainly humoral or a mainly cell-mediated response. In particular, cytokines such as interleukin-2 (IL-2), interferon-gamma (IFN-γ), IL-12, and IL-18 have the ability to promote cell-mediated responses. Furthermore, evidence derived from animal models suggested that local production of cytokines around a tumor mass can lead to production of an antitumor immune response and a reversal of T-cell anergy (nonresponsiveness).[43,44] Thus there appears a rationale for using cytokine molecules in cancer patients to improve the antitumor immune response to tumors that present weakly antigenic epitopes or epitopes that evade immune recognition. In the 1980s and 1990s, a number of clinical studies were undertaken using recombinant cytokine proteins to improve the survival of human cancer patients. However, cytokines tend to be autocrine or paracrine in nature and the levels of protein required to demonstrate a biologic effect were often too toxic for the patient to withstand. However, a more promising approach has been to deliver the actual cytokine genes to cancer cells rather than delivery of the protein to the whole patient.[45–47] Many trials have now combined this approach with gene-directed immunotherapy. In this approach, cytokine genes, and the prodrug-activating gene, are delivered to cancer cells. The conversion of an inactive prodrug by the activating gene leads to destruction of the cancer cells by necrosis. The codelivery of cytokines that enhance cell-mediated immune responses such as IL-2, IFN-γ, IL-12, and IL-18 enhances the antitumor response and may potentially improve the distant bystander effect against micrometastatic disease.[1] This approach has also been adopted in a number of small-scale veterinary studies, including one on canine malignant melanoma, which used cells to deliver IL-2 to tumors.[48,49] These studies have had encouraging results and warrant further larger scale trials.

More recently, cancer immunotherapy based on the genetic modification of autologous T cells has gained a great deal of attention for successes in the treatment of leukemias and lymphomas resistant to standard therapies.[50,51] In this, autologous CD8+ T cells are engineered to recognize and kill tumor cells bearing specific surface antigens. This is achieved through cellular modification by the incorporation of a chimeric antigen receptor (CAR) to redirected T cells, and combines the specificity of a monoclonal antibody with the proliferative and cytotoxic ability of an activated CD8+ T cell.[50–52] A similar approach has been employed in dogs, creating CD20-directed CAR T-cells that demonstrated feasibility, if with only modest clinical responses.[53]

Gene Modification to Improve Chemotherapy and/or Radiation Therapy Outcomes

An alternative approach to gene therapy for cancer involves the delivery of genes to normal cells of the bone marrow to protect them against the cytotoxic effects of conventional chemotherapeutic drugs. In particular, the multidrug resistance (MDR) gene has been cloned and delivered to normal bone marrow cells. When patients are given high doses of chemotherapy, the normal cells with the MDR gene are able to export the toxic drugs across their membranes, reducing potential side effects.[54–56] However, this approach does not protect gastrointestinal cells, which limits its usefulness. Furthermore, there is also a danger that the MDR gene could transfer to malignant cells, rendering them insensitive to the effects of standard drugs.

An alternative approach is to enhance the sensitivity of cancer cells to either chemotherapy or radiation therapy (RT) to improve clinical outcomes. As an example, the transcription factor Slug has been identified as a potential mediator of radio-resistance and has been found to have an antiapoptotic effect. A recent study demonstrated that the modulation of Slug expression by siRNA affected oral squamous cell carcinoma sensitivity to RT through upregulating p53 upregulated modulator of apoptosis (PUMA).[57] Furthermore, inhibition of the Notch and epidermal growth factor receptor (EGFR) pathways in cancer have been shown to modulate chemotherapy and radiosensitivity, opening the possibility of gene modulation during treatment with standard conventional modalities.[58,59] The limitation, as with all other gene therapy approaches, is in the capacity for efficient gene delivery.

The Use of Replication-Competent Viral Vectors

Progress has been made in the development of replication-competent viruses that conditionally replicate in cancer cells.[60–63] As an example, the ONYX-015 vector (as described earlier) was one of the earliest vectors to enter into clinical trials. Since that time, oncolytic viruses (OVs) have been emerging as important therapeutics in cancer management, combining both tumor-specific cell killing, together with stimulation of host immunity.[64] OVs represent a diverse group of agents that cause lysis during their natural life cycle (e.g., vaccinia) or can be engineered to be lytic by toxic transgene expression. OVs can cause selective tumor cell killing by virtue of virus-specific receptors on the surface of the cancer cell and/or by the tumor cell replicative machinery. In addition, tumor lysis can lead to the promotion of antitumor immunity. There are some wild-type viruses that are in clinical use (e.g., reoviruses, vaccinia virus and Newcastle disease virus), but many are attenuated and/or engineered to improve selectivity or mode of action (e.g., E1b-deleted Ad5).[64,65]

The effectiveness of OVs has been demonstrated in preclinical models and has led to the FDA approval and conditional European Medicine Agency's approval of the first OV for use in human melanoma, the immunostimulatory herpesvirus, talimogene laherparepvec. In this, the Herpes simplex virus has been engineered such that both copies of the viral gene coding for ICP34.5 have been deleted and replaced with the gene coding for human granulocyte-macrophage colony-stimulating factor (GM-CSF), and the

VetBooks.ir

gene coding for ICP47 (ICP47 suppresses the immune response to the virus) has been removed. To date, increased survival or protection from metastasis has not been definitively demonstrated.[66]

In veterinary oncology, there have been a number of limited clinical studies. Recent pilot safety studies have been performed in dogs using systemically delivered recombinant oncolytic reovirus and vesicular stomatitis virus.[67,68] This demonstrated the feasibility and safety of this approach and opens the door to future studies to demonstrate efficacy in the clinical setting. A cautionary note, however, is that the majority of dogs in the United States and Europe are vaccinated against some viruses such as canine adenovirus and these types of vectors may not be able to overcome host immunity with long-term treatments.[1,69]

Safety Considerations in Gene Therapy

One of the major considerations in gene therapy revolves around issues of safety, in particular the safety of the vectors used for gene delivery. In 1999, gene therapy suffered a major setback with the death of a patient as a direct result of adenovirus gene therapy. Problems associated with vector delivery include inappropriate inflammatory responses caused by vector delivery (e.g., adenoviruses), the generation of replication-competent viruses (although this is unlikely with new generation vectors), and insertional mutagenesis caused by integrating viruses (e.g., retroviruses).[1]

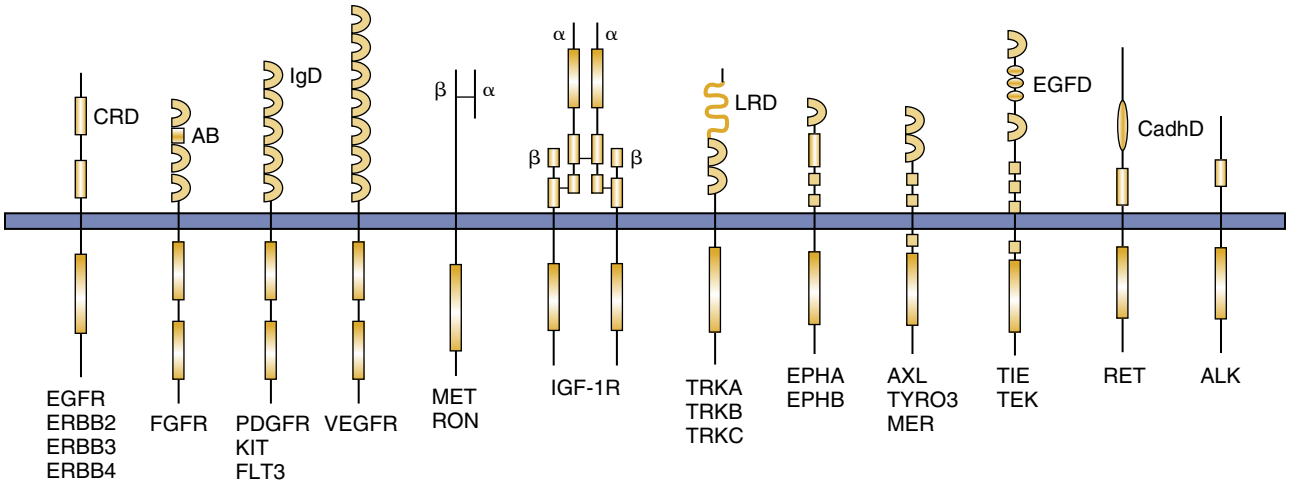
Until recently, many gene therapy trials had utilized retroviral vectors for gene delivery. There are many advantages to using retroviruses as outlined in Table 15.1; however, retroviruses are also associated with serious diseases of domestic animals and the use of these in gene therapy poses a risk of insertional mutagenesis and/or the production of replication-competent viruses during the manufacturing process. Realistically, insertional mutagenesis leading to a malignant transformation is an unlikely event because cancer is a multistep process. In fact, there may be a greater risk of malignant transformation from external beam RT than from the use of retroviruses to treat cancer. The production of replication-competent retroviruses during the production process would also be unlikely because of the rigorous testing that is required before clinical application. Many of these issues are resolving with the development of new generation vectors.[1] As an example, in the use of retroviruses and to prevent insertional mutagenesis in normal tissues, one group recently described the use of zinc finger nucleases (engineered DNA-editing enzymes) that allows the insertion of DNA to a site of choice within the genome.[69] This adds a further level of safety in a high-risk procedure.

One might imagine that the delivery of naked DNA may offer a safer alternative. However, all of the potential safety issues using this technology are still not fully answered. These include potential risks of autoimmunity and also the actual fate of the DNA when it has been delivered to the patient; in the case of the former, however, there would appear to be no evidence of autoimmunity being a problem in preclinical models.

One of the most exciting developments in cancer gene therapy is the use of conditionally replicating OVs. However, the safety of these vector systems needs special consideration as many of them in their native form could pose a risk to both human and animal health. Despite this, published trial data have not demonstrated any significant safety issues. Local delivery has been associated in human medicine with mild flulike symptoms, which have resolved with symptomatic treatment with paracetamol/acetaminophen.[65] In addition, OVs do not reach a maximum tolerated dose (MTD), mainly because of a high tolerance for the virus. However, as OVs with greater potency are developed, or used in combination with other treatments, then safety should remain a concern. One of the major issues may be the development of resistance through immune clearance. Although immunosuppressive therapy has been suggested as part of the treatment with OVs, this should be considered with caution relating to both safety and ensuring that the optimal performance of the virus is not blocked.[65]

Conclusions

Gene therapy promises a completely new approach to the treatment of cancer and represents an emerging area of therapeutics. It has suffered over the past 20 years as clinical trials in human medicine have not delivered what they had originally promised. However, many of these studies were conducted in patients with high-grade or end-stage disease and many studies were conducted prematurely without refining the delivery technologies. Clearly, there are a number of technical issues such as safety surrounding the delivery and efficiency of the vectors that need to be resolved before gene therapy becomes established clinical practice. Despite gene therapy being very much in its infancy, the field is advancing at a rapid rate and resent successes have given the field a significant optimistic boost. A number of clinical trials have begun in companion animals, and products are in development for clinical application. However, although these treatments would appear to be powerful in preclinical models, it is likely that their greatest benefit will be in the management of patients with minimal disease states. Thus gene therapy will probably have its greatest advantage not as a stand-alone treatment but as an adjunct to more conventional therapies such as surgery, RT, or chemotherapy.



SECTION B: SIGNAL TRANSDUCTION AND CANCER

CHERYL A. LONDON

In normal cells, signals are generated that begin at the outside of the cell and are transmitted through the cytoplasm to the nucleus, regulating cell growth, differentiation, survival, and death. Several components of cellular signal transduction pathways are typically dysregulated in cancer cells, resulting in uncontrolled cell growth and thereby contributing to tumorigenesis. Because many tumors have similar alterations in signal transduction components, these have become promising targets for therapeutic intervention. This section focuses primarily on the role of a particular group of signal transducers called *protein kinases,* their role in normal cells, the mechanisms by which they contribute to tumorigenesis, and the use of agents designed to inhibit them when they become dysfunctional.

Protein Kinases and Normal Cells

Protein kinases play critical roles in normal cell signal transduction, acting to tightly regulate cellular processes such as growth and differentiation. These proteins work through phosphorylation; that is, they bind adenosine triphosphate (ATP) and use it to add phosphate groups to key residues on themselves (a process called *autophosphorylation*) and on other molecules, thereby stimulating a downstream signal inside the cell. This process typically occurs in response to external signals generated by growth factors

• **Fig. 15.5** Structure of receptor tyrosine kinases. The structures of receptor tyrosine kinase families implicated in a variety of malignancies are shown. *AB*, Acid box; *ALK*, anaplastic lymphoma kinase; *CadhD*, cadherin-like domain; *CRD*, cysteine-rich domain; *EGFD*, epidermal growth factor-like domain; *EGFR*, epidermal growth factor receptor; *Eph*, member of ephrin receptor family; *FGFR*, fibroblast growth factor receptor; *IgD*, immunoglobulin-like domain; *LRD*, leucine-rich domain; *IGF-1R*, insulin like growth factor receptor 1; *PDGFR*, platelet-derived growth factor receptor; *TIE*, tyrosine kinase receptor on endothelial cells; *TRK*, member of nerve growth factor receptor family; *VEGFR*, vascular endothelial growth factor receptor. (GFs) or other stimuli that initiate the cascade. Protein kinases are classified as tyrosine kinases (TKs) if they phosphorylate proteins on tyrosine residues or serine/threonine kinases if they phosphorylate proteins on serine and threonine residues. In some cases, the kinases perform both functions (i.e., dual-function kinases). Protein kinases can be expressed on the cell surface, in the cytoplasm, and in the nucleus. The human genome encodes more than 500 kinases, of which 90 are classified as TKs.[70]

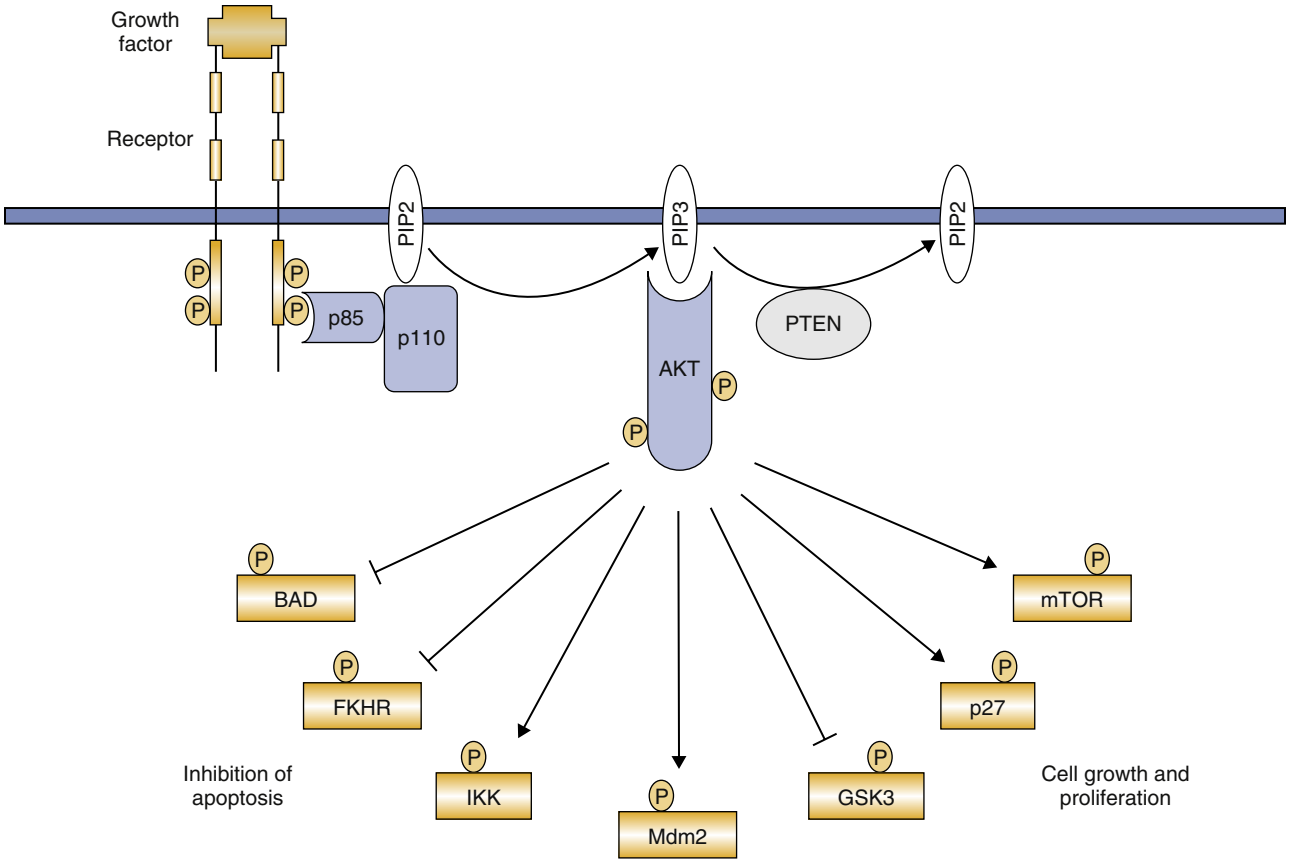
TKs on the cell surface that are activated through binding of GFs are called receptor TKs (RTKs). Of the 90 identified TKs, approximately 60 are known to be RTKs. Each RTK contains an extracellular domain that binds the GF, a transmembrane domain, and a cytoplasmic kinase domain that positively and negatively regulates phosphorylation of the RTK (Fig. 15.5).[71–73] Most RTKs are monomers on the cell surface and are dimerized through the act of GF binding; this changes the three-dimensional structure of the receptor, permitting ATP to bind and autophosphorylation to occur, generating a downstream signal through subsequent binding of adaptor proteins and nonreceptor kinases.[71] Dysregulation of RTKs resulting in pathway activation/uncontrolled signaling is known to contribute to several human cancers, and work is ongoing to characterize such abnormalities in canine and feline cancers. Examples of RTKs known to play prominent roles in specific cancers include KIT, Met, EGFR, and ALK, all which can be activated by overexpression, mutation, and/or chromosomal translocation.[74–78]

Although RTK signaling is critical for regulating typical cell functions, it is also an important driver of angiogenesis, a process considered essential for continued tumor cell growth. The RTKs involved in angiogenesis include the vascluar endothelial growth factor receptors (VEGFRs), platelet-derived growth factor receptors (PDGFRs), fibroblast growth factor receptors (FGFRs), and Tie-1 and Tie-2 (receptors for angiopoietin).[79–82] VEGFRs are expressed on vascular endothelium and VEGFR signaling drives endothelial migration and proliferation.[79] PDGFR-alpha and -beta are expressed in stroma and pericytes that are critical for the maintenance of newly formed blood vessels.[81,82] FGFR-1 and -2 are expressed on vascular endothelium and work with VEGFR to promote increased expression of VEGF.[81] Tie-1 and Tie-2 are expressed on blood vessels in tumors and are important in the recruitment of pericytes and smooth muscle cells to the newly forming vascular channels.[83]

Kinases in the cytoplasm act as bridges, conducting signals generated by RTKs to the nucleus through a series of intermediates that become phosphorylated.[84] The cytoplasmic kinases may be directly on the inside of the cell membrane or free in the cytoplasm. With respect to tumor cell biology, two particular cytoplasmic pathways are often dysregulated in cancer. The first includes members of the RAS-RAF-MEK-ERK/p38/JNK families (Fig. 15.6).[85,86] Most of these are serine/threonine kinases and their activation leads to ERK phosphorylation, translocation into the nucleus, and subsequent alteration of transcription factor and nuclear kinase activity important for controlling the cell cycle. Some examples of dysregulation in human cancers include RAS mutations in lung cancer, colon cancer, and several hematologic malignancies and BRAF mutations in cutaneous melanomas and papillary thyroid carcinomas.[87–89] Interestingly, BRAF mutations synonymous to those in human malignant melanomas are also found in canine transitional cell carcinomas, with more than 80% of tumors testing positive.[90]

The second cytoplasmic pathway includes phosphatidyl inositol-3 kinase (PI3K) and its associated downstream signal transducers AKT, nuclear factor κB (NFκB), and mTOR, among others (Fig. 15.7).[91,92] PI3K is activated by RTKs and in turn activates AKT, which alters several additional proteins involved in the regulation of cell survival, cycling, and growth.[93] AKT phosphorylates targets that promote apoptosis (BAD, procaspase-9, and Forkhead transcription factors) and activates NFκB, a transcription factor that has antiapoptotic activity.[91–93] AKT also phosphorylates other proteins such as mTOR, p21, p27, and GSK3. This leads



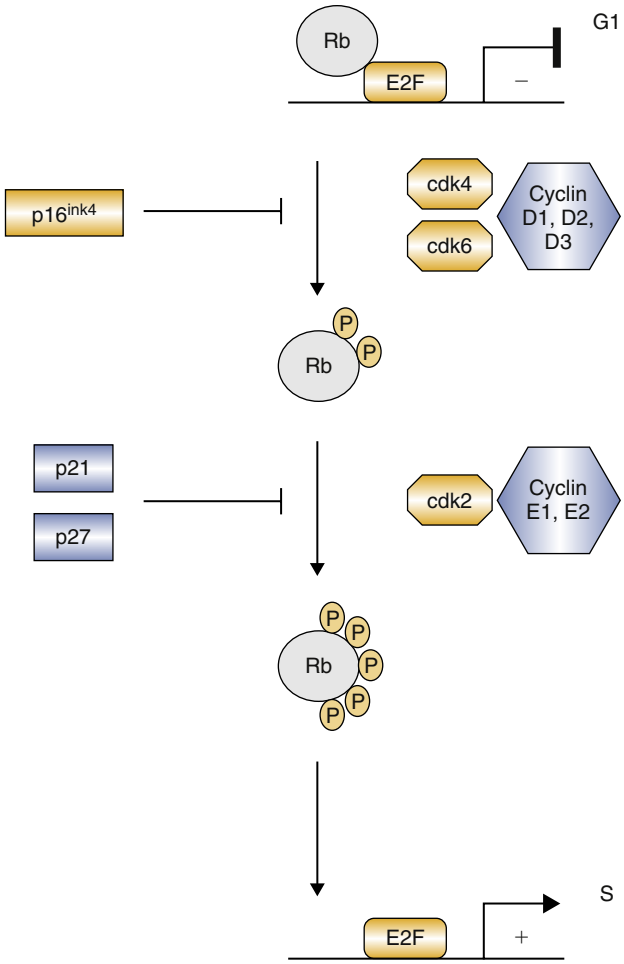
• **Fig. 15.6** Ras signal transduction. Activated receptor tyrosine kinases recruits SOS to the plasma membrane through binding of SHC and GRB2. SOS replaces bound GDP with GTP, thereby activating RAS. The downstream target RAF is then phosphorylated by RAS, leading to subsequent activation of MEK, then ERK. ERK has several substrates both in the nucleus and in the cytoplasm, including ETS transcription factors such as ELK1 and RSK, which regulate cell cycle progression. (Reprinted with permission from Blackwell Publishing, London CA, Vet Comp Oncol 2:177–193, 2004.)

to redistribution of these proteins either in or out of the nucleus, ultimately inhibiting apoptosis while promoting cell cycling.[91–93] Abnormalities of PI3K resulting in pathway activation are commonly found in human cancers including mutations (breast and colorectal cancers and glioblastoma) and gene amplifications (gastric, lung, ovarian cancers).[94] This pathway may also become dysregulated through loss of activity of phosphatase and tensin homolog (PTEN), a phosphatase that dephosphorylates AKT and terminates signaling.[91,95,96] PTEN mutations and/or decreased PTEN expression are present in several human cancers (e.g., glioblastoma and prostate cancer)[94,95] and have been documented in canine cancers (osteosarcoma, melanoma).[97–99]

RTK-induced signaling ultimately influences cellular events by affecting transcription and the proteins that control cell cycling. The cyclins and their kinase partners (cyclin-dependent kinases [CDKs]) act to regulate the progression of cells through various phases of the cell cycle (Fig. 15.8).[100–102] There are several cyclins (A–F); however, cyclins D and E play key roles in cell cycling through regulation of restriction point passage by the activation of their respective CDKs (CDK4 and CDK6 for cyclin D and CDK2 for cyclin E). Coordinated function of cyclins D and E is required for cells to progress from G1 into S phase (Fig. 15.8). In many cases, RTK-generated signals induce expression of cyclin D, which complexes with CDK4 and CDK6, resulting in phosphorylation of the tumor suppressor Rb, partially repressing its function.[101,102] Functional cyclin D/CDK complexes induce transcription of cyclin E, and active cyclin E/CDK complexes further reduce Rb activity through phosphorylation. This in turn initiates the process of DNA replication necessary for cells to cycle. Dysregulation of the cylins and CDKs is common in human cancers; for example, overexpression of cyclins D and E is often present in breast, pancreatic, and head and neck carcinomas.[102] Consequently, CDK4/CDK6 have become relevant targets for therapeutic intervention, particularly in the setting of breast cancer.[103]

Protein Kinases and Cancer Cells

Dysfunction of protein kinases is a common event in tumors. Although this has been best characterized in human cancers, data indicate that dog and cat cancers experience similar dysregulation (Table 15.2). Kinases may be dysregulated through a variety of mechanisms, including mutation, overexpression, fusion proteins, or autocrine loops. In many cases, these alterations result in phosphorylation of the kinase in the absence of an appropriate signal. Mutations documented in kinases include a single amino acid change through a point mutation, deletion of amino acids, or insertion of amino acids, usually in the form of an internal tandem duplication (ITD). For example, a point mutation



• **Fig. 15.7** PI3 kinase signal transduction. After receptor tyrosine kinase activation, PI3 kinase is recruited to the phosphorylated receptor through binding of the p85 adaptor subunit leading to activation of the catalytic subunit (p110). This activation results in the generation of the second messenger phosphatidylinositol-3,4,5-triphosphate (PIP3). PIP3 recruits AKT to the membrane and after its phosphorylation, several downstream targets are subsequently phosphorylated leading to either their activation or inhibition. The cumulative effect results in cell survival, growth, and proliferation. (Reprinted with permission from Blackwell Publishing, London CA, *Vet Comp Oncol* 2:177–193, 2004.)

occurs in the *BRAF* gene (V600E, exon 15) in approximately 60% of human cutaneous melanomas.[87,104,105] This amino acid change causes a conformation change in B-Raf, mimicking its activated form and thereby inducing constitutive downstream ERK signaling and abnormal promotion of cell growth and survival.[106,107] RAS is another kinase that is dysregulated through point mutation in several hematopoietic neoplasms (multiple myeloma, juvenile chronic myelogenous leukemia [CML], acute myelogenous leukemia [AML], and chronic myelomonocytic leukemia [CMML]) and in lung cancer, colon cancer, and several others.[86,108,109]

Another example of a mutation involves KIT, an RTK that normally is expressed on hematopoietic stem cells, melanocytes, in the central nervous system, and on mast cells.[110] In approximately 30% of canine grade 2 and grade 3 mast cell tumors (MCTs), mutations consisting of ITDs are found in the juxtamembrane domain of KIT, resulting in constitutive activation in the absence of ligand binding. These mutations are associated with a higher risk of local recurrence and metastasis.[111–113] Additional activating mutations in the extracelluar domain of KIT (specifically exons 8 and 9) have also been identified in canine MCTs.[114] Interestingly, KIT mutations consisting of deletions in the juxtamembrane domain are also found in approximately 50% of human patients with gastrointestinal stromal tumors (GISTs) and are also found in canine GISTs.[115–118] There are other well-characterized mutations involving RTKs in human cancers including FLT3 ITDs in AML,[119–122] EGFR point mutations in lung carcinomas,[123,124] and PI3K-α mutations in several types of carcinomas.[94]

Overexpression of kinases usually involves the RTKs and may result in enhanced response of the cancer cells to normal levels of growth factor; or, if the levels are high enough, the kinase may become activated through spontaneous dimerization in the absence of signal/growth factor. In humans, the RTK HER2 (also known as ErbB2, a member of the EGFR family) is overexpressed in both breast and ovarian carcinomas and this often correlates with a more aggressive phenotype.[125,126,73] EGFR is also overexpressed in human lung, bladder, cervical, ovarian, renal, and pancreatic cancers, and some tumors have as many as 60 copies of the gene per cell.[76,127,128] As with HER2, such overexpression is linked to a worse outcome in affected patients.[76]

Fusion proteins are generated when a portion of the kinase becomes attached to another gene through chromosomal rearrangement and the normal mechanisms that control protein function are disrupted. One of the best characterized fusion proteins is BCR-ABL, which is found in 90% of patients with CML.[129–132] ABL is a cytoplasmic TK that, when fused to BCR, results in dysregulation of ABL, inappropriate activity of the protein, and

• **Fig. 15.8** Cyclin and CDK regulation of G1–S transition. CDK inhibitors such as p16ink4 and p21 restrict the activity of cyclin D– and cyclinE–dependent kinases. Progressive Rb phosphorylation by the cyclins results in liberation of E2F and the resultant transcription of S phase genes. (Reprinted with permission from Blackwell Publishing, London CA, *Vet Comp Oncol* 2:177–193, 2004.)

TABLE 15.2 Receptor Tyrosine Kinases Associated with Human Cancer

Tyrosine Kinase	Cancer Association
EGFR family	Breast, ovary, lung,[a] stomach, colon, glioblastoma
Insulin receptor family	Sarcomas, cervix, kidney
PDGFR family	Glioblastoma, ovary, CMML, GISTs
KIT	AML, GISTs,[a] seminoma, MCTs,[a,b] melanoma
FLT3	AML[a]
VEGFR family	Angiogenesis,[a,b] Kaposi's sarcoma, hemangiosarcoma/angiosarcoma,[a] melanoma
FGFR family	AML, lymphoma, breast, prostate, multiple myeloma, TCC
NGFR family	Thyroid cancer, neuroblastoma, fibrosarcoma, AML
Met/Ron	Thyroid cancer, osteosarcoma,[a] rhabdomyosarcoma, liver, kidney, colon
EPHR family	Melanoma, stomach, colon, breast, esophagus
AXL	AML
Tie family	Angiogenesis, stomach, hemangioblastoma
RET family	Thyroid cancer, multiple endocrine neoplasia
ALK	Non-Hodgkin's lymphoma, lung

[a]Also associated with canine cancer.

[b]Also associated with feline cancer.

ALK, Anaplastic lymphoma kinase; *AML,* acute myelogenous leukemia; *CMML,* chronic myelomonocytic leukemia; *EGFR,* epidermal growth factor receptor; *EPHR,* ephrin receptor; *FGFR,* fibroblast growth factor receptor; *GISTs,* gastrointestinal stromal tumors; *MCTs,* mast cell tumors; *NGFR,* nerve growth factor receptor; *PDGFR,* platelet-derived growth factor receptor; *TCC,* transitional cell carcinoma; *Tie,* tyrosine kinase receptor on endothelial cells; *VEGFR,* vascular endothelial growth factor receptor.

resultant malignant transformation. Other examples of fusion proteins include TEL-PDGFR-β in CMML, FIP1-PDGFR-α in hypereosinophilic syndrome with mastocytosis, and EML4-ALK in non-small-cell lung cancer (NSCLC).[133]

Autocrine loops of activation primarily occur when the tumor cell expresses both the RTK and the corresponding GF; in most cases, one or the other usually is also overexpressed, resulting in constitutive activation of the RTK. Examples include coexpression of transforming growth factor-alpha (TGF-) and EGFR in glioblastoma and squamous cell carcinoma, insulin-like growth factor-1 (IGF-α) and its ligand, IGF-1R, in breast and colorectal cancer, and VEGF and VEGFR in melanoma.[73,134–136] In canine cancers, possible autocrine loops have been documented in osteosarcoma (OSA) (coexpression of MET and its ligand, HGF) and hemangiosarcoma (HSA, coexpression of KIT and its ligand, SCF).[137–139]

Inhibition of Kinases

Given the detailed molecular characterization of signal transducer dysregulation in cancer cells, significant efforts have been directed at developing strategies to inhibit those transducers that participate in tumorigenesis through direct effects on cancer cells or through modulation of the local tumor microenvironment (stroma and neovasculature). The two most successful approaches to date have been monoclonal antibodies (mAbs) and small molecule inhibitors.

Several mAbs have been developed to target the extracellular domain of RTKs known to be important in a variety of tumors. These antibodies may prevent the growth factor from binding, promote internalization of the RTK and subsequent degradation, or may induce an immune response against the cancer cell. One of the most successful examples is a humanized mAb called trastuzumab (Herceptin). This antibody targets HER2, which as previously discussed is overexpressed in approximately 30% of human breast cancers.[140] Initial clinical trials of trastuzumab as single-agent treatment for HER2-positive breast cancer resulted in a response rate of approximately 25% in the setting of metastatic disease.[141] The response rate approached 50% when trastuzumab was combined with chemotherapy.[142] When used in the adjuvant setting, multiple studies have demonstrated that trastuzumab significantly improves survival rates of women with HER2-positive disease; consequently, it is now part of the routine standard of care for this type of cancer.[143,144] Other examples of mAbs that have significant activity in human cancers include rituxumab (Rituxan), which targets CD20 expressed in a number

VetBooks.ir

of B-cell malignancies[145,146] and cetuximab (Erbitux), which targets ErbB1/HER1/EGFR known to be overexpressed in several carcinomas.[76,140,147]

Small molecule inhibitors work primarily by blocking the ATP binding site of kinases, essentially acting as either reversible or irreversible competitive inhibitors; a smaller number of these inhibitors work by preventing necessary protein–protein interactions (allosteric inhibition).[148] In the absence of ATP, the kinase is unable to phosphorylate itself or downstream signaling elements, thereby interrupting a survival/growth signal essential to the tumor cell, ultimately resulting in cell death. As the molecular characterization of tumors has improved, the development and application of small molecule inhibitors has rapidly expanded in human oncology, and their use is markedly altering how cancers are managed. Such inhibitors are often easy to synthesize in large quantities, frequently orally bioavailable, and can readily enter cells to bind the intended target.

The first small molecule inhibitor to be approved for human use was imatinib (Gleevec), an orally administered drug that binds the ATP pocket of ABL and the RTKs KIT and PDGFR-α.[149] As previously discussed, BCR-ABL fusion proteins are present in 90% of human patients with CML, making ABL a good target for therapeutic intervention. The application of imatinib to CML has been transformative, with significant biologic activity demonstrated in several clinical trials resulting in the approval of imatinib for first-line care of affected individuals.[150–155] In the chronic phase of the CML, imatinib induces a remission rate of close to 95%, and most patients remain in remission for longer than 1 year. Unfortunately, the remission rate is much lower for patients in blast crisis (20%–50%), often lasting less than 10 months. Resistance to imatinib has been well characterized and is primarily a result of the development of mutations in ABL that prevent drug binding, although gene amplification has also been documented.[156,157] Imatinib also has clinical activity against human GIST, in which 50% to 60% of the tumors have point mutations or deletions in the juxtamembrane domain of KIT resulting in constitutive activation.[158,159] Imatinib therapy for GIST patients results in response rates of 50% to 70%, far better than the 5% response rate observed with standard chemotherapy.[160,161] A small number of GISTs have activating mutations in PDGFR-α instead of KIT mutations; these patients also respond to imatinib.[162]

There are now more than 30 FDA-approved protein kinase inhibitors for the treatment of human cancers, ranging from those that target specific mutations in a single kinase to those that are multitargeted in nature, affecting both tumor cells and the microenvironment. For example, a subset of people with NSCLC have tumors with activating mutations in EGFR (in exons 19 or 21) that respond to erlotinib (Tarceva) or gefitinib (Iressa), small molecule inhibitors of EGFR.[163] Response rates in patients with EGFR mutations can be as high as 80% compared with less than 10% to 20% for those without, demonstrating that the efficacy of targeted therapies is often dependent on the presence of a known activated signaling element. Resistance to erlotinib/gefitinib is often mediated by a second mutation at codon 790 (T790M), and a protein kinase inhibitor osimertinib (Tagrisso), which targets this specific resistance mutation, has been approved.[164] A small number of patients with NSCLC also exhibit activation of the RTK ALK through its fusion to EML4.[165] A small molecule inhibitor of ALK, crizotinib (Xalkori) has demonstrated significant activity against lung cancer patients whose tumors express the EML4–ALK translocation. Objective response rates of greater than 50% to crizotinib are typical in this subset of patients, with many more of patients experiencing long-term disease stabilization.[165,166]

Vemurafenib (Zelboraf) is a small molecule inhibitor of B-raf that has significant activity against cutaneous malignant melanomas that possess activating mutations in the *BRAF* gene. Response rates in the setting of *BRAF* mutant melanoma exceed 50%, compared with less than 5% for patients treated with dacarbazine.[167] Inhibition of mTOR has become of interest in several cancers, given the activation of the PI3K pathway and the critical role of mTOR in mediating its effects. Rapamycin (Rapamune), a drug used for many years as an immunosuppressive agent, is the prototypic mTOR inhibitor.[168,169] Temisorlimus (Torisel) and evorolimus (Zortress), two rapamycin analogs, have been approved for use in patients with metastatic renal carcinoma, and other mTOR inhibitors are currently under investigation for their potential utility in treating soft tissue and bone sarcomas.[168,169]

Several new kinase inhibitors target signal transduction pathways in hematologic malignancies. Ibrutinib (Imbruvica) blocks signaling through the BTK cytoplasmic kinase that is critical for B cell receptor activity.[170] It is approved for use in several B-cell malignancies including CLL, follicular lymphoma, and Waldenström's macroglobulinemia; response rates in these diseases typically exceed 70% to 80% and are often durable in nature. With respect to T-cell malignancies, small molecule inhibitors of PI3Kγδ (tenalisib, duvelisib) have shown significant activity against peripheral and cutaneous T-cell lymphomas, with response rates ranging from 40% to 50%.[171]

Whereas the inhibitors discussed earlier tend to inhibit a restricted set of kinases, there are other inhibitors that exhibit more broadly targeted inhibition. Sunitinib (Sutent) is a small molecule inhibitor of several RTKs including VEGFR1/2, PDGFR-α/β, KIT, FLT3, CSFR1, and RET.[172] The multitargeted nature of this inhibitor may be responsible for its observed activity in several types of cancer including GIST, renal cell carcinoma, thyroid carcinoma, and insulinoma, among others.[172] Although such agents often have significant clinical activity, they are typically associated with a broader range of toxicities that may limit their use.

Kinase Inhibitors in Veterinary Medicine

There are now two small molecule inhibitors approved for use in dogs in veterinary oncology. Toceranib (TOC) phosphate (Palladia) is a multitargeted inhibitor closely related to sunitinib that exhibits a similar target profile including VEGFR, PDGFR, KIT, FLT3, and CSF1R. TOC has demonstrated activity against MCT and sarcomas and carcinomas. In the original phase I study, 28% of dogs experienced objective responses to treatment, with an additional 26% experiencing stable disease for an overall clinical benefit of 54%.[173] A pivotal study of TOC was subsequently conducted in dogs with recurrent or metastatic intermediate or high-grade MCTs, resulting in an objective response rate of 42.8% (21 complete responses (CR), 42 partial responses (PR)), with an additional 16 dogs experiencing stable disease for an overall clinical benefit of 60%.[174] Dogs whose MCT harbored activating mutations in KIT were roughly twice as likely to respond to TOC than those without mutations (69% vs 37%). After approval of TOC in 2009, it has been used to treat a number of different solid tumors.[175] Biologic activity has been reported in dogs with anal sac adenocarcinoma, thyroid carcinoma, head and neck carcinoma, and nasal carcinoma. Work is ongoing to more clearly define the role of TOC in the treatment of canine and feline cancer.

Mastinib (MAS, Kinavet, Masivet) is a small molecule inhibitor of KIT, PDGFR-α/β and Lyn that has been evaluated in both

VetBooks.ir

dogs and cats, although it is not currently approved by the US FDA. In dogs with MCTs, MAS significantly improved time to progression compared with placebo, and outcome was improved in dogs with MCT harboring KIT mutations.[176] Subsequent follow-up of patients treated with long-term MAS identified an increased number of patients with long-term disease control compared with those treated with placebo (40% vs 15% alive at 2 years).[177] Small studies have also evaluated the efficacy of imatinib for the treatment of canine and feline MCT.[178–180] Imatinib was well tolerated, and objective antitumor responses were observed in dogs with both mutant and wild-type KIT. Responses have also been observed in cats with MCT.[181,182]

Other small molecule inhibitors are currently under development for the treatment of canine cancer. RV1001 is an orally bioavailable PI3Kδ inhibitor that has demonstrated significant activity against naïve and relapsed T- and B-cell lymphomas in dogs. In phase I and II clinical trials, objective response rates ranged from 62% to 77% (respectively), with hepatotoxicity as the primary dose limiting event.[183] Verdinexor (KPT-335) is an orally bioavailable small molecule inhibitor of XPO-1, a nuclear export protein shuttle responsible for transporting several tumor suppressor proteins, thereby extinguishing their function. Blockade of XPO1 forces retention of these proteins, including such key cellular regulators as p53, p21, RB, FOXO, and NFκB. Verdinexor has been evaluated in both phase I and II studies in dogs with lymphoma; objective response rates in both studies were approximately 35%, with several dogs experiencing long-term stable disease, and hyporexia was determined to be the dose-limiting toxicity.[184,185]

Conclusion

With the advent of molecular techniques, the characterization of signal transduction pathways that are dysfunctional in cancer cells has become commonplace. Advances in computer modeling and small molecule engineering have led to the rapid development of inhibitors capable of blocking specific pathways critical for cancer cell proliferation and survival. The success of kinase inhibitors such as imatinib and crizotinib indicate that the application of this therapeutic strategy can markedly improve clinical outcomes. Perhaps the greatest challenges will be determining how these novel therapeutics can be effectively combined with standard treatment regimens such as surgery, chemotherapy, and radiation therapy to provide optimal anticancer efficacy without enhancing toxicity, and identifying strategies to use these therapeutics that are less likely to result in drug resistance.

SECTION C: ANTIANGIOGENIC AND METRONOMIC THERAPY

ANTHONY J. MUTSAERS AND BARBARA BILLER

Tumor Angiogenesis

For a solid tumor to grow beyond a few millimeters in size, it must recruit a blood supply to provide adequate nutrients and oxygen to the dividing cell mass and remove waste products.[186,187] Inducing angiogenesis is a hallmark of cancer progression,[188] yet angiogenesis is also a prominent aspect of normal physiology and transient pathology (e.g., in wound healing) and is tightly regulated. A large number of proangiogenic growth factors and signaling pathways promote the process of blood vessel growth.[186] Similarly, endogenous inhibitors of angiogenesis are temporally expressed to suppress vessel expansion and maintain angiogenic balance.[189] The net effect depends on this relative balance, which is tipped toward promoting angiogenesis during tumor growth. Therapeutic interventions aim to tip the scales back toward inhibiting angiogenesis.[190] Importantly, the vessels produced to support tumor growth are vastly different from normal vasculature. Tumor vessels are characterized by profound leakiness and sparse intermittent coverage of the endothelium by structural mural components, such as pericytes. These abnormalities inherent in tumor vessels contribute to the poor perfusion and high interstitial fluid pressure that are consistent features of the tumor microenvironment.

"Classical" angiogenesis occurs through the sprouting of new vessels from existing vasculature. The term vasculogenesis describes the de novo formation of new blood vessels from bone marrow–derived progenitor cell populations that respond to locally produced proangiogenic signals.[191,192] Numerous cell types that originate from bone marrow, including circulating endothelial progenitor cells (CEPs), may contribute to tumor angiogenesis by traveling to tumor sites and incorporating into existing vessel walls.[193–196] Finally, in certain circumstances, cancer cells may also access a blood supply through means other than sprouting new vessels. In certain highly vascular tissue environments, cancers may use *vessel co-option* to grow along existing blood vessels, which may ultimately lead to vessel collapse as the tumor grows.[197] In other contexts, cancer cells may produce microvascular channels that conduct fluid through a tumor cell–lined network in a process first described in uveal melanoma, known as *vasculogenic mimicry.*[197,198] The relative contributions of classical angiogenesis, CEP contribution, vessel co-option, and vasculogenic mimicry are likely cancer cell, organ/tissue environment, and stage dependent, potentially evolving as the tumor mass grows and becomes more heterogeneous and therapy resistant.

In addition to blood vessels, lymphatics are important components of the tumor microenvironment and a prominent feature of tissue homeostasis, immunosurveillance, and a gateway to metastatic spread.[199] Lymphatic vessel growth regulation is physiologically similar in principle to that of blood vessels,[200] and therefore targeting lymphangiogenesis may also represent an attractive treatment strategy in clinical oncology worthy of focused research.[201]

Antiangiogenic Therapy

Angiogenesis became a validated therapeutic target in oncology with the widespread approval of drugs that inhibit a potent signaling pathway for blood vessel growth, the vascular endothelial growth factor (VEGF) receptor tyrosine kinase pathway.[202–206] Drugs such as bevacizumab (Avastin), the humanized anti-VEGF monoclonal antibody, and small molecule receptor tyrosine kinase inhibitors (RTKIs) such as sunitinib (Sutent) in human oncology and TOC phosphate (Palladia) in veterinary medicine are considered to be efficacious, at least in part, because of the antiangiogenic effects of VEGFR signaling inhibition.[207,208]

Multiple mechanisms have been proposed to explain the antitumor effects of antiangiogenic therapies.[204] The first and most intuitive is *vascular collapse* resulting in impaired oxygen delivery to the tumor, leading to nutrient starvation, hypoxia, and death of cancer cells that cannot survive in this environment.[209] Conversely, a second perhaps paradoxical mechanism involves more efficient delivery of oxygen, nutrients, and indeed other drugs

VetBooks.ir

(such as chemotherapeutics) to tumor cells by the process of *vessel normalization*.[210,211] Normalization occurs when smaller, tortuous, inefficient, and leaky tumor vessels are selectively destroyed by the therapy, resulting in improved blood flow through more established vasculature, increasing perfusion to the tumor as a whole.[212] Vascular normalization has been demonstrated clinically using functional magnetic resonance imaging (fMRI) in patients treated with VEGF pathway inhibitors.[213,214] The most common clinical approach to targeting tumor angiogenesis has been either inhibition of overexpressed proangiogenic stimuli or supplementation of factors that inhibit angiogenesis, to tip the overall balance in favor of suppressing vessel growth.

Inhibition of Proangiogenic Factors

Currently, most RTKIs target numerous receptors to varying degrees.[208,215] TOC is an example of an RTKI that complements its direct effects on tumor cells (e.g., via mutated c-*kit* inhibition) with angiogenesis inhibition because it directly targets VEGFRs.[216] In addition, drugs that inhibit PDGFRs, such as TOC, disrupt signaling pathways important for blood vessel support structures, such as the stromal pericyte component of larger vessels.[217,218] These drugs need not necessarily be purely antiangiogenic, as blood vessel receptors such as VEGFR and PDGFR may also be expressed by certain cancer cells, resulting in an autocrine growth factor loop within the tumor.[219,220] The end result is that, in specific instances, targeting angiogenic pathways may have concurrent direct antitumor cell and antiangiogenic effects.

Significant cross-influence exists between growth signaling pathways, and as a result there is strong interaction between tumor oncogene and suppressor gene expression and regulation of blood vessel expansion through growth factors such as VEGF. Therefore many drugs that target oncogenes have demonstrated antiangiogenic "off-target" effects as a byproduct of VEGF reduction.[221–223] For example, the anti-HER2 (*ErbB-2*) human MAb trastuzumab (Herceptin) and anti-EGFR antibodies such as cetuximab (Erbitux) are examples of drugs that indirectly suppress angiogenesis because neutralization of their oncogenic targets leads to a dramatic reduction in tumor cell VEGF production, which increases again at the time of targeted drug resistance.[224,225] Through reduction in VEGF or other growth factor expression, there is an antiangiogenic component to many forms of cancer treatment, including not only targeted inhibitors but also cytotoxic chemotherapy and RT. Therefore antiangiogenic effects are not necessarily restricted to treatment modalities that target known angiogenesis pathways directly.

Angiogenic Inhibitor Supplementation

Since the discovery of endogenous proteins and protein fragments that inhibit blood vessel growth, such as angiostatin, endostatin, and thrombospondins, there has been clinical interest in using angiogenesis inhibitors as cancer therapeutics.[189,226] In veterinary medicine, thrombospondin-1 mimetic peptides were evaluated in dogs with multiple tumor types. Treatment with the mimetic peptides ABT-526 and ABT-510 in a prospective clinical trial of 242 dogs with multiple tumor types showed an objective response or substantially stabilized disease in 42 dogs and a lack of dose-limiting toxicity.[227] Interestingly, most objective responses were recorded after 60 days of continuous drug treatment. Subsequently, an updated formulation, ABT-898, demonstrated a response rate of 32% in 28 dogs with soft tissue sarcoma.[228] Results of a prospective randomized placebo-controlled clinical trial in dogs with multicentric lymphoma treated at first relapse revealed significantly improved time to tumor progression and remission duration, but not remission rate, when ABT-526 was used in combination with lomustine chemotherapy, compared with dogs treated with lomustine alone.[229] No ABT-526–specific toxicities were noted in this trial. In addition to thrombospondin-1, preliminary studies documenting detection of the endogenous inhibitors angiostatin and endostatin in normal and tumor-bearing dogs have been reported.[230,231] In a pilot study of endostatin as a therapeutic agent, 13 dogs with soft tissue sarcomas were treated with the canine endostatin gene delivered via liposome–DNA complexes.[232] Although endostatin gene expression was not detected in the tumors after treatment, objective responses were documented in two dogs, and eight dogs experienced stable disease, suggesting potential nonspecific antitumor activity.

Targeting Tumor Endothelial Cell Markers

Tumor endothelial cells (ECs) differ from normal endothelia in their gene and protein expression.[233] These differences may represent an opportunity for a favorable therapeutic index when drugs are designed to bind differentially expressed targets on tumor-specific endothelium. If not naturally destructive to these cells, drugs can be designed to carry a payload to induce local cytotoxicity, producing an antiangiogenic effect. A phage vector delivering tumor necrosis factor-alpha (RGD-A-TNF) to αV integrins on tumor endothelium is an example of this strategy that has undergone evaluation in dogs.[234] Through serial biopsy, this dose escalation trial demonstrated selective targeting of tumor endothelium via αV integrin-targeted expression of TNF, and treatment of a cohort of tumor-bearing dogs at the MTD resulted in partial remission in 2 of 14 and stable disease in 6 of 14 dogs.

Other Antiangiogenic Agents

A vast array of drugs not necessarily designed as anticancer therapeutics may derive at least a portion of their activity through inhibition of angiogenesis. Two examples investigated in a veterinary setting include inhibitors of matrix metalloproteinases (MMPs) and cyclooxygenases (COXs). The MMPs are a family of enzymes that degrade the extracellular matrix and basement membrane, thereby mediating tumor invasion, angiogenesis, and metastasis.[235] Unfortunately, clinical evaluation of compounds that inhibit these enzymes has to date been largely unrewarding,[236,237] including results from a large randomized trial of 303 dogs with OSA, in which treatment with the MMP inhibitor Bay12-9566 or placebo after doxorubicin (DOX) chemotherapy did not improve overall survival.[238] Inhibition of the proinflammatory COX enzymes has been reported in numerous tumor types in veterinary oncology.[239–241] The effects of COX inhibition on angiogenesis were evaluated with piroxicam treatment of canine transitional cell carcinoma (TCC). In a study of 18 dogs, piroxicam treatment was associated with reduced urinary concentrations of the proangiogenic growth factor basic fibroblast growth factor (bFGF) and induction of apoptosis.[242] In a subsequent study evaluating these parameters in 12 dogs treated with piroxicam in combination with cisplatin, reductions in urinary bFGF and VEGF were associated with response to the combination regimen.[243]

Another agent with demonstrated antiangiogenic effects, thalidomide, has been approved for treatment of human multiple

VetBooks.ir

myeloma.[244] Thalidomide has been evaluated in veterinary oncology for treatment of canine hemangiosarcoma (HSA) and other tumors as a single agent and in combination with chemotherapy, including metronomic chemotherapy protocols.[245,246] Targeting angiogenesis in combination with chemotherapy has been considered a useful strategy,[204] particularly as drug delivery may be enhanced through a "normalized" vasculature.[210] Many reported early clinical trials utilize a cocktail of multiple drugs, such as COX inhibitor, kinase inhibitor, thalidomide, and/or chemotherapy agent(s). Multiple drug trial design may increase the chances of documenting anticancer activity, but is challenging to decipher the relative contributions of a particular agent to the outcome of the treatment protocol.

Metronomic Chemotherapy

Ideal anticancer therapies would be highly efficacious, widely available at low cost, and associated with a low risk of causing adverse events. Keeping this in mind, along with the statement of Fidler and Ellis that "Cancer is a chronic disease and should be treated like other chronic diseases," one path taken toward the identification of optimal therapies has been the exploration of metronomic drug delivery.[247] Characterized by chronic administration of chemotherapeutic agents at low doses, metronomic chemotherapy (or low-dose continuous chemotherapy) is being used with increasing understanding and frequency in the treatment of humans and companion animals with cancer.

The term metronomic chemotherapy (MC) was originally introduced by Hanahan and colleagues in 2000 to describe the concept that the continuous administration of certain cytotoxic drugs targeted tumor ECs, impairing their ability to repair and recover as long as no extended drug-free gaps were allowed.[248] Although a number of cytotoxic chemotherapy agents achieve at least a portion of their therapeutic efficacy through inhibition of tumor angiogenesis, their delivery at the MTD in conventional chemotherapy protocols necessitates a break period to permit recovery of normal cell populations.[249,250] When many of the same drugs are instead delivered in a metronomic fashion, the therapeutic target shifts from the rapidly dividing tumor cell population to the more slowly proliferating tumor endothelium. Although this approach was initially designed to overcome the development of chemotherapeutic drug resistance via inhibition of tumor angiogenesis, additional mechanisms of action have since been uncovered. These include activation of antitumor immunity, induction of tumor dormancy, and inhibition of cancer stem cells. Compared with typical MTD treatment regimens, the low toxicity profile, ease of administration for orally delivered drugs, and decreased cost make MC protocols particularly appealing in veterinary oncology. However, mechanistic and clinical evaluation in veterinary patients is still at a relatively early stage.

Mechanisms of Action

Tumor Angiogenesis

When different types of cells in culture were exposed to continuous ultralow doses of chemotherapy, proliferating EC populations displayed an exquisite sensitivity compared with other cell types, including tumor cells in many instances.[251,252] Although the reasons for EC selectivity are not entirely clear, the explanation likely goes beyond mere targeting of rapidly dividing cells. Experimental evidence has suggested that upregulation of thrombospondin-1 occurs during treatment with metronomic cyclophosphamide and possibly other chemotherapy agents.[253,254] The resulting angiogenic suppression may be complemented by decreased tumor cell production of proangiogenic growth factors such as VEGF, through reduced tumor cell mass.

Other components of angiogenesis may also be targeted by metronomic delivery of chemotherapy. Mechanistically, tumor angiogenesis involves recruitment of CEPs.[195] These CEP cells may be most influential in rebuilding tumor vessels during the break period after the acute damage of MTD chemotherapy exposure.[255] Preclinical models have demonstrated that CEPs acutely decrease with MTD treatment, only to rapidly rebound during the break period (similar to other bone marrow-derived cells), when they may contribute to EC repopulation.[256] In contrast, metronomic chemotherapy delivery does not appear to be associated with a CEP surge, leading instead to a sustained antiangiogenic effect.[256–258]

Immunomodulatory Effects

The ability of tumors to grow undetected by the host immune system is a well-recognized feature of malignancy. Through the dynamic process of immunoediting the phenotype of neoplastic cells evolves to escape immune detection. Two major immune cells, regulatory T lymphocytes (Treg), and myeloid-derived suppressor cells (MDSCs), are key players in this process. Although they limit pathologic inflammation under normal conditions, Treg and MDSC efficiently suppress antitumor immune responses in cancer patients.[259–261] Treg are particularly adept at inhibiting effector (cytotoxic) T cells through direct cell-to cell contact and secretion of immunosuppressive cytokines such as TGF-β and IL-10. MDSC and other immune cells such as poorly functional dendritic cells and inhibitory macrophages also help establish tumor tolerance and an immunosuppressive tumor microenvironment.

Although it may seem counterintuitive, a number of chemotherapeutic agents display both immunostimulatory and immunosuppressive effects, a difference that sometimes depends only on the dose and schedule of drug administration. One of the best examples of this concept is illustrated by the alkylating agent cyclophosphamide (CYC). Whereas high doses have long been used as a myeloablative preconditioning therapy for procedures such as bone marrow transplantation, metronomic delivery of CYC is associated with multiple immunostimulatory effects including decreases in the number and function of Treg, dendritic cell activation, and stimulation of tumor-specific cytotoxic T cells.[262]

The clinical effect of metronomic CYC chemotherapy on the host immune system was first demonstrated in a key study by Ghiringhelli in which human patients with advanced cancer experienced a selective decrease in circulating Treg numbers with marked restoration of T effector cell proliferation and NK cell function.[263] Numerous additional studies have since uncovered direct and specific inhibitory effects of low-dose CYC on Treg function, often with corresponding increases in effector T-cell function and decreased expression of immunosuppressive cytokines.[262,264] Worth noting, however, are results of studies in mouse tumor models and in human cancer patients documenting stimulation of MDSC recruitment and rebounding tumor growth during administration of metronomic CYC.[265–267]

Immunomodulatory effects of CYC have also been reported in dogs with spontaneous cancer. Metronomic administration of CYC, for example, appears to be immunostimulatory based

VetBooks.ir

on two small studies in which circulating Treg were significantly decreased when CYC was given alone or in combination with TOC.[268,269] Interestingly, dogs receiving the two drugs concurrently had significant increases in serum concentrations of IFN-γ that were inversely correlated with Treg numbers after 6 weeks of treatment.[269]

Administration of low, noncytotoxic concentrations of other chemotherapeutic agents such as paclitaxel, DOX, methotrexate and gemcitabine have also been shown to improve antitumor immunity. Mechanisms for this vary but include dendritic cell activation, improvement of cytotoxic T-cell function and reduction of MDSC activity.[270–272] For example, administration of low doses of paclitaxel to mice with metastatic lung tumors led to a selective decrease in Treg number and function without interfering with tumor-specific cytotoxic T cell function.[273] The nucleoside analog gemcitabine appears to decrease MDSC accumulation within tumor tissues, likely in part through the differentiation of MDSC into functionally active immunostimulatory DCs.[265,266]

Similar to CYC, the alkylating agent temozolomide (TMZ) has also been shown to reduce circulating Treg numbers in human cancer patients.[274] Denies and colleagues recently investigated daily low dose TMZ therapy in 30 tumor-bearing dogs, administered either alone or in combination with daily low-dose CYC.[275] In these dogs the primary study endpoints were circulating Treg numbers and plasma concentrations of TSP-1 and VEGF. The investigators found that dogs receiving CYC (12.5 mg/m^2/day) or the combination of CYC and TMZ (6.6 mg/m^2/day) had significantly lower percentages of Treg after 2 weeks of therapy whereas dogs receiving TMZ alone did not. Neither drug nor the combination was found to influence pre- and posttreatment plasma concentrations of TSP-1 or VEGF. As TMZ has been well tolerated in dogs at higher doses in conventional chemotherapy protocols, additional pharmacodynamic studies may lead to identification of a biologically effective dose when used in the metronomic setting.[276,277]

Other Targets of Metronomic Chemotherapy

Dormancy is a stage of tumor development in which viable neoplastic cells are present but inactive as a result of dynamic equilibrium between apoptosis and proliferation. Dormancy may arise in the early phases of tumor progression before conditions are in place to adequately support tumor cell proliferation and again in the posttreatment remission period. Not surprisingly, reactivation of dormant tumor cells represents one reason for the development of progressive disease after completion of conventional MTD chemotherapy protocols.[278] Similar to dormant tumor cells, cancer stem cells (CSCs) may also be present both before and after conventional anticancer therapy. Also known as tumor initiating cells, CSCs display a unique and formidable phenotype within the tumor cell population, characterized by their capabilities for self-renewal and DNA repair. Accumulating experimental data suggest MC may be able to target CSCs and dormant tumor cells because of the tendency of both cell populations to reside in close proximity to tumor vasculature.[279] For instance, in mice with glioma and hepatocellular carcinoma, antiangiogenic therapy was found to disrupt this close association, leading to apoptosis of CSC and bystander damage to dormant tumor cells immediately adjacent tumor vasculature.[280,281] Whether this mechanism of action of MC will translate into a therapeutic benefit for human or veterinary patients awaits further investigation.

Clinical Trial Evaluation

Summary of Human Clinical Trials

Nearly 20 years ago, the results of a pivotal clinical trial were reported in which women with metastatic breast cancer received daily low dose CYC and twice weekly methotrexate. This study found a disease control rate (defined as a complete or partial response or durable stable disease) of 32% and a low incidence (13%) of mild to moderate leukopenia.[282] As most of the women had already failed MTD chemotherapy protocols containing CYC, these results stimulated significant interest in further investigation of MC for the treatment of advanced cancers.

Since that time, numerous phase I and II studies have described the clinical benefits of MC, many reporting encouraging tumor control rates and very low toxicity rates. The majority of these studies have paired a conventional chemotherapy drug with a noncytotoxic drug that also targets angiogenesis. Noncytotoxic drugs typically include those with indirect effects on angiogenesis such as COX inhibitors, tetracyclines, and thalidomide or those with more direct effects such as bevacizumab.

In a meta-analysis of 80 published human clinical trials, the most frequently used cytotoxic drugs were CYC (43%) followed by capecitabine, etoposide, and vinorelbine.[283] In this systematic literature review, most studies (80%) were reports from single-arm trials, often relying on historical controls. In 72% of the trials, the patient sample size was 50 or less. Of the few trials with multiple arms (n = 16), only seven were randomized. Recent clinical data compiled from larger MC clinical trials for cancer patients living in India have found that methotrexate and celecoxib are used most often, likely owing to the wide availability and low cost of these agents.[284]

To date there has been only one double-blinded, placebo-controlled randomized clinical trial reported in human cancer patients.[285] This study compared a four-drug metronomic regimen of daily celecoxib and thalidomide with alternating periods of etoposide and CYC to placebo in 108 pediatric patients with solid tumors (mostly OSA or primitive neuroectodermal tumors). The primary study end point was the progression-free rate (PFR) as defined by the proportion of patients without disease progression at 6 months after starting MC. Unfortunately, there was no difference in PFR between the two groups as more than 96% of patients developed progressive disease within 3 months. Interestingly, patients receiving MC for a tumor type other than a bone sarcoma demonstrated significantly longer overall progression-free survival (PFS) time compared with those receiving placebo. The authors concluded that MC may not display efficacy across all classes of pediatric solid tumors, underscoring the importance of tumor histology in predicting treatment response.

Summary of Veterinary Clinical Trials

Similar to human clinical studies, veterinary clinical trials evaluating MC have been mostly small, phase I and II and/or retrospective. Metronomic administration of CYC, given alone or in combination with a nonsteroidal antiinflammatory drug (NSAID), has been the approach most often tested; however, the treatment protocol, disease setting and outcomes assessed have all varied considerably. The majority of trials have investigated dogs with various malignancies and advanced disease, using the

VetBooks.ir

disease control rate as the main indicator of tumor response. A handful of studies have also examined pharmacodynamic measures of response including biomarkers of angiogenesis or immunomodulation.[268,269,277]

Veterinary Trials with Alkylating Agents

Thus far there have been roughly 20 published reports of clinical trials investigating metronomic delivery of an alkylating agent in dogs with cancer; only two have included cats. Of these about 80% have utilized CYC with the remainder employing other alkylators. An early trial by Lana et al tested the administration of oral CYC (12.5–25 mg/m^2/day) alternating with etoposide (50 mg/m^2 PO, daily) and combined with daily piroxicam for the adjuvant treatment of dogs with splenic HSA.[286] These investigators found that the approach had similar efficacy and less toxicity compared with control dogs receiving conventional DOX chemotherapy. The metronomic protocol was well tolerated over a 6-month period although two of nine dogs developed a transient sterile hemorrhagic cystitis (SHC). A more recent investigation by Wendelburg and colleagues found a similar result when comparing metronomic CYC chemotherapy versus conventional DOX chemotherapy for dogs with splenic HSA.[287] In this study, however, the median overall survival time (OST) was strikingly short (3.4 months) for dogs receiving either adjuvant metronomic or conventional chemotherapy and not significantly different from dogs treated with splenectomy alone.

Metronomic delivery of CYC has also been investigated in the maintenance setting after completion of adjuvant MTD chemotherapy in dogs with HSA or OSA. For dogs with HSA treated with splenectomy and six doses of DOX, daily or every other day CYC plus an NSAID had no effect on PFS or OST.[288] In dogs with OSA, the addition of daily CYC with an NSAID after limb amputation and four doses of carboplatin yielded similar PFS and OST as dogs treated with amputation and carboplatin alone.[289] In a larger multicenter study, dogs with OSA were randomized to receive piroxicam and CYC with or without TOC after limb amputation and four doses of adjuvant carboplatin.[290] Compared with historical control dogs treated with amputation and four doses of carboplatin, there was no improvement in the median PFS or OST in dogs of either treatment arm.

Other alkylating agents including chlorambucil, lomustine, and TMZ have also been evaluated in veterinary treatment protocols. In most of these trials the primary study endpoint has been toxicity, with tumor response evaluation a secondary goal.[275,291–293] When administration of lomustine at a daily oral dose of 2.84 mg/m^2 was tested in 81 dogs with a various malignancies, an unexpectedly high incidence of adverse events occurred and led to the discontinuation of the therapy in nearly 30%.[293] Oral chlorambucil is typically well tolerated when given at 4 mg/m^2/day in metronomic protocols. But when given at higher daily doses of 6 or 8 mg/m^2, a retrospective study found significantly increased gastrointestinal and bone marrow toxicities with no improvement in tumor response.[292] Chlorambucil at 4 mg/m^2/day combined with monthly doses of lomustine was also well tolerated based on investigation of eight dogs with glioma. In this study, three of the dogs developed grade I or II thrombocytopenia after 8 to 16 months of chronic therapy but there was no neutropenia attributable to chlorambucil and no grade III, IV, or V bone marrow toxicity.[291]

Combination of Metronomic Chemotherapy with Other Treatment Modalities

The question of whether concurrent MC and conventional MTD chemotherapy can be safely administered has been the focus of several recent clinical trials. In dogs with various malignancies, the combination of MTD DOX with concurrent metronomic CYC was found to be well tolerated in a recent phase I study.[294] DOX (30 mg/m^2 intravenous [IV]) was given once every 3 weeks for four treatments with concurrent daily oral CYC. Dose escalation for CYC was performed according to a standard 3 + 3 cohort schema starting at 10 mg/m^2/day and extending to 15 mg/m^2 by 2.5 mg/m^2 increments. There were no significant toxicities in dogs of any cohort but the duration of the treatment period was potentially too short to determine the incidence of SHC or DOX-induced cardiomyopathy. Unfortunately, administration of DOX was associated with nonselective depletion of circulating lymphocytes such that any potential benefits of Treg depletion by low-dose CYC would have been lost.

RT combined with MC is another area under active investigation in both people and companion animals. In one study, Cancedda et al treated 50 dogs with macroscopic soft tissue sarcoma using a 5 × 6 Gray hypofractionated RT protocol. Twenty of these dogs then received daily oral piroxicam and thalidomide plus every other day oral CYC. The addition of this MC protocol had no effect on PFS but treated dogs displayed a significantly longer OST compared with dogs treated with RT alone (757 vs 286 days, respectively).[295] RT has also been combined with metronomic dosing of lomustine in the treatment of dogs with OSA.[296] When combined with palliative RT, the lomustine was well tolerated but did not extend the OST compared with dogs receiving RT alone.

As in the human oncology field, there is significant interest in combining MC with immunotherapy for dogs and cats with cancer; however, published reports are few. Cicchelero et al investigated the immunologic and antiangiogenic effects of intratumoral electrogene therapy with IL-12 in six dogs that also received daily oral CYC at 12.5 mg/m^2.[297] Although study design did not permit determination of the contribution of each treatment separately, there was a significant decrease in circulating Treg numbers from pretreatment values and decreased intratumoral blood volume in five of the six dogs. The intratumoral concentration of the angiogenic inhibitor TSP-1 was significantly increased compared with baseline for the duration of the 35-day study period.

Adverse Events

Despite the therapeutic index achieved by treating activated versus dormant vasculature, there is still potential risk that drug effects on vessels have unwanted consequences. For bevacizumab, potential side effects of a vascular etiology include hypertension, edema, hemorrhage, thromboembolism, proteinuria, intestinal perforation, and impaired wound healing.[298] Similarly, in veterinary oncology, side effects for TOC may include hypertension, proteinuria, dose-dependent gastrointestinal upset, bleeding, myelosuppression, azotemia, anemia, lethargy, lameness, or disruption of the hypothalamic–pituitary–thyroid axis.[299–302]

CYC is a commonly employed drug for metronomic scheduling but is associated with the potential for SHC.[303] The incidence of SHC may be more frequent in metronomic protocols. Recent reports document that cystitis may occur in up to 34% of cases, and SHC risk increases with longer treatment duration, which is

common with metronomic therapy.[304,288,289] These toxicity results echo the finding that cumulative dose is a risk factor for SHC in dogs with lymphoma treated with MTD CYC.[305] Close urinary monitoring is strongly recommended for patients receiving MC, and recent studies demonstrate reduced SHC with concurrent use of furosemide as a preventative therapy.[306,307] Chlorambucil has also been used as an alternative to CYC that negates the risk of SHC. With these drugs and any type of therapy intended to be administered continuously for long periods of time, adverse events associated with cumulative dosing must be investigated, as these side effects may not be observed in more commonly reported short-term clinical trials.

Although not initially expected, acquired resistance to antiangiogenic therapy has become evident from clinical trial results. Given the genetically stable nature of the blood vessel/EC target compared with the mutation-prone cancer cell population, antiangiogenic treatment was originally postulated to be less likely to demonstrate drug resistance.[308] Proposed mechanisms of resistance to antiangiogenic therapies involve both tumor and host-mediated pathways that can be intrinsic or induced by treatment.[309] One alarming consequence of antiangiogenic treatment that emerged from preclinical studies with certain antiangiogenic RTKIs is the potential to alter the host microenvironment (e.g., in the lungs), leading to metastatic conditioning.[310,311] This phenomenon of increased invasion and metastasis as a result of antiangiogenic drug treatment was observed with sunitinib, an RTKI with a similar target spectrum to TOC.[311] However, a randomized clinical trial of TOC used in the adjuvant setting for canine OSA revealed no difference in the disease-free interval.[290]

Biomarkers

The incorporation of biomarkers into clinical decision making is increasingly important in the era of targeted therapeutics.[312] The aims of validated biomarkers include (1) predicting patients who will or will not respond to treatment, (2) monitoring response to therapy, or (3) determining the therapeutic dose for agents that often possess optimal biologic activity at doses well below the traditionally defined MTD. The use of validated biomarkers to guide the application of antiangiogenic agents is relevant in all three of these areas.

Tumor tissue expression and/or blood-based circulating growth factor levels have been the most popular approaches to predicting response to antiangiogenic treatment, with VEGF being the most studied molecule.[313–315] For example, in a pilot study of MC and celecoxib therapy in 15 dogs with various cancers, low baseline plasma VEGF was predictive of response.[316] The temporal comparison of pretreatment with posttreatment levels may provide the most useful information for certain surrogate biomarkers, as was demonstrated with urinary bFGF and VEGF with piroxicam treatment of canine TCC.[242,243] Biomarkers that are particularly valuable for antiangiogenic therapy may be those that define tumor response because inhibiting angiogenesis does not necessarily result in reduced tumor volume in the short term. A static tumor response sharply contrasts that observed with successful MTD chemotherapy approaches that result in overt measurable tumor shrinkage. Imaging modalities that can provide information about vascular function are potentially valuable tools for monitoring tumor angiogenesis and the effects of antiangiogenic therapy.[317] Dynamic contrast-enhanced MRI (DCE-MRI) has been studied for its ability to quantitatively assess vascular parameters.[318] A study by MacLeod and colleagues demonstrated blood volume and permeability measurements in canine intracranial masses using this modality.[319]

The area of dose optimization also represents an unmet need for biomarkers in antiangiogenic and metronomic chemotherapy. In the absence of dose limiting toxicities, the choice of drug dose may be highly empirical without information on target modulation. The assessment of Treg may provide insight as a dose optimization biomarker. A study that utilized serial sampling in canine soft tissue sarcoma demonstrated dose-dependent reduction in Treg with MC treatment. Reduced Treg were observed at 15 mg/m^2 but not 12.5 mg/m^2 doses, leading to the conclusion that 15 mg/m^2 may be a more appropriate dose for future clinical trials.[268] In addition to Treg levels, temporal evaluation of other markers has been studied. Assessment of CECs and/or CEPs has been applied for biomarker analysis of dosing antiangiogenic and metronomic therapy.[320–322] For example, in the study by Rusk and colleagues, decreasing CEC levels in dogs treated with the thrombospondin-1 mimetic peptide ABT-526 may have indicated adequate exposure to the antiangiogenic drug, which in this study was utilized at a single dose.[227] However, total CEC levels were not associated with soft tissue sarcoma response to TSP peptides in another trial.[228]

Finally, in dogs with solid tumors, temporal increases in plasma VEGF over 30 days of TOC treatment occurred at doses considerably lower than the FDA-approved MTD.[323] These results suggested that biologic activity of TOC through VEGF pathway inhibition occurs within an optimal dose range that has an improved adverse event profile compared with the MTD. Blood pressure changes may also reflect the biologic activity of this class of drugs and measuring hypertension has also been suggested as a surrogate biomarker for VEGF pathway inhibitors, including TOC.[324,300]

Conclusion

Numerous forms of conventional and targeted cancer therapies produce antiangiogenic effects that may contribute to their overall efficacy, and the field of tumor angiogenesis has come of age with the successful application of drugs that inhibit the VEGF receptor and other relevant pathways. The metronomic application of chemotherapy has antiangiogenic effects and demonstrates significant immunomodulatory activity that warrants further study, particularly in combination with other targeted approaches. However, well-powered prospective clinical trials to evaluate efficacy are currently lacking. Optimization of drug choices, combinations, and tumor applications remain as significant challenges, as does the emergence of drug resistance. Biomarker research may provide insight into patients that are more likely to benefit, optimal dosing for agents with activity below the MTD, and predict clinical benefit that may often manifest as sustained stable disease.

SECTION D: NOVEL AND EMERGING THERAPEUTIC AGENTS

DOUGLAS H. THAMM AND DAVID J. ARGYLE

The recent explosion in available tumor bioinformatic information, rational and combinatorial drug design, and high-throughput drug screening have resulted in a massive increase in potential therapeutic targets and anticancer treatment strategies. An exhaustive survey of all potential novel targets for cancer therapy would

VetBooks.ir

be impossible, and thus this review is designed to present a brief overview of some of the more promising and well developed, "druggable" targets that have been discovered recently, with an emphasis on those for which in vitro or in vivo data in veterinary species are available.

DNA Methylation

In addition to the information encoded within the genome sequence, epigenetic changes are of great importance in the modification and maintenance of gene expression. These changes take place through a number of mechanisms, including polymerase enzyme modulation, microRNAs, chromatin condensation, and DNA methylation. Mammalian DNA is methylated at cytosines within CpG dinucleotide sequences. During tissue differentiation, methylation pattern is one governor of tissue-specific gene expression and thus phenotype.[325–327]

Two different methylation-related phenomena have been identified in cancer. Tumor DNA in dogs and other mammals is globally hypomethylated,[328,329] specifically in pericentromeric satellite sequences. This may lead to decreased genome stability and an increase in the incidence of oncogenic chromosome defects. Indeed, the purposeful induction of genomic hypomethylation by reduction in germline DNA methyltransferase-1 (DNMT1) levels in genetically engineered mice is associated with a high incidence of T-cell lymphomas displaying trisomy 15.[330] Cancer cells also acquire sequence-specific promoter hypermethylation and transcriptional repression in normally unmethylated regions, several of which have been shown to be associated with known tumor suppressor genes, including Rb, p16, p73, and the von Hippel–Lindau protein (VHL),[325,326,331–334] or other important tumor-associated genes, such as E-cadherin, estrogen, retinoic acid receptors, and P-glycoprotein.[335,336] In addition, downregulation of expression of cytokines, tumor antigens, and/or antigen presentation machinery has been demonstrated to be regulated by promoter methylation in some cancers, which could contribute to tumor immune avoidance.[337–339]

The methylation of DNA is controlled by four known DNMTs, of which DNMT1 may be the most important in cancer.[325–327] A variety of agents can inhibit DNMT function. The two best studied are 5-azacytidine (Vidaza, Celgene) and 5-aza-deoxycitidine (decitabine, Dacogen, Otsuka), nucleoside analogs that incorporate into DNA and inhibit DNMT activity, but allow replication to proceed. A large number of single-agent human clinical trials with these agents have been reported, and significant activity has been demonstrated in hematopoietic neoplasia, leading to the US FDA approval of 5-azacytidine and decitabine for the treatment of myelodysplastic syndrome.[340,341] Encouraging response rates to the nucleoside analog decitabine have also been seen in patients with imatinib-refractory chronic myelogenous leukemia.[342,343] Results in advanced solid tumors have been generally disappointing[344–346]; however, studies in combination with standard antineoplastic therapy and other targeted agents are ongoing.[347] Interestingly, the commonly used cardiac medications procainamide and hydralazine also possess demethylating activity,[335,348] and clinical trials have demonstrated alterations in promoter methylation and reactivation of silenced genes after administration of well-tolerated doses of hydralazine to human cervical cancer patients.[349] Hydralazine–valproic acid (VPA) combinations have demonstrated activity in myelodysplastic syndrome and cutaneous T-cell lymphoma in early human trials.[350, 351] Procainamide and hydralazine have long track records of use in veterinary medicine, and as such could serve as inexpensive and available drugs for the evaluation of methylation inhibition in veterinary cancer patients.

Recent genome-wide studies have demonstrated significant changes in patterns of specific gene methylation in canine lymphomas, some of which appear capable of providing prognostic information.[352,353] Multiple in vitro studies have demonstrated selective growth inhibition and/or induction of apoptosis in canine and feline tumor cells treated with demethylating agents.[354–358] Importantly, a phase I clinical trial of the demethylating agent 5-azacitidine has been performed in dogs with urothelial carcinomas. Objective responses were reported, but there was no correlation between gene methylation changes after treatment and clinical outcome.[359]

Two potential problems exist regarding the wide clinical implementation of DNMT inhibitors for cancer treatment. As discussed earlier, induction of long-term genome-wide hypomethylation could decrease chromosome stability leading to potentially tumorigenic chromosome rearrangements.[327] Demethylation could also trigger the reactivation of genes promoting a more aggressive or metastatic phenotype.[327] In support of this theory, treatment of nonmetastatic breast cancer cells with 5-azacytidine was shown to upregulate expression of urokinase-like plasminogen activator, an enzyme important in tumor invasion and metastasis, leading to enhanced metastatic potential.[360]

Histone Deacetylase

Another critical determinant of gene expression is the condensation of chromatin in the form of heterochromatin, which results in transcriptional silencing. This is accomplished by a number of pathways, one of which is the acetylation and deacetylation of histones, controlled by histone acetyltransferases and histone deacetylases (HDACs). The HDACs specifically maintain chromatin in a condensed form, and can associate with specific transcription factors resulting in transcription repression. Histone acetylation reduces electrostatic charge interactions between histones leading to chromatin decondensation. Histone acetylation may be key in regulating the expression of genes associated with cellular proliferation, differentiation and survival, both in development and carcinogenesis.[361,362] Induction of HDAC expression, leading to transcriptional repression, is a common feature in human cancers such as colon cancer,[363] and negatively regulates the expression of multiple tumor suppressor genes, including *p53* and *VHL*.[364] Certain HDAC isoforms are capable of acetyating nonhistone proteins, such as DNMT1, tubulin, and p53, which can alter protein stability, intracellular trafficking, and protein–protein or protein–DNA interactions.[365–367] Differential expression of certain HDAC isoforms has been associated with outcome in a variety of human tumors, with HDACs 2 and 6 studied most completely.[368]

Pharmacologic inhibition of HDAC can affect multiple facets of the malignant phenotype. HDAC inhibition inhibits colon carcinogenesis in the APC mouse model.[363] Angiogenesis can be inhibited through upregulation of VHL and subsequent inhibition of hypoxia-inducible factor-1alpha (Hif-1α) function and vascular endothelial growth factor production[364,369,370]; decreased expression of other proangiogenic factors, such as basic fibroblast growth factor, angiopoietin-2, and Tie-2[369,370]; inhibition of endothelial nitric oxide synthase and endothelial cell proliferation and tube formation[371,372]; and inhibition of the commitment of endothelial progenitor cells to the endothelial lineage.[373] Inhibition of HDACs can

VetBooks.ir

enhance apoptosis in tumor and endothelial cells,[370,374–376] and directly inhibit tumor cell proliferation.[375,377–379] Consistent with its role as a transcriptional repressor, inhibition of HDACs has been shown to induce differentiation in thyroid and prostate cancer, neuroblastoma, and the leukemias.[380–384] HDAC inhibition enhances the in vitro and in vivo efficacy of multiple standard cytotoxic therapies, antibodies and small molecules.[367,370,376,385–393]

Two HDAC inhibitors, vorinostat (SAHA, Zolinza, Merck) and romidepsin (FK228, Istodax, Celgene), have been approved by the FDA for the treatment of cutaneous T-cell lymphoma,[394–396] and a large number of additional agents are in intermediate- to late-stage clinical trials. A number of studies are being conducted evaluating HDAC inhibitors for various other hematologic and solid tumors, and early studies combining these drugs with other targeted and cytotoxic therapies have been reported.[397–400]

Recent in vitro studies have demonstrated potent induction of histone acetylation, growth inhibition, and induction of apoptosis in a variety of canine tumor cell lines treated with either vorinostat or the novel HDAC inhibtior OSU-HDAC42 (AR-42) [401,402]; and inhibition of canine prostate cancer metastasis to bone was observed after AR-42 treatment in a murine xenograft model.[403] Synergy between vorinostat and the DNMT inhibitor zebularine has been observed in canine OSA cell lines.[358] The commercially available anticonvulsant drug VPA can function as an HDAC inhibitor, and is capable of inhibiting tumor cell invasion, P-glycoprotein expression, proliferation and angiogenesis, and enhancing chemosensitivity.[404,367,381] VPA was recently shown to enhance the efficacy of DOX in canine OSA cell lines in vitro, and to synergize with DOX in a canine OSA xenograft.[391] A recent study demonstrated that VPA could be administered before a standard dose of DOX in tumor-bearing dogs, at dosages sufficient to enhance histone acetylation in tumor and peripheral blood mononuclear cells, but not associated with toxicity or apparent potentiation of DOX's adverse effects.[392]

The Proteasome

The abundance of cellular proteins is tightly controlled at the levels of both production and destruction. Protein production can be modified at the transcriptional and posttranscriptional level, and therapies based on these approaches are relatively abundant. Until relatively recently, little attention had been paid to the manipulation of protein degradation as a therapeutic modality. The ubiquitin–proteasome pathway (UPP) is responsible for the degradation of the majority of intracellular proteins, and is responsible for the regulation of many proteins with key roles in cancer.

The 26S proteasome is a large multiprotein complex containing ubiquitin recognition domains, which bind ubiquitinated proteins tagged for degradation, and proteolytic domains with trypsin-like, chymotrypsin-like, and caspase-like activity, which degrade proteins into short polypeptide sequences.[405] It is responsible for the degradation of a variety of proteins responsible for cell-cycle regulation, angiogenesis, apoptosis, and chemotherapy and radiation sensitivity (Table 15.3).[405–407]

Tumor cells are generally more sensitive to the effects of proteasome inhibition than are normal cells. Various studies have demonstrated a 3- to 40-fold increase in susceptibility to proteasome inhibitor-associated apoptosis when comparing tumor cells with corresponding normal tissues.[407–411] The mechanisms for this differential sensitivity are unclear, but proliferating cells generally appear more sensitive than do quiescent cells.[405,407] In

TABLE 15.3 Molecular Targets and Consequences of Proteasome Inhibition

Process	Proteins Degraded by Proteasome	Cellular Consequences
NFκB activation	IκB	Accumulation of IκB inhibits nuclear translocation and activity of NFκB, leading to decreased proliferation, survival, invasion, angiogenesis.
Apoptosis	p53, Bax, tBid, Smac, JNK, Noxa	Accumulation of these proteins directly or indirectly promotes apoptosis through various pathways.
Cell cycle regulation	p21, p27, other CDK inhibitors, cyclins, p53	Accumulation of CDK inhibitors can cause cell-cycle arrest and apoptosis. The increased expression of multiple cyclins can send contradictory signals to the cell resulting in apoptosis.
Signal transduction	MKP-1 phosphatase	Accumulation dephosphorylates p44/42 MAP kinase, leading to decreased MAPK pathway signaling, proliferation, survival, +/– angiogenesis.
Oncogenic transformation	c-Fos, c-jun, c-myc, N-myc	Unclear how overabundance of these proteins exerts an antitumor effect.
Unfolded protein response	Various damaged/ misfolded proteins	Accumulation of damaged proteins leads to endoplasmic reticulum stress and apoptosis.
Chemo / radiation sensitivity	IκB, P-glycoprotein, topoisomerase IIα, DNA damage repair enzyme downregulation	NFκB is induced in response to DNA damage; normal proteasome function is required for correct folding of P-GP; downregulation of topoisomerase IIα may reduce sensitivity to doxorubicin.

NFκB, Nuclear factor κB.

Adapted from Adams J: The development of proteasome inhibitors as anticancer drugs, *Cancer Cell* 5:417–421, 2004; Rajkumar SV, Richardson PG, Hideshima T, et al: Proteasome inhibition as a novel therapeutic target in human cancer, *J Clin Oncol* 23:630–639, 2005; Voorhees PM, Dees EC, O'Neil B, et al: The proteasome as a target for cancer therapy, *Clin Cancer Res* 9:6316–6325, 2003.

addition, dysregulation of UPP function appears to occur in many types of cancer, thus potentially rendering them more sensitive to inhibition.[407,412]

Although a number of chemicals appear capable of proteasome inhibition in vitro, only the boronic acid derivatives appear suitable for clinical use and only two drugs, bortezomib (Velcade, Takeda) and carfilzomib (Kyprolis, Amgen), have received FDA approval, for the treatment of human multiple myeloma and mantle cell lymphoma.[413–417] Several additional proteasome inhibitors are in clinical development. Meaningful antitumor activity has been observed in patients with other hematopoietic neoplasms,[418–420] but less activity has been seen in solid tumors to date.[421–424]

Bortezomib and the investigational proteasome inhibitor ONX0912 have demonstrated in vitro and/or in vivo (xenograft) antiproliferative effects in canine melanoma and OSA cells,[393,425,426] and drugs targeting valosin-containing protein, another regulator of cellular proteostasis, have shown in vitro activity against canine lymphoma cells.[427,428]

Toxicology studies with bortezomib have been performed in dogs,[429] and a biologically effective and tolerable dose has been established in golden retrievers with golden retriever muscular dystrophy.[430] There are no published reports of proteasome inhibitor use in veterinary clinical oncology.

Heat Shock Protein 90

Given the complex nature of cancer and the multiple pathways that can be subjugated to contribute to the malignant phenotype, an optimal cancer drug might target a variety of oncogenic pathways simultaneously. One molecular target that has the potential to interrupt a wide variety of pathways important in cancer is heat shock protein 90 (HSP90), a molecular chaperone responsible for the conformational maturation of many proteins involved in diverse oncogenic activities such as cell adhesion/migration/invasion, signal transduction, cell cycle progression, angiogenesis, and survival (Table 15.4). HSP90 and other chaperones are responsible for ensuring the correct folding and prevention of aggregation of their client proteins.[431] Misfolding and aggregation of proteins lead to ubiquitination and proteasomal destruction, resulting in proteins with diminished function and greatly shortened half-lives.[432] Although several classes of compound are capable of inhibiting HSP90 chaperone function,[433–435] the best studied are ansamycin antibiotics of the geldanamycin class.

Many HSP90 inhibitors appear to demonstrate significant preferential activity against malignant cells versus normal cells. The HSP90 derived from most tumor cells has a binding affinity for the HSP90 inhibitor 17-allylaminogeldanamycin (17-AAG) approximately 100-fold higher than HSP90 derived from normal cells.[436] This may occur as a result of the overaccumulation of mutated, misfolded, and overexpressed signaling proteins in tumor cells leading to increased HSP90 chaperone activity and a greater proportion of the molecule in the bound, active, and 17-AAG sensitive state.[436]

Tumor cells display considerable variation in sensitivities to HSP90 inhibition. Although the mechanisms underlying this differential sensitivity are incompletely characterized, some important characteristics include reliance on certain kinase cascades, expression of apoptotic and cell-cycle regulators, and P-glycoprotein expression.[437]

Many receptor tyrosine kinases targeted by the geldanamycins may have important roles in canine and feline tumors. For example, geldanamycins are capable of inhibiting the function of mutant and wild-type KIT,[438] which is important in canine MCT[439]; MET,[440] which is expressed in multiple canine tumor types[441,442]; PDGF receptor,[443] which is expressed in feline injection-site sarcoma and OSA[444,445]; and IGF-1 receptor,[438] which is expressed and functional in canine OSA and melanoma.[446–448] The geldanamycins are likewise able to attenuate the function of the Hif-1 protein, a key transcription factor responsible for sensing and responding to hypoxia and activating the angiogenic switch.[433,449,450] They are also able to deplete key antiapoptotic proteins such as mutant p53 and survivin,[451–454] contributing to enhanced in vitro sensitivity to standard cytotoxic therapies such as RT and chemotherapy when used in combination.[455–460]

Under certain circumstances, HSP90 inhibitors could have negative effects on cancer outcomes. For example, 17-AAG has been shown to protect colon carcinoma cells from cisplatin-mediated toxicity,[461] whereas it has additive or synergistic activity when combined with cisplatin against human neuroblastoma and OSA cells.[455] In addition, although 17-AAG inhibited primary tumor formation, it potentiated bone-specific mammary carcinoma metastasis by enhancing osteoclastogenesis in one murine model.[462]

The impressive preclinical data generated with compounds such as HSP90 inhibitors has led to published phase I human clinical trials of multiple agents,[463–469] including some early combinatorial studies,[465–467,470,471] although none are yet approved.

TABLE 15.4 Molecules and Processes Targeted by HSP90 Inhibition

Process	Targets	References
Invasion and migration	Urokinase-like plasminogen activator,[a] FAK phosphorylation	507–509
Cell cycle progression	Cyclin D3, cdk4	510
Signal transduction	Akt, Kit, Raf-1, EGFR, HER2, Jun, Lyn, Src, IGF-1R, PDGFR, Met, Bcr-Abl, ILK, androgen receptor, progesterone receptor, glucocorticoid receptor	437,438,440,455–458,460,461,510–514
Hypoxic response / angiogenesis	Hif-1, VEGF, Glut-1, nitric oxide synthase	433,434,437,449,450,456,515
Antiapoptosis	Wild-type and mutant p53, survivin	435,451–454,512,516
Cell senescence	Telomerase	517,518

[a]Urokinase-like plasminogen activator activity appears to be inhibited by geldanamycin class drugs through a mechanism other than HSP90 inhibition. *EGFR*, Epidermal growth factor receptor; *HIF-1*, hypoxia-inducible factor-1; *IGF-1R*, insulin-like growth factor receptor 1; *ILK*, integrin-linked kinase; *PDGFR*, platelet-derived growth factor receptor; *VEGF*, vascular endothelial growth factor.

VetBooks.ir

Evidence of biologic effect in the form of upregulation of HSP70 chaperone expression in peripheral blood mononuclear cells (PBMCs) has been observed.

There is in vitro evidence of antitumor activity of HSP90 inhibitors in canine OSA, pulmonary carcinoma, and MCT cell lines.[472–476] The HSP90 inhibitor STA-1474 has been evaluated in a phase I clinical trial in dogs with spontaneous cancer. Upregulation of HSP70 after drug administration was observed in both tumor cells and PBMCs, and clinical responses were observed in dogs with MCT, OSA, melanoma, and thyroid carcinoma.[477]

Poly ADP-Ribose Polymerase and Poly ADP-Ribose Glycohydrolase

Poly ADP-ribose polymerase (PARP) is a "nick-sensor" that signals the presence of DNA damage and facilitates DNA repair.[478] The first PARP enzyme was discovered by Chambon et al and is now recognized as a superfamily of 18 members,[479] although only PARP-1 and PARP-2 are known to act in DNA damage.[480] The PARP family are also involved in the regulation of several transcription factors, such as NFκB in modulating the expression of chemokines, adhesion molecules, inflammatory cytokines, and mediators.[478] Poly ADP-ribose glycohydrolase (PARG) is the main enzyme in catabolizing PAR to ADP-ribose. To date, only one single PARG gene has been detected in mammals, encoding for three RNAs, which generate three isoforms.[478]

PARP has multiple intracellular functions, including signaling DNA damage and recognizing and binding to DNA strand breaks generated by DNA-damaging agents (cytotoxic drugs and ionizing radiation).[481] Activation of PARP is one of the earliest DNA damage responses. PARP is also a modulator of DNA base excision repair, which constitutes a major mechanism for genomic stability. There is increasing evidence demonstrating that both PARP and PARG repair DNA.[479] When PARP binds to DNA strand breaks, it activates an enzyme causing shuttling of PARP and, subsequently, opening of the chromatin. PARG enters the nucleus, moves to the PARP substrate, and DNA strand breaks are repaired. Because of excessive PARG, PAR decreases and thus chromatin returns to its original structure.

PARP inhibition has been suggested as an important approach in sensitizing cancer cells to conventional cancer therapy, leading to early clinical trials with PARP inhibitors as single agents and in combination.[481–483] PARP inhibitors have been shown to be lethal in BRCA-deficient cells because of persistence of DNA lesions that would normally be repaired in a BRCA-dependent fashion,[484] suggesting that PARP inhibitors might be an effective monotherapy in these cancers. Indeed, single-agent antitumor activity is observed in *BRCA*-mutant breast and ovarian cancer patients,[485–487] which has led to the FDA approval of olaparib (Lynparza, AstraZeneca), rucaparib (Rubraca, Clovis Oncology), and niraparib (Zejula, Tesaro) for the treatment of BRCA-mutant ovarian cancer; however, one might expect that their major benefit would be to enhance conventional cytotoxic drug treatment or RT, and studies have demonstrated that PARP inhibition potentiates the cytotoxicity of anticancer drugs and ionizing radiation through inhibition of DNA repair in cancer cells.

Inhibition of PARG could also be one of the pathways selected for cancer management because of its effects on increased sensitivity to both radiation and chemotherapy. Although PARG inhibitors have lagged behind PARP inhibitors, a number of molecules have been developed that target these pathways, with varying degrees of specificity. In experimental mouse models these have shown promise in breast, colon, lung, brain tumors, and melanoma, either as monotherapy or combined with conventional drugs or RT.[488–492]

Recent studies suggest that polymorphisms in BRCA1 and BRCA2 may predispose certain dog breeds to mammary tumors[493]; however, evidence of a similar functional deficit in DNA repair to those observed in BRCA-mutant humans, which might confer sensitivity to PARP inhibitors, is lacking, as is any information regarding in vitro or in vivo efficacy of this class of drug in canine or feline cancer.

Nuclear Export

The transport of proteins between the nucleus and cytoplasm is a tightly regulated process. Export of proteins from the nucleus to the cytoplasm is governed by a series of proteins called the exportins. Exportin 1 (XPO1, CRM1) is a member of this series that is responsible for the nuclear export of a broad variety of target proteins, including a large number of known tumor suppressor proteins, including p53, survivin, Rb, p21, and IkB.[494] XPO1 is upregulated in many cancers versus normal tissues, and increased expression can be associated with higher tumor grade and inferior treatment outcomes.[495–497]

Multiple small molecule inhibitors of XPO1 have been developed and evaluated preclinically. Small molecule elective inhibitors of nuclear export (SINE) inactivate XPO1 and have shown considerable selective antiproliferative and proapoptotic activity in multiple solid and hematopoietic human tumor types,[498–501] and early-phase human clinical trials have been conducted with the SINE selinexor with evidence of objective antitumor activity.[502–504]

The SINE KPT-335 has in vitro antiproliferative activity in canine tumor cell lines derived from melanoma, lymphoma, MCT, and OSA, and nuclear exclusion of target proteins such as P21 and p53 after KPT-335 treatment has been demonstrated.[505,506] Oral KPT-335 was evaluated in a phase I clinical trial in tumor-bearing dogs: hepatotoxicity, hyporexia, and weight loss were dose limiting, and clinical responses were observed in several dogs with lymphoma.[506] KPT-335 is being developed as a veterinary cancer therapeutic, but at the time of writing it does not have FDA approval.

16 Supportive Care for the Cancer Patient

SECTION A: MANAGEMENT OF CHRONIC CANCER PAIN

MICHAEL W. NOLAN, CONSTANZA MENESES, TIMOTHY M. FAN, AND B. DUNCAN X. LASCELLES

This chapter explains the underlying mechanisms of cancer-induced pain. It also provides a guide for assessment and treatment of pain in canine and feline cancer patients. Finally, the future of analgesic therapies is discussed. Given the modicum of clinical studies in dogs and cats, the information in this chapter cannot be based solely on peer-reviewed investigations. Rather, it is a combination of the authors' experiences and the experiences of others who collectively are contributing to the treatment of cancer patients. It also is based on considered extrapolations from physician-based medicine and from veterinary research on other chronically painful conditions, such as osteoarthritis (OA).

Mechanisms of Cancer-Induced Pain

In veterinary medicine several types of tumors have been associated with painful symptoms (Table 16.1). However, the presence and manifestation of pain in cancer patients are not predictable, and its prevalence and severity depend on numerous factors commonly linked to the characteristics of the patient, the cancer type, the anatomic location, and associated therapeutic interventions.

The generation of noxious (painful) signals generally starts in the peripheral nervous system (PNS), triggered by tissue compromise, invasion, and injury generated by the tumor itself. Pronociceptive mediators (e.g., cytokines, interleukins, chemokines, prostanoids, endothelins, and growth factors) can be released by both cancer cells and the immune cells that infiltrate the tumor microenvironment.[1–7] The release of these factors sets off an inflammatory signaling cascade, which modifies the intracellular homeostasis of the surrounding sensory neurons' primary afferent fibers and cell bodies located at the level of the dorsal root ganglia (DRG). This powerfully modulates excitatory synaptic transmission in the central nervous system (CNS), sensitizing spinal cord neurons and enhancing nociceptive transmission within supraspinal circuits.[4,8,9]

Central neuronal plasticity and hyperexcitability can originate either from increased and sustained peripheral inputs or from primary or metastatic CNS tumors, or both. Significant overlap is seen between mechanisms underlying peripheral and central plasticity. Cancer models of pain in rodents have shown that persistent noxious signals can lead to genetic alterations that modify the synaptic ultrastructure of spinal neurons (e.g., recruitment of wide dynamic range neurons in the superficial spinal cord) and induce dysregulation of the neuron–glia–immune system and the descending inhibitory/facilitatory system.[10–16] It has been hypothesized that these events could preserve the nociceptive transmission without the need for algesic mediators.[8] Currently, the exact intracellular signaling pathways that explain the interconnected mechanisms among all these elements remains unclear. However, new research has identified the potential role of various therapeutic targets for cancer pain management (see the section Future Analgesic Therapies later in the chapter). The failure of clinical studies regarding this signaling pathway might be representative of the current limitation of translating data from the commonly used animal models to humans, as has been discussed in several reviews of translational pain research.[17–20]

Pain as a Consequence of Cancer Therapy

Clinical interventions represent an important and often underappreciated source of discomfort in patients. Invasive diagnostic interventions, such as tumor biopsy and bone marrow aspiration, are obvious examples, but other potential sources for at least transient iatrogenic pain include positioning for radiographic studies (which could exacerbate or upset orthopedic diseases such as OA) and physical examination (e.g., digital rectal examination, tumor palpation).

Surgery is perhaps the most obvious cause for treatment-related pain in cancer patients. Surgery is the most common treatment for canine and feline tumors, and it causes a visible wound. The control of acute perioperative pain in cancer patients is very important, and readers are referred to appropriate texts for information on perioperative pain control.[21] Though phantom limb pain is commonly discussed with regard to amputation of tumor-bearing limbs, little is known about the epidemiology of pain in animals related to chronic tumor surgery.

Radiation therapy (RT) can also cause painful side effects. Late radiation-induced neuropathies and tissue fibrosis can cause significant disability. Fortunately, although those late effects are both chronic and progressive, they are also uncommon, affecting about 5% of patients 2 to 3 years after finishing a typical definitive course of RT. Uncomfortable acute radiation side effects, such as dermatitis and oral mucositis, are far more common. The incidence and severity of these side effects depend on a variety of factors, including the radiation prescription, the planning technique and treatment delivery modality, and the anatomic site and species. In veterinary medicine radiation-induced pain is more

VetBooks.ir

TABLE 16.1 Tumor Types Most Likely to Be Associated with Pain[a]

Category	Notes
Tumors involving bone	Primary bone tumors (both of the appendicular and axial skeleton) and metastasis to bone are painful. Just as in humans, sometimes metastasis to bone can be relatively nonpainful; however, this should be considered the exception.
Central nervous system tumors	Extradural tumors that expand and put pressure on neural tissue are often associated with pain. Tumors originating from within the neural tissue are often not associated with pain until later in the course of the disease. In humans with primary brain tumors or metastases to the brain, up to 90% suffer from headaches; it should be presumed that animals also suffer such headaches.
Gastrointestinal tumors	Pain from gastrointestinal tumors may be very difficult to localize and may manifest as vague signs and behavioral changes. Colonic and rectal pain is often manifested as perineal discomfort.
Inflammatory mammary carcinoma	Inflammatory carcinomas can be particularly painful, manifested as reluctance to move and perform activities.
Genitourinary tract tumors	Stretching of the renal capsule appears to produce significant pain. Bladder tumors appear to be predictably associated with pain. Tumors of the distal genitourinary tract are often manifested as perineal pain or pain that appears to be located in the lumbar region.
Prostate tumors	Pain may be manifested as lower back or abdominal pain.
Oral and pharyngeal tumors	Soft tissue tumors that project from the surface appear to be relatively nonpainful. Tumors involving bone or that are growing within the tissues of the maxilla or mandible appear to be significantly more painful. Soft tissue tumors of the pharynx and caudal oral cavity are particularly painful.
Intranasal tumors	Pain caused by intranasal tumors usually manifests as a diminished willingness to engage in normal behaviors.
Invasive soft tissue sarcomas	In the authors' experience, injection-site sarcomas in cats can be particularly painful, and the size of the lesion does not necessarily correlate with the degree of pain. Other invasive sarcomas in both species are painful. In the authors' experience, one form of soft tissue sarcoma, the peripheral nerve sheath tumor, is often associated with pain, both spontaneous and associated with palpation.
Invasive cutaneous tumors	Especially those that are ulcerative.
Liver and biliary tumors	Especially those that are expansile, stretching the liver capsule.
Disseminated intrathoracic and intraabdominal tumors (e.g., mesothelioma, malignant histiocytosis)	The signs associated with such tumors are particularly vague; however, intracavitary analgesia (e.g., an intraabdominal local anesthetic) often can markedly improve the animal's demeanor.
Lung tumors	Although significant pain is reported in humans with lung cancer, animals often appear to show few signs of pain. However, even in those animals, provision of an analgesic can often improve demeanor.
Pain after surgical removal of a tumor	Chronic postoperative pain has not been documented in animals, but it is a common problem after oncologic surgery in humans. Phantom pain (e.g., phantom limb pain), a form of neuropathic pain, does appear to exist in animals.

[a]Very often it is difficult for the veterinarian to appreciate that pain may be present. However, the administration of an analgesic to animals suffering from these conditions is reported by owners to result in an improvement in demeanor. In the face of lack of evidence to the contrary, it is suggested that this improvement is due to the alleviation of pain.

commonly observed in dogs than cats, and the most evident pain signs include decreased interaction with the surroundings, lameness, or increased interest in the affected site (e.g., licking, chewing).[22] Acute radiation-associated pain (RAP) is poorly responsive to standard antiinflammatory and analgesic therapies and thus can be quite difficult to treat. Although acute side effects are transient and self-limiting, the discomfort they cause can have significant implications for long-term oncologic outcomes, because the discomfort can result in early termination of treatment regimens, with a consequent decrease in radiotherapeutic efficacy. Development of more effective RAP therapies is hindered because little is known about the etiology of RAP. Indeed, the first model of RAP was described only recently.[23] Until the underlying pathophysiology is better understood, treatment of RAP will remain empiric.

In humans, pain results from a wide range of chemotherapy-associated complications. Extravasation reactions are perhaps the best recognized potential source of chemotherapy-associated pain in dogs, and they have been reported with both conventional cytotoxic agents (e.g., doxorubicin) and drugs that are generally regarded as "safer" (e.g., bisphosphonates).[24,25] Chemotherapy also represents a significant cause of chronic neuropathic pain in human cancer patients.[26] The risk of chemotherapy-induced peripheral neuropathy (CIPN) varies from patient to patient, depending on the drug agent, treatment protocol, and coexisting neuropathic disorders.[27] In general terms the pathophysiology involves (1) recruitment and activation of immune and glial cells, which leads to the production and release of pronociceptive mediators in the DRG and spinal cord[28–31]; (2) oxidative stress, with increased production of reactive oxygen species (associated with mitochondrial dysfunction)[32,33]; and (3) increased activity of both voltage-gated and ligand-gated ion channels (including voltage-activated sodium, calcium, and transient receptor potential [TRP]

VetBooks.ir

channels).[34–36] The resulting inflammatory response and neuronal injury lead to the increased nocifensive behaviors observed in patients undergoing chemotherapy. In these patients, pain usually has an insidious development, but acute or subacute onset can be observed. Clinically, reported signs include paresthesia, abdominal pain, painful muscle cramps, burning-like sensations, numbness, and a specific paclitaxel-associated acute pain syndrome.[37] Cisplatin, oxaliplatin, gemcitabine, vincristine, and others drugs can induce both peripheral and central modifications. To date, only two reports have confirmed CIPN in veterinary medicine.[38,39] This low rate of reporting may reflect a truly low incidence of CIPN in dog and cats or, alternatively, it may reflect the inability to diagnose accurately what may be a higher incidence of low-grade subclinical CIPN. Currently no systematic studies in veterinary medicine have annotated the prevalence of cancer pain caused by chemotherapy. Given the difficulty in assessing pain, especially chronic conditions resulting from prolonged courses of chemotherapy, only subjective states of chemotherapy-induced pain have been evaluated, from the pet owner's perspectives.[40–42]

Assessment of Cancer Pain

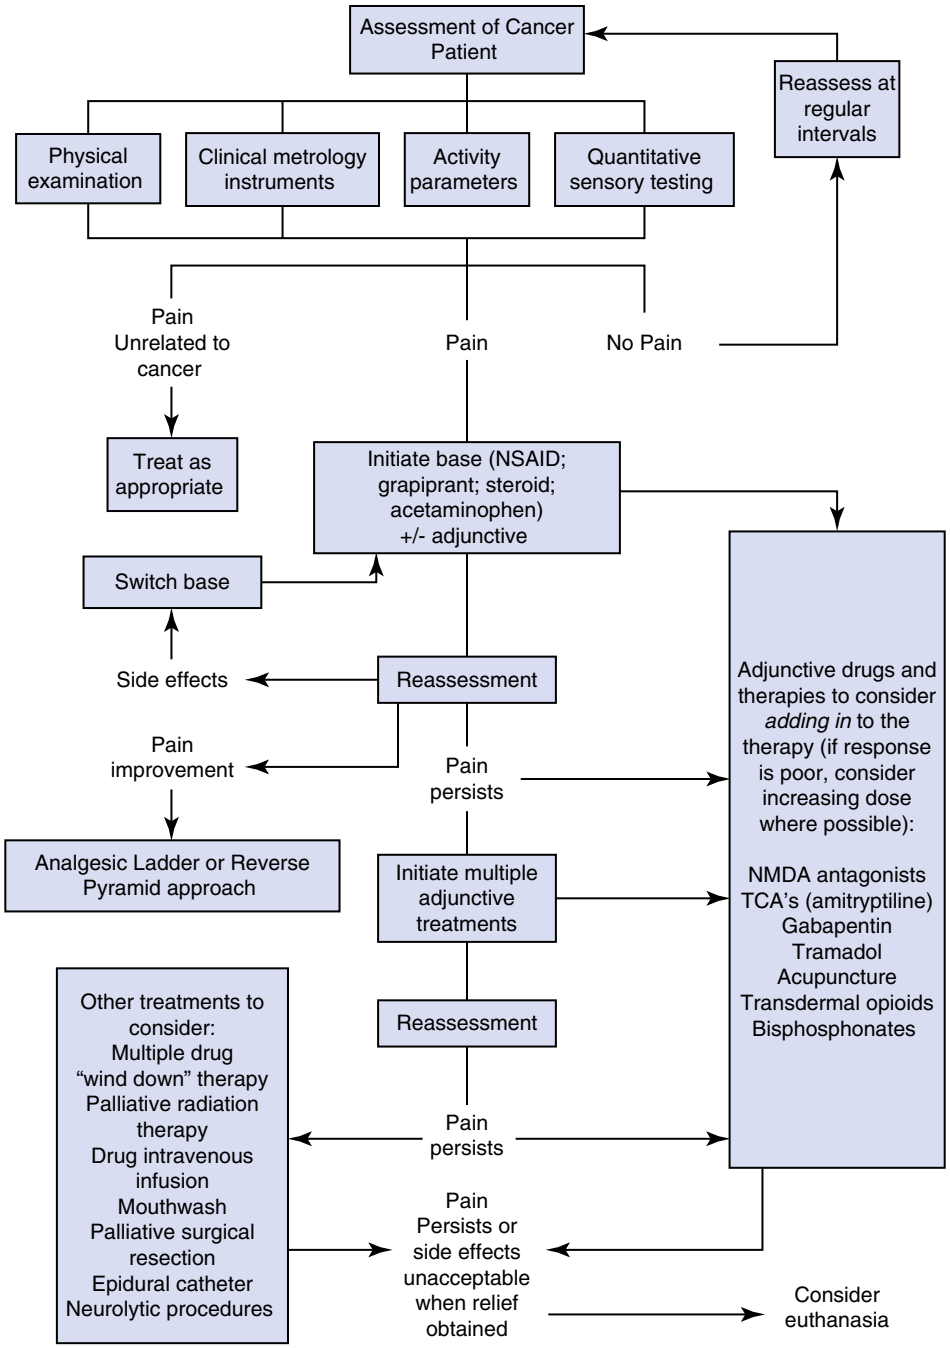
The prevalence of cancer-related pain in humans ranges from 33% in patients after curative treatment to 64% in the setting of metastatic disease.[43] Despite the fact that pharmacologic strategies have improved in the past 10 years, a significant fraction of surviving cancer patients still endure pain that is ineffectively managed[44]; this makes chronic pain one of the key elements underlying deterioration in the quality of life of these patients. In small animal practices cancer is one of the leading causes of morbidity and mortality.[45] Even though currently no documentation exists of the actual prevalence of cancer pain in dogs and cats, it is reasonable to deduce that a significant population of companion animals experiences cancer-related pain during their disease progression, in a manner similar to humans.

Assessment of pain in animals, although often difficult, is extremely important. It is likely that the tolerance of pain by an individual animal varies greatly and is further complicated by the innate ability of dogs and cats to mask significant disease and pain. It is important to remember that cancer pain significantly differs from other types of chronic painful conditions, and differences in clinical and behavioral manifestations among individuals and breeds can be influenced by the type of cancer, tumor location, disease progression, and general state of the patient. In general, if a tumor is considered to be painful in humans, it is appropriate to give an animal with a similar condition the benefit of the doubt and treat it for pain.

The approach of the author (BDXL) to the assessment of cancer pain is to evaluate these aspects (Fig. 16.1):

- Physical examination findings
- Owner observations using clinical metrology instruments (CMIs)
- Activity
- Quantitative sensory testing

Physical Examination



Physiologic variables, such as heart rate, respiratory rate, temperature, and pupil size, are not reliable measures of acute perioperative pain in dogs and are unlikely to be useful in chronic pain states. However, physiologic parameters and the use of complementary clinical techniques (i.e., imaging and laboratory studies) allow for a broader and more comprehensive view of the patient's general state and disease progression when establishing an analgesic regimen. Additionally, the examination of every patient must include palpation of the tumor area. One of the most useful ways of determining if a tumor is painful is to palpate the area and evaluate the animal's response. This may not correlate precisely with the amount of pain the animal spontaneously experiences, but if a tumor is painful on manipulation or palpation, it is highly likely that spontaneous pain is associated with it. As veterinarians we struggle to measure spontaneous pain. It is perhaps reassuring that the way to measure spontaneous pain in rodent models is the subject of considerable debate among researchers.

Clinical Metrology Instruments

In humans the importance of patient-reported outcomes (PROs) is widely recognized.[46] PROs may refer to a large variety of different health data reported by patients, such as symptoms, functional status, quality of life (QOL), and health-related quality of life (HRQOL).[46] QOL is a complex, abstract, multidimensional concept that defines an individual's satisfaction with life in domains he or she considers important. The designation HRQOL reflects an attempt to restrict this complex concept to aspects of life that are specifically related to the individual's health and that potentially could be modified by health care.[47] In veterinary medicine assessing the effect of cancer in a companion animal's life has become a fundamental practice to ensure an animal's welfare. Assessment of the QOL has become a worldwide outcome measure in cancer patients, and it is an extremely useful tool when making decisions about treatment and continuity of life.

A pragmatic approach to the recognition of cancer-related pain has been adopted in veterinary oncology and pain research, and the establishment of CMIs in clinical and research practice is essential to reduce the inherent variability in pain assessment in animals.[48] CMIs use a proxy to provide information about the effect of both disease and interventions in pets. The use of validated questionnaires has made pet owners an important component in the assessment of animals with painful diseases. Table 16.2 presents a list of pain behaviors associated with cancer and/or cancer therapy in cats and dogs. Owners have the advantage of being able to detect behavioral changes in their pets in nonstressful circumstances. However, to evaluate properly behaviors affected by pain, in addition to the animal's QOL, pet owners need to be educated by veterinary practitioners on what signs and behaviors may indicate pain.

Owner-completed questionnaires have been designed to measure the severity of pain in dogs and cats. Several features are evaluated to determine pain severity and subsequent analgesic efficacy. The best developed and validated of these were created to measure chronic musculoskeletal pain; in dogs they are the Liverpool Osteoarthritis in Dogs[49,50]; the Canine Brief Pain Inventory[51,52]; and the Helsinki Chronic Pain Index[53]; and in cats it is the Feline Musculoskeletal Pain Index.[54–57] Some work has focused on developing cancer-specific owner questionnaires in dogs and cats undergoing either chemotherapy or RT.[40–42,58–65] In general, questionnaires include questions about the owner's perceptions of the pet's physical state (appetite, sleep patterns, gastrointestinal problems), interaction with the owner (anxiety, depression, happiness), activity levels (mobility, play activity), and perceived pain level, in addition to the owner's level of worry about the pet's health issues.[42,60,64,65] Several QOL scoring systems have been created to evaluate cancer patients; however, the use of nonvalidated instruments currently represents a source of bias in the measurement

• **Fig. 16.1** Scheme illustrating the strategic planning process of the author (BDXL) to assess and treat pain in cancer patients. *NSAID,* nonsteroidal anti-imflammatory; *NMDA,* N-methyl D-aspartate; *TCA's.*

of the effects of various cancer treatments.[42] Recent publications have advocated rigorous assessment of the validity and reliability of these metrology instruments.[42,65] Table 16.3 shows QOL instruments and validation criteria that have been developed for use in veterinary cancer patients.

Activity

Reduced mobility is a common symptom in pain conditions. In the mid-2000s, accelerometers were validated as surrogate measures of distance moved in dogs[66] and cats,[67] and since then accelerometry has been shown to detect increased activity in response to nonsteroidal antiinflammatory drugs (NSAIDs)[50,68,69] and an anti-nerve growth factor (NGF) antibody[70] in dogs with OA. Objective measurements of mobility or activity may be a particularly good outcome measure in cats, whose activity is spontaneous and not influenced by owners taking them on walks; improvements in this spontaneous activity in the home environment have been detected in cats with OA that were fed a diet rich in omega-3 fatty acids,[71] NSAIDs,[56,57,72] and anti-NGF neutralizing antibody.[73] Activity monitors may allow for disruption of sleep-wake cycles associated with pain, although recent initial work in this area by the authors

TABLE 16.2 Behaviors That May Be Seen with Cancer and Cancer Therapy–Associated Pain in Cats and Dogs

Behavior	Notes
Activity	Decreased activity and diminished engagement in the activities of daily living (playing); altered gait or lameness can be associated with generalized pain but is more often associated with limb or joint pain; quality of sleep may be adversely affected, manifesting as increased restlessness or altered sleep-wake cycles.
Appetite	Often diminished with chronic cancer pain.
Attitude	Any change in behavior can be associated with cancer pain—aggressiveness, dullness, shyness, 'clinging,' increased dependence.
Facial expression	Head hung low and squinted eyes in cats. Sad expression in dogs, head carried low.
Grooming	Failure to groom can result from a painful oral lesion or generalized pain.
Response to palpation	(One of the best ways to diagnose and monitor pain.) Pain can be elicited by palpation of the affected area, or manipulation of the affected area, which exacerbates the pain present. This is manifested as an aversion response from the animal (i.e., the animal attempts to escape the procedure, or yowls, cries, hisses, or bites).
Respiration	May be elevated with severe cancer pain.
Self-traumatization	Licking at an area (bone with primary bone cancer, the abdomen with intraabdominal cancer) can indicate pain. Scratching can indicate pain (e.g., scratching at cutaneous tumors, scratching and biting at the flank with prostatic or colonic neoplasia).
Urinary and bowel elimination	Failure to use litter box (cats); urinating and defecating inside (dogs).
Vocalization	Vocalization is rare in response to cancer pain in dogs and cats; however, owners of dogs often report frequent odd noises (whining, grunting) associated with cancer pain. Occasionally cats will hiss, utter spontaneous plaintive meows, or purr in association with cancer pain.

did not uncover any effects of osteoarthritis pain. Recent work has extended our understanding of factors affecting accelerometer output in dogs.[74] Accelerometry is performed in client-owned animals, in their home environments, with the accelerometers mounted on collars. Human chronic cancer patients with pain are more likely to present with sedentary behavioral patterns and fatigue.[75] Similar studies have not been performed in small animals with cancer, but accelerometry and activity measures hold promise as a tool to assess pain and cancer-related changes in activity. Approximately 10 activity monitors are marketed specifically for small animals, although current understanding of what the output of each activity monitor actually relates to is limited.

Quantitative Sensory Testing

Objective methods to measure central sensitization secondary to chronic pain recently have been developed in veterinary medicine. Quantitative sensory testing (QST) consists of the measurement of evoked responses to mechanical and thermal stimuli through the use of various devices. Feasibility and repeatability studies of these modalities have being performed in normal and osteoarthritic dogs.[76,77] Currently, published QST studies in dogs or cats with cancer pain exist, although the authors (MN, BDXL) have used QST to assess sensitivity associated with RT. The use of QST and related testing modalities has significant potential to help us understand the pathophysiology of cancer pain and potentially in the "cage-side" diagnosis of cancer pain–related abnormalities in sensory processing.

Drugs and Strategies Used for Management of Pain in Cancer Patients

The drugs that can be used for chronic cancer pain management are listed in Tables 16.4 and 16.5. The following discussions are not a comprehensive appraisal of each class of drug, but rather are suggestions for their use for cancer pain. Fig. 16.1 presents an assessment and treatment scheme to help the reader easily devise a strategic plan to manage pain in cancer patients. If pain scores improve after the initial base treatment, an analgesic ladder or a reverse pyramid approach can be applied (i.e., the number and dosages of drugs administered can be reduced). If pain persist, a more aggressive and multimodal analgesic strategy must be implemented. The adjunctive drugs listed in this scheme can be used on their own, or potentially two "base" analgesics could be combined (e.g., an NSAID and acetaminophen). However, the way this influences the side effects likely to be seen is unknown, except in the case of NSAIDs plus steroids, a combination known to increase the risk of serious adverse events (gastrointestinal ulceration). Euthanasia should be considered only when pain persists and significantly affects the patient's QOL or when the necessary analgesic relief caused unacceptable side effects (e.g., moribund, unresponsive, comatose).

Nonsteroidal Antiinflammatory Drugs

NSAIDs are commonly the first line of treatment in cancer pain. Several excellent reviews on NSAID use in small animals have been published, and the reader is referred to these.[72,78–82] The choice of available NSAIDs can be bewildering, but a few key points should be kept in mind.

- On a population basis, all NSAIDs are probably equally efficacious in relieving pain; however, for a given patient, one drug often is more effective than another.
- Gastrointestinal side effects associated with NSAID use appear to be more common with drugs that preferentially block COX-1 over COX-2.
- No difference in renal toxicity is seen between COX-1 selective drugs and COX-2 selective drugs.
- Liver toxicity can occur with any NSAID.
- No NSAID is completely safe, but the approved NSAIDs are significantly safer than the older, nonapproved NSAIDs.
- Longer term or continuous NSAID use appears to be more effective than short-term or reactive use[80]; however, when the disease is relatively stable, gradual dose reduction may be possible while maintaining efficacy.[69]

TABLE 16.4 Suggested Dosages of Analgesics to Alleviate Chronic Cancer Pain in Dogs[a]

Drug	Dosage	Comments
Amantadine	4–5 mg/kg given orally (PO) every 24 hours (q24hrs)	Loose stools and excess GI gas can be seen at higher doses for a few days. Should not be combined with drugs such as selegiline or sertraline until more is known about drug interactions. Should not be used in seizure patients, and caution should be exercised in patients in heart failure.
Amitriptyline	0.5–2 mg/kg PO q24hrs	Has not been evaluated for clinical toxicity in the dog. Should be used cautiously in combination with tramadol.
Fentanyl, transdermal	2–5 mcg/kg/hrs	Can be very useful in short-term control of cancer pain. Long-term use is limited by need to change patch every 4–7 days. Clinicians should be aware of the abuse potential and danger to children of fentanyl patches.
Gabapentin	3–10 mg/kg PO q6–12hrs	Has not been evaluated in dogs as an analgesic. Most likely side effect is sedation.
Grapiprant	2 mg/kg PO q24hrs	Mild GI disturbances can be observed but generally are infrequent. Other EP_4 receptor antagonists (piprant NSAIDs) are being evaluated as anticancer agents for humans, but no studies of grapiprant in veterinary cancer patients have been performed.
Pamidronate	1–1.5 mg/kg diluted in 4 mL/kg normal saline (NaCl), given intravenously (IV) slowly over 2 hrs. Repeat every 4–6 wks.	Inhibits osteoclast activity and thus provides analgesia only in patients suffering from a primary or metastatic bone tumor that is causing osteolysis. Nephrotoxicity may be a concern.
Paracetamol (acetaminophen) + codeine (30 or 60 mg)	10–15 mg/kg of acetaminophen PO q12hrs	Sedation can be seen as a side effect with doses at or above 2 mg/kg codeine.
Paracetamol (acetaminophen)	10–15 mg/kg PO q12hrs	Associated with fewer GI side effects than regular NSAIDs; has not been noted to be associated with renal toxicity. However, toxicity has not been evaluated clinically in dogs. Can be combined with regular NSAIDs for severe cancer pain, but combination has not been evaluated for toxicity.
Prednisolone	0.25–1 mg/kg PO q12–24hrs; taper to q48hrs if possible after 14 days	Do NOT use concurrently with NSAIDs. Can be particularly useful in providing analgesia when a significant inflammatory component is associated with the tumor, and for CNS or nerve tumors.
Prednisone	0.25–1 mg/kg PO q12–24hrs; taper to q48hrs if possible after 14 days	Do NOT use concurrently with NSAIDs. Can be particularly useful in providing analgesia when a significant inflammatory component is associated with the tumor and for CNS or nerve tumors. In animals with diminished liver function, prednisolone may be more appropriate.
Tramadol	4–5 mg/kg PO q6–12hrs	Has not been evaluated for efficacy or toxicity in dogs. On balance, tramadol does not appear to be effective for osteoarthritis pain.
Zoledronate	0.1–0.2 mg/kg in 50–100 mL 0.9% NaCl, given IV over 15 min Maximum of 4 mg per dog; can be repeated q21–28days	This drug inhibits osteoclast activity and can provide analgesia in cases suffering from a primary or metastatic bone tumor that is causing osteolysis. Nephrotoxicity may be a concern.

CNS, Central nervous system; *GI,* gastrointestinal; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PO,* oral.

Empty cells denote that the aspect of validity has not been determined.

[a]None of these drugs have been evaluated for efficacy in the treatment of cancer pain. **None of these drugs are approved or licensed for use in chronic cancer pain**. Nonsteroidal antiinflammatory drugs (NSAIDs) have not been included in this table. NSAIDs should be used as a first line of pain relief if it is clinically appropriate to use them and should be used at their approved dosage. The dosages given are based on the authors' experience and the experience of others working in the area of clinical cancer pain control.

VetBooks.ir

TABLE 16.5 Suggested Dosages of Analgesics to Alleviate Chronic Cancer Pain in Cats[a]

Drug	Dosage (mg/kg)	Notes
Paracetamol (acetaminophen)	Contraindicated	Contraindicated – small doses rapidly cause death in cats.
Amantadine	3–5 mg/kg PO q24hrs	This drug has not been evaluated for toxicity but is well tolerated in dogs and humans, with occasional side effects of agitation and GI irritation. May be a useful addition to NSAIDs in the treatment of chronic cancer pain conditions. Amantadine powder can be purchased and formulated into appropriately sized capsules. The kinetics have recently been evaluated in cats.
Amitriptyline	0.5–2 mg/kg PO q24hrs	This drug appears to be well tolerated for up to 12 months of daily administration. May be a useful addition to NSAIDs for treatment of chronic pain conditions.
Aspirin	10 mg/kg PO q48hrs	Can cause significant gastrointestinal ulceration.
Buprenorphine	0.01–0.02 mg/kg sublingual q8–12hrs	The sublingual route is not resented by cats and may be a good way to provide postoperative analgesia at home. Feedback from owners indicates that after 2–3 days dosing at this dosage, anorexia develops. Smaller doses (5–10 mcg/kg) may be more appropriate for long-term administration, especially in combination with other drugs.
Butorphanol	0.2–1 mg/kg PO q6hrs	One study suggests that using oral butorphanol after surgery may be beneficial. Generally considered to be a poor analgesic in cats except for visceral pain, but the author has found it to be useful as part of a multimodal approach to cancer pain therapy.
Carprofen	Not enough data to enable recommendations for long-term administration	—
Etodolac	Not recommended	—
Firocoxib	—	Use has not been reported in clinical cases; however, firocoxib has a half-life of 8–12 hours in the cat, and at 3 mg/kg provided antipyretic effects in a pyrexia model.
Flunixin meglumine	1 mg/kg PO daily for 7 days	Daily dosing for 7 days results in an increased rate of metabolism of the drug; however, a rise in liver enzymes suggests that liver toxicity may be a problem with prolonged dosing.
Gabapentin	10 mg/kg q12hrs	Appears to be particularly effective in chronic pain in cats when an increase in sensitivity has occurred or when the pain appears to be excessive compared to the lesion present.
Ketoprofen	1 mg/kg PO q24hrs	Probably well tolerated as pulse therapy for chronic pain, with approximately 5 days of "rest" between treatments. Has also been used by some long term at a dosage of 1 mg/kg every 3 days. Another approach has been to use 0.5 mg/kg daily for 5 days (weekdays), and then no drug over the weekend, with this regimen repeated.
Meloxicam	0.1 mg/kg PO on day 1; then 0.05 mg/kg PO daily for 4 days; then 0.05 mg/kg every other day thereafter (approved in the EU at 0.05 mg/kg daily indefinitely for musculoskeletal pain)	The liquid formulation makes it very easy to gradually and accurately reduce the dosage. However, a decreasing regimen (as suggested here) has not been evaluated for efficacy in cats, although it has been found to be successful in dogs. The lowest dosage that has been demonstrated to be effective (in osteoarthritis pain) is 0.035 mg/kg/day. Meloxicam should be dosed accurately using syringes.
Piroxicam	1 mg/cat PO daily for a maximum of 7 days. If longer term medication is considered, suggest every other day dosing	Daily dosing for 7 days results in a slight increase in the half-life.
Prednisolone	0.5–1 mg/kg PO q24hrs	Can be very effective. **NOT to be combined with concurrent NSAID administration.**
Prednisone	0.5–1 mg/kg PO q24hrs	Can be very effective. **NOT to be combined with concurrent NSAID administration.** In animals with diminished liver function, prednisolone may be more appropriate.

Continued

TABLE 16.5 Suggested Dosages of Analgesics to Alleviate Chronic Cancer Pain in Cats[a]—cont'd

Drug	Dosage (mg/kg)	Notes
PSGAGs (polysulphated glycosaminoglycans) (Adequan)	5 mg/kg subcutaneously twice weekly for 4 weeks; then once weekly for 4 weeks; then once monthly (other suggested regimens call for once weekly injections for 4 weeks, then once monthly)	There is no clinical evidence that it provides any effect; however, anecdotal information suggests improvement can be seen after a few injections.
Robenacoxib	1–2 mg/kg q24hrs	Recently gained approval in the EU and other countries for long-term administration to cats for chronic musculoskeletal disorder pain. It is the first NSAID that is a coxib, has a short half-life, and demonstrates tissue selectivity.
Tolfenamic acid	4 mg/kg PO q24hrs for 3 days maximum	Has not been evaluated for chronic pain, but recent objective measurements demonstrated analgesia in the cat when administered perioperatively.
Tramadol	1–2 mg/kg once to twice daily	Recent evidence suggests it may be effective for chronic pain in the cat. Tablets are very bitter and aversive to cats.
Transdermal fentanyl patch	2–5 μg/kg/hrs	The patch may provide 5–7 days of analgesia in some cases and should be left on for longer than 3 days. After removal, the decay in plasma levels is slow.
Vedaprofen	0.5 mg/kg q24hrs for 3 days	Has not been evaluated for chronic pain but was evaluated for controlling pyrexia in upper respiratory infection and for controlling postoperative pain after ovariohysterectomy.

[a]None of these drugs have been evaluated for efficacy in the treatment of cancer pain. **None of these drugs are approved or licensed for use in chronic cancer pain**. Some drugs are approved for inflammatory or painful conditions in the cat in certain countries, and dosages for the control of cancer pain are extrapolated from these. The dosages given come from the authors' experience, and the experience of others working in the area of clinical cancer pain control.

GI, Gastrointestinal; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PO*, oral.

The choice of NSAID predominantly depends on the patient's response (closely evaluated both by the veterinarian and by the owner). Currently, limited evidence is available in small animal medicine on the incidence of adverse events in patients prescribed NSAID therapy,[83,84] and most of what we know is related to administration to dogs with OA. Veterinary professionals (including veterinary surgeons and nurses) more commonly associate side effects with postoperative use of NSAIDs rather than chronic administration in dogs.[82]

Unfortunately, pain treatment in cats has not evolved to an equivalent maturity in scientific and clinical analysis, and a consequent suboptimal analgesic efficiency currently exists in the management of felines.[85,86] Emesis, anorexia, lethargy, renal insufficiency, dehydration, and death have been observed after the use of oral NSAID formulations in cats.[87] Moreover, no NSAIDs have been licensed in North America for long-term administration in cats, and two NSAIDs, meloxicam and robenacoxib, have been approved in the European Union only for long-term treatment of musculoskeletal pain. However, a number of these compounds probably can be used safely (see Table 16.5). The key to safe chronic administration of an NSAID in cats is to use the smallest effective dosage and avoid using it (or use a reduced dosage) in cats with renal insufficiency. Another factor the author (BDXL) considers important is to select drugs with a short half-life to minimize the likelihood of adverse toxicities.

The patient on NSAIDs must be monitored for toxicity. The owner should be informed of the potential for toxicity and the signs to watch for (lethargy, depression, vomiting, melena, increased water consumption). Blood work (and urinalysis) should be performed regularly to monitor renal and liver function. Baseline health panels (complete blood count and serum chemistry) should be obtained when therapy is started, and these parameters should be monitored on a regular basis thereafter. The author (BDXL) repeats evaluations after 2 to 4 weeks and then at 1- to 4-month intervals as dictated by the individual patient and client.

If pain relief with NSAIDs is inadequate, a comprehensive multimodal therapeutic plan can be established. A common first additional option among veterinarians seems to be tramadol[82]; however, the recognized analgesic effect of tramadol has been questioned in clinical efficacy studies of chronic pain in dogs, with conflicting results.[88] Acetaminophen or acetaminophen/codeine combinations often can be used in conjunction with NSAIDs, but the influence of this combination on adverse events is unknown. Other agents that are used to treat chronic pain include amantadine, an *N*-methyl D-aspartate (NMDA) antagonist; anticonvulsants (e.g., gabapentin); and tricyclic antidepressants (e.g., as amitriptyline). These can all be combined with NSAIDs, although we do not know the full extent of side effects. Readers are cautioned that they should not assume that combinations of different adjunctive drugs are without side effects; quite the contrary, there is much to be learned about potential adverse interactions, especially in cancer patients that may be on other therapies.

Piprant NSAIDs

Grapiprant is a highly selective EP_4 prostaglandin PGE_2 receptor antagonist, a member of the piprant class of NSAIDs. In experimental settings, this drug has shown antiinflammatory function in models of acute and chronic inflammation in rodents.[89,90] Recently grapiprant was approved by the US Food and Drug Administration (FDA) as a veterinary drug for chronic OA pain in dogs. The recommended clinical dosage for canine OA pain is 2 mg/kg given orally (PO). The advantage of this drug may be the wide safety margin (see Table 16.4).[91,92] In cats, no adverse events have been associated with oral administration of grapiprant in toxicokinetic analyses (15 mg/kg, PO, once daily for 28 days),[93] but no studies have been performed to evaluate the efficacy of grapiprant for the

VetBooks.ir

treatment of cats with chronic painful diseases. Interestingly, the EP_4 receptor has been implicated in cancer metastasis in murine models. EP_4 activity on tumor and host cells promotes breast cancer progression via tumor cell migration, invasion, angiogenesis, and lymphangiogenesis.[94–98] Therefore EP_4 pharmacologic blockade may not only mitigate pain, but also attenuate multiple protumorigenic properties. This potential benefit has yet to be studied in the setting of clinical veterinary oncology.

Acetaminophen

Acetaminophen is a nonacidic NSAID. Many authorities do not consider it an NSAID because it probably acts by somewhat different mechanisms.[99] Some evidence indicates an antiinflammatory effect in dogs.[100] The exact mechanism of action remains controversial,[101] and the antiinflammatory features of this drug are associated mainly with the inhibition of central prostaglandin synthesis.[102] Other potential antinociceptive mechanisms include the serotonergic descending inhibitory pathway,[103] the endocannabinoid system,[104] and possibly brain TRPV-1 and TRPA1 receptors.[105,106] Although highly toxic in the cat, it can be effectively used in dogs for pain control in the acute setting.[100,107] No studies of toxicity in dogs have been done, but if toxicity is encountered, it probably will affect the liver. In common with all NSAIDs and opioids, acetaminophen should be used cautiously in dogs with liver dysfunction. The author (BDXL) often uses acetaminophen as the first line of analgesic therapy in dogs with renal compromise, in which NSAIDs should be avoided, and in dogs that appear to be otherwise intolerant to NSAIDs (e.g., vomiting or gastrointestinal ulceration).

Opioids

Opioids are considered an effective part of the management of cancer pain in humans, particularly when they are used as part of a multimodal approach (i.e., including NSAIDs or adjunctive analgesics). The use of opioids in cancer patients is recommended in moderate to severe cases of pain. Moreover, a recommended measure is to combine the use of opioid and nonopioid drugs both to relieve pain and to reduce the opioid dosage and consequent adverse events.

Oral morphine, transdermal fentanyl, oral butorphanol, sublingual buprenorphine (cats only), and oral codeine have been tested for the alleviation of chronic cancer pain. However, none of these drugs has been fully evaluated for clinical toxicity when administered long term or for efficacy against chronic cancer pain. Furthermore, recent evidence has indicated that oral opioids may not reach effective plasma concentrations in dogs when dosed at the currently recommended levels due to a high first-pass effect in dogs.[108–111] Given this fact, and the ongoing opioid crisis in the human population, we do not recommend using or dispensing oral opioids in companion animals. Also of concern is the dispensing of fentanyl patches, although data does support efficacy in dogs and cats.[112,113]

Currently no information is available on the long-term use of oral opioids for chronic pain in the cat. Buprenorphine, a partial μ-agonist, appears to produce predictable analgesia when given sublingually[114] and is well accepted by most cats. The small volume required (maximum 0.066 mL/kg [20 μg/kg]) makes administration simple. Based on clinical feedback from owners, this is an acceptable technique for home use. Inappetence can occur after several days of treatment, but lower doses (5–10 μg/kg) may be able to overcome this problem. When buprenorphine is administered concurrently with other drugs, less frequent dosing of buprenorphine often is required.[114]

Tramadol

Tramadol, a synthetic derivative of codeine, is classified as an opioidergic/monoaminergic drug.[115,116] The pharmacodynamic effects of tramadol result from complex interactions between opiate, adrenergic, and serotonin receptor systems. However, tramadol undergoes extensive metabolism. Thus the analgesic efficacy of tramadol may vary between species because of differences in the metabolic profiles of this drug. Tramadol is considered efficacious in a variety of human conditions, including cancer pain.[117] The benefits arise in part from opioid receptor–mediated activity of the active metabolite, *O*-desmethyltramadol (M1), which arises from hepatic demethylation of tramadol. Several studies have reported lower circulating concentrations of tramadol M1 metabolite in dogs compared with humans and cats,[108,118–123] and clinical benefits have not been observed after oral administration in dogs with chronic pain associated with OA.[88] It is important to highlight that little is known about the side effects of tramadol in dogs, and almost nothing is known about the side effects when tramadol is combined with other drugs in human or canine medicine.

In contrast to dogs, oral administration of tramadol induces antinociceptive behaviors in cats in a dose-dependent manner. The analgesic effects of tramadol in cats are supported by pharmacokinetic data that cats do produce the active metabolite M1.[124,125] Recently, prospective studies in a research colony of cats with naturally occurring OA demonstrated that oral tramadol at 3 mg/kg every 12 hours for 19 days resulted in measurable pain relief without clinically important adverse effects. The most common adverse events were mydriasis, sedation, and euphoria.[126] Tramadol is difficult to administer to cats because of its highly aversive taste. Even custom flavoring of compounded liquid formulations has been largely ineffective at improving palatability. Nonetheless, the drug can be of significant value in cats that will tolerate oral administration and in cats with feeding tubes (e.g., esophagostomy and gastrostomy).

Serotonin syndrome, which is manifested as altered mental status and neuromuscular and autonomic dysfunction, can follow co-administration of two or more drugs that affect serotonin signaling. Thus caution is advised when prescribing tramadol in patients also receiving drugs such as trazodone or mirtazapine, which are commonly used in veterinary cancer patients.

The dosages given in Tables 16.4 and 16.5 are for the regular form of tramadol, but not for the prolonged release form, which has not yet been thoroughly evaluated for toxicity in the dog or cat.

N-Methyl D-Aspartate Antagonists

The NMDA receptor appears to be central to the induction and maintenance of central sensitization,[127,128] and the use of NMDA receptor antagonists is beneficial when central sensitization has become established (i.e., especially chronic pain). Ketamine, tiletamine, dextromethorphan, and amantadine have NMDA antagonist properties, among other actions.

Ketamine is not obviously useful for the management of chronic pain because of the formulation available and the tendency for dysphoric side effects even at low doses. Furthermore, oral ketamine has not been evaluated in dogs or cats for long-term

VetBooks.ir

administration. Intraoperative "microdose" ketamine, administered intravenously (IV), appears to provide beneficial effects for a variety of oncologic surgical procedures, including limb amputations,[129] and this may reduce the incidence of chronic pain later. Other reports suggest a benefit to using ketamine perioperatively in low doses,[130] and the authors recommend its use in cancer surgery to help control pain later postoperatively.

Amantadine has been used for the treatment of neuropathic pain in humans,[131] and one study suggests a benefit to adding amantadine to an NSAID treatment in dogs that do not get complete relief from the NSAID alone.[132] The toxic side effects have been evaluated in dogs but not cats, and the dosages suggested are considered safe.[133] Amantadine should be avoided in patients with congestive heart failure, a history of seizures, or those on selegiline, sertraline, or tricyclic antidepressants.

The active metabolite of dextromethorphan may not be produced in dogs, probably negating its use in that species for chronic pain.[134]

Anticonvulsant Drugs

Many anticonvulsants (e.g., carbamazepine, phenytoin, baclofen, and more recently, gabapentin) have been used to treat chronic pain, including neuropathic pain, in humans, in addition to chemotherapy-induced peripheral neuropathies. Gabapentin and pregabalin are among the most effective drugs available for neuropathic pain in humans. Although the exact mechanism of action of these drugs is unclear, one potential mode by which they exert their analgesic effect is by binding to the α_2-δ protein subunit of voltage-gated calcium channels, thereby reducing excitatory neurotransmitter release through channel modulation or channel trafficking. Although considerable information is available on gabapentin disposition in dogs and cats,[135–138] and some information has been reported on its use as an anticonvulsant in dogs,[139] no information has been produced about its use for the control of chronic or long-term pain.

A potential analgesic value can be attributed to gabapentin (and theoretically to pregabalin). Although the indications for gabapentin and pregabalin presently are unclear in veterinary patients, these drugs do appear to be useful for cancer pain in some patients and are probably particularly effective in cancers that have some neurogenic or nerve destruction component. However, further clinical trials are required to assess the efficacy of these drugs in domestic animals.

Tricyclic Antidepressants

Tricyclic antidepressants have been used for many years for the treatment of chronic pain syndromes in people and are becoming widely used for the modulation of behavioral disorders in animals. Within the CNS are descending inhibitory serotonergic and noradrenergic pathways that reduce pain transmission in the spinal cord. Tricyclic antidepressants (e.g., amitriptyline, clomipramine, fluoxetine, imipramine, maprotiline, and paroxetine) primarily inhibit the reuptake of various monoamines (serotonin for clomipramine, fluoxetine, and paroxetine; noradrenaline for imipramine, amitriptyline, and maprotiline). Tricyclic antidepressants can also interact directly with 5-hydroxytryptamine and peripheral noradrenergic receptors and may also contribute other actions, such as voltage-gated sodium channel blockade and reduction in peripheral prostaglandin E_2-like activity or tumor necrosis factor production. However, human medicine has a relative lack of controlled, clinical trials specifically evaluating the efficacy of antidepressants in treating cancer pain,[140] with the exception of two studies demonstrating a lack of efficacy in the treatment of chemotherapy-induced peripheral neuropathy.[141,142]

The tricyclic antidepressant amitriptyline appears to be effective in cats for pain alleviation in interstitial cystitis,[143] and many practitioners are reporting efficacy in other chronically painful conditions in the cat, including OA. Amitriptyline has been used daily for periods up to 1 year for interstitial cystitis, and few side effects are reported. The authors have also used amitriptyline in cats for cancer pain, with some encouraging results. Only two case reports have been documented on the use of oral amitriptyline for neuropathic pain in dogs (dosages of 1.1 mg/kg and 1.3 mg/kg PO were used); the reports described improvement in the patients' clinical signs after long-term administration (longer than 3 months).[144] In dogs, pharmacokinetic analyses have shown that oral administration of amitriptyline at a dosage of 4 mg/kg produces low amitriptyline plasma concentrations, suggesting that this dosage is an inappropriate therapeutic option for dogs.[145] More experimental and clinical comparative analyses are needed to validate amitriptyline as a safe and clinically relevant therapeutic option in veterinary medicine. Amitriptyline probably should not be used concurrently with other drugs that modify the serotonergic system (e.g., amantadine, tramadol) until more is known about drug interactions.

Sodium Channel Blockade

Alterations in the level of expression, cellular localization, and distribution of sodium channels are seen in many pain states. These aberrantly expressed sodium channels result in hyperexcitability and ectopic activity in peripheral and central nerves that encode nociceptive information. Low doses of lidocaine and other sodium channel blockers readily block these aberrantly expressed sodium channels, producing pain relief. Low-dose IV lidocaine has proven as effective as other commonly used medications for the treatment of neuropathic pain in humans,[146] and the author (BDXL) uses such an approach to downregulate central sensitization in veterinary cancer patients. The use of transdermal lidocaine patches for the treatment of cancer pain is attracting increasing interest.[147] Much of this interest revolves around using the patch to administer a low systemic level of lidocaine that blocks the aberrantly expressed sodium channels. Studies have been performed evaluating the kinetics of lidocaine absorbed from patches applied to dogs and cats.[148–150] Peak plasma concentrations of lidocaine were obtained between 10 and 24 hours after application in dogs and at 65 hours after application in cats. The results of these studies indicate that, similar to what is seen in humans, systemic absorption of lidocaine from the patch is minimal. Potential systemic toxicity associated with lidocaine administration, including bradycardia, hypotension, cardiac arrest, muscle or facial twitching, tremors, seizures, nausea, and vomiting, was not noted in any study. Dosing guidelines have been suggested,[151] although to date no reports have been published evaluating the analgesic efficacy of topical lidocaine (whether in patches or cream) in veterinary cancer patients; however, the technique holds promise.

Steroids

Glucocorticoids provide an effective strategy for counteracting inflammatory pain. The mechanism of actions of steroids involves inhibition of collagenase and proinflammatory cytokines.

VetBooks.ir

Moreover, they are able to trigger lipocortin synthesis and thus block the production of eicosanoids, such as prostaglandins.[152–155] This pharmacologic targeting can exert an effect both on the PNS and on the CNS because free steroids can cross the blood-brain barrier.[155,156] Currently, in human patients, the evidence is conflicting on the usefulness of steroids for preventing painful conditions such as acute or recurrent migraines.[157–159] Studies in neuropathic pain models in rodents have demonstrated that steroids could inhibit or attenuate this pain, but the underlying mechanism remains unknown.[160,161] Steroid use has been shown to provide analgesia in certain human cancer patient subpopulations, including those with bone cancer, spinal cord compression, or brain tumors.[162–166] Likewise, corticosteroids may provide benefit to veterinary cancer patients, including those with ulcerated or inflamed cutaneous mast cell tumors or with cerebral edema secondary to intracranial neoplasia. However, the analgesic utility of drugs such as prednisone and dexamethasone have not been systematically evaluated in dogs and cats with cancer, and nuisance side effects (polyuria/polydipsia, panting, behavioral changes, anxiety) have the potential to diminish QOL in a substantial fraction of treated patients. Additionally, exogenous steroids should not be used concurrently with NSAIDs because this dramatically increases the risk of side effects, especially gastrointestinal ones.

Bisphosphonates

Malignant bone disease creates a unique pain state with a neurobiologic signature distinct from that of inflammatory and neuropathic pain.[167–169] Bone cancer–related pain is thought to be initiated and perpetuated by dysregulated osteoclast activity and activation of nociceptors by prostaglandins, cytokines, and hydrogen ions released within resorptive pits. Therapies that block osteoclast activity not only have the potential to markedly reduce bone pain, but may also mitigate other skeletal complications associated with neoplastic conditions, including pathologic fractures, neuronal compression, and hypercalcemia of malignancy.

Bisphosphonates are synthetic analogs of pyrophosphate, and their primary effect is to inhibit osteoclast activity through inhibition of the mevalonate pathway. Bisphosphonates accumulate in metabolically active bone by virtue of their chemical structure, and after osteoclast-mediated bone resorption, they are released and disrupt cellular functions, resulting in osteoclast death. The antiresorptive activities of bisphosphonates has been demonstrated in normal and cancer-bearing dogs by means of a reduction in urine N-telopeptide excretion and enhanced bone mineral density.[170] This activity contributes to the risk of osteonecrosis, which is most frequently reported in the mandible.[171,172] Mandibular osteonecrosis is uncommonly reported in tumor-bearing dogs that are being treated with bisphosphonates,[173] and it is this activity which is also the mechanism likely responsible for significant analgesia that may last for several months in approximately 30% of dogs treated with injectable bisphosphonate drugs.[170,174]

Oral absorption of bisphosphonates tends to be poor, and IV dosing is the preferred route of administration in dogs and cats. In human cancer patients potential acute adverse effects include nephrotoxicity, electrolyte abnormalities, and acute-phase reactions[175,176]; however, it is the experience of the author (TF) that these notable toxicities are not observed in companion animals receiving IV bisphosphonate therapies. For many years pamidronate was the drug of choice for dogs with malignant bone pain. It may be administered at a dosage of 1 to 2 mg/kg over 2 hours as a constant rate infusion ([CRI] diluted in saline) every 3 to 4 weeks. Zoledronate is now preferred because of its 100-fold greater antiresorptive potency relative to pamidronate and more rapid infusion rate. It is dosed at 0.1 mg/kg, diluted in physiologic saline, and administered as a CRI over 15 minutes. Many practitioners give a maximum dose of 4 mg per dog. The infusion time is important; longer or shorter treatment times may increase the risk of nephrotoxicity.[177]

At odds with the fact that clinically apparent analgesic benefit is often in excess of a month, many veterinary oncologists currently recommend that bisphosphonate injections be repeated at 3- to 5-week intervals. Although this dosing regimen is not substantiated by investigations of how bisphosphonate therapy modifies the biomechanical integrity of bone having undergone malignant osteolysis or by clinical data reflecting the effect of such therapy on the risk of pathologic fracture, one hope for such frequent administration is that modulation of bone turnover will reduce the risk of pathologic fracture. In addition to the inhibitory effects of bisphosphonates on osteoclasts, in vitro reports suggest that they may also exert directly beneficial effects on cancer cells, including canine osteosarcoma (OSA) and fibrosarcoma lines.[178,179] Hence, the intent to maximize potential antineoplastic effects also has been proffered as a rationale for ongoing monthly administration of bisphosphonates. However, caution must be exercised, because the preclinical data is inconclusive and conflicting. For example, one recent publication describing experiments performed in a canine OSA xenograft model suggests that zoledronate therapy may actually increase the incidence of pulmonary metastasis.[180] To better define the ideal treatment protocol, clinical trials are underway investigating the effect of monthly zoledronate administration on metastatic propensity in canine OSA. Such comparative oncologic studies of zoledronate's potential influence in canine OSA metastatic progression might help explain the absence of benefit exerted by adjuvant zoledronate in the upfront setting of pediatric OSA.[181]

Palliative-Intent Radiation Therapy

RT often is administered with the goal of controlling cancer. Because higher doses of radiation typically are associated with a higher probability of favorable tumor control, definitive-intent RT protocols are intensive and typically involve delivery of large total doses of radiation to the tumor. In this situation the goal is to maximize the antineoplastic efficacy of RT. By contrast, some patients are irradiated with the primary goal of reducing cancer-associated symptoms, including cancer pain. Palliative-intent RT can be given using a variety of administration techniques. For example, samarium is a radioisotope that has been evaluated for use in dogs.[182] Although the use of samarium Sm153 lexidronam in veterinary medicine is still limited, the results of a noncontrolled clinical study with subjective assessments reported improvement in lameness scores in 63% of dogs, suggesting that this therapy may be useful in the palliation of pain in dogs with bone tumors in which curative-intent treatment is not pursued.[183] External beam RT is most commonly applied. Regardless of the delivery system, the dose-response relationships for radiation-induced reductions in cancer pain have not been well studied, but they are not necessarily the same as the dose-response relationships for tumor control. In fact, they are likely quite different. This is exemplified by the fact that malignant bone pain in humans often can be effectively treated with low total dose, hypofractionated radiation protocols. For example, high-quality data shows that the pain relief associated with a single 8 Gy fraction is equivalent to

VetBooks.ir

that achieved with 30 Gy in 10 fractions in patients with painful bone metastases.[184]

In veterinary medicine the use of RT for palliation of patients with malignant osteolytic bone pain has been reported in several diseases, including feline oral squamous cell carcinoma[185–187] and canine oral melanoma.[188–193] The best studied use of RT for pain control is palliation of canine appendicular OSA. Interestingly, Weinstein and collaborators[194] demonstrated that a single fraction of 8 Gy failed to measurably reduce lameness in dogs with appendicular OSA. However, a subset of those dogs did have improved limb function and, in a separate study, 91% of dogs experienced clinically appreciable analgesia after delivery of 16 Gy in two consecutive daily fractions of 8 Gy.[195] Higher doses of radiation have been investigated in other studies. Although dissimilar methodology precludes direct comparison, results are similar with response rates up to 92%, median time to onset of pain relief ranging from 2 to 14 days, and median duration of pain relief ranging from 67 to 95 days.[195,196] Unfortunately, the lack of both proper controls, and failure to use validated objective measures of cancer pain make complete and reliable interpretation of these studies challenging.

Analgesia for Radiation Side Effects

Whereas palliative-intent RT can be used to relieve cancer pain, definitive-intent RT can itself result in painful side effects. RAP can result from acute or late radiation side effects. Although late side effects can be quite severe, they are also relatively uncommon. Thus the most commonly encountered forms of RAP occur during and shortly after a course of RT.

As mentioned previously, painful RT side effects are common in dogs but less common in cats. Canine RAP is often associated with grade II or higher RT-induced dermatitis or oral mucositis, which is characterized by moist desquamation and edema. In a prospective study of 80 dogs undergoing RT for head and neck cancer, 80% of dogs undergoing definitive-intent RT developed grade II radiation-induced mucositis, with 44% progressing to grade III lesions.[22]

The treatment of RAP is empirical. Whereas many dogs with RAP once were treated with glucocorticoids, practice patterns have shifted, and patients with non–round cell neoplasms that have RAP now often are managed with NSAIDs instead. This is due in part to the expectation of enhanced analgesia, but it is also influenced by the hope for additive antineoplastic effects.[197–199] Other systemic and topical therapies are frequently used; complete discussion of this topic is beyond the scope of this chapter but has been summarized elsewhere.[200] Because that review focused on management of radiation-induced dermatitis, it is also worth noting that some veterinary radiation oncologists use "magic mouthwash" to manage radiation-induced oral mucositis. Magic mouthwash is a term used to describe lidocaine-based rinses. Several formulations are used in clinical practice, and many include ingredients such as diphenhydramine, corticosteroids, antifungals, and antibiotics. In a recent phase III clinical trial, the severity of RAP was significantly lower in humans with oral mucositis that had been treated with magic mouthwash versus placebo.[201] The methods included a rinse and spit technique. Unfortunately, rinsing and gargling cannot be used in dogs. Thus it is unclear whether there is sufficient distribution or contact time to promote a clinically advantageous effect in dogs with oral mucositis. Furthermore, because of the risk of promoting multidrug-resistant infections via exposure to prophylactic antibiotics, clinicians are strongly cautioned against prescribing antibiotic-containing formulations for patients that have oral mucositis without clear evidence of a superimposed bacterial infection.[202]

Pharmacologic Desensitization Strategy

Many of the aforementioned treatments have been formulated to target both peripheral and central mechanisms, mainly designed as long-term therapies. However, a large number of cancer patients must undergo surgical procedures that can exacerbate the signs of pain. In this context the perioperative management of pain is a critical step in avoiding upregulation of peripheral and central components that contribute to pain hypersensitivity syndromes.[203–205] Meta-analyses have been performed to evaluate the efficacy of various systemically administered drugs for the prevention of chronic pain after soft tissue surgery in human adults. The most common pharmacologic interventions include perioperative use of oral gabapentin, pregabalin, mexiletine, venlafaxine, NSAIDs, and IV steroids, ketamine, fentanyl, and lidocaine.[206]

In veterinary medicine a multimodal approach is most often applied in small animal medicine, with apparent improvement in acute postoperative pain.[207–214] Fentanyl, hydromorphone, morphine, medetomidine, ketamine, and lidocaine are the most common drug infusions used both intraoperatively and postoperatively (Table 16.6); however, no study has evaluated the effect of such an approach on the incidence, severity, and/or character of chronic pain after surgery (whether associated with nociceptive, neuropathic, or cancer pain).

Acupuncture

Acupuncture can be provided through simple needle placement or by needle placement combined with electrical stimulation (of high or low frequency, although most types of pain respond to low-frequency stimulation). Results of a study in normal experimental dogs demonstrated a weak analgesic effect of electroacupuncture in anesthetized patients, as evaluated by a reduction in the minimum alveolar concentration of an inhaled anesthetic agent.[215] Recent data from a rodent model suggests that electroacupuncture may have beneficial effects in the treatment of pain associated with bone cancer.[216,217] As yet, no evidence indicates that acupuncture provides pain relief in veterinary patients, but the authors do encourage its use along with known analgesics.

Future Analgesic Therapies

Over the past few years, evidence has shown that the pain transmission system is plastic (i.e., it alters in response to inputs). This plasticity results in a unique neurobiologic signature within the PNS and CNS for each painful disease. Understanding the individual neurobiologic signatures for different disease processes should allow novel, targeted, and more effective treatments to be established.[218] This approach should also allow for a more informed choice to be made on which of the currently available drugs might be most effective.

Several new approaches to pain treatment revolve around the use of mechanisms to destroy or "exhaust" neurons involved in pain transmission. One approach is to use targeted neurotoxins to cause neuronal death.[219] An example of this is the combination of a neurotoxin (saponin) and a conjugate of substance P, called substance P saporin (SP-SAP). Substance P binds to the neurokinin receptor (NKR), and the conjugate is internalized (a normal phenomenon of the receptor-ligand interaction), resulting in cell

VetBooks.ir

TABLE 16.6 Dosages of Selected Analgesic Drugs for Constant Rate Infusions in Dogs and Cats

Drug	Dog Dosage	Cat Dosage	Notes
Fentanyl	2–5 μg/kg loading dose, followed by 2–6 μg/kg/hr (10–30 μg/kg/hr for surgical analgesia)	1–3 μg/kg loading dose, followed by 2–6 μg/kg/hr (10–30 μg/kg/hr for surgical analgesia)	Appears to result in significant anorexia, especially at higher doses. Can become expensive for larger dogs. Cats do not always "look happy" on this. Cats can become hyperthermic.
Hydromorphone	0.05 mg/kg loading dose followed by 0.01–0.02 mg/kg/hr	0.05 mg/kg loading dose followed by 0.005–0.01 mg/kg/hr	Appears to be very effective in cats, but hyperthermia can be seen.
Morphine	0.5 mg/kg loading dose followed by 0.1 mg/kg/hr (often need to reduce this when other analgesics are administered concurrently because of excessive sedation)	0.2 mg/kg loading dose followed by 0.05 mg/kg/hr	Morphine may not be as effective in cats as in dogs and humans because of their inability to form an active metabolite. This seems to vary from cat to cat. Avoid in GI surgery because of induced stasis.
Dexmedetomidine	1 μg/kg loading dose followed by 0.5–2.5 μg/kg/hr	0.5 μg/kg loading dose followed by 0.5 μg/kg/hr	Caution needed in heart disease patients; increase in systemic vascular resistance can be significant.
Ketamine	0.5 mg/kg bolus followed by 10 μg/kg/min intraoperatively, then 0.002 mg/kg/min postoperatively	0.5 mg/kg bolus followed by 10 μg/kg/min intraoperatively, then 0.002 mg/kg/min postoperatively	Small doses are thought to provide analgesia by virtue of NMDA antagonism.
Lidocaine	1 mg/kg bolus followed by 30 μg/kg/min	Best avoided because of tendency for cardiotoxicity	Provides analgesia (when given in small quantities) probably by interaction with aberrantly expressed sodium channels. Intravenous CRI should not be used with "analgesic" catheters using local anesthetics or other intermittent dosing of local anesthetics.

CRI, Constant rate infusion; *GI,* gastrointestinal; *NMDA, N*-methyl *D*-aspartate.

death as a result of the neurotoxin.[220,221] Because sensory neurons are rich in NKRs, if the conjugate is targeted appropriately (e.g., given intrathecally), sensory neurons are killed. Research indicates that in models of chronic pain, general sensory function is left intact, whereas hyperalgesia associated with chronic pain is reduced. Some toxicity work has been performed in dogs,[222] and clinical trials in pet dogs with naturally occurring OSA have been performed. In this model of pain SP-SAP significantly reduced experimental pain behaviors within 6 weeks. However, signs of motor dysfunctions were observed over 5 to 7 weeks after injection in some cases.[223] The current status of development of this therapeutic is unknown. A phase I study currently is underway in humans.[224]

Chemokine CCL2 and its receptor, CCR2, are involved in neuropathic pain. The exact mechanism by which CCR2 induces pain it is not completely defined, but overexpression of CCR2 has been observed in DRG and microglial cells after nerve or spinal injury, suggesting both peripheral and central mechanisms.[225] In a rat model of bone cancer, spinal cord expression of CCR2 was significantly increased, and central neuronal excitation, in addition to mechanical and thermal hyperalgesia, was attenuated after spinal administration of a selective CCR2 antagonist, AZ889.[226] Additional studies are needed to develop an effective and safe pharmacologic formulation for use in humans. Furthermore, CCR2 antagonists have not been evaluated for potential usefulness in veterinary pain management and/or oncology, and thus can be considered only as a putative therapeutic target.

Another approach uses Transient Receptor Potential Vanilloid 1 (TRPV1) to target neurons involved in pain. If the activation of TRPV1 by drugs such as capsaicin or resiniferatoxin occurs for long enough or is intense enough, the resulting calcium influx can cause neuronal degeneration. Capsaicin is used in humans for neuropathic pain and is being developed for long-term management of OA pain in humans.[227] Resiniferatoxin has been evaluated through preliminary studies in both rodents and dogs.[228–231] Short-lived and self-limiting side effects were reported by pet owners, including lethargy, lack of interaction with the family, and inappetance[223,229]; nonetheless, these studies provide encouraging evidence that intrathecal administration of resiniferatoxin can be associated with prolonged pain relief in dogs with OSA-associated pain.

Nerve growth factor also represents an attractive druggable target for preventing chronic pain. Experimental and clinical studies indicate that NGF is a key component in the establishment and maintenance of pain.[232–234] NGF is expressed by several cell types, including structural, tumor, inflammatory and immune cells.[235,236] Increased levels of this protein have been described in inflammatory, neuropathic, and cancer models of pain, and this overexpression appears to induce long-lasting pain in animals and humans.[237–240] In cancer models NGF induces sensory and sympathetic nerve sprouting and neuroma formation.[241,242] In mouse models preemptive and sustained administration of anti-NGF monoclonal antibodies significantly attenuated tumor-induced nerve sprouting and nociceptive behaviors in bone cancer models.[242] The anti-NGF tanezumab currently is being evaluated in phase III human trials for its usefulness in OA management.[243] NGF inhibition appears to produce substantial improvements in pain and function; some studies indicate that it is superior to either NSAIDs or opioid monotherapy.[240,244] In veterinary medicine the potential participatory role of NGF in cancer pain has been supported by its active secretion by canine OSA cells.[245] Furthermore,

VetBooks.ir

anti-NGF monoclonal antibody therapy has been tested in clinical pilot studies in both dogs and cats with OA; analgesic relief without associated side effects was achieved.[70] Nevertheless, more preclinical and clinical evaluations need to be performed to provide a better understanding of the potential role of such a targeted agent in small animal clinical practice.

SECTION B: NUTRITIONAL MANAGEMENT OF THE CANCER PATIENT

JOSEPH WAKSHLAG

Over the past 80 years the examination of nutrients and their relationship to cancer and cancer prevention has led to a better understanding of how nutrition may play a role in the management of the disease. The paucity of well-controlled studies in companion animals and the extrapolation of data derived from humans studies in the investigation of uncommon tumor types in companion animals (colon, prostate, pancreas) are frustrating and make general recommendations for nutritional interventions challenging. However, owners often wish to alter their pets' feeding regimen, regardless of proven efficacy. That said, three areas of nutrition often are discussed with clients: modification of tumor metabolism; adjustment of nutritional risk factors that may affect outcomes; and nutritional intervention during therapy. All of these are addressed in this section.

Metabolism of Cancer

Substrate Utilization

Numerous neoplastic cell lines have been propagated successfully in cell culture, allowing examination of cellular behavior. One fundamental finding from cell culture is that most neoplastic cells propagate better in a high-glucose media. This likely is due to limited fatty acid metabolism coupled with increases in metabolic pathways that utilize glucose; this traditionally has been termed the "Warburg effect," after Otto Warburg's seminal work suggesting that glycolysis is the primary pathway for energy production in neoplastic cells.[246,247] Studies in humans have shown that certain cancer patients liberate excessive lactate from solid tumors,[248,249] providing evidence that glycolysis and pyruvate production are critical to neoplastic cell metabolism. This has led to the Cori cycle hypothesis of neoplasia; that is, neoplastic tissue, much like skeletal muscle tissue, appears to undergo regeneration of glucose from lactate through hepatic resynthesis of glucose.[250] Unfortunately, this regeneration of glucose is an energy-costly cycle and is thought to contribute to increases in resting energy requirements.

In veterinary medicine a significant body of work has examined metabolism and cancer, often through the application of indirect calorimetry assessments to study whole body metabolism. Such studies investigate oxygen consumption and carbon dioxide liberation; the ratios of carbon dioxide production to oxygen consumption can provide estimates of energy consumption (resting energy expenditure [REE]) and substrate utilization (respiratory quotient [RQ]). In one study healthy dogs displayed a higher REE than dogs with stage III or stage IV lymphoma.[251] RQ values between the groups were no different, suggesting that the dogs were all burning similar substrate and that the dogs with lymphoma were not preferentially burning more glucose than their control counterparts.[251] Dogs with lymphoma that were fed either a high-fat or a high-carbohydrate diet during doxorubicin chemotherapy did not differ in remission times, survival times (STs), or tumor burden, suggesting that lymphoma was not sensitive to this basic dietary alteration.[252] During this study the REE and RQ assessed during treatment did not change significantly when the tumor burden was eliminated through chemotherapy, suggesting that no significant changes occurred in energy expenditure or metabolism. These data collectively indicate that removal of the tumor burden does not alter the resting energy requirement (RER) and that no fundamental differences were observed between normal healthy dogs and dogs with lymphoma.

Canine nonhematopoietic malignancies were also examined in this context before and 4 to 6 weeks after excision of the primary tumors (including mammary carcinoma, OSA, high-grade mast cell tumors [MCTs], and lung carcinoma). As in dogs with lymphoma, the REE was no different from that of control dogs, and no difference in REE was seen before and after excision of the primary tumor, suggesting no futile cycling of energy in these patients.[253] Interestingly, the RQ values were above 0.8 for all control and tumor-bearing dogs, suggesting that the resting energy was not from lipolysis; this was contradictory to a follow-up study performed in dogs with OSA. In dogs with OSA, a difference was observed in the REE; affected dogs had a higher REE than control dogs, and the RQ was closer to 0.7 in both affected and control dogs.[254] This increased REE was still present after excision of the primary lesion, suggesting that the modest increase in REE was due to factors other than the primary neoplasia and could possibly be associated with micrometastasis, inflammation associated with neoplastic disease, or heightened pain response associated with the primary tumor and surgical procedure.[254] These findings were surprising in light of the previously mentioned studies but likely were more valid considering that the REE calculations were based on lean mass rather than total kilograms of body weight in the OSA study.[254] In general, fat mass is considered to be metabolically inert; therefore an REE based on lean body mass is more appropriate. The previous studies in nonhematopoietic malignancies and lymphoma did not adjust for body condition or lean body mass in tumor-bearing or normal populations,[252,253] and the inability to document differences in REE noted in these two studies may have been at least partly due to a lack of body condition assessment.

Metabolic changes were observed in dogs with OSA in addition to an increased REE. Alterations in glucose metabolism (potentially higher glucose turnover), increased protein turnover, and urinary protein losses in affected dogs were also observed.[254] Studies in dogs with lymphoma identified alterations in carbohydrate metabolism, such as increased serum lactate, and insulin concentrations during glucose tolerance testing suggesting insulin resistance.[251,255,256] This may be partially explained by aberrant interleukin-6 (IL-6) cytokine influences on glucose metabolism resulting in insulin resistance in dogs with lymphoma.[257] Insulin insensitivity and serum lactate did not change once remission was achieved in one of the previously mentioned studies. [251] Additionally, mild alterations in lipid metabolism in dogs with lymphoma were seen as higher basal triglyceride and cholesterol concentrations compared with control dogs,[258] and treatment with doxorubicin lowered serum cholesterol, perhaps as a result of hepatic effects of the chemotherapy[258]; however, the dyslipidemia was not ameliorated once the primary tumor burden was eliminated, which is logical in light of the insulin resistance observed.

Anorexia and Cachexia

Anorexia is common in cancer patients. In some patients this may be partially explained by adverse events associated with the use of chemotherapy. Chemotherapeutics can cause a variety of

alterations in olfactory and taste senses.[258] Because dogs and cats rely heavily on olfactory cues, the loss of olfactory bulb stimulus diminishes the palatability of foods.[258,259] Additionally, the loss or alteration of taste (ageusia or dysgeusia) can further complicate anorexia and may last for several months before neuronal regeneration can take place at the olfactory bulb and tongue.[258,259]

Cachexia, on the other hand, although identified in many human cancer patients, does not appear to be common in dogs with nonhematopoietic malignancies.[251,255,260,261] Evidence in humans and mouse models suggests that the most prominent influence inciting the cachectic phenomenon may be excessive cytokine stimulation, which leads to insulin resistance, extensive lipolysis, and proteolysis of tissue stores.[262,263] The three primary cytokines thought to be involved in promoting enhanced proteolysis are tumor necrosis factor-alpha (TNF-α), interleukin-1β (IL-1β), and IL-6.[262,263] TNF-α and IL-1β have both been directly associated with anorexia and upregulation of the mitochondrial uncoupling protein, whereas IL-6 and TNF-α have been observed to increase myofibrillar degradation machinery—all of which may play a role in the anorexia/cachexia syndrome associated with neoplasia.[264,265] IL-6 and C-reactive protein, both markers of inflammation, are increased in canine lymphoma patients.[257,266,267] Yet it does not appear that cachexia is a common occurrence in dogs diagnosed with neoplasia, because dogs examined 6 months before diagnosis of cancer showed no difference in body weight or body condition than when presenting with various neoplasias.[260] This may be partially explained by differences in common tumor types between species. Cachexia in humans is often associated with epithelial cancers, such as pancreatic, colon, mammary, and prostate cancer. Additionally, human patients undergo dramatically different and more aggressive treatment protocols over lengthy periods, which we typically do not encounter in veterinary medicine because of owners' financial constraints and quality of life decisions.

Cats may show a more typical cachectic response involving excessive lean body mass wasting. Approximately 56% of cats with lymphoma and other solid tumors have body condition scores less than 5 out of 9.[268] More intriguing is that the ST for cats with lymphoma with a body condition score of 5 or greater was 16.9 months, compared with 3.3 months for cats with lower scores.[268] This warrants monitoring of caloric intake and aggressive implementation of nutritional interventions in feline oncology patients.

These sensitivities should be taken into consideration during radiation therapy, for which cats often stay overnight and are fasted for multiple days in a row. Providing ample time to consume calorie-dense foods should be considered for the hospitalized cat to ensure that food is offered often enough for the cat to maintain a normal caloric intake. Anecdotally, 19 of 20 cats undergoing RT at the author's (JJW) facility for a month lost weight during treatment, suggesting that feeding patterns and weight loss should be monitored and ameliorated when possible.

Metronomic feeding surrounding chemotherapy protocols may be beneficial to tumor growth and progression. The exact nature of how this would be implemented in dogs and cats is in its infancy; however, the concept of starving the tumor during chemotherapy may be beneficial for chemotherapeutic efficacy.[269,270] The typical protocols involve either not feeding the patient or limiting feeding in the 24 to 72 hours before chemotherapy to help sensitize the tumor cells to a more stressful environment and dampen the inflammation associated with the tumor. Many clinical trials are underway in humans to achieve a better understanding of this phenomenon.

Epidemiology, Prevention, and Risk Factors

In humans the two major nutritional factors associated with the relative risk of developing cancer are body weight (obesity) and fruit and vegetable consumption.[271–274] Although these parameters may be interrelated, both appear to play a role in carcinogenesis. Convincing data indicate that the westernized diet and lack of fruit and vegetable matter are linked to an increased relative risk of nearly all types of neoplasia, including prostate, colon, and breast cancers, lymphomas, and leukemias.[275–277] It is not yet clear whether this increased relative risk is due to a decreased dietary intake of fiber, carotenoids, and flavonoids or to an increased intake of saturated fat and protein. In people consuming higher amounts of fruits and vegetables, it is apparent that combined factors may be involved, in addition to confounding lifestyle differences, that may be important.

Few studies in veterinary medicine have examined the effects of dietary substrate (protein, fat, and carbohydrate) and plant-based dietary intake and cancer incidence. Two epidemiologic studies used validated food frequency questionnaires to examine the calories coming from fat, protein, and carbohydrate for 1 year before diagnosis of mammary carcinoma and after diagnosis and compared this with survival data.[278,279] This data was contradictory to human findings because dogs with an increased protein intake had increased STs after diagnosis, and fat and carbohydrate intake did not play a role in progression of the disease.[278,279] In another study the risk of neoplasia was increased in dogs fed nontraditional, poorly balanced diets (i.e., table foods as primary consumption).[280] Further examination showed no association between blood selenium concentration and mammary carcinomas compared with healthy, age-matched and hospitalized control dogs; however, tissue retinol status was decreased in dogs with mammary carcinoma.[280] Whether the lower serum retinol resulted from the dogs being fed a commercial diet with inadequate retinol or was a manifestation of the disease was not determined. Because feeding an incomplete diet was associated with an increased risk, feeding a complete and balanced commercial diet is highly recommended. These results are not surprising considering that food stuffs and methods of feeding are dramatically different between dogs and people. In many cases a high-protein food may be evaluated as higher quality because protein is an expensive ingredient; therefore many confounding variables—such as ingredient inclusion, ingredient quality, digestibility, and owner socioeconomic-associated health provisions—should be considered in studies of this nature, and such studies cannot be directly compared with human studies.

A study that examined nutritional risk factors in Scottish terriers, which have a genetic predisposition to developing transitional cell carcinoma (TCC), found that the addition of vegetables to the diet resulted in a lower incidence of the disease[281]; however, there were confounding lifestyle factors that cannot be accounted for in this epidemiologic investigation, including better health care, variation in nutrition supplied as commercial food, and other associated environmental exposures. Nevertheless, the findings of this study are provocative and suggest that further study is warranted.

Recent investigations of specific nutrients and cancer treatment primarily have focused on oxidative damage in tumors and antioxidants (addressed in a later section of the chapter). Specific vitamins and their relationship to cancer development have received significant attention, including retinol, ascorbic

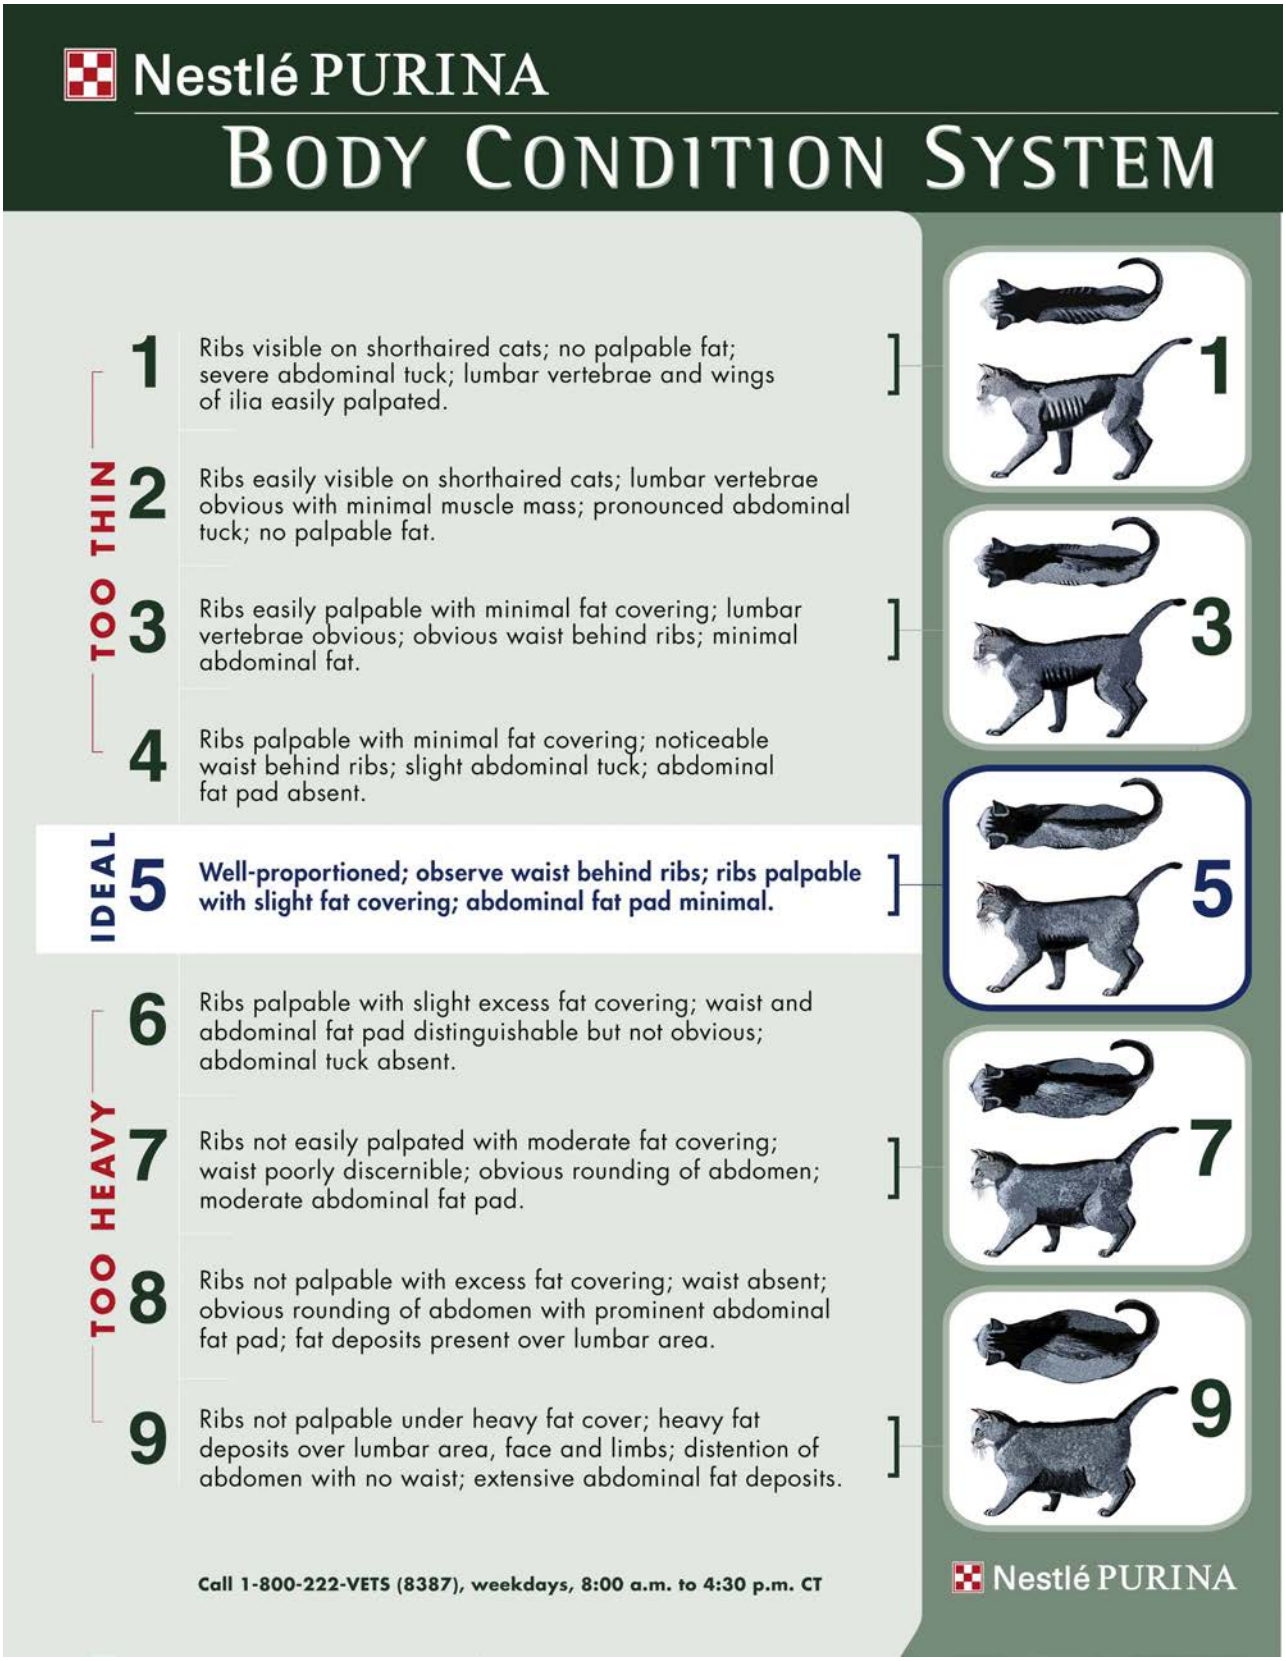
VetBooks.ir

acid, vitamin E, selenium, and vitamin D. In veterinary medicine these nutrients have not been studied in a prospective or retrospective fashion. The findings in human meta-analyses examining oral supplementation for single nutrients (e.g., ascorbate, selenium, vitamin E) have been inconclusive or negative with regard to protective antineoplastic effects.[282] β-Carotene, the precursor to retinol, currently is thought to be ineffective as an antineoplastic agent, and in some instances has proven to be harmful in certain populations (i.e., smoking populations).[283–285] Currently vitamin D status and supplementation have been an area of intense epidemiologic investigation because of the relative risks of various neoplastic diseases being higher for individuals with low serum vitamin D.[286–288] Unlike in humans, vitamin D status in dogs and cats directly depends on dietary intake because they cannot convert 7-OH-dehydrocholesterol to pre–vitamin D. One would expect that serum vitamin D concentrations would not fluctuate tremendously in dogs fed commercial dog food.[289] Multiple investigations suggest that dogs with lymphoma and MCT (but not OSA) have lower serum vitamin D levels than healthy, breed- and age-matched dogs, which makes vitamin D status an interesting area of investigation.[290,291] Part of the conundrum in dogs is that the serum concentrations are about double normal human values, and it is possible that the supplementation of pet foods ensures adequate serum concentrations. The lower limit of normal ranges from 60 to 100 ug/mL.[291] The lack of uniformity in laboratory testing, such as methods involving high- performance liquid chromatography versus mass spectroscopy are examples of differences in methodology and applied reference ranges.[292,293] More interestingly, when dogs with serum concentrations of less than 100 ug/mL are supplemented with oral cholecalciferol at the safe upper limit established by the National Research Council, serum 25-OH-cholecalciferol serum concentrations do not increase.[294] This suggests that there may be inherent pathways in individuals to eliminate vitamin D from the body which may just represent metabolic differences between dogs. These findings further corroborate that serum 25-OH-cholecalciferol status may be a marker for hepatic and renal cytochrome activity that makes individual dogs more prone to develop cancer based on each individual dog's inherited metabolism. Whether this is a direct reflection of dietary intake or a reflection of the biochemical disposition in affected dogs with cancer remains to be determined.

In humans obesity has been associated with an increased risk of many cancers, including breast, prostate, colon, and pancreatic cancers; leukemias; and lymphomas.[270–272] Studies examining this association in companion animals are limited. The largest retrospective study in dogs showed no association between body condition and cancer,[260] whereas other epidemiologic studies suggest obese cats and dogs may have a slightly higher rate of neoplastic diseases.[295,296] Two other investigations revealed a more definitive link between obesity in female dogs and mammary carcinoma.[278–280] The risk of mammary carcinoma was greater in obese spayed dogs in one study, whereas obesity was an increased risk independent of spay status in another study.[278,280] Both studies suggested an increased risk when obesity is present at 1 year of age and one suggested that obesity at 1 year before diagnosis also was associated with an increased risk.[280] The question of whether early-onset obesity, much like early spaying, epigenetically predisposes mammary glands to an altered risk of cancer remains to be addressed.

Implementing a Nutritional Plan for the Oncology Patient

Nutritional Assessment



To fully assess the cancer patient, information about body weight, the body condition score, and a dietary history are crucial. The dietary history, before and during treatment, should be obtained to assess kilocaloric intake appropriately. This information allows the practitioner to feed the patient appropriately during hospitalization and, more importantly, to recognize hypophagic behaviors, allowing for interventions. A typical diet history should include the forms of food (wet or dry), amounts fed daily, and treats, human table foods, and additional supplements provided.

Serial assessment of body weight is important, particularly when malnutrition is a consideration. Malnutrition often is associated with cachexia and/or anorexia. Anorexic behavior can be deduced from the dietary history and can be treated aggressively with nutritional and/or pharmacologic intervention; however, if cachexia is suspected, then alternative treatments can be sought. The difficulty in clinically differentiating cachexia from anorexia is our inability to measure loss of lean versus fat mass. The loss of fat mass is typical during anorexia, whereas equal loss of lean and fat mass suggests cachexia. Although this cannot be deciphered efficiently in veterinary practice, overall weight loss guidelines have been offered in the human literature; that is, body weight loss of 5% in 1 month or 10% in 3 months without conscientious dieting suggests cancer cachexia.[297] This approach may be difficult in veterinary species because routine loss and gain of weight may be seasonal, and the burden of gastrointestinal (GI) parasites potentially confounds weight loss issues. Two body condition scoring systems have been adopted as a means of nutritional assessment in companion species; however, the 1 to 9 body condition scoring system (see Fig. 16.2) is better validated in the literature.[469, 470] Modest differences in body condition scoring between dogs and cats exist because of preferential deposition of body fat along the inguinal and abdominal areas in cats, whereas dogs tend to have no preferential deposition. These differences may justify a muscle condition scoring system in cats (Table 16.7).[268]

The final component of nutritional assessment consists of a routine physical examination, complete blood cell count, and chemistry evaluation. Physical exam findings consistent with malnutrition include poor hair coat, chronic GI disturbance, seborrhea, lethargy, and pallor. The first signs of chronic nutrient deficiency are often manifested in areas of rapid cellular anorexia/cachexia syndrome turnover, leading to skin, GI, and hematologic signs, and should be considered in cases of prolonged anorexia. Chronic malnutrition can result in low hemoglobin and red blood cell counts, in addition to hypoproteinemia and hypoalbuminemia. Additionally, with the trend toward nontraditional feeding practices, diets may lack sufficient mineral content, including calcium, iron, and copper, resulting in bone and hematologic manifestations. Many homemade diets lacking supplementation with bone meal can lead to secondary hyperparathyroidism and clinical osteopenia.[298,299] Clients using nontraditional diets should be educated through consultation with a veterinary nutritionist.

In dogs, excess body condition (i.e., obesity) may be more of a concern than malnutrition or deficiency. Treatment of obesity is not a priority in many cancer patients, considering the metabolic changes that may occur during chemotherapy and the potential for treatment-related changes in eating patterns. In one study body condition did not change from 6 months before diagnosis to

TABLE 16.8 Maintenance Energy Requirement Equations for Adult Cats and Dogs

Animal	MER Equation
Neutered adult dog	$(70 + 30[BW_{kg}]) \times 1.6$
Intact adult dog	$(70 + 30[BW_{kg}]) \times 1.8$
Obesity-prone adult dog	$(70 + 30[BW_{kg}]) \times 1.2$ to 1.4
Neutered adult cat	$(70 + 30[BW_{kg}]) \times 1.2$ to 1.4
Intact adult cat	$(70 + 30[BW_{kg}]) \times 1.4$ to 1.6
Inactive obesity-prone adult cat	$(70 + 30[BW_{kg}]) \times 1$

BW, Body weight; *MER,* maintenance energy requirement.

the day of diagnosis.[260] Another study showed that 68% of dogs lost weight during treatment[300]; however, in this study the loss was less than 5% of body weight, and nearly 30% of dogs were scored as obese before treatment. The occurrence of obesity in dogs with neoplasia appears to follow the national trends in canine obesity.

Feeding the Hospitalized Oncology Patient

Hospitalization during RT is common. Repeated radiation treatments or complications associated with chemotherapy treatment are frequent reasons for overnight or extended hospitalization. The provision of more than the RER often is unnecessary except in extreme circumstances, such as when extensive tissue repair is ongoing (e.g., epithelial sloughing or mucositis). This increased energy requirement, known as the *illness energy requirement* (IER), often is considered to be 1.1 to 2 times the RER, particularly when transudates or exudates are involved with the repair process and protein losses are excessive. Table 16.8 presents the calculations for the RER and IER used in veterinary patients based on activity status. Exponential equations are preferred in dogs and cats under 2 kg or over 30 kg to derive a more accurate estimate of the RER:

$$\text{RER} \doteq 70 \times (\text{Body weight [kg]})^{0.75}$$

The exponent of the equation may be different for cats (e.g., 0.67).[301] Once a patient returns home, the RER typically increases slightly as a result of increased activity. Therefore clinicians should adjust the energy intake after discharge.

Coax Feeding and Pharmacologic Appetite Stimulation

Ensuring full energy requirement intake enterally may be difficult because of a diminished appetite in cancer patients. Many considerations are involved in trying to promote adequate intake, and these may be different in dogs and cats. Hand feeding in dogs and cats that enjoy this approach should be considered, rather than putting a bowl in the cage and leaving it there. Hand feeding may be best achieved during owner visits, when the animal is most comfortable and often away from the busy atmosphere of most intensive care units or oncology wards.[302,303] For cats, having a quiet place away from distractions that create a fearful environment may be helpful to achieving adequate intake. Making one cage an eating cage that is covered and located away from the litter box is ideal, because some cats will not eat near the litter box during hospitalization.[302,303]

Addition of flavorings may also be helpful. Dogs have salt and sweet receptors, and the addition of sugar, syrups, or other sweeteners sometimes can improve appetite.[302,303] Cats do not have the sweet receptors; salt can be used to entice cats to eat, but they tend to be more averse to oversalted foods.[302,303] Adding protein to the diet of both dogs and cats can improve appetite and enhance intake, because dogs appear to prefer higher protein diets, and cats have an increased density of lingual amino acid receptors, which makes high-protein choices logical.[302,303] Supplementing with fat through the use of animal- or vegetable-based fat may increase palatability but must be monitored, because additional fat can dilute the nutrient content of the food. If the animal has nausea, introducing multiple foods can create long-term aversions, limiting choices of form and texture once the nausea has resolved.[302,303] Using one or two foods to coax feed, rather than an entire array of products from the kitchen, is the ideal approach.

Pharmacologic approaches to improve enteral support may be attempted. Human interventions have not been proven successful in veterinary patients, including pharmacologic alterations in serotonergic stimulation in the brain, decreased cytokine stimulation, and the promotion of hypothalamic satiety center signaling.[303,304] Approaches in veterinary medicine have revolved around use of the antiserotonergic drug mirtazapine which does appear to increase appetite and reduce vomiting in cats.[305] Equally promising, if not more so, is the recent release of the ghrelin agonist, capromorelin, which has been shown to promote short-term food intake in hospitalized dogs.[306] Capromorelin appears to be moderate to good at improving appetite in the author's (JJW) experience, and trials are ongoing to examine the effects in cats. In addition, propofol can be used to induce eating behavior in dogs. It has been used as an appetite stimulant on a single-time basis to see if eating induces ill effects (i.e., vomiting) when the enteral status is uncertain.[307]

Assisted Enteral Support

In many instances the use of assisted enteral nutrition should be considered, particularly if the animal is not consuming appropriate kilocaloric requirements. In the hypophagic cancer patient, it may be essential to provide assisted feeding through various techniques, including syringe, nasogastric, esophagostomy, or gastrostomy feeding. Syringe feeding is the easiest and requires the least attention to detail by owners and clinicians. In the nauseous and anosmic patient, this can be difficult to implement because of patient resistance. Nasogastric tubes can be easily placed without anesthesia and can be useful in hospitalized animals; however,

VetBooks.ir

they often are problematic to manage at home and are limited to the use of liquid enteral products because of the small tube diameter. The two most widely accepted means of implementing long-term enteral support involve placement of an esophagostomy tube or a gastrostomy tube. The esophagostomy tube typically is placed under light anesthesia (techniques for placement have been described elsewhere).[308] Once secured the tube site typically is wrapped, and the insertion site should be examined every 24 to 48 hours for signs of cellulitis and discharge. These tubes typically are recommended for intermediate- to long-term feeding (2 weeks to 3 months).

Gastrostomy tube placement should be considered when supplemental feeding is required for longer than 6 to 8 weeks.[308,309] Advantages include direct gastric delivery of nutrients, and the fact that emesis does not cause tube eversion. Anesthesia is required for placement, which can be performed via surgical or percutaneous endoscopic approaches. The endoscopic approaches are generally safe and effective but are associated with a higher risk of complications.[309] The author (JJW) prefers surgical placement in large breed dogs because they may be predisposed to separation of the stomach from the body wall after endoscopic placement, increasing the risk of cellulitis, and/or peritonitis. Peritonitis is the most serious complication after tube placement, because the peritoneum is disturbed with this approach, which also leads to a permanent stoma from the stomach to the outside of the body.[308,309] After successful placement the gastrostomy tube can be used within 24 hours; it should not be removed before 2 weeks to allow adhesion and fibrosis of the gastric wall to develop. Once a stoma has formed, the original surgically placed tube may be replaced with a low-profile or "button" feeding device. Owners should be aware that these low-profile devices need replacing every 6 to 8 months and require mild sedation for replacement.[310]

Esophagostomy and gastrostomy tubes allow for a diverse number of products to be used for feeding, beyond the liquid veterinary diets. Many over-the-counter and veterinary therapeutic diets can be blended for feeding; however, when some products are blended with water, they result in less than 1 kcal per milliliter. Table 16.9 list some diets that provide higher caloric density and can be passed through a 7 French or greater diameter catheter. These products tend to be higher in protein and fat and can be fed at reduced volumes and rates when nausea or food volume is an issue. In addition, a typical dog or cat receiving a slurry of food at 1 kcal/mL is meeting its fluid requirements.[311] Similarly, dogs and cats that are not actively consuming water at home should be provided 1 kcal/mL.

Parenteral Support

If enteral support is not an option, then parenteral nutrition (PN) support should be considered. Parenteral support can be either partial (PPN) or total (TPN). PPN has also been termed *peripheral PN* because it is typically delivered through peripheral veins. Prospective clinical studies examining outcomes after parenteral support have not been performed in veterinary medicine, and only a handful of retrospective investigations characterize complication rates.[312–317] In veterinary patients, particularly cats, the metabolic complication most often encountered is hyperglycemia. Mechanical complications also are prevalent, such as feeding line problems and inadvertent removal. A common misconception is that sepsis is a common complication, when in fact it is quite rare.[312–317] Parenteral support should be considered only when enteral support is not an option because of medical complications; enteral support is considered superior because it prevents transmigration of bacteria to the portal blood and improves the patient's immunologic status.[318]

Parenteral support is not well studied in veterinary medicine and the relative use and utility of the three main substrates (glucose, amino acid, and lipid) differ, depending on the source of information.[319–321] Some advocate using glucose and lipid to meet the energy requirements and then add in amino acids to the formulation based on the protein needs per kilogram of body weight. Others advocate adding just above the minimal protein requirement as amino acids making up part of the RER. The protein requirements for ill cats and dogs currently is unknown, and we can only assume that the requirement is similar to that of healthy normal animals. Extrapolation from human data suggests that protein turnover may be higher during catabolic illness, and we often add slightly more protein than required. An elegantly designed study found that approximately 2.3 grams of protein per kilogram of body weight is sufficient for an IV amino acid solution in dogs.[322] This suggests that adding 2.5 to 3 g/kg of amino acid solution for a dog appears sufficient, and 4 g/kg often is used as a starting point for cats. Amino acids come in several different formulations and strengths (e.g., 5.5%, 8.5%, and 10%). Additionally, amino acid solutions come with and without electrolytes. Amino acids with electrolytes typically provide basal sodium, chloride, magnesium, phosphorus, and potassium when used at 1.5 to 2.5 g/kg body weight of protein; however, these are used less often in cats and dogs, particularly in cats whose protein requirement may be higher. When amino acids are used with electrolytes, the electrolytes provided should be considered before additional electrolytes are supplemented in fluids. Fig. 16.3 describes a typical

TABLE 16.9 Selected High Protein/Calorie Products for Tube Feeding of Cancer Patients and the Amount of Water Needed to Make a 1 Kcal/mL Mixture to Meet Daily Fluid Requirements

Product	Calories (kcal/mL)	Protein (g/100 kcal)	Fat (g/100kcal)	Water needed for 1 kcal/mL
Royal Canin Recovery RS (5.8 oz)	1.1	9.9	6.4	18

RER = 30(kg BW) + 70 or 70(kg BW)$^{0.75}$ RER = _____

A. Protein requirement:
DOGS: 3 grams/kg BW CATS: 4 grams/kg/BW

Protein requirement (gm/day) = _____ gm/kg × W kg = _____ gm/day

Protein calories (gm/day) × 4 kcal/gm = _____ kcal/day

Total kcal − protein calories = _____ nonprotein calories

B. Nonprotein calories (NPC)

Glucose (40-60%) NPC = _____ × _____ NPC = _____ kcal glucose

Lipid (40-60%) NPC = _____ × _____ NPC = _____ kcal lipid

C. Volumes of substrates

10% amino acid solution = 0.10 gm/mL

Protein gm req _____ / 0.10 gm = _____ mL of AA solution. (½ volume day 1_____)

50% dextrose (kcals) _____ / 1.7 kcal/mL = _____ mL of 50% dextrose. (½ volume day 1_____)

20% Lipid (kcals) _____ / 2.0 kcal/mL = _____ mL of 20% lipid. (½ volume day 1_____)

Total volume of TPN solution = _____ mL/24 hrs / 24 hrs = _____ mL/hr. (½ rate day 1_____)

Fluid req _____ mL − TPN volume _____ mL = Remaining fluid req _____ mL

Remaining fluid requirement/24 hours = _____ mL/hr of fluids

• **Fig. 16.3** Small animal total parenteral nutrition (TPN) formulation sheet.

TPN feeding program using a 10% amino acid solution without electrolytes. It is typically recommended that, during the first day of TPN, only half of the calorie requirement should be provided, particularly if the animal has a history of anorexia. This recommendation is due to the potential for refeeding syndrome, in which rapid glucose metabolism can lead to hypophosphatemia, hypokalemia, and hypomagnesemia. This also illustrates the need to assess electrolyte status every 12 to 24 hours for the first 48 to 72 hours when implementing TPN.

PN formulation should be done in a laminar flow hood with appropriate aseptic procedures to prevent contamination of solutions. A sterile catheter should be used, and PN should be administered through its own port in a multilumen catheter, with the most distal port reserved for PN. The addition of other medications or treatments should be avoided because some medications are not compatible with PN. The typical osmolality and pH of a TPN solution is far different from plasma osmolality (around 1000–1300 mOsm and a pH less than 7). This may be irritating to the vascular endothelium and requires a large vessel for administration.[321] Such high osmolar solutions cannot be used in a peripheral vein because they may induce thrombophlebitis; this is the reason 5% glucose is used to dilute PPN, rather than the 50% glucose solution used in TPN solutions.[313–319] Using 5% dextrose creates an osmolality of less than 700 mOsm, which is a guideline from human medicine that has been adopted by many veterinary nutritionists and internists.[323] Fig. 16.4 describes guidelines for PPN formulation for dogs and cats.[313,319] The addition of B-complex vitamins should also be considered when TPN or PPN is used. Most preparations do not include folate and cobalamin, and supplementation should be considered separately if long-term IV support is required. Furthermore, if chronic use of TPN is required, calcium should be added separately to TPN, and the use of amino acids with electrolytes and trace mineral additions to the TPN should be considered.

The proportions of glucose and lipids in parenteral solutions have become the subject of much debate, particularly in the cancer patient because neoplastic tissue may utilize glucose more readily, as well as the potential for mild insulin resistance.[255,256] However, increasing the use of lipid to meet energy requirements also has been met with some trepidation because of lipids' potential to mildly suppress the immune system.[324] Lipid also has been incriminated as causing microemboli[325]; however, lipid particles remain well emulsified in a typical veterinary-formulated TPN solution, and no bacterial growth was evident for 3 days after formulation when the solution was kept refrigerated.[326] PPN, with its lower osmolality, is at an increased risk of sequestering microbial growth.

Nutritional Support in the Cancer Patient

Substrate

Based on our present understanding, the use of specific dietary regimens in cancer patients is premature. Because of the glycolytic nature of neoplastic cell growth, altering the substrates to hypothetically "starve the tumor" by eliminating some carbohydrates may be indicated[246,247,255,256]; however this argument falls short for a number of reasons. If carbohydrates are limited, energy

VetBooks.ir

RER = [30(kg BW) + 70] or 70 (kg BW)$^{0.75}$ RER = _____ × 0.50 = _____ Partial Energy Req

A. Nutrient Distributions:

1) Cats and Dogs 2-10 kg

PER = _____ × 0.25 = _____ kcal/day from carbohydrates

PER = _____ × 0.25 = _____ kcal/day protein

PER = _____ × 0.50 = _____ kcal/day lipid

2) Dogs 10-25 kg

PER = _____ × 0.33 = _____ kcal/day from carbohydrates

PER = _____ × 0.33 = _____ kcal/day protein

PER = _____ × 0.33 = _____ kcal/day lipid

3) Dogs > 25 kg

PER = _____ × 0.50 = _____ kcal/day from carbohydrates

PER = _____ × 0.25 = _____ kcal/day protein

PER = _____ × 0.25 = _____ kcal/day lipid

B. Volumes of solutions required

1) 5% dextrose solution = 0.17 kcal/mL

_____ kcals from carbohydrate/ 0.17 kcal = _____ mL/day

2) 10% amino acid solution = 0.1 gm/mL = 0.4 kcal/mL

_____ kcals from protein/0.4 kcal/mL = _____ mL/day

3) 20% lipid solution = 2 kcal/mL

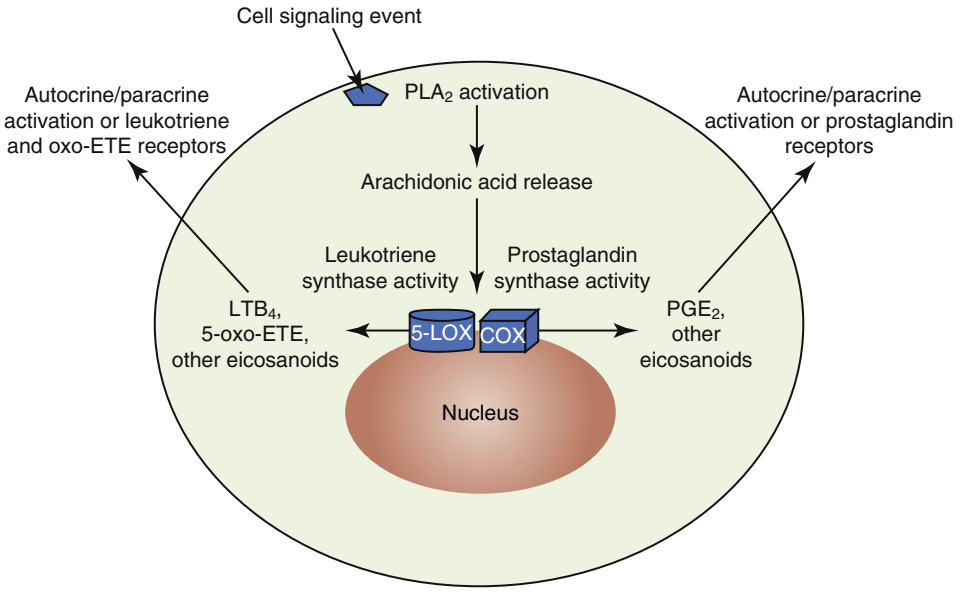
_____ kcals from lipid/2 kcal = _____ mL/day

Total volume = _____ mL/day/ 24 hours = _____ mL/hr

C. _____ mL osmolarity of solutions 5% dextrose × 0.252 (mOsm/mL) = _____ mOsm

_____ mL 10% amino acid soln without electrolytes × 1.0 (mOsm/mL) = _____ mOsm

_____ mL 20% lipid solution × 0.25 (mOsm/mL) = _____ mOsm



_____ mL Total volume of PPN solution = _____ mOsm

(Total mOsm/Total volume) × 1000 =_____ mOsm/L (MUST BE LESS THAN 700 mOsm)

• **Fig. 16.4** Small animal partial parenteral nutrition (PPN) formulation sheet.

sources are replaced with additional fat and/or protein. Added protein leads to increased transaminase and deaminase activity, causing conversion of the protein to glucose and carbon precursors for glucose or fatty acid synthesis, and serum glucose and delivery of glucose to the tumor tissue may remain constant. If appetite is diminished, choosing a higher protein and higher fat food may enhance palatability and caloric density, making these foods appropriate for long-term management during treatment.[305] Previous sections have discussed the discordance of the results of studies investigating advantages of low-carbohydrate, high-fat, and modified-fat diets.[252] One study documented slight increases in remission and STs when a diet high in polyunsaturated fat (high in omega-3 fatty acids) and arginine was used.[257]

Cats appear more prone to weight loss during hospitalization. Many cats receive inadequate caloric intake, particularly during RT, when food availability is limited each day because of repeated induction of anesthesia. Many cats eat 12 to 20 small meals throughout the day and night, based on observed feeding patterns.[327] The use of higher protein diets may be worthwhile, because recent rodent data showed that a high-protein, low-carbohydrate diet reduced tumor growth in a variety of different xenografted tumors.[328] In this diet, dietary calories were met with approximately 50% protein, implying that high protein may be the benefit, rather than low carbohydrate.[328] The use of high-protein diets also may have benefits in cats with lean body mass wasting issues.[329,330] Although the studies conducted were small,

• **Fig. 16.5** Arachidonic acid (AA) is released from the cell membrane as a result of cell signaling events that lead to nuclear translocation of AA. Cyclooxygenase and lipoxygenase activity, coupled with leukotriene synthase or prostaglandin synthase, allows the formation of bioactive eicosanoids; when released, these can have autocrine or paracrine cell proliferation signaling activities, depending on receptor presence.

skeletal muscle in cats may respond to a higher protein intake by increasing lean mass slightly. With these ideas in mind, we often recommend feeding cats higher protein (>35% dry matter) and fat (>20% dry matter); dogs can be fed similarly, even though many commercial dog foods have lower protein levels (typically >30% dry matter is recommended) than cat food.

Amino Acids

The benefits of additional protein to the diet of cancer patients may result from increased circulating amino acids as inhibitory molecules in neoplastic cell proliferation.[328] Arginine has received considerable attention, because low millimolar concentrations of arginine can inhibit various neoplastic cell lines by altering cell cycle progression.[331–334] A diet higher in arginine and omega-3 fatty acids improved remission and STs in dogs with lymphoma[257]; however, the practicality of using an amino acid supplement such as arginine leaves much to be desired, because the required dose is in excess of 100 mg/kg body weight. Additionally, the bitter taste of arginine and the potential for creating amino acid imbalance prevent its use in long-term feeding regimens. The benefits of glutamine also have been touted because of its abilities to preserve lean body mass and enhance mucosal barrier function[335,336]; however, enterocytes' ability to utilize glutamine and first-pass hepatic metabolism do not allow glutamine to have any pronounced effects on lean mass. The use of high-protein mixed meals to support enterocyte health and mucosal barrier function often is recommended anyway.

Polyunsaturated Fats

Using fat in diets is helpful for increasing palatability and energy density, but in many instances the fatty acid constituents can influence neoplastic cell growth. Human and rodent model studies suggest that consumption of high concentrations of omega-3 fatty acids, namely eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), in the form of marine oils may perturb loss of lean body mass and possibly reduce the tumor growth rate.[337–344] These fatty acids may transform into inert eicosanoids (PGE_3, LTB_5, 12-HEPE, and 5-HEPE) rather than proinflammatory eicosanoids (PGE_2, LTB_4, 12-HETE and 5-HETE). The pathways and eicosanoids liberated are highly dependent on the enzymatic machinery present in the cells. Although the addition of fatty acids into the cell membrane may affect intracellular signaling events, the intracellular enzymatic machinery that modifies the primary fatty acid into promitogenic, or inert, eicosanoids may be more important.[343–346] Cell signaling events that lead to the release of arachidonic acid from the cell membrane can be converted to eicosanoids which, when released from the cell, can have local or paracrine effects on cell growth through interactions with eicosanoid receptors (Fig. 16.5). The two enzymes that have received the most attention are cyclooxygenase and 5-lipoxygenase because of the promitogenic mechanisms of action observed by their respective eicosanoids, PGE_2 (COX) and 5-oxoETE/LTB_4 (5-LOX).[343–346] Although this may be relevant to many types of human cancers, little data is available on companion animals; the most intriguing studies focused on the use of COX inhibition in TCC.[347,348]

A study in dogs with cancer that were fed a fish-based. omega-3 fatty acid–enhanced diet showed a small improvement in STs; however, there were multiple changes in the dietary trial, including arginine and energy substrate differences, which may have played a role.[257] The increased EPA may inhibit promitogenic eicosanoid formation[346]; but it is unclear to what tumor types this may apply. Some neoplastic tissues use the proinflammatory cytokine milieu to promote proliferation or upregulate pathways that may promote metastasis.[349] The benefits of fish oils may go beyond mild suppression of tumor cell proliferation, because the antiinflammatory effects of fish oil may also quench the inflammatory reactions associated with certain cancers.[350–352] Hence, there is little downside to increasing dietary omega-3 fatty acid consumption in cancer patients. The lack of clinical studies in this area precludes an optimal dosing regimen, and the findings of a recent meta-analysis of human trials using fish oils for quality of life issues were inconclusive.[353] Additionally, cats seem to be more sensitive to fish

VetBooks.ir

oil supplementation than dogs because of greater effects on platelet reactivity, resulting in alterations of clotting times.[354] A safe and tolerable dose for fatty acids in dogs can be extrapolated from studies in cardiac cachexia in dogs,[355,356] in which the dosage used was 45 mg EPA and 25 mg DHA per kilogram of body weight (e.g., 1 teaspoon per 20 kg body weight). Unpublished data from our laboratory suggests that the same dosing schedule did not alter thromboelastography results in cats.

During RT the paradigm may be altered, because RT has the effect of causing irreparable damage to tumor cellular microstructure, resulting in apoptosis of cells and negative effects on surrounding tissues. Polyunsaturated fats, the longest being the omega-3 fatty acid DHA, may be oxidized to a greater extent during RT, and this may lead to increased membrane compromise and cellular death.[357] Surrounding tissues may not exhibit as aggressive of an inflammatory action because of the hastened eicosanoid response with EPA and other essential fatty acids quenching this proinflammatory response, which may lead to less surrounding tissue damage.[358] This principle has not been studied in veterinary patients but has proven to diminish radiation-induced tissue damage in pig models.[359]

Vitamins and Minerals

Essential vitamin and mineral supplementation is an interesting area of investigation in human cancer, with nutrients such as vitamin A, vitamin D, and selenium receiving attention.[286,288,359–363] Much of the research has centered on cancer prevention rather than cancer treatment. That being said, certain vitamins and minerals are being used in therapeutic clinical trials in humans because of their ability to reduce tumor cell proliferation in preclinical models. Vitamin A, in the form of retinoic acid and synthetic derivatives, has been used to treat certain cancers; however, discordant effects on nuclear signaling occur with different heterodimers.[361–363] Some heterodimers drive the proliferative response, whereas others diminish cell proliferation.[364] Their use cannot be recommended at this time.

Low concentrations of vitamin D in people may promote tumorigenesis, and treatment with active vitamin D may cause tumor regression in some cases[286–288,365]; however, the antiproliferative form, calcitriol, can be toxic at high levels, and the repercussions of vitamin D toxicity can lead to calcification of soft tissue and hypercalcemia, resulting in low margins of safety. This was illustrated in a recent trial in dogs with MCTs, in which many patients developed clinical signs of hypercalcemia, inappetence, and vomiting.[365,366]

Selenium has generated considerable interest in certain human neoplastic diseases, such as lung, dermal squamous cell, and prostatic carcinomas.[367–370] Low serum concentrations have been associated with an increased risk of prostatic cancer in humans[367,369]; however, meta-analysis of human intervention studies suggests no definitive benefits from selenium supplementation in the treatment or prevention of neoplastic diseases.[282]

B-vitamins of interest include folate and vitamin B_{12} (cobalamin). The interest once again derives from human literature, which has shown that the effects of these two vitamins on epigenetic alterations may affect tumor suppressor and oncogene expression over time.[371–373] Considering the consistent intake of folate and cobalamin in the pet population, a considerable gap exists in applying these paradigms of subclinical deficiency to pet populations. Furthermore, the lack of clinical or in vitro investigation prevents any postulation as to their effects on cancer cells.

Antioxidants/Supplements

The use of supplements, most commonly substances termed "antioxidants," has grown tremendously in the past 15 years. Approximately 65% of pet owners are using some sort of alternative treatments; more than 30% of owners are giving their pets oral supplements, and more than 50% say their veterinarian approves of this use.[374] More recent epidemiologic data on conventional diets and supplementation shows that more than 50% of owners incorporate some sort of nontraditional feeding pattern after cancer diagnosis, and 39% supplement the diet of their dog.[375] This is a concern, because most oncology referral centers generally recommend that clients refrain from using antioxidants or herbal supplements, and from feeding raw and home-prepared foods because of the lack of clinical data to support their use.[376]

It is clear that antioxidant and oxidative balance is altered in tumor tissue. Canine mammary cancer tissue has an increased presence of lipid peroxidation coupled with an increase in upregulated antioxidant mechanisms, including glutathione peroxidase, glutathione, superoxide dismutase, and catalase.[377] In one study of dogs with lymphoma, reductions in serum antioxidants (tocopherols) and increased lipid peroxidation were observed, whereas total oxygen radical absorption capacity and glutathione peroxidase were increased, suggesting an increase in antioxidant capability.[378] Therefore the addition of an antioxidant is unlikely to have a dramatic effect on the overall antioxidant capability of tumor cells compared with normal tissue.

Further complicating this issue, many substances given as antioxidants may be considered pro-oxidants in some environments.[379] Many isothiocyanates, flavonoids, and carotenoids actually may cause alteration of cell signaling or depletion of specific antioxidant systems.[379,380] Furthermore, the evidence increasingly indicates that many of these compounds upregulate or downregulate specific cell signaling systems to alter the proliferative cycle from activities such as cell cycle disruption (CDKs, p16, p21), prosurvival signals (nuclear factor-κB [Nf-κB], AKT), mitochondrial-induced apoptosis (Bcl and Bax family proteins), and proliferative signaling pathways (i.e., mitogen-activated protein [MAP] kinase, tyrosine kinase [TK] activity).[381–383] Primary cancer cell culture data in lymphoma and OSA supports these principles. Astaxanthin and lycopene, two carotenoids, showed limited antioxidant capability in canine OSA cells lines, and when coupled with doxorubicin or irradiation, no protective effects were seen on cell proliferation indices or cell death.[384,385] Isoflavones appear to induce mitochondrial apoptosis in canine lymphoma cells.[386] Further examination of the flavonoid baicalein from *Scutellaria* root, shows mitochondrial-induced apoptosis.[387] Rosemary and curcumin extracts supplemented at slightly higher than presumed physiologic doses have antineoplastic activity and act synergistically in round, spindle, and epithelial canine cancer cells to promote cell death; they do not hinder chemotherapeutic cell death and may augment it.[388] These in vitro data must be interpreted with caution because another recent study examining the isothiocyanate sulforaphane, which has been touted to protect cells during cisplatin chemotherapy, may also augment cell growth in the canine OSA cell culture environment.[389]

Even if some of these compounds have little to no detrimental effect on current chemotherapy or RT protocols, the limiting factor to their effective use is absorption, hepatic metabolism, and the attainment of tissue concentrations that recapitulate what has been used in vitro.[381] Pharmacokinetic data has been collected on three nutraceuticals: genistein in cats (an isoflavone),

VetBooks.ir

epigallocathecin gallate (EGCG, a flavone from green tea), and lycopene in dogs (carotenoids).[390–392] All of these nutraceuticals required dosing at very high concentrations, which may preclude their clinical use. There is tremendous disconnect between what is available and what may be required, in addition to a lack of clinical trial investigations to assess the efficacy and safety of these compounds. Furthermore, metabolism of these compounds may be different in cats and dogs; therefore caution is advised. Dosages over 150 mg/kg of EGCG in dogs caused hepatic necrosis, and the use of lipoic acid (an antioxidant thought to help salvage glutathione) has potential for toxicity and hepatic damage in cats when used at dosages thought safe in dogs and humans.[393,394]

In conclusion, set nutritional requirements during neoplasia do not exist in companion animals. In part this is due to the variety of neoplastic diseases involved and the danger of trying to extrapolate data generated in human cancers. Many aspects remain to be addressed, including nutritional interventions for anorexia/cachexia during treatment and remission, and nutrition recommendations based on specific disease processes. Therefore no one dietary recommendation can be made for cancer patients; rather each case should be evaluated based on the patient's body condition, the specific neoplastic process, and the treatment protocol initiated by the oncologist. The topics discussed are merely guidelines for interested clients and clinicians – the most important factor in nutritional intervention is to supply a complete and balanced ration that meets the patient's energy requirements to prevent weight loss.

SECTION C: RELATIONSHIP-CENTERED APPROACH TO CANCER COMMUNICATION

JANE R. SHAW

Recognition of the relationships that people develop with their companion animals brings an awareness of the impact of animal illness on pet caregivers and the veterinary team.[395,397] Increasing acknowledgment of pets as family members is associated with greater expectations by pet owners for the highest quality medical care for their companion animals, in addition to compassionate care and respectful communication for themselves.[395,396,398–400] The human-animal bond is particularly stressed and fragile when an animal is sick, and even more so after a diagnosis of cancer. Appreciating the effect of animal companionship on the health and well-being of humans creates a new dimension in public health. Today, the responsibilities of veterinary professionals include the emotional health and well-being of clients and their pets.[398]

Communication about the diagnosis, treatment, and prognosis of cancer presents challenges both for veterinarians and for clients. From the veterinarian's perspective, a number of factors may contribute to discomfort with this conversation, including lack of training, insufficient time, practice culture, feeling responsible for the patient's illness, perceptions of failure, unease with death and dying, lack of comfort with uncertainty, the effect on the veterinarian-client-patient relationship, worry about the patient's quality of life, concerns about the client's emotional response, and the veterinarian's own emotional response to the circumstances.[400,402] Some of these same reasons may account for clients' anxiety during difficult conversations; these include self-blame, unease with death and dying, anticipatory grief, effect on the human-animal bond, effect on the veterinarian-client-patient relationship, pet's QOL, and concerns about their emotional response to the situation. Research in human medicine indicates that breaking bad news, discussions of the prognosis, and end-of-life discussions often are suboptimal because of many of these barriers and a lack of specific training in communication.[401–404]

The content, duration, and methods of communication training in veterinary curricula are highly diverse and variable. Many practitioners have not received formal communication training and may feel unprepared to engage in difficult conversations.[405–407] The veterinary profession identified a skills gap between the content of the veterinary school curriculum and the actual skills required to be a successful veterinarian.[408] Using experiential techniques, defining key skills, and creating practice opportunities enhance effective communication.[409–412] In accreditation standards, the American Veterinary Medical Association's Council on Education recognizes communication as a core clinical competency for success.[413]

Several aspects of cancer care make it a unique communication context.[414] The initial diagnosis frequently is made by the primary care veterinarian, who may refer the client and patient to a specialist. Therefore the first visit with the specialist often occurs after the patient receives at least a tentative diagnosis, and the focus of the conversation is on confirming the diagnosis, treatment and prognostic information, and decision making. In this setting tough conversations occur on the back of a newly formed veterinarian-client-patient relationship. Cancer is an emotionally laden diagnosis, and clients often have high levels of uncertainty, anxiety, fear, frustration, and guilt, which heightens the stakes for both parties. Fortunately today we can offer clients a menu of sophisticated diagnostic and therapeutic options for treating their pet's cancer. This also presents the challenge of navigating complex information sharing and the decision-making processes of making the "right choice" for their pet without overwhelming clients. The initial visit may require as much listening as talking to hear what is most important to clients to address these challenges.

Cancer communication is a process that occurs over time, starting with delivering the diagnosis (i.e., often delivering bad news); making decisions about treatment options; discussing the prognosis; assessing the QOL; transitioning to palliative, supportive, or hospice care when required; and ending with preparing families for euthanasia, dying, and/or natural death. These difficult conversations are spread throughout multiple visits over time; during this time, the relationship grows and a partnership develops, making it more comfortable to address end-of-life conversations when appropriate.

Another special consideration is that cancer conversations frequently are managed by a team of veterinarians, including the referring veterinarian and multiple specialists. Most pets with cancer are treated with a combination of therapies involving different types of expertise (i.e., medical oncology, surgical oncology, or radiation oncology) or different disciplines (i.e., cardiology, neurology, or internal medicine). For example, the medical oncologist may determine the diagnosis and conduct the clinical staging; a surgical oncologist may remove the tumor; and a medical and/or radiation oncologist presents the efficacy of adjunct therapies after surgery. Each of these experts layers on information for the client about potential treatment options and the effect on the pet's QOL and prognosis. Then a medical oncologist might discuss palliative, supportive, or hospice care and facilitate end-of-life decisions. Referring veterinarians are involved throughout, because they share the closest bond with the client, who often trusts their opinions and seeks their guidance. This shared case management model underscores the importance of continuity of communication among all care providers. Given the team approach to cancer

VetBooks.ir

care, the inclusive term "veterinarian" is used in this section to encompass the roles of the referring veterinarian and specialists in conducting cancer conversations.

The purpose of this section is to present best practices for cancer communication. Only limited empiric studies are available in the veterinary literature concerning cancer communication,[400,415] and information is based largely on clinical experience.[447,479,460] In contrast, the literature on human medical communication contains a large number of empiric studies; however, in relation to cancer communication, what is available is based on expert opinion, case studies, reviews, and predominantly descriptive studies.[414,416] The objectives of this section are to describe relationship-centered care, define core cancer communication skills, and highlight communication approaches to difficult discussions. The medical cancer communication literature[402,404,416–420] and clinical experience provide the foundation for communication techniques presented here.

Before moving on we should address one of the most common concerns expressed in communication training: there is not enough time in the clinical interview. It seems as if the conversational approach of relationship-centered care takes more time; however, it was found in veterinary general practice visits that relationship-centered care appointments were shorter because the veterinarian and the client achieved common ground early in the appointment.[419] In human medicine, when patients are left to tell their story uninterrupted, their average talking time was 92 seconds, and they provided key clues to the diagnosis.[444] Empathy also can be expressed without prolonging the appointment time; in one study as little as 40 seconds of empathy reduced the patient's anxiety level.[421] Although it seems counterintuitive, evidence suggests that using the core communication skills actually saves time and allows for a more efficient veterinarian-client-patient interaction. In addition, spending time to build a relationship at the beginning of the appointment creates trust, and this will pay off when diagnostic and treatment recommendations are made.

Paradigm Shift: Paternalism to Partnership

Recent societal changes caused a paradigm shift in the veterinarian-client-patient relationship. Growing client expectations, the strong attachment between people and their pets, and increasing consumer knowledge demand a swing in communication style from the traditional paternalistic approach to a collaborative partnership.[399,400,419,281] Many clients are no longer content with taking a passive role in the healthcare of their animal, preferring to take an active role in the decision-making process.[399,400,419,422]

Paternalism is characterized as a relationship in which the veterinarian sets the agenda for the appointment, assumes that the client's values are the same as the veterinarian's, and takes on the role of a guardian for the patient.[419,423–425] Traditionally, paternalism is the most common approach to medical and veterinary visits. In a quantitative study published in 2006, companion animal practitioners used a paternalistic approach in 31% of wellness visits and 85% of problem visits.[419] In a qualitative study published in 2017, livestock practitioners used a directive communication style reflective of a paternalistic approach.[422] The topic of conversation was primarily biomedical in nature, focusing on the medical condition, diagnosis, treatment, and prognosis.[419]

In a paternalistic relationship the veterinarian does most of the talking and the client plays a passive role. This approach often is referred to as the *data dump* and symbolized by a shot-put.[412] Throwing a shot-put is unidirectional, the intent is on the delivery, the information to be presented is large in mass and scale, and it is challenging to receive the message. Intuitively, it seems as if this "take charge" approach enhances efficiency and promotes time management. The challenge is that the agenda and subsequent diagnostic or treatment plan may not be shared by the veterinarian and client, compromising the ability to reach agreement and achieve adherence to recommendations or, moving forward too quickly may lead to client regrets. This could result in a roadblock and the need to take steps backward to recover and regain client understanding, commitment, and trust.

In contrast, partnership or relationship-centered care represents a balance of power between veterinarian and client and is based on mutuality.[419,423–425] In the relationship-centered model the relationship between veterinarian and client is characterized by negotiation between partners, resulting in creation of a joint venture, with the veterinarian taking on the role of advisor for the client and advocate for the patient. Respect for the client's perspective and values and recognition of the role the animal plays in the client's life are incorporated into all aspects of care. In companion animal practice, 69% of wellness visits and 15% of problem visits were characterized as relationship-centred.[419]

The conversation content of relationship-centered visits is broad; it includes biomedical topics, lifestyle discussion of the pet's daily activities (e.g., exercise regimen, environment, travel, diet, and sleeping habits), and social interactions (e.g., personality or temperament, behavior, human-animal interaction, and animal-animal interactions) that are key indicators of the patient's QOL.[419] In addition, a relationship-centered approach encompasses building rapport, establishing a partnership, and encouraging client participation in the animal's care, all of which have the potential to enhance clinical outcomes.

This collaborative relationship is a dialog and is symbolized by a Frisbee.[412] In playing Frisbee, the interaction is reciprocal; the intent is on the exchange of information, small pieces of information are delivered, the client responds, and the message is adjusted to target the individual. The emphasis of the Frisbee analogy[412] is on eliciting client feedback to assess how the client perceives, processes, and understands the information presented.

Relationship-Centered Care

Combining several frameworks Mead and Bower[426] identified five distinct dimensions of relationship or patient-centered care in the human medical setting.

1. The biopsychosocial perspective—A perspective on illness that includes social, psychological, lifestyle, and biomedical factors.
2. The "patient/client as a person"—Understanding the personal meaning of the illness for each individual patient or the personal meaning of the animal's illness for the client.
3. Sharing power and responsibility—Sensitivity to preferences of the patient and/or client for information and shared decision making.
4. The therapeutic alliance—Developing common therapeutic goals and enhancing the physician-patient or veterinarian-client-patient relationship.
5. The "doctor as person"—Awareness of the influence of the subjectivity of the doctor on the practice of medicine.

Incorporating these dimensions, cancer communication strives to balance exchanging information, making decisions, fostering healing relationships, enabling clients to provide patient care, managing uncertainty, and responding to emotions.[414]

VetBooks.ir

These principles translate readily to the veterinary context.[419,427,428] Expanding data gathering to explore the broader lifestyle of the client and pet enhances the veterinarian's understanding of the animal's cancer. Discussing unique details, such as financial resources, the role of the primary caregiver, feasibility of implementing a plan, and recent life events (e.g., new birth, death, new job, or moving) promotes adherence to recommendations. With increased recognition of the human-animal bond, it is important to assess the level of attachment and the effect of the animal's cancer on the family. Eliciting information on the client's expectations, thoughts, feelings, and fears about the pet's cancer fosters client participation and satisfaction and promotes shared decision making.

Studies found potential missed opportunities for eliciting client perspectives during euthanasia discussions. In a quantitative study investigating the use of client-centered communication in euthanasia discussions with undisclosed standardized clients (USC) (i.e., "secret shopper" in the marketing setting), veterinarians did not fully explore clients' feelings, ideas, and expectations, or the effect of the illness on the animal's function.[428] Veterinarian and client perceptions of the client-centeredness of the euthanasia discussions differed—veterinarians perceived that client-centeredness components were addressed more thoroughly than was perceived by the USC.[427] For both euthanasia scenarios, the veterinarian and client agreed that discussion of personal and family issues was lacking.[428] Identifying clients' background, experiences, perspectives, and preferences is critical to shared decision making, and working toward consensus is important to achieve significant clinical outcomes for the veterinarian, client, and patient.

Relationship-centered communication can be learned and taught. Communication interventions conducted in the practice setting focused on relationship-centered care, and effective communication resulted in a more client-centered approach.[410,411] After a 1-year training, veterinarians gathered more lifestyle-social data and used more partnership-building and positive rapport-building communication; clients provide more lifestyle-social information and emotional statements.[410] After a 6-month communication program veterinarians used more facilitative and emotional rapport communication; clients felt more involved in the appointment and veterinarians expressed greater interest in their opinions.[411]

Clinical Outcomes

Based on medical communication studies, relationship-centered care is associated with significant improvements in clinical outcomes. Broadening the explanatory perspective of disease beyond the biomedical to include lifestyle and social factors is related to expanding the field of inquiry and improved diagnostic reasoning and accuracy.[420] Building a strong relationship is associated with increased accuracy of data gathering,[420] patient satisfaction,[429–431] and physician satisfaction.[432,433] Encouraging participation, negotiation, and shared decision making promotes patient satisfaction,[429–431] adherence to recommendations,[434] and improved health.[435]

Veterinarian-client communication also is correlated with clinical outcomes. In a study in which closed- and open-ended solicitation of client concerns were compared, open-ended inquiry elicited more concerns and client dialog, with decreased odds of a new concern arising at the close of the interview.[436] Investigation of the relationship between veterinarian-client communication and adherence to dentistry and surgical recommendations revealed that enhanced adherence was associated with clear recommendations, relationship-centered care, client satisfaction, an empathetic and unhurried atmosphere, longer appointment time, and use of positive rapport-building statements.[437] Moreover, evaluation of the association between veterinarian-client communication and veterinarian satisfaction with the visit revealed that veterinarian positive talk (e.g., compliments, laughter, statements of approval and agreement) was correlated with veterinarian satisfaction with wellness visits (i.e., pets brought to the veterinarian for routine examination), and client rapport building and veterinarian-to-pet talk were associated with veterinarian satisfaction with problem visits (i.e., pets brought to the veterinarian because of a health problem).[438] In a detailed analysis of the use of communication skills by companion animal veterinarians, the veterinarian's expressions of empathy resulted in higher levels of client satisfaction.[439]

Client Uncertainty

Uncertainty is at the core of the illness experience and the practice of medicine. During in-depth interviews of oncology clients at a tertiary referral center, client uncertainty arose as a dominant client psychological experience during oncology appointments.[440] Traditionally veterinarians focus on treating the animal's disease, and the results of this study highlighted the importance of the veterinarian's role in managing the client's experience of the animal's illness. The diagnosis of cancer and its association with death shifted clients' worldviews from orderly, predictable, and reliable to one of chaos, unpredictability, and ambiguity. Client experiences of uncertainty were greatest in the early stages and again in the late stages of cancer treatment. For many clients uncertainty was seen as danger, although some saw opportunity expressed through optimism, hope, and living in the present. Veterinarians can facilitate adaptive uncertainty management by supporting clients' efforts to reduce uncertainty; this can be done by meeting the client's informational and relational needs.

Client informational needs[440] include orientation to the oncology appointment provided by the primary care veterinarian and the oncology service, such as new client information packages, service websites, conversations with a client liaison, walking clients through the hospital processes and protocols, hospital tours, and meeting members of the oncology team, all of which prepare clients for the initial visit. For some clients, providing information can be empowering, but for others this can be incapacitating; for a few clients avoidance, denial, or minimizing may be vital coping mechanisms. Therefore it is critical to tailor the approach to giving information and identifying clients' background and experiences, need for information, and information preferences (e.g., presenting the big picture or a highly-detailed discussion). It is equally important to discuss with clients the efficacy and success of treatment approaches, in addition to potential adverse effects, so clients are prepared for all treatment outcomes. Provide warnings when necessary when delivering test results or progress reports to reduce unnecessary client distress. Set the course of cancer ahead of time, if required, so clients anticipate transitions from focusing on treatment to conversations addressing QOL, palliative, hospice, or end-of-life care.

Client relational support plays an equally critical role in reducing client uncertainty.[440] The foremost relationship is that with the veterinarian or nurse, and continued, established, and trusting relationships are paramount. Another source of relational support is timeliness of service, including booking appointments, returning client's phone calls, conducting diagnostic tests, providing test

VetBooks.ir

results, and starting treatment. Providing 24-hour information support in case of an unexpected event or complication, allowing clients to seek advice and guidance, manages uncertainty by addressing the client's questions and concerns and unexpected outcomes in a timely manner. In addition, peer support, waiting room interactions, social communities (i.e., family, friends, or neighbors), and formal Internet groups offer opportunities to share and normalize the client's experiences.

Veterinarian Expressions of Uncertainty

As much as is known today about cancer, much is still unknown, and veterinarians need to express uncertainty to their clients. Studies in human medicine contradict each other on whether a clinician's expressions of uncertainty enhance or undermine a patient's confidence and satisfaction. A qualitative survey study in veterinary medicine explored veterinarian and client expressions of clinical uncertainty.[441] All clients wanted to know about clinical uncertainties related to diagnostic accuracy and treatment appropriateness, and expressions of uncertainty did not erode clients' confidence. Behavioral expressions of uncertainty (e.g., consulting with or referring to a specialist) were less damaging to client confidence than verbal expressions (e.g., *"I need to find our more"* or *"This might be…"*).

Client Expectations

In a survey study of members of the online Pet Cancer Support group 77% of respondents were satisfied with their veterinarian, 71% with the information the veterinarian provided about treatment options, and 70% with the support they received from their veterinarian.[442] In a study of in-depth interviews of oncology clients at tertiary referral center, clients identified important aspects of veterinarian-client communication.[400,415] These client comments can be divided into those related to communication content (i.e., what is said[415]) and process (i.e., how it is said[400]). Interweaving communication content and process ensures effective sharing of information.

Regarding the content of information delivery,[415] the central theme was that clients wanted the truth about all aspects of their animal's cancer and treatment. In particular they expected the veterinarian to share information in relation to the client's background, previous experiences, and information preferences (i.e., presenting the big picture or a highly-detailed discussion), in other words, tailored to each client. This information was empowering for clients and enabled them to make treatment decisions, granted a sense of control, and fostered hope and overall ability to cope with their pet's cancer diagnosis and treatment process.

From a process perspective,[400] clients wanted information to be delivered upfront in a forthright manner, in lay language, and using multiple formats, such as oral, written, and visual client education tools (e.g., discharge instructions, brochures, handouts, diagrams, drawings, models, images, and websites). It was important to clients that the oncologists take time to listen, address their questions, and repeat information as needed, facilitating understanding of their pet's disease. Survey respondents of the Pet Cancer Support group identified problem-focused support (i.e., sharing information, engaging in open discussion, and considering options) as a common source of support provided by their veterinarians.[443] Clients appreciated an established relationship with the oncologist or nurse, and having 24-hour information support in case of an unexpected event or complication, allowing them to seek advice and guidance. Likewise, survey respondents of the Pet Cancer Support group stated that problem-focused tangible support (i.e., veterinarian investment in animal care and being available and accessible to clients) was the other customary source of support provided by their veterinarians.[443] It was supportive to clients when information was conveyed in a positive, compassionate, empathetic, and nonjudgmental manner, which provided much needed emotional support. In contrast, emotional-focused support was not expected of their veterinarians.[443] Meeting informational needs and creating a humanistic environment helped clients cope with their pet's cancer.[400]

Core Communication Skills for Cancer Communication

The Calgary-Cambridge Guide[412] is an evidence-based communication model that provides structure to the clinical interview, describing the tasks and identifying key communication skills to help veterinarians achieve clinical outcomes. Defining and demonstrating specific skills and behaviors are instrumental first steps to enhancing communication approaches.[409–412] The communication tools described in the following discussions were identified as core communication skills in human cancer communication literature[402,409,414,416] and are highly applicable to veterinarian-client-patient interactions.[442,446]

Gathering Information

Identify the Client's Full Agenda[442]

Eliciting the client's full agenda through open-ended inquiry promotes early detection of problem(s) and sets a plan for the rest of the visit.[437] This includes exploring the client's reasons for the visit, concerns, goals, expectations, and priorities. An open-ended question is designed to draw out a full response from the client rather than a brief one; it usually begins with "how," "what," "tell me," "describe for me," or "explain to me." In a quantitative study of soliciting client concerns, the use of open-ended solicitations resulted in significantly more client concerns being revealed than with closed-ended solications.[437]

"Your referring veterinarian diagnosed Mandy with [disease]. What specific questions would you like me to address today?" [reasons for visit]
"I see that your veterinarian referred you for [disease]. What else would you like to discuss?" [reasons]
"What are your greatest concerns about Mandy's cancer?" [concerns]
"What other worries do you have about Mandy?" [concerns]
"What are your goals for our time together?" [goals]
"How can I best help you today?" [expectations]
"What is the most important thing for us to address today?" [priorities]

This process of questioning may seem redundant, but clients often bring a laundry list (i.e., three to four[444]) of concerns, questions, or topics that they would like to discuss with their veterinarian. Given the overwhelming nature of cancer conversations, these steps help identify the key questions and information sought by the client. Helping generate the client's list of concerns and melding it with your agenda sets the structure for the remainder of the appointment and optimizes efficient use of the visit time.

Elicit the Client's Perspective[415,442]

Invite clients to share their thoughts, beliefs, opinions, ideas, feelings, and perceptions.[427,428] Again, a client's perspectives are best obtained by asking open-ended questions. How the client perceives the pet's cancer can have a major effect on the decision-making process and adherence to recommendations. Many clients have had previous experiences with cancer, and it is helpful to hear these stories to address the client's concerns, provide reassurance, and identify misconceptions or barriers to patient care. Pick up on the client's verbal cues (*"I am not sure how she will do with chemotherapy."* or *"I am really concerned about her loss of appetite."* or *"My big fear is that we won't get quality time."*) and invite the client to share his or her worries. Knowing the client's expectations enables you to get on the same page and customize the message to the client's concerns and meet the individual's needs.

"I am wondering what experiences you have had with cancer in your life, because they may affect decisions we make for Mandy."
"How are you coping with all of this?"
"What are your greatest hopes in caring for Mandy?"

Explaining and Planning

Assess the Client's Starting Knowledge[415,442]

Assessing the client's prior knowledge allows you to evaluate his or her understanding and determine at what level to deliver the information. Each client brings his or her own knowledge, background, experiences, and ideas to the table. Assessing the client's starting knowledge through open-ended questions allows you to gauge the entry point to the conversation and enables the veterinary team to meet the client where the person is.

"What do you know about cancer in general?"
"What have you heard or read about osteosarcoma?"
"I am wondering what your veterinarian told you about Mandy's cancer."

Ascertain the Client's Information Preferences[415,442]

An equally important goal is to ascertain the type and kind of information the client desires, because not all clients may want the same degree of information. Client preferences for information may change over time; initially, overwhelmed clients may want just the big picture; as they absorb and process the information, they may produce a list of detailed questions for follow-up discussions. Open-ended inquiry is a key technique for evaluating the client's information preferences.

"Some clients prefer the big picture and for others it is important to get into the details. What is your preference?"
"What additional information would be helpful to you?"
"Let me know if you would like me to go into greater detail."

Give Information in Manageable Chunks and Checks[442]

Chunk-and-check consists of giving information in small pieces (i.e., chunks), followed by checking for understanding before proceeding further (i.e., check)—the Frisbee approach in action.[412] Sharing small pieces of information, one to three sentences at a time, allows your client time to absorb the news, and checking-in encourages client participation in the discussion and ensures that the client stays with you to achieve shared understanding. This approach to giving information avoids lecturing to the client and aims to increase recall, understanding, and commitment to plans. In this manner the process of giving information is responsive to the client's needs and provides an opportunity for the client to participate in the conversation, provide feedback, or ask for clarification. The check takes the form of an open-ended question.

"What questions do you have at this point?"
"What needs more explanation?"
"What part will be most difficult for you and Mandy?"

Building Relationships

Offer Partnership[442]

Partnership is inclusive language (e.g., let's, we, together, our, or us), which reflects that you and the client are working as a team toward mutual goals. Offering partnership informs clients that they are not alone and that they have a working partner in their veterinarian, who will guide and advise them at each stage. Often clients may arrive at the appointment on their own, and it may be helpful to assess their support system and offer to include other key decision makers in the conversations.

"We'll work together to determine the best treatment plan for Mandy."
"I'm here for you. Take your time. We have a few days to decide how to proceed."
"Who else will take part in making decisions in Mandy's care?"

Ask Permission[442]

Asking permission is a gentle approach to assess the client's readiness to take the next step. This act of respect allows the client to ready his or her mind, be receptive to what you have to say, and pace the conversation with you. Asking permission is a method of structuring the conversation by proposing a transition to the client and to determine whether the client would like to move on.

"Would it be alright if we sit down and I asked you some questions about Mandy?"
"I am wondering if we could talk more about pain management."
"Are you okay with talking about how we can reduce the tumor size?"
"Maybe you could write down your specific questions before our next visit."

Express Empathy[442]

The stress of cancer can result in intense emotions: sadness, fear, anxiety, uncertainty, and guilt, and acknowledging these emotions reduces client distress.[421] Empathy is an affective response resulting from perceiving the situation of another, vicariously experiencing what it might be like, and paying deep attention to another person's emotions. As a result, three tasks are involved in expressing empathy.[445] The first is to appreciate the client's situation, perspective, and feelings, and the attached meanings. The second is to communicate that understanding to the client and check its accuracy. The third is to move forward in the clinical interview and act on that understanding with the client and patient in a helpful way. Simply, empathy is putting yourself in clients' shoes and communicating that you understand where they are coming from. Expressing empathy acknowledges, validates, and normalizes the client's emotional response and

VetBooks.ir

is essential to establishing a trusting veterinarian-client-patient relationship.

"I'm so sorry to tell you this. I know it was not what you were expecting."
"I can only imagine how hard this is to hear. Mandy has been your companion for so long."
"I can see that you are agonizing over the right decision for Mandy."

Demonstrate Appropriate Nonverbal Behavior[442]

Expression of all of the verbal core communication skills is strengthened when accompanied by complementary nonverbal communication. As much as 80% of communication is nonverbal in nature, whereas 20% is based on verbal content.[446] When verbal and nonverbal communication are incongruent, the nonverbal behaviors reveal the truth. There are two areas of focus for nonverbal communication: the first is to increase your sensitivity to picking up on client cues, and the second is enhanced awareness of the nonverbal messages you are sending out. Tune in closely to the client's nonverbal behaviors, such as breaking eye contact, nervous body movements, or tone of voice, because nonverbal behaviors often reflect the client's true underlying feelings and responses. Out of respect for their relationship with their veterinarian, clients often express hesitation indirectly through their nonverbal behaviors and may not feel comfortable with directly verbalizing their concerns, doubts or criticisms. It is important to pick up on these client clues and follow-up on them with the client to explore the concerns (*"I sensed some hesitation when I mentioned chemotherapy as a treatment option."* or *"You seem worried about taking Mandy to surgery; what are you most scared about?"*)

Veterinarian nonverbal cues include attentive body posture, appropriate distance from the client, turning your body toward the client, sitting at the same level, maintaining good eye contact, and complementary gestures. Display your compassion through nonverbal cues, such as sitting at a comfortable distance with your client; using a gentle, calm tone and soft volume; slowing your pace of speech; and leaning forward and reaching out through touch when appropriate. Use silence to create time for clients to examine their thoughts and feelings. It can be difficult at times to find the right words to say, and simply being a caring presence can provide just as much comfort to the client as any spoken words. Being mindful of the non-verbal messages sent is important because when veterinarians are triggered or feeling judgmental, these sentiments can be leaked to the client through nonverbal behaviors.

Providing Structure

Provide a Warning Shot[442,446,447]

A warning shot forewarns of difficult discussions or decisions ahead. It warns clients of bad news and allows them to prepare themselves for what they are about to hear. This approach reduces the chances of blind-siding and enhances the client's ability to process versus react to the information.

"This may be difficult for you to hear."
"Unfortunately, we do not have effective treatments for this kind of cancer."
"I am sorry to tell you that Mandy's cancer is growing and no longer responding to the chemotherapy."
"I have disappointing news. Mandy's cancer has spread to her lungs."

Summarize[442]

Summarizing is an explicit review of the information that has been discovered and discussed with the client. Multiple opportunities arise to present a summary: reflect back what you heard and learned at several stages during information gathering, take time to repeat the key aspects of the diagnostic and treatment plan, and finally provide a full and complete summary at the end of the clinical interview. Summarizing helps structure the conversation by reviewing what has been discussed, identifying data that needs further clarification, providing an opportunity for reflection on where the interview could go next, and managing effective use of time during the visit. The skill of summarizing creates a window to inform clients that they have been heard and time for clinicians to gather their thoughts, synthesize and integrate the data, and work through the diagnostic reasoning process.

"So, if I understand it correctly, your referring veterinarian felt the large lymph nodes, took a sample, and diagnosed lymphoma. You were sent here for further testing to determine if the lymphoma has spread to other organs. What other tests did your referring veterinarian perform?"
"What we talked about doing today is requesting a second opinion from our pathologist on the tumor sample, and taking chest x-rays and conducting an ultrasound exam to look at the abdominal lymph nodes, liver, and spleen for spread of the tumor. What further questions do you have about those diagnostic tests?"

"I Don't Have Time for This…"

The concern about how veterinarians find the time to elicit the client's agenda, perspectives, starting knowledge, and information preferences, and managing client emotions, may still remain. But contrary to popular belief the skills just discussed enhance appointment efficiency. More time with the client may be needed upfront, but this will pay dividends in time savings by streamlining decision making during diagnostic and treatment planning.

1. *Eliciting clients' full agenda, goals, and expectations* early in the appointment is critical to optimizing appointment time.[436] Clients often bring a laundry list of issues, topics, or questions they would like to discuss with their veterinarian.[444] Exploring this list and melding it with your agenda determines the structure and tasks for the remainder of the appointment. If you are unable to fully meet the client's agenda, it allows you to reset client expectations and consider alternatives, such as a drop-off, recheck visit, follow-up phone call, further discussion with a veterinary nurse, or counseling support or referral.
2. *Identifying clients' perspectives* is important, because these can act as either promoters or inhibitors of clients' decision-making process in considering diagnostic and treatment options. Identifying concerns a client brings to the visit enables the veterinarian to tailor a care plan that aligns with the client's needs, enabling the client to move forward more quickly.[415]
3. *Assessing what clients already know* helps veterinary professionals deliver information that is appropriate to the individual's level, enhancing understanding and recall.[415] This step also helps identify gaps, misunderstandings, or misinformation that can be addressed in the moment before confusion arises. Also, appointment efficiency can be enhanced by identifying clients who are already well informed and need less education.
4. *Assessing clients' information preferences* enables you to gauge what information the client desires and how much detail is preferred.[415] This promotes explanations that are on target on initial delivery, reducing the need to revisit material or to start over again and provide the big picture or more in-depth details.

5. *Defusing clients' emotions* (e.g., frustration, sadness, anxiety) can be accomplished by building rapport; expressing empathy; creating a safe, nonjudgmental space and providing opportunities to be heard; and posing questions. This puts clients at ease and enhances their ability to process, understand, and recall information; it also prepares them to make decisions.[421,447]

Approaches to Cancer Conversations

As presented in the introduction, cancer communication is a series of conversations over time, starting with delivering the diagnosis (i.e., delivering bad news); discussing the prognosis; making decisions about treatment options; assessing the patient's QOL; transitioning to palliative, supportive, or hospice care; and ending with preparing families for euthanasia, dying, or natural death. These difficult conversations are spread throughout multiple visits. This step-by-step approach is guided by the veterinarian's expertise, the client's agenda and perspective, and the patient's condition, response to treatment, and QOL.

Conduct these conversations in an appropriate setting to ensure privacy, client and patient comfort, lack of distractions, ability to sit down together, and place to include multiple individuals (e.g., examination, consultation, or comfort room). Start by creating a safe space for clients by taking time to establish initial rapport, checking in on their well-being, and demonstrating interest in the client. (*"How are you doing? Thank you for bringing Mandy in so that we could address this problem. Sounds like it's a stressful time for you all."*) Identify the client's support system and extend an invitation for key decision makers, family members, and friends to track information and provide emotional support ("*I am wondering who makes decisions regarding Mandy's care"* or *"Who else may want to participate in this discussion?"*) Because these are emotionally laden discussions loaded with complex information and associated with decision making, compose and center yourself beforehand, pace yourself with your client, and offer some time for reflection. Allow for silence or offer a break to create space for clients and yourself to work through emotions and process the information exchanged.

Delivering Bad News

Bad news is defined as any news that drastically and negatively alters the person's views of her or his future with their pet, such as a cancer diagnosis.[402] Clients interpret bad news on an individual basis, and their response is related to their relationship with their companion animal, the severity of the diagnosis, past experiences, other stressors in their lives, and their support system. Grief often accompanies change, and clients may express a wide range of emotions that are largely unpredictable. One useful model for delivering bad news is the SPIKES six-step model developed by Buckman[402] and used in many medical school curricula. The SPIKES model[402] (i.e., *s*etting, *p*erception, *i*nvitation, *k*nowledge, *e*mpathize, and *s*ummarize) provides guidelines on how to present information, structure the conversation, and create a supportive environment.[447, 479]

Explore clients' perspectives by asking open-ended questions about their concerns, ideas, thoughts, beliefs, previous experiences, and the effect of the pet's illness on their lives ("*What worries you most about Mandy's cancer?"* or *"What types of treatment did you have in mind?"*). Assess what the client knows about the pet's cancer or cancer in general ("*Tell me what you understand about Mandy's cancer?"* or *"Share with me your experiences with cancer or those of others in your life."*). Determine the client's information preferences to tailor your discussion to the individual client's needs ("*Some clients like to know all the details about their pet's cancer, and others prefer the basic facts. What would you prefer?"*).

Provide a warning shot to forewarn the client of information that may be difficult to hear ("*Unfortunately, we do not have good options for treating this cancer."*). Then deliver the bad news in stages, giving information in small, easily understandable pieces and checking for the client's understanding before moving on ("*This is going to be difficult to hear. The cancer has spread to Mandy's lungs, making it hard for her to breathe. What concerns would you like to discuss at this point?"*). To pace the conversation with your client, ask permission to proceed to the next step in the conversation ("*Would it be alright if I went over Mandy's prognosis?"* or *"Is it alright if we talk about what this will mean for Mandy?"*). Avoid use of technical jargon and define medical terms. Use supplemental educational tools, such as written materials (e.g., client handouts, information sheets, or discharge statements), website resources, whiteboard notes, or audiotape recordings, so clients can review the information at a later date.

Empathize throughout the conversation to acknowledge, validate, and normalize the client's emotional responses ("*This is not what you were hoping to hear."; "This is overwhelming."*; or *"I can feel your sadness."*). Allow for silence and display compassionate and caring nonverbal cues (e.g., sit close to the client; mirror facial expressions; use a gentle, calm, and caring tone of voice; use a slow pace of speech; lean forward; reach out with touch if appropriate) (*"I'm here for you. Take your time."*). Offer partnership so the client does not feel alone in processing the information and making decisions (*"I will talk you through this, and we will make decisions for Mandy together."*). Summarize what was discussed, negotiate a plan for treatment, palliative or hospice care, and a timeline for follow-up (*"Today, we talked about the cancer spreading to Mandy's lungs. Unfortunately, it will be more and more difficult for Mandy to breathe. We discussed ways to monitor Mandy's quality of life. I am going to talk to your veterinarian about Mandy's supportive care. What questions do you have?"*).

Discussing the Prognosis

Three different approaches have been described in the medical communication literature for presenting prognostic information—realism, optimism, and avoidance.[404] The challenge with realism in human medicine is that approximately 20% of patients do not want full information about their prognosis.[448–451] In veterinary medicine, clients wanted the truth and information about all aspects of their pet's cancer and its treatment.[443] The drawback of optimism is that clients may lose opportunities to fulfill last wishes, prepare themselves and their family, and spend quality time with their pet. Finally, the shortcoming of avoidance is appearing evasive or dishonest, risking the trust that has been built between the veterinarian and client and potentially compromising the pet's care.

Based on recommendations in human[404,415,416] and veterinary medicine,[443] information should be tailored to the client's background, previous experiences, and information preferences (*"How much would you like to know about the course of Mandy's cancer?"* or *"Some clients would like all the details and others would like the big picture. What works best for you?"*). Provide a warning shot, so the client can prepare to hear the information (*"Unfortunately, the prognosis is serious for Mandy."* or *"This is the next difficult step in our conversation."*) Break the information into small pieces (i.e., chunks) and then check for client understanding and how the

VetBooks.ir

prognostic information is affecting the client (*"This is hard to talk about."* or *"I am wondering if this is the kind of information you need."*). Asking permission is a key skill in this conversation to assess the client's readiness to hear more information (*"What questions do you have at this point?"* or *"Would you like me to continue?"*).

Read the client's nonverbal cues to assess how clients are processing the information (*"I notice that you seem hesitant when I was talking about survival time with chemotherapy. Could you tell me more about this?"*). To balance sustaining hope and maintaining reality, it may be helpful to frame the prognosis using both positive and negative language (*"Median survival time means that half the patients live longer than 2 years and half the patients live less than 2 years."*).[452] Given the overwhelming nature of this discussion, take time to empathize with the client (*"This is a lot of information to take in. How are you doing?"* or *"I can see how sad this is for you."*). Offer partnership to walk beside the client during this conversation (*"This is really difficult to talk about, and we can take it one step at a time."*).

Assessing Quality of Life

In human medicine a spectrum of hopes lies from the initial cancer diagnosis to preparing for death.[453] In veterinary medicine a cancer diagnosis means a client's initial expectations may center around curing the cancer and the pet living longer, and then move toward spending special time with their pet and then seeking a peaceful death. This breakpoint discussion is a crucial conversation that signals the transition from striving for quantity of time to embracing QOL.[452] It can be challenging for clients who have been working so hard to treat the cancer to shift their energy to living the fullest life with their pet right now and preparing to let go (*"It seems like it may be helpful to focus on what time Mandy has left with you."* or *"Just because we can do something does not mean that we should."*). Warn clients of the difficulty in making the transition from treating cancer to focusing on QOL (*"It can be difficult to switch gears from fighting the cancer to preserving Mandy's quality of life."*).

Ask permission to ready the client to enter into a quality of life discussion (*"Would it be alright if we took some time to talk about Mandy's quality of life?"*) Pose open-ended questions to elicit the client's perspective of the pet's quality of life (*"What do you think Mandy's quality of life is like now?"; "What makes life worth living for Mandy?"* or *"Under what circumstances would life not be worth living for Mandy?"*). Obtain the client and patient goals to move the conversation forward (*"Can we create a plan together to ensure Mandy's quality of life?"* or *"What is most important to you in caring for Mandy at the end of life?"*). A supportive way to acknowledge the client's desire to do more is through expressions of "I hope" or "I wish" statements (*"I wish there was something we could do to cure Mandy's cancer."* or *"I hope that Mandy has many good weeks ahead."*).[454] At this stage it is equally important to reflect on the veterinarian's conversational emphasis and what influence the presentation of information may have on the client's decision making,[455] such as how much time is spent talking about anticancer therapy compared with QOL; supportive, palliative, or hospice care; or euthanasia. The veterinarian inadvertently can influence the client's decisions through the prioritization of the options for care.[456]

Educate the client on how to monitor the pet's condition and assess the pet's QOL. Clients often wonder aloud "how they are going to know when it is time?" Anticipating that the end of life care can be intimidating, overwhelming, and anxiety provoking for clients. Concrete information about what to watch for and what to do may make the decisions feel more manageable (*"Things to watch for in Mandy are a decrease in appetite or interest in drinking water; reduced activity level; difficulty breathing, such as panting or increased effort; and change in personality, a lack of interest or responsiveness to you and her daily activities."*)

To validate and support clients, veterinarians may need to reassure their clients that they did everything they could for their pet (*"You have given Mandy every chance possible."*).[456] Words of empathy, reassurance, and partnership can be highly supportive ("*All along you have made your decisions with Mandy's best interests in mind."* or *"We will do this together, just as we have done everything that got us to this point."*).[456] Clients often are overwhelmed and feel alone, and it is comforting to know that their veterinarian will guide, advise, and inform them through this process.

Transitioning to Palliative Care or Hospice Care

Fortunately much can be done for a veterinary cancer patient's comfort, despite the inability to effect a cure; this includes symptom management, supportive care, enrichment, and pain management to ease suffering. Depending on the resources in your region, it may be appropriate to provide palliative care or refer the client and patient to a veterinary hospice service.[457,458] Palliative care begins at the cancer diagnosis and is incorporated into the treatment plan. Hospice care begins after treatment of the cancer is stopped. Veterinary hospice is the care provided after a terminal diagnosis of weeks to months has been given; it includes providing supportive care for the animal and emotional support for the family to prepare for the imminent death of the animal and to help clients focus on spending quality time with their pet. At-home patient care entails administering medications, assessing and monitoring pain management, emotional well-being and social enrichment, evaluating proper hydration and nutrition, and educating families about euthanasia, the grief process, and death and dying.[458] Today, statements such as "There is nothing more we can do" can be replaced with words of encouragement and offers of partnership to comfort clients (*"There is still much that we can do to make sure that Mandy is content and comfortable."*).[454]

Client and patient abandonment may be a concern that arises during this stage of care. The value placed by the client on the relationship with the veterinarian may increase as the patient's cancer progresses, as the desire for information lessens, and the need for support grows.[459] The relationship with the veterinarian or nurse is foremost in reducing client uncertainty at the late stages.[400] With the change in the care provided from cancer treatment to palliative care, the client may perceive that the veterinarian's relationship with the client and patient has ended. Offering partnership helps create a sense of support for the client (*"We will work through these decisions together."* or *"I will be here to help you and Mandy whatever your decisions may be."*) Clients may want to hear explicitly that their veterinarian will still be taking care of their pet, even if they decide to discontinue treatment. Depending on the client's relationship with the specialist and the referring veterinarian, it may be critical to determine the client's expectations and offer to maintain the relationship to provide end-of-life care. Caring for clients and patients at the end of life can be a source of meaning and fulfillment for the specialist, in addition to an opportunity to recognize the special relationships formed during this difficult time.

VetBooks.ir

Euthanasia Decision Making

Clients may be waiting for the veterinarian to raise the option of euthanasia to give permission to consider euthanasia as a valid and supported option (*"One of the options that is important to discuss is euthanasia."*). Clients may be worried that the oncologist may perceive them as "giving up" if they bring up the option of euthanasia, therefore clients may need your validation (*"It is a valid and caring decision to consider euthanasia at this time."* or *"Euthanasia is a humane option for Mandy given how the cancer has spread."*). Client anxiety results from the uncertainty that lies ahead, and a large part of these conversations is helping clients cope with the unknown.[440] Previously clients had a clear plan for how to treat the cancer, and it may be helpful to have a designated path for how to care for their animal at the end of life. Discussing end-of-life wishes for the patient is crucial to preparing the client for euthanasia decision making, and creating a euthanasia plan often eases the client's discomfort and anxiety.[447] Once completed, it can be put on the shelf until it is needed, and the client can focus his or her energies on being present with the pet during these final precious days, weeks, or months. Being prepared ensures that the client's needs are met, minimizes regrets, and reduces uncertainty during this difficult time of grief.[440]

Use the communication skills to walk a client through euthanasia decision making; discuss the procedure and present options for location, body care, memorializing, and family presence.[447,460,479] Begin by asking the client about previous experiences with euthanasia (*"Could you share with me your previous experiences with euthanasia?"* or *"I am wondering whether you have been present at a euthanasia procedure in the past. Tell me about that situation."*). If appropriate, explore the client's religious or spiritual beliefs, which may affect a decision about euthanasia. (*"Some clients have religious or spiritual beliefs that guide the euthanasia decision. I am interested in how these beliefs might guide your decision-making process."*)

Provide a warning shot ("*This is one of the most difficult decisions in caring for your pet."* or *"There is a lot to consider, and the decision-making process can feel overwhelming."*)

Give information in small, easily understandable pieces, pause, and check for the client's understanding before proceeding (*"Max is probably feeling like you do when you have a bad flu. It probably hurts just to move, and it is difficult for him to get comfortable. What questions do you have about his condition?"*). Ask permission throughout to move from one topic to the next (e.g., timing, location, body care, being present, and memorializing [e.g., paw prints, hair clippings, pictures, videos, readings, or songs]) (*"I am wondering if it would be alright with you if I were to walk you through the euthanasia procedure we use at our clinic."* or *"There are a few options and decisions in relation to the euthanasia procedure and body care, and I am wondering if you would like to discuss them now."*) During the conversation, avoid use of technical jargon and define medical terms.

Empathize throughout the conversation; acknowledge, validate, and normalize the client's emotions (*"You have taken such good care of Mandy throughout his illness. I can tell how much you love her."*; *"These are difficult decisions. It feels like an enormous responsibility.";* or *"It is normal to feel sad. Mandy means so much to you."*). Use silence and display compassionate and caring nonverbal cues. Offer partnership so the client feels you by his or her side (*"We will talk through each step together."* or *"I want you to know that I fully support your decision, and will do my best to honor your wishes for Mandy"*). At the end, summarize what has been discussed and the decisions made, and outline the next steps for the client.

Providing Support for Grief and Loss

Research indicates that 70% of clients are affected emotionally by the death of their pet, and as many as 30% of clients experience severe grief in anticipation of or after the death of their pet.[397] In addition, approximately 50% of clients studied reported feeling guilty about their decision to euthanize their pet.[397] One of the factors contributing to client grief was the perception of the professional support provided by the veterinarian. A qualitative interview study described the emotional, informational, and instrumental social support veterinarians provide to grieving clients; the study revealed that these skills were often learned on the job, and little or no training was provided in veterinary school.[461] A qualitative ethnographic study documented the emotional work of veterinarians in attending to the death of their patients and managing the guilt and grief of their clients as a gratifying experience for clients and a fulfilling part of being a veterinarian.[462]

The manner in which the veterinarian provides care for a client whose pet has died has the potential to alleviate or aggravate grief. Use your communication toolbox to acknowledge, validate, and normalize client grief responses and provide emotional support.[460] Offer written materials and verbal grief education to help clients understand their grief experiences (*"Grief is hard. You may find it difficult to sleep; you may feel disoriented, restless, or exhausted, and unable to focus or concentrate; you may gain or lose your appetite. It can be crazy making."*). Send condolences in a timely manner after euthanasia (e.g., a card, memorial gift, or flowers) or place a phone call to check in with the client to see how she or he is doing (*"I wanted to call to see how you are doing. I know that you miss Mandy terribly."*). Assess the client's support system and identify at-risk clients who may need more active grief support (*"Who will you speak with about losing Mandy?"* or *"Who do you turn to during difficult times?"*). Provide information on support services (e.g., grief counseling, pet loss support hotlines and groups, and websites) (*"We have a grief counselor who works with our practice and hosts regular pet loss support groups. Our clients share that it is helpful to them."* or *"I have a list of pet loss support hotlines, if it would be helpful to speak with someone who understands how difficult it is to lose a pet."*).

Caring for Yourself

The health and wellness of veterinary professionals is a current and poignant issue in the veterinary profession. Veterinarians' risk of suicide is four times that of the general population and twice that of other health professionals,[79] and attitudes toward and involvement in death and euthanasia are possible influences.[463,464] One in 11 veterinarians have reported serious psychological distress, and 1 in 6 veterinarians have experienced suicidal ideation since graduating from veterinary school.[465]

Compassion fatigue is deep physical, emotional, and spiritual exhaustion that can result from working day to day in an intense caregiving environment.[466,467] The natural response to this downward spiral is to work harder until there is nothing left to give, which is counter to the adaptive response of taking a break. The symptoms are the same as those of chronic stress and are a consequence of caring for the needs of others before caring for your own needs.[466,467] Compassion fatigue results from a lack of daily self-care practices that create opportunities to reflect, refuel, and rejuvenate.

The good news is that compassion fatigue results from being a deeply caring person. When veterinarians care for themselves, they can care for others from a place of abundance, not scarcity. By developing healthy self-care routines, practitioners can continue to successfully provide compassionate care to others. This includes asking

VetBooks.ir

for help, using the expertise of colleagues (i.e. client service coordinators, veterinary nurses or client liaisons) to address clients' concerns, to answer out-of-hours calls, and to provide support or counseling if available to care for clients. Recognizing the signs of compassion fatigue is the first step toward positive change, and the second step is making a daily, firm commitment to choices that lead to resiliency. The American Veterinary Medical Association provides resources for veterinary well-being on their website https://www.avma.org/ProfessionalDevelopment/PeerAndWellness/Pages/default.aspx.[468]

Conclusion

Given the growing expectations of clients, the strength of the human-animal relationship, and the resultant emotional impact of cancer communication on pet caregivers and the veterinary team, relationship-centered care is integral to providing quality cancer care.[399,400,418,427,428] Compassionate cancer communication is related to significant clinical outcomes for the veterinarian, client, and patient, including enhancing client[439] and veterinarian satisfaction,[438] improving adherence to recommendations,[437] and working through emotions.[400,440] Effective techniques for cancer communication can be taught and are a series of learned skills.[409–412] Through supportive approaches, cancer communication can be made less distressing to the client, fostering client relationships and optimizing patient care while promoting professional fulfillment for the veterinarian.
