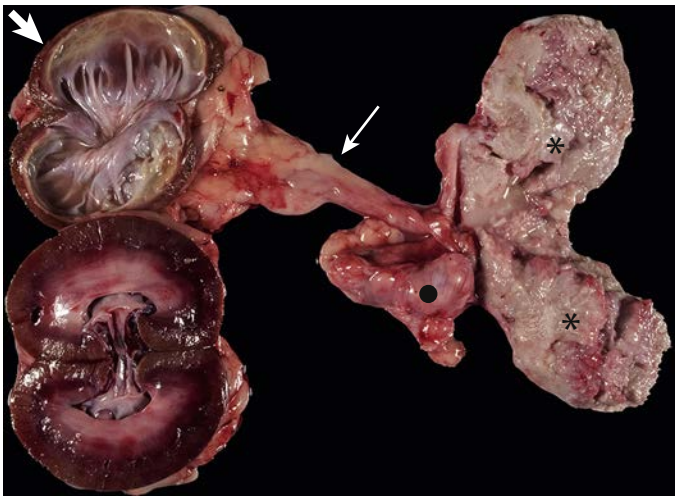
Tumors of the Urinary System

CHRISTOPHER M. FULKERSON AND DEBORAH W. KNAPP

Canine Urinary Bladder Tumors



Urinary bladder cancer accounts for approximately 2% of all reported malignancies in the dog.[1–3] With more than 65 million dogs in the United States, and the estimated 6 million new canine cancer cases in the United States each year, even less frequent forms of cancer, such as bladder cancer, affect tens of thousands of dogs each year.[2,3] Invasive urothelial carcinoma (iUC), also referred to as invasive transitional cell carcinoma, is the most common form of canine urinary bladder cancer.[1–3] Most iUCs are intermediate- to high-grade papillary infiltrative tumors.[1–3] A series of 232 iUCs included 70% grade 3 (high grade) tumors, 29% grade 2 (intermediate grade) tumors, and 1% grade 1 (low grade) tumors.[3] Other types of bladder tumors reported less frequently include squamous cell carcinoma, adenocarcinoma, undifferentiated carcinoma, rhabdomyosarcoma, lymphoma, hemangiosarcoma, fibroma, and other mesenchymal tumors.[1–8]

iUC is most often located in the trigone region of the bladder. Papillary lesions and a thickened bladder wall (Fig. 30.1) are common features, and can lead to partial or complete urinary tract obstruction. In a series of 102 dogs with iUC of the bladder, the cancer also involved the urethra in 56% of dogs and the prostate in 29% of male dogs.[1] Nodal and distant metastases were present in 16% and 14% of dogs, respectively, at diagnosis.[1] Following World Health Organization (WHO) criteria for staging canine bladder tumors (Box 30.1),[9] 78% of dogs had T_2 tumors and 20% had T_3 tumors.[1] In a necropsy study of 137 dogs with iUC, 58% of dogs had distant metastases and 42% had nodal metastases (including 33% of dogs with both nodal and distant metastases).[3] The lung was the most common site of distant metastases (50% of dogs), with other sites including liver, kidney, adrenal gland, spleen, bone, skin, heart, brain, and gastrointestinal (GI) tract.[3] At necropsy, second primary tumors were noted in 13% of dogs, including hemangiosarcoma, lymphoma, thyroid carcinoma, and others.[3] Bone metastases were reported in 17 (9%) of 188 canine iUC cases reviewed retrospectively, and in 3 (14%) of 21 dogs prospectively undergoing total body computed tomography (CT) at euthanasia followed by a standardized pathologic examination.[10] In a series of 12 dogs with cutaneous iUC metastases, gross lesions consisted of plaques, papules, and nodules.[11] iUC can occur in the abdominal wall, either through seeding from instruments and needles used in surgical and nonsurgical procedures, or through natural spread of transmural lesions along bladder ligaments.[12] iUC in the abdominal wall is typically aggressive and poorly responsive to medical therapy.[12]

Etiology and Prevention

The etiology of canine bladder cancer is multifactorial. Risk factors include exposure to older generation flea control products and lawn chemicals, obesity, possibly cyclophosphamide exposure, female gender, and a very strong breed-associated risk (Table 30.1).[1–3,13–15] The female-to-male ratio of dogs with TCC has been reported to range from 1.71:1 to 1.95:1, although the sex predilection is less pronounced in high-risk breeds.[3] TCC risk is higher in neutered dogs than intact dogs of both genders, although the reason for this has not been determined.[1–3,13]

In a case control study of 166 Scottish terriers (STs), TCC risk was significantly higher in STs that had been exposed to lawn herbicides and insecticides than in dogs not exposed, and the risk was significantly lower in dogs that ate vegetables at least three times per week in addition to their dog food.[14,16] The specific vegetable with the most benefit could not be determined, but carrots, given as treats, were the most frequently fed vegetable. In contrast to older types of flea dips, exposure to spot-on products containing fipronil was not associated with an increased TCC risk.[15] It would appear appropriate to inform owners of dogs in high-risk breeds

• **Fig. 30.1** Dog, urinary bladder. Urothelial (transitional cell) carcinoma. Transmural neoplastic growth involving the entire bladder (*asterisk*). One of the iliac lymph nodes (*black circle*) is also infiltrated by this neoplasm. One of the ureters is dilated (hydroureter, *thin arrow*) and the corresponding kidney (opened, *thick arrow*) has hydronephrosis as a result of blockage of the ureter at the trigone. (Courtesy J. A. Ramos-Vara, Purdue University.)

VetBooks.ir

of the risk, to limit exposure to lawn chemicals and older types of flea control products, and to feed vegetables at least three times per week, especially in dogs in breeds at high risk for iUC.

Urinary tract ultrasonography and urinalysis with sediment examination at 6-month intervals, plus cystoscopy and biopsy of suspicious lesions, has allowed detection of iUC in STs before the onset of clinical signs, and treatment response has been better than in more advanced iUC (D. Knapp, personal communication). Other screening tests for iUC are emerging. A *BRAF*^{V595E} mutation has been detected in more than 80% of canine iUC cases with urine detection closely correlating to tumor tissue genotype.[17,18] In one study, the *BRAF*^{V595E} mutation was detected in 19 of 23 dogs presenting with iUC and in 0 of 37 dogs that were either normal or had cystitis.[18] Copy number aberrations in urine DNA from dogs with iUC have also been reported.[19] Screening strategies including these tests could help identify dogs for further evaluation for potential iUC.

• BOX 30.1 TNM Clinical Staging System for Canine Bladder Cancer

T—Primary Tumor

T_{is}	Carcinoma in situ
T_0	No evidence of a primary tumor
T_1	Superficial papillary tumor
T_2	Tumor invading the bladder wall, with induration
T_3	Tumor invading neighboring organs (prostate, uterus, vagina, and pelvic canal)

N—Regional Lymph Node (Internal and External Iliac Lymph Node)

N_0	No regional lymph node involvement
N_1	Regional lymph node involved
N_2	Regional lymph node and juxtaregional lymph node involved

M—Distant Metastases

M_0	No evidence of metastasis
M_1	Distant metastasis present

Modified from Owen LN: TNM classification of tumors in domestic animals, Geneva, 1980, World Health Organization.[9]

Presentation, Diagnosis and Differential Diagnoses, and Clinical Staging

Common clinical signs in dogs with iUC include hematuria, dysuria, pollakiuria, and less commonly lameness caused by bone metastasis or hypertrophic osteopathy.[1] Urinary tract signs mimic those of dogs with urinary tract infections (UTIs) and may resolve temporarily with antibiotic therapy if a concurrent UTI is present. Concern for iUC or other urinary tract abnormalities, such as calculi, arise when clinical signs do not resolve with antibiotics or recur soon after a course of antibiotics is completed. In dogs with iUC, a physical examination, which includes a rectal examination, may reveal thickening of the urethra and trigone region of the bladder, enlargement of lymph nodes, prostatomegaly in male dogs, and sometimes a mass in the bladder or a distended bladder. However, a normal physical examination does not rule out iUC.

Many conditions mimic iUC in regard to clinical signs, presence of abnormal epithelial cells in urine, and mass lesions within the urinary tract (Fig. 30.2 and 30.3). Differential diagnoses include other neoplasia, chronic bacterial cystitis, polypoid cystitis, fibroepithelial polyp, granulomatous cystitis/urethritis, gossypiboma, calculi, and inflammatory pseudotumor.[4–8,20–22] It is important to differentiate non-iUC conditions from iUC because the treatments and prognosis differ considerably and are dependent on the condition present.

A definitive diagnosis of iUC is made through histopathologic examination of tissues. Immunohistochemistry for uroplakin III and potentially GATA-3 can be used to determine urothelial origin of the cancer in difficult cases.[3] Methods for obtaining tissue for histopathologic diagnosis include cystotomy, cystoscopy (Fig. 30.2), and traumatic catheterization.[1,23] Cystoscopy provides the opportunity to visually inspect the urethra and bladder and to obtain biopsies via a noninvasive method. With the small size of cystoscopic biopsies, the operator must be diligent to collect sufficient tissue for diagnosis. Placing tissue samples in a histology cassette before processing helps prevent loss of small samples (Fig. 30.2F). The use of a wire basket designed to capture stones during cystoscopy (Fig. 30.2D, E) allows collection of larger samples. Traumatic catheterization to collect tissues for diagnosis can also be performed, although samples are usually small and the diagnostic quality is variable. Percutaneous biopsy methods can lead to tumor seeding and should be avoided.[24]

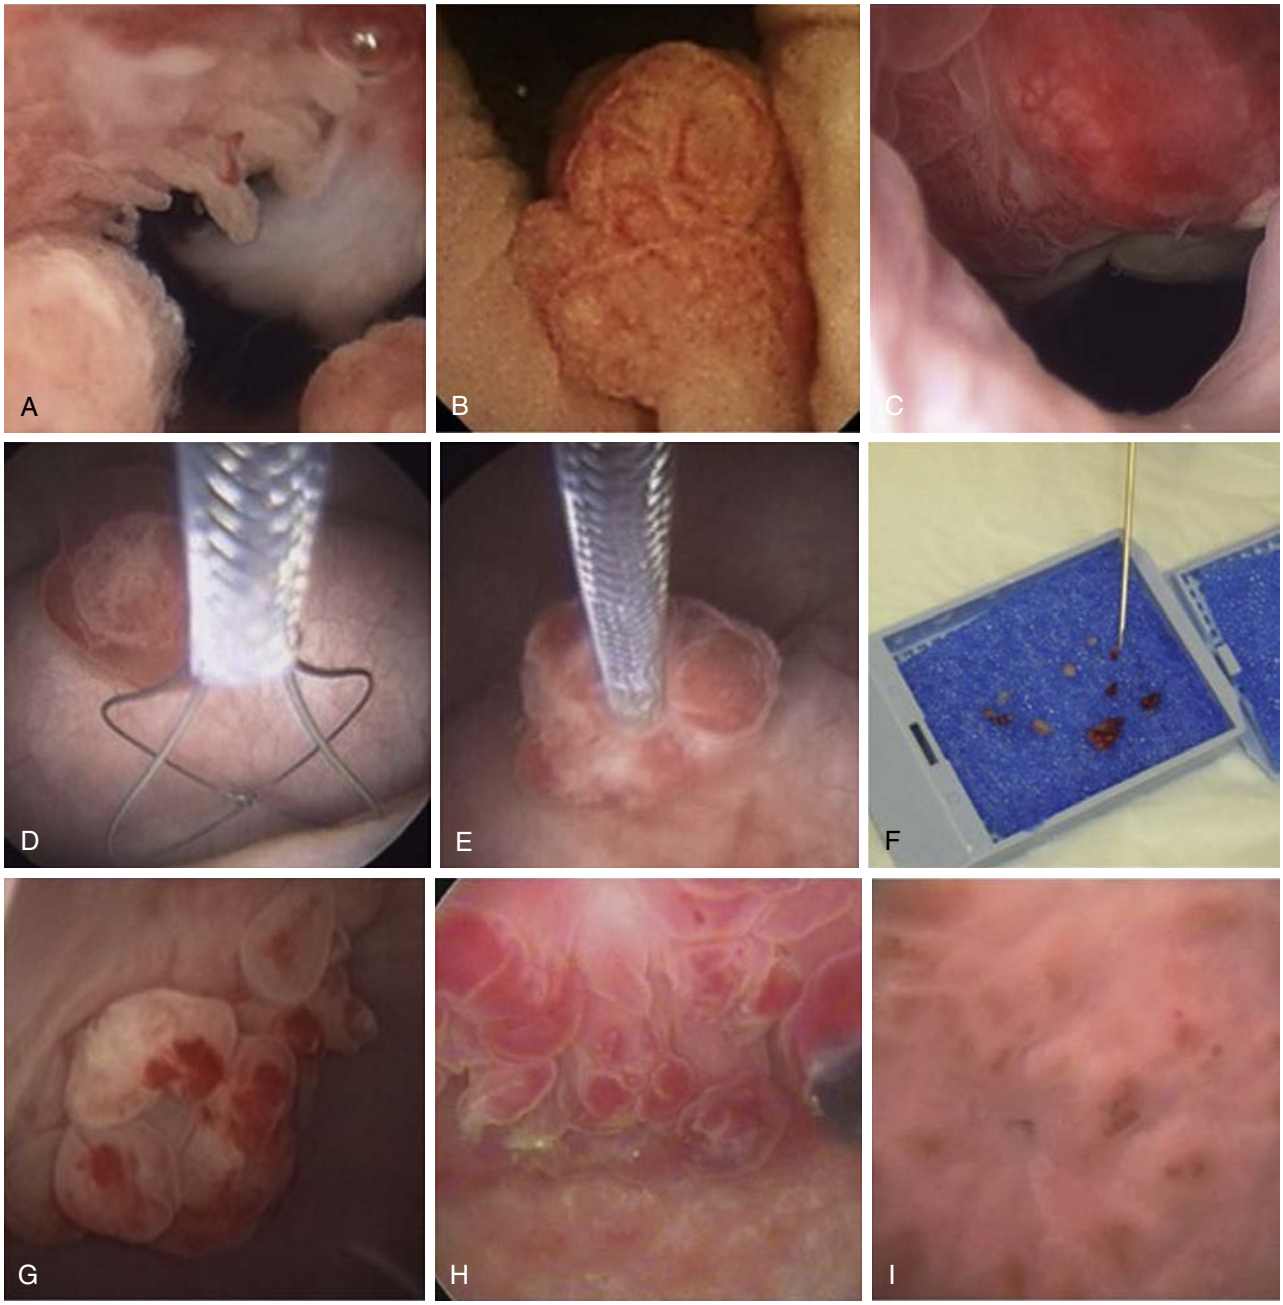


TABLE 30.1 Breed and Risk of Invasive Urothelial Carcinoma (iUC) in Pet Dogs[3]

Breed	Number of Dogs in That Breed in Database	TCC Cases in That Breed in Database	OR compared with mixed breed	95% confidence intervals
Mixed breed dog (Reference Category)	42,777	269	1.0	NA
Scottish terrier	670	79	21.12	16.23–27.49
Eskimo dog	225	9	6.58	3.34–12.96
Shetland sheepdog	2521	93	6.05	4.76–7.69
West Highland white terrier	1234	44	5.84	4.23–8.08
Keeshond	381	10	4.26	2.25–8.07
Samoyed	471	10	3.43	1.81–6.49
Beagle	3236	62	3.09	2.34–4.08
Dalmatian	1253	19	2.43	1.52–3.89

The odds ratios (ORs) of TCC risk compared with the risk in mixed breed dogs are included for breeds with an OR > 2.0 and at least 9 cases of iUC in the breed.

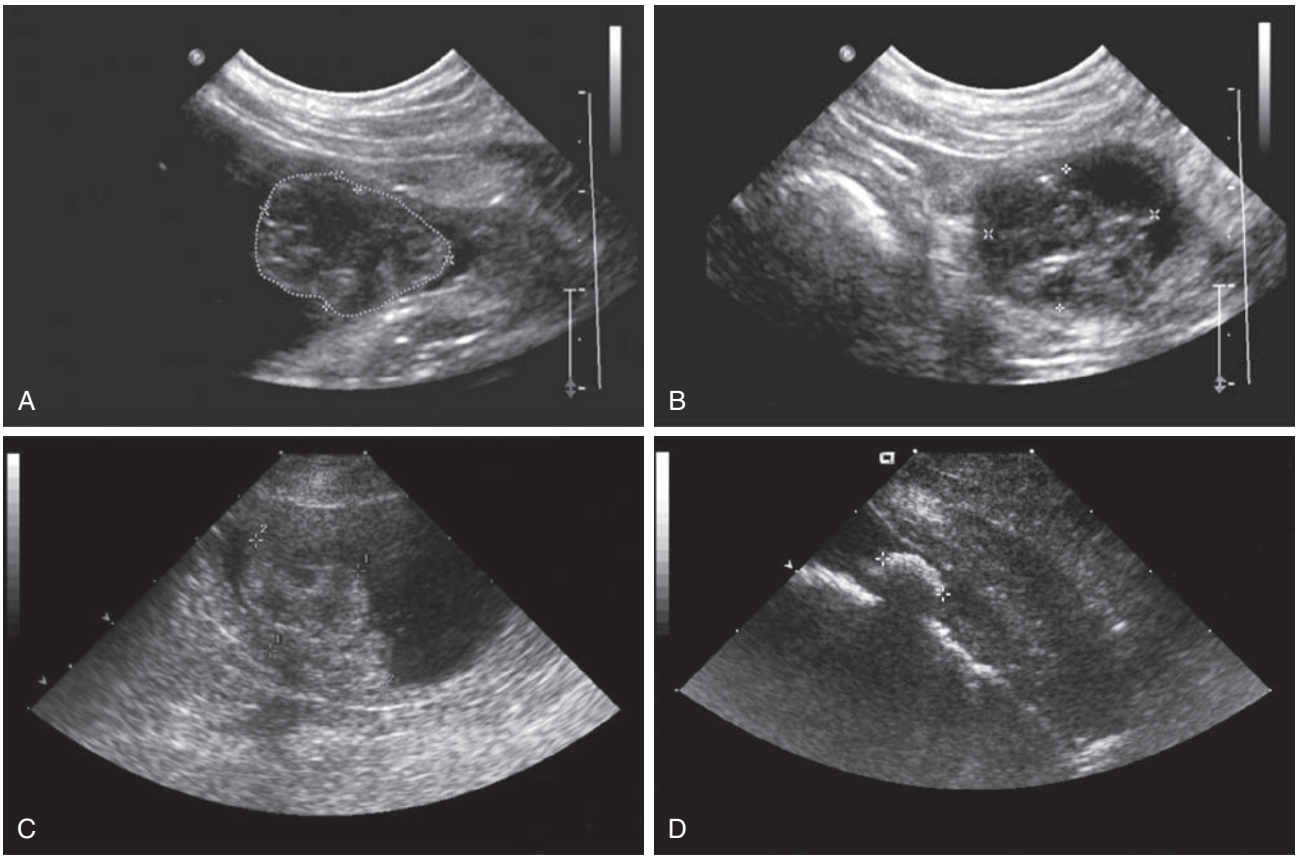
VetBooks.ir

In dogs with confirmed or suspected iUC, evaluation should include an assessment of overall health (complete blood count, serum biochemistry profile, urinalysis, ± urine culture) and staging of the cancer (three-view thoracic radiographs, abdominal ultrasonography or computed tomography [CT], and urinary tract imaging). To avoid the risk of seeding iUC through cystocentesis, urine may be collected by free catch or catheterization. Catheterization must be performed carefully to avoid penetrating the diseased bladder or urethral wall. Urinary tract imaging is used to assess the tumor location for potential surgical intervention

• **Fig. 30.2** Images from cystoscopy of dogs with invasive urothelial carcinoma (iUC, A–E) and biopsy material obtained (F), and images of dogs with polypoid cystitis (G–I). TCC can appear as a ruffled frond-like mass, a solid smooth mass, or as polyp-like lesions. High-quality images can be obtained with rigid cystoscopes typically used in female dogs (A, C–E) and in digital flexible scopes used in male dogs (B, image from a male Scottish terrier). The use of a cystoscopic wire stone basket (D, E) allows collection of larger biopsies. Regardless of the biopsy instrument used, however, cystoscopic biopsies are relatively small, and placing the samples in a tissue cassette (F) may facilitate processing. Polypoid cystitis (G–I) appears very similar to TCC, but it is treated differently and has a better prognosis than TCC. Images (H) and (I) are from a dog with polypoid cystitis before (H) and after (I) a month of clavamox treatment alone with no other therapy. The polpys had regressed by more than 80% (I) at the time of rescoping. Cases such as this one emphasize the importance of histopathology in the diagnosis of urinary tract masses, especially when selecting therapy, and even more so when dogs are participating in clinical trials. (Courtesy L. G. Adams and D. W. Knapp, Purdue University.)

VetBooks.ir

and to map and measure iUC masses to subsequently determine response to therapy. Cystosonography, cystography, or CT may be employed.[25–28] To accurately track response to therapy, regardless of the imaging approach, it is essential to follow a consistent protocol from visit to visit for imaging modality, bladder distention, patient positioning, and images acquired. When using cystosonography to monitor response, it is critical to have the same operator perform examinations over multiple visits.



Treatment

Localized Therapy

Surgery

Surgery may be indicated to (1) obtain tissue for a definitive diagnosis, (2) eradicate lesions amenable to wide excision (e.g., tumors distant from the trigone), and (3) relieve urinary tract obstruction. Local recurrence after partial cystectomy and the presence of multifocal lesions within the bladder in many dogs with iUC support the notion of the field effect or malignant transformation of the entire urothelium in response to carcinogen exposure.[29] Surgical removal of iUC is typically followed by systemic therapy, usually with a cyclooxygenase (COX) inhibitor, to reduce risk of recurrence.[1,29] When considering surgery, patient selection and owner counseling regarding risks (procedural risk, risk of recurrence) are essential. The risk of tumor seeding at the time of surgery is well documented and careful surgical technique is critical.[12,29,30]

Full-thickness removal of part of the bladder may be considered in dogs with discrete iUC lesions away from the trigone. In a retrospective study of 37 dogs with iUC treated with partial cystectomy (all gross tumor removal in 92% of dogs) plus COX inhibitors, with or without chemotherapy, the median progression-free interval (PFI) was 235 days, and the median survival time (MST) was 348 days.[29] In a subset of 22 dogs treated with surgery and daily piroxicam (with or without other systemic therapy), the MST was 722 days.[29] This result is similar to results in a series of nine dogs that had surgical resection of iUC (three dogs with tumor-free margins and six dogs with residual microscopic disease) followed by single-agent deracoxib, in which the MST was 749 days.[1] More complex surgical approaches in dogs with iUC have also been reported including total cystectomy plus various urinary diversion strategies, but serious complications limit the success of these approaches.[31–34] Prepubic cystostomy catheters or low-profile cystostomy tubes can be placed to bypass urethral

• **Fig. 30.3** Cystosonography images from dogs with bladder masses. Images made in the sagittal (A) and transverse (B) planes (5 mL/kg fluid distention of the bladder) of an 11-year-old neutered male Shih Tzu with invasive urothelial carcinoma. To measure bladder masses over multiple time points, it is important to follow a consistent protocol in regard to level of bladder distention, and patient and probe positioning; and to have the same operator perform the ultrasonography on each visit. Polypoid cystitis (C, D), which can appear very similar to iUC, can occur in any part of the bladder including the mid/apex (C) and trigone (D). The dog imaged in (D) was a 13-year-old spayed female Bichon Frise with history of previous urinary tract infection, current hematuria, stranguria, atypical epithelial cells in urine, and masses in the mid and trigone areas of the bladder. Surgical biopsies of the masses confirmed they were polyps. (Courtesy J. F. Naughton, Purdue University.)

obstruction in a palliative setting or to maintain urine flow while other therapies are instituted.[35–37] Complications can include urine leakage and tumor seeding, infection, tube displacement, and tube damage if the dog is allowed to chew on the tube.

Urethral and Ureteral Stent Placement and Laser Ablation

In recent years, the use of interventional radiology approaches has gained favor over tube cystostomy and other surgical procedures for palliative management of obstruction secondary to iUC.[30,38–41] Most urethral stents and some ureteral stents can be placed with minimally invasive approaches, and stents do not require pet owners to manipulate a urine collection system. Survival after urethral and ureteral stent placement is variable and largely dependent on the extent of tumor lesions. In three reports, MSTs have ranged from 20 to 78 days (range, 2–536 days) after urethral stent placement for iUC or prostatic adenocarcinoma.[39–41] After urethral stent placement, lower urinary tract signs, including stranguria, can persist. Incontinence has been reported in 25% to 39% of dogs.[39–41] Urethral stents are typically placed using fluoroscopic guidance, but the use of digital radiography to guide stent placement has also been reported.[42] Ureteral stents can be placed surgically, and in some cases, nonsurgically in dogs with iUC. The MST after ureteral stent placement was 57 days (range, 7–337 days) in one study.[43] Nephrectomy can be considered for severe unilateral hydronephrosis if persistent renal pain or infection is present.

Transurethral carbon dioxide (CO_2) and near-infrared diode laser ablation of iUC (performed in combination with cytotoxic chemotherapy and COX inhibitors) has been reported, with its main application being in dogs with discrete tumor masses causing urinary tract obstruction.[44,45] Complications include perforation with iUC spread, transient postprocedural worsening of stranguria and hematuria, urethral stenosis, and infection.[44,45] In a small series, the outcome of dogs treated with laser ablation and medical therapy was not better than medical therapy alone.[44]

Radiation Therapy

Although iUC cells are generally thought to be sensitive to radiation therapy (RT), an in vitro study of three canine iUC cell lines revealed a low α/β ratio, suggesting moderate radioresistance and supporting treatment protocols using higher doses and less fractionation.[46] The early use of large doses and less fractionation, however, was associated with chronic colitis, cystitis, and urethral strictures, and little improvement in MST compared with medical therapy alone.[47,48]

With new advanced image-guided targeting technology and increasing availability of RT, there is renewed interest in RT to treat iUC.[49–53] A retrospective report of intensity-modulated and image-guided radiation therapy revealed lower complication rates compared with earlier studies in the dog.[49] In a series of 21 dogs, acute side effects were mild and self-limiting and included colitis (38%), erythema or hyperpigmentation (19%), and stranguria (5%).[49] Late complications included urethral stricture (9%), ureteral stricture (5%), or rectal stricture (5%). The median event-free survival was 317 days and the overall MST was 654 days.[49] In a report of 13 dogs with urogenital carcinomas treated with a low dose palliative RT (10 daily fractions of 2.7 Gy with CT planning) plus antineoplastic drugs, acute side effects were mild including colitis, cystitis, vaginitis, and dermatitis, and no late complications were noted.[50] Complete remission (CR) or partial remission (PR) was reported in 61% of dogs and stable disease (SD) in 38% of dogs.[50]

Medical Therapy

Systemic Medical Therapy

Systemic medical therapy is the mainstay of iUC treatment in dogs, and usually consists of chemotherapy, COX inhibitors (nonselective and COX-2 selective inhibitors), and combinations thereof (Table 30.2).[1–3,27,54–62] Although medical therapy is not usually curative, several different drugs lead to remission or SD of iUC, and most therapies are well tolerated. Resistance to one drug does not imply resistance to other drugs. Some of the best results are seen in dogs

[a]Diagnosis based on histopathology.

[b]When dogs receiving vinblastine alone failed, there was then the option for the dogs to receive piroxicam alone or other drugs. Twenty dogs received piroxicam alone after failing vinblastine alone. The responses to piroxicam were 3 (15%) PR, 9 (45%) SD, 5 (25%) PD, and 3 (15%) NA. Twelve of these dogs received additional therapy after failing piroxicam. In the combined therapy arm, 15 dogs received additional therapy after failing vinblastine/piroxicam.

[c]Dogs that initially received cisplatin alone and had tumor progression were then treated with piroxicam alone; two dogs had PR and five dogs had SD with piroxicam treatment. This could have contributed to the favorable survival in that treatment arm.

[d]Despite favorable tumor response, the combination of cisplatin and piroxicam is not recommended for routine use because of frequent renal toxicity.

[e]After failing cisplatin alone, options were given for the dogs to receive firocoxib alone or other drugs. Thirteen dogs received firocoxib alone after failing cisplatin alone, and tumor responses included 2 PR, 4 SD, and 7 PD. This (and other drugs) could have contributed to the longer survival time.

[f]Study included dogs with cytologic evidence of TCC and dogs with biopsy-proven TCC.

[h]The majority of dogs had failed prior therapy before receiving vinblastine. The dosage of vinblastine used in this trial was 3 mg/m^2 every 2 weeks. In most dogs in the trial, however, subsequent dose reduction was necessary because of myelosuppression. The currently recommended starting dosage of vinblastine for dogs with iUC is 2.5 mg/m^2 every 2 weeks for medium to large dogs and 2.0 mg/m^2 every 2 weeks for small dogs with subsequent dose escalation in the absence of toxicity.

[i]Seventeen of the dogs had failed a COX inhibitor before enrolling in the trial and continued to receive the COX inhibitor during the vinblastine treatment.

[j]In the study, the tumor masses were measured by ultrasound and by computed tomography. At 8 weeks, two different ultrasound operators reported tumor responses of 33% and 55% respectively.

More advanced TNM stage is associated with a poorer prognosis; the percentages of dogs with metastasis for each study are included.

CR, Complete remission; *NA*, information not available; *PD*, progressive disease; *PFI*, progression-free interval; *PR*, partial remission; *SD*, stable disease.

that sequentially receive multiple different treatment protocols over the course of their disease. Baseline measurements of the iUC masses are obtained, an initial treatment protocol is instituted, and the iUC masses remeasured at 4- to 8-week intervals. The initial treatment is continued as long as the iUC is controlled (PR, SD), side effects are acceptable, and quality of life is good. Clinical signs do not consistently follow changes in tumor size with therapy; thus remeasuring the tumor is essential. If cancer progression or unacceptable toxicity occurs, then a different treatment is instituted. Subsequent treatment changes are based on change in tumor size and treatment tolerability. With this approach, iUC growth can be controlled in approximately 75% to 80% of dogs, quality of life is usually very good, and MSTs have extended well beyond a year.[1–3] Simultaneously combining multiple chemotherapy agents in dogs with iUC is not currently recommended because the benefit has not been determined, toxicity is likely to increase, and the potential development of resistance to multiple drugs at the same time could limit the options for subsequent therapy.

VetBooks.ir

The optimal length of chemotherapy for iUC has not been defined. Although the authors continue a chemotherapy protocol as long as the cancer is controlled, quality of life is good, and no serious adverse events are noted, other oncologists cap the number of chemotherapy doses because of concerns of chronic toxicity. The effects of discontinuing chemotherapy in dogs with PR or SD, or administering COX inhibitors or metronomic chemotherapy as "maintenance therapy," have not been determined. It is certainly expected that residual iUC will progress if drugs controlling it are withdrawn. Anecdotally, the authors have administered vinblastine or mitoxantrone for well beyond a year without ill effects (D. Knapp, personal communication), but further study is needed.

Systemic chemotherapy agents investigated in dogs with iUC are summarized in Table 30.2.[1–3,48,55–62] Although cisplatin appears to be one of the more active agents, it is seldom used because of renal, GI, and bone marrow toxicities.[1–3,60,62] In a recent report, the administration of cisplatin and piroxicam concurrently with a chemoprotectant agent (Tavocept) was associated with less renal toxicity than a historic control group receiving similar doses of cisplatin and piroxicam, but the response rate was inferior in the dogs that received Tavocept.[60]

In recent years, vinblastine has emerged as a preferred chemotherapy agent in dogs with iUC because of very good antitumor activity and a good safety profile.[58,59] After promising results in a single arm trial in dogs with advanced resistant iUC, a follow-up trial was performed in which dogs with histologically diagnosed iUC were randomly assigned to receive vinblastine (2.5 mg/m^2 intravenously every 2 weeks) plus piroxicam (0.3 mg/kg daily PO) or vinblastine alone (same dose).[59] Remission was more frequent with vinblastine–piroxicam (58%) than with vinblastine alone (22%). The median PFI was 143 days with vinblastine alone and 199 days with the combination. Interestingly, the MST was significantly longer in dogs receiving vinblastine alone followed by piroxicam alone (531 days) than in dogs receiving the two drugs given concurrently (299 days). The longer survival was possibly due to the dogs not developing resistance to both drugs simultaneously. The treatment was well tolerated in both arms. Therefore vinblastine combined with piroxicam (or another COX inhibitor) has become the preferred chemotherapy protocol at the authors' institution.

Another commonly used chemotherapy protocol, mitoxantrone combined with piroxicam, induced remission in 35% of dogs with iUC with a MST was 291 days.[1] Carboplatin combined with piroxicam induced remission in 38% of dogs, but is usually reserved for later use because of more frequent side effects.[1] Other chemotherapy studies are summarized in Table 30.2.

Low-dose frequent (metronomic) chemotherapy has also been used in dogs with iUC.[61] A clinical trial of metronomic oral chlorambucil (4 mg/m^2 daily) was performed in 31 dogs with iUC, 29 of which had failed prior therapy.[61] Tumor responses included PR in one dog (3%) and SD in 20 dogs (67%). The median PFI and MST from the start of chlorambucil was 119 days and 221 days, respectively. The quality of life was excellent. Although toxicity was minimal in this study, with increased use of chlorambucil, especially for several months in dogs, chronic myelosuppression persisting for weeks to months has emerged as a concern. The chlorambucil dose used in the iUC trial (4 mg/m^2 daily) was selected because it was more effective than lower or less frequent doses in early work.[63] In a recent study, three different doses of chlorambucil (4 mg/m^2, 6 mg/m^2, or 8 mg/m^2) were given to 78 dogs with a variety of cancer types.[64] Doses greater than 4 mg/m^2 were associated with more GI and bone marrow toxicity, but no improvement in antitumor effects. Of 34 dogs receiving 4 mg/m^2, bone marrow suppression was noted in 10% of dogs at 90 days and in 80% of dogs at 1 year. Most toxicity was grade 1 or 2, but this justifies the need for careful monitoring.

A more conservative treatment for iUC is a single-agent COX inhibitor, including the nonselective COX inhibitor piroxicam or COX-2 selective inhibitors such as deracoxib and firocoxib.[1,3,54,62] All three of these agents have induced remission (with most being PRs) in 15 to 20% of dogs with iUC, and have resulted in SD in up to 55% of dogs. Information on 94 dogs with iUC treated with piroxicam (0.3 mg/kg daily) has been published.[3] Tumor responses were known in 76 dogs and included 3% CR, 18% PR, 59% SD, and 20% PD. The median PFI was 120 days, and MST was 244 days.[3] The MST compared favorably to that of 55 dogs in the Purdue Comparative Oncology Program Tumor Registry that were treated with cytoreductive surgery alone (median survival 109 days).[3] GI adverse events (due to piroxicam or comorbid conditions) were noted in 31% of dogs.[3] Although most were grade 1 or 2, piroxicam can cause GI ulceration. It is critical for pet owners to observe their dog, stop piroxicam, and contact their veterinarian if anorexia, vomiting, or melena occurs. If the clinical signs are thought to be piroxicam related, it is safest to give a drug holiday and then switch to a COX-2 inhibitor. Interestingly, in an expanded series of dogs with multiple types of cancer receiving piroxicam, the use of GI-protectant drugs was associated with greater GI toxicity, but the reasons for this require further study.[65] Although piroxicam can cause toxicity, the majority of dogs have notably improved quality of life on the drug.[3]

COX-2 selective inhibitors are also used in dogs with iUC. In a randomized trial, firocoxib (Previcox, Merial) had antitumor activity as a single agent (20% PR and 33% SD) and greatly enhanced the activity of cisplatin.[62] Firocoxib did not worsen the renal toxicity of cisplatin (as piroxicam does), but other toxicities inherent to cisplatin still limit its use. In a clinical trial of single-agent deracoxib (Deramaxx, Novartis, 3 mg/kg PO daily) in 26 dogs with iUC, tumor responses included 17% PR, 71% SD, and 12% PD.[54] The MST after deracoxib and subsequent therapies was 323 days. Mild GI toxicity occurred in 20% of dogs.

Targeted therapies are also receiving considerable interest in treating TCC and other cancers in dogs. Folate-targeted vinblastine (EC0905, Endocyte) and the BRAF targeted drug vemurafenib have shown good promise in iUC (D. Knapp, personal communication).[66] Toceranib combined with vinblastine and COX inhibitor has been studied, although responses did not appear better than for other vinblastine protocols.[27] The injectable demethylating agent 5-azacitidine resulted in PR in 22% and SD in 50% of treated dogs.[67] The pharmacokinetics, toxicity, and dosing of the oral demethylating agent zebularine in dogs with iUC have been reported, and a phase II trial is in progress (C. Fulkerson, personal communication).[68]

Localized Drug Delivery

The use of localized drug delivery in dogs with iUC has been limited, but has included intravesical mitomycin C and photodynamic therapy (PDT).[69,70] Both have shown promise, but neither is used to any extent owing to the risk for systemic toxicity (when drugs instilled enter the circulation via vascularized tumors), local irritation to the bladder, and initial inflammation and tissue swelling after PDT.[69,70]

Urinary Tract Infections

The risk of urinary tract infections (UTIs) is high in dogs with iUC, especially in female dogs with urethral disease.[71,72] This is due at least in part to urine retention, acquired structural defects

VetBooks.ir

in the bladder and urethra, damaged urothelium, and, in some cases, potentially compromised immune function.[71,72] UTIs are problematic because they can result in worsening clinical signs, the false impression of cancer progression, and further malignant transformation, invasion, and metastasis secondary to inflammation.[73–75] Antibiotic use can negatively affect the immune response through changes in the microbiome and other mechanisms.[73] Another major problem with UTIs is the increasing resistance to antibiotics.[71,76–79] For example, between January 2013 and February 2015, 168 resistant bacterial isolates from urine were reported at the Purdue University Veterinary Teaching Hospital, and 60% of the resistant isolates were from dogs with TCC (Fulkerson, unpublished data). In a 1-year period, 7 of 57 dogs with iUC developed infections that were sensitive only to nephrotoxic antibiotics, very expensive antibiotics, or were not sensitive to any antibiotics tested.[1] These issues point out the need to appropriately treat UTIs, but to also refrain from prescribing antibiotics when not indicated, as this can promote antibiotic resistance. A positive urine culture, especially with a low colony count in the absence of worsening clinical signs and supporting findings on urinalysis, is not an indication to treat with antibiotics.

If a dog with iUC develops new or progressive lower urinary tract signs, a urinalysis with sediment evaluation should be performed. If the urinalysis reveals pyuria or the presence of intracellular bacteria, a urine culture is recommended. Because of the risk of tumor seeding, urine samples for culture are collected via midstream voiding or through a urinary catheter. While waiting on culture results, an initial antimicrobial choice should target *Escherichia coli* and *Staphylococcus* spp., which are among the most common uropathogens in non–tumor-bearing and tumor-bearing dogs with UTIs.[72] The authors typically prescribe amoxicillin–clavulanate or trimethoprim–sulfa pending culture results. Amoxicillin, doxycycline, and enrofloxacin (but not amoxicillin-clavulanate or cephalexin) have been associated with resistance patterns in cultures performed within 30 days after use.[80] The benefits and risk of other approaches to treat or control UTIs, such as methenamine maleate or bacterial transfer, have not yet been determined.[81,82]

Prognosis

Although iUC is not usually curable in dogs, it is considered very treatable because of the 75% chance of cancer control or remission with treatment. The quality of life in most dogs is excellent. Survival has been strongly associated with the TNM stage at the time of diagnosis.[1,3] Factors associated with a more advanced TNM stage at diagnosis include younger age (increased risk of nodal metastasis), prostate involvement (increased risk of distant metastasis), and higher T stage (increased risk of nodal and distant metastasis).[1,3]

Feline Urinary Bladder Tumors

Bladder cancer is rarely reported in cats. iUC is the most frequently reported form of feline bladder cancer, with mesenchymal tumors, lymphoma, and other tumors being less common.[83–89] Clinical signs of iUC in the cat are similar to those in the dog.[84] In contrast to dogs, more than half of iUCs in a series of 20 cats were away from the trigone.[84] Cats in this series were treated with surgery, cytotoxic chemotherapy, COX inhibitors, or combinations thereof, and the MST was 261 days.[84] As in canine and human iUC, most feline iUCs express COX-1 and COX-2.[89] The MST of 11 cats treated with meloxicam was 311 days.[89] The optimal drugs for feline iUC and possible role of RT requires more study. Surgical approaches and the placement of stents and cystostomy tubes to improve urine flow have been reported in cats with iUC.[35,90–92]

Canine Urethral Tumors

Most urethral tumors in dogs are malignant epithelial tumors including iUC and squamous cell carcinoma, with other cancers being less common.[93] Staging procedures and treatment recommendations for urethral iUC are generally the same as for iUC located in the bladder. It is important to note that granulomatous/chronic active urethritis comprised 24% of urethral lesions in a series of 41 dogs, and the clinical signs and lesions associated with granulomatous urethritis can mimic iUC.[93] Complete urethral obstruction has been reported with granulomatous urethritis. Histopathology is particularly important for urethral masses to rule out granulomatous urethritis, as treatment and prognosis differ from those of iUC.[93]

Canine Renal Tumors

Canine renal cancer includes renal cell carcinoma (RCC), adenocarcinomas, iUC, papillary cystadenocarcinomas, and less commonly, sarcomas.[94–97] Nodular dermatofibrosis in association with renal cystadenocarcinoma and uterine tumors has been reported, mostly in German shepherd dogs.[98,99] This condition arises as a result of a dominantly inherited missense mutation in *FLCN*, a tumor suppressor gene coding for the protein folliculin, and is similar to Birt–Hogg–Dubé syndrome in people.[98,99]

Epithelial renal tumors and sarcomas tend to occur in older dogs.[94] Nephroblastoma has been reported in young dogs (including a 3-month-old dog), middle-aged, and older dogs.[94–96] A male predisposition has been reported.[97] Clinical signs, when present, include hematuria, pain in the area of the kidneys, a palpable abdominal mass, bone pain secondary to hypertrophic osteopathy, or other nonspecific signs such as GI upset or behavior changes.[94–96,100]

Laboratory findings can include mild to moderate anemia, neutrophilia, azotemia, elevated alkaline phosphatase, hypoalbuminemia, hypercalcemia, and paraneoplastic polycythemia secondary to erythropoietin production.[94,101–104] In a case report of a dog with renal carcinoma and suspected paraneoplastic leukocytosis, immunohistochemistry revealed expression of granulocyte-macrophage colony-stimulating factor by the tumor.[103]

Clinical staging should include thoracic and abdominal imaging. Tumor extension into the caudal vena cava is possible; thus CT may be useful for surgical planning. Evaluation of glomerular filtration rate via scintigraphy can also be useful. Histopathology is required for a definitive diagnosis and can be obtained by ultrasound-guided percutaneous biopsy or at the time of nephrectomy. Immunohistochemistry can help differentiate subtypes of RCC.[105]

Nephrectomy remains the treatment of choice for dogs with unilateral renal tumors with no evidence of metastasis and normal renal function. Even in dogs with metastasis, surgery can be palliative. Renal lymphoma is typically treated with chemotherapy (see Chapter 33), but effective chemotherapy protocols have yet to be described for most primary renal tumors.

In one study, the MSTs were 16 months for 49 dogs with renal carcinomas, 9 months for 28 dogs with renal sarcomas, and 6 months for 5 dogs with nephroblastomas.[94] Higher mitotic index, increased COX-2 expression, specific histologic subtypes, and Fuhrman nuclear grade have reported negative prognostic value for RCCs.[106,107] The MSTs for dogs with a mitotic index of <10, 10 to 30, and >30 were 1184 days, 452 days, and 187 days,

VetBooks.ir

respectively.[106] The MST appears shorter for clear cell (87 days) versus chromophobe, papillary, and multilocular cystic RCCs.[106] Fuhrman nuclear grade, a human RCC histologic grading scheme based on morphologic features of nuclei and nucleoli, was prognostic in one study of 70 dogs with RCC with MSTs not reached, 1065 days, 379 days, and 87 days in dogs with grade 1, 2, 3, and 4 RCCs, respectively.[106] Radiographic evidence of metastasis is present in 16% to 34% of dogs with primary renal tumors.[94,97] Metastasis at death was reported in 88% of dogs with sarcomas, 75% with nephroblastomas, and 69% with carcinomas.[94]

Feline Renal Tumors

Primary renal tumors are rare in the cat. Excluding lymphoma, reported feline primary renal tumors include tubular RCC, tubulopapillary RCC, sarcomatoid RCC, adenocarcinoma, adenoma, iUC, squamous cell carcinoma, leiomyosarcoma, nephroblastoma, and hemangiosarcoma.[108–115] The tubular and tubulopapillary RCC were most common in a series of 19 cats.[108] The most common presenting complaint was weight loss. Metastasis was frequently detected at the time of diagnosis.[108]

Polycythemia has been reported in cats with primary renal tumors.[108,115] In two cats with renal adenocarcinoma, polycythemia resolved after nephrectomy.[115] Hypertrophic osteopathy has been reported in a cat with renal adenoma.[110] In contrast to canine and human RCC, immunohistochemistry did not correlate with RCC subtype in a small series of cats.[114] Nephrectomy could be considered in unilateral cancer. The role of chemotherapy is undefined. Limited information on survival is present, but most reports are associated with short survival times.

Comparative Aspects

Invasive Urothelial Carcinoma

There are more than 65,000 new cases and more than 16,000 deaths from urinary bladder cancer in the United States each year, with most deaths from iUC.[116] Cigarette smoking is by far the most common cause of human bladder cancer.[116] In humans, more than two-thirds of bladder tumors are superficial low-grade non–muscle-invasive tumors.[116] These tumors generally respond well to transurethral resection and intravesical therapy, although recurrence is common and progression to iUC is a risk. Approximately 20% of human bladder cancers are higher grade muscle-invasive urothelial carcinoma at the time of diagnosis. Metastasis to the regional lymph nodes, lungs, and other organs occurs in approximately 50% of human iUC cases.[116] iUC in dogs is very similar to iUC in humans in histopathologic characteristics, cellular features, biologic behavior including metastasis, and response to therapy.[2,3,116–125] Canine iUC has emerged as a highly relevant naturally occurring model for human invasive bladder cancer.[2,3] Successful therapies in dogs have been translated into human clinical trials, and similar effects observed between the two species.[2,3,126]

Molecular analyses have further strengthened the role of canine TCC as a model for human iUC.[127–134] In microarray and RNA-seq analyses, hundreds of genes that are differentially expressed between normal bladder tissues and iUC have been found that are shared between dogs and humans.[127,128] Altered expression of genes shared between canine and human iUC includes *COX-2*, *EGFR*, *HER2*, *p53* family genes, *DNMT1*, and *VIM*.[121–125,129–133] The *BRAF*^{V595E} mutation, which is present in 80% of canine iUC, leads to continuous activation of the MAPK pathway.[17] This mutation is the canine homolog of the *BRAF*^{V600E} mutation that drives 8% of all human cancer. Although *BRAF* mutations are rare in human iUC, other molecular variants are present that turn on the MAPK pathway in approximately 30% of human iUC cases.[133] Mutations in several other genes implicated in the development and progression of iUC and other cancers in humans have been identified in canine iUC including *EGFR, CDKN2B, PIK3CA, BRCA2, NFκB, ARHGEF4, XPA, NCOA4, MDC1, UBR5, RB1CC1, RPS6, CIITA, MITF,* and *WT1*.[17,128,133] Another intriguing finding in canine iUC is the presence of molecular subtypes defined by gene signatures including luminal and basal subtypes initially observed in human breast cancer and then found in human iUC.[127,134] This is important because cancer behavior, treatment response, and prognosis differ between subtypes in humans.[134]

Renal Cancer

Major types of renal cancer in humans include RCC, urothelial carcinoma of the renal pelvis, and Wilms' tumor (nephroblastoma), which is most commonly diagnosed in children.[135] Renal cancer is newly diagnosed in 64,000 people and results in 15,000 deaths each year in the United States. RCC accounts for 90% of adult renal carcinomas.[135] Risk factors for RCC include cigarette smoking, obesity, and hypertension.[136] Multiple subtypes of RCC exist including clear cell, papillary types I and II, and chromophobe types. The clear cell type can be sporadic or associated with von Hippel–Lindau disease in which mutations occur in the *VHL* gene. With recent progress in targeted and immunotherapies, the outlook for human RCC has improved substantially in recent years.

Tumors of the Nervous System

JOHN H. ROSSMEISL, JR AND THERESA E. PANCOTTO

Nervous System Tumor Classification and Grading

Tumors of the nervous system can be broadly categorized into primary and secondary varieties.[1–4] Primary brain (PBT) or spinal cord (SC) tumors arise from the constitutive tissues of the brain or SC, such as neurons, glia, and the meninges. Secondary brain (SBT) or SC tumors represent those cancers that metastasize to the brain or SC from a distant site or affect nervous tissue by direct extension from an adjacent tissue (e.g., pituitary, nasal, or calvarial tumors).[4]

In recent years, efforts have been made to model classification of domestic animal nervous system neoplasms after the 2007 World Health Organization (WHO) criteria applied to human tumors.[5] This has been motivated principally by the remarkable clinical, diagnostic imaging, phenotypic, molecular, and genomic similarities observed between many canine and human PBTs,[6–10] as well as attempts to address limitations in the previous system used to describe nervous system tumors of animals.[11] The 2007 WHO criteria are grounded in traditional principles of histogenesis where light microscopic phenotypic similarities define the various tumor types, each type putatively originating from different cellular lineages (Table 31.1). The benefits of using this WHO system include the availability of a more comprehensive descriptive library of histologic tumor subtypes and the inclusion of a tumor grading scheme applicable across tumor types.

The tumor grades represent the range of potential biologic behaviors displayed by tumors. Grades are assigned based on the presence and degree of classic cytoarchitectural features of malignancy, such as cellular atypia, nuclear pleomorphism, mitotic rate, microvascular proliferation, and necrosis.[5] For example, in humans, grade I tumors are well differentiated with low proliferative potential that may often be cured by surgical excision, whereas grade IV tumors are cytologically malignant, mitotically active tumors that are refractory to therapy. Thus in humans, the tumor grade represents one piece of a composite system that uses patient clinicopathologic data to guide therapeutic decision making and predict long-term prognosis.[5] Within the closed confines of the calvarium or vertebral column, even slow-growing grade I tumors will cause progressive morbidity and eventual death of the patient in the absence of therapy regardless of presence of benign versus malignant characteristics. By prospectively applying WHO criteria in animal populations with nervous system tumors, efforts are ongoing to assess if this type of methodological approach can provide clinically useful correlations between tumor histology, biologic behavior, and therapeutic outcomes in a manner similar to those that exist for other veterinary neoplasms, such as mast cell tumors.[12]

Since the late 1990s, key discoveries have been made regarding the fundamental genetic aberrations that drive tumorigenesis in many types of human nervous system tumors. These studies have revealed that considerable molecular and genotypic heterogeneity exists between tumor types, even among of tumors of the same histology, and these features can have important prognostic implications that transcend phenotype.[13] This has resulted in a departure of the most recent human WHO classification of nervous system tumors from a histology-based platform to an integrated system that incorporates tumor genotypic, molecular, and classic phenotypic information into the definition of neoplastic entities.[13] As the genetic characterization of canine and feline nervous system tumors continues to advance, it is likely that this approach to classification will also become relevant in veterinary medicine.[7–10]

Intracranial Tumors

Epidemiology

Besides humans, dogs and cats are the only mammalian species in which spontaneous brain tumors are encountered frequently.[1–4,14–19] The overall estimated incidences of canine and feline nervous system tumors have been reported as 14.5 cases per 100,000 and 3.5 per 100,000 at risk, respectively.[14,18] Other studies indicate that intracranial neoplasms are observed in 2.0% to 4.5% of dogs and 2% of cats at necropsy.[1,17–19]

Dogs

In dogs, approximately 90% of PBTs (see Table 31.1) are represented by meningiomas (45%), gliomas (40%), and choroid plexus tumors (CPTs; 5%), although the distribution of specific PBTs in individual studies varies substantially.[1,2,17–19] Less commonly reported PBTs in dogs include ependymomas, primary central nervous system (CNS) lymphoma, primitive neuroectodermal tumors (PNETs), gliomatosis cerebri, and primary CNS histiocytic sarcoma (HS) (see Table 31.1); numerous other rare PBT have been described[1,2,14–19] SBTs comprise one-half of all

TABLE 31.1 World Health Organization Classification and Frequency of Primary Brain Tumors in Dogs and Cats

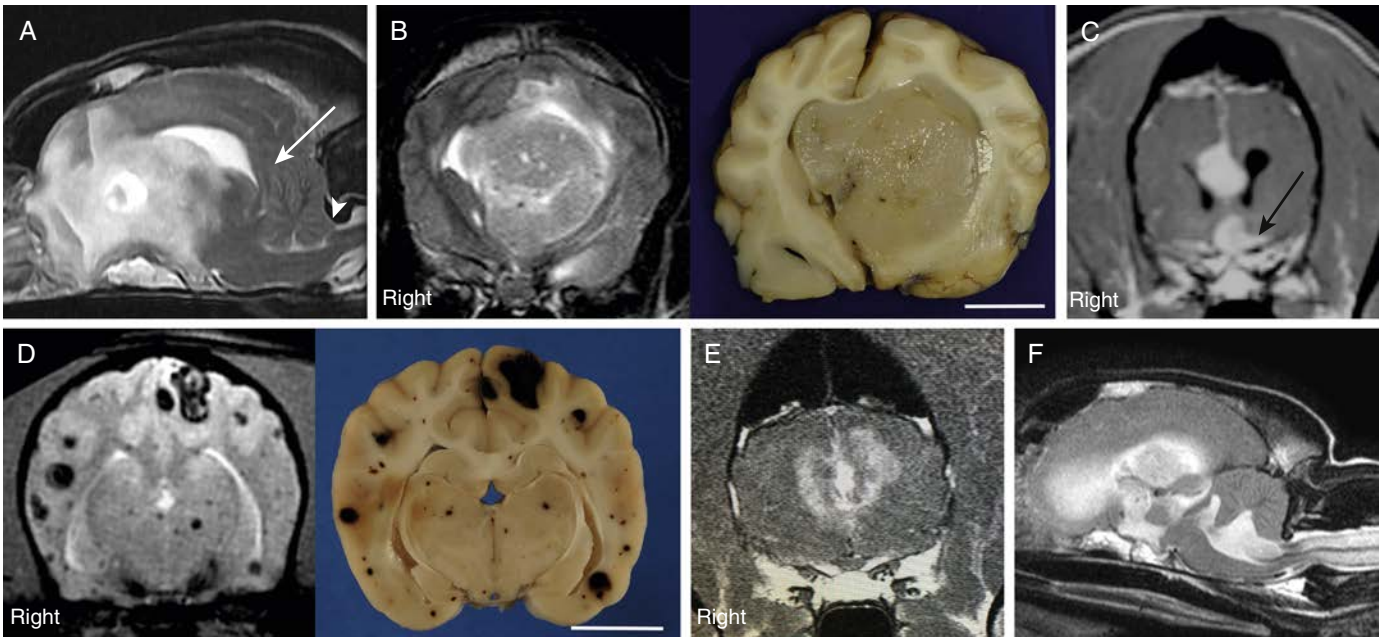
Tissue of Origin	Tumor Types/Grades	Frequency of Tumor Diagnosis[a]	
		Canine[1,2,5–7,20,21,24,25]	*Feline*[3,5,6,21–23]
Meninges	Meningioma • Grade I • Grade II (atypical) • Grade III (malignant)	42%–52%	40%–59%
Neuroepithelium	Astrocytic tumors • Grade I (pilocytic) • Grade II (diffuse) • Grade III (anaplastic) • Grade IV (glioblastoma)	13%–60%	<1%–3%
	Oligodendroglial tumors • Grade II (oligodendroglioma) • Grade III (anaplastic)	1%–23%	<1%–3%
	Oligoastrocytic tumors • Grade II (oligoastrocytoma) • Grade III (anaplastic)	<5%	NA
	Choroid plexus tumors • Grade I (papilloma) • Grade II (atypical papilloma) • Grade III (carcinoma)	5%–8%	<1%
	Embryonal tumors • Primitive neuroectodermal tumor (Grade IV)	<0.5%	<1%
	Ependymoma • Grade II (ependymoma) • Grade III (anaplastic)	0.2%–6%	3%

[a]Frequency of diagnosis among all primary brain tumors.

NA, data not available.

canine intracranial tumors, with hemangiosarcoma (HSA, 29%–35%), pituitary tumors (11%–25%), lymphoma (12%–20%), and metastatic carcinomas (11%–20%) accounting for 77% to 86% of all SBTs.[1,4]

Brain tumors in dogs may occur at any age and in any breed with no reported sex predispositions. Most PBTs and SBTs occur in middle-aged to older dogs, with the majority of cases described being greater than 5 years of age. Pooled data from the most current retrospective studies indicate that the median ages at diagnosis for dogs with meningiomas, gliomas, and CPTs were 10.5 years, 8.0 years, and 5.5 years, respectively.[1,2,20,21] There is a propensity for PBTs in juvenile animals to be neuroepithelial tumors of glial, neuronal, or embryonal origin.[1,22] One study identified a significant linear relationship between age and body weight and the occurrence of PBTs; large-breed dogs were at significantly increased risk for developing meningiomas and CPTs.[1] Golden retrievers, boxers, miniature schnauzers, and rat terriers have been identified as breeds in which intracranial meningiomas are overrepresented.[1,2,19,20]



Although CPTs were overrepresented in golden retrievers in one report,[21] this breed predisposition was not corroborated in a subsequent investigation.[1] Gliomas (astrocytomas and oligodendrogliomas) are highly overrepresented in brachycephalic breeds including boxers, Boston terrier, bullmastiffs, and English and French bulldogs.[1,2] A recent study has also identified a locus on canine chromosome (CFA) 26 that is strongly associated with glioma across multiple dog breeds, with subsequent mapping of the region revealing single nucleotide variants in three neighboring genes *DENR, CAMKK2,* and *P2RX7* that are highly associated with glioma susceptibility.[23] The *CAMKK2* and *P2RX7* genes have been previously recognized as relevant to the development or progression of human cancers.[23]

Cats

Intracranial tumors are less common in cats compared with dogs. Approximately 70% of all feline intracranial tumors are PBTs and more than 50% of PBTs in cats are meningiomas.[3,6,15] Other types of PBTs, such as ependymomas, gliomas, and choroid plexus tumors, are infrequently reported (see Table 31.1).[3,6,15] The most common SBTs in cats are lymphoma and pituitary tumors, which accounted for nearly 50% and 30%, respectively, of all feline SBTs in one study.[3] The median age at diagnosis of cats with meningioma is 11 years, whereas neuroepithelial tumors and lymphoma are typically seen in cats in the 7- to 8-year age range.[3,24] There are no known breed or sex predilections for cats to develop brain tumors.

Pathophysiology, History, and Clinical Signs

PBTs and SBTs are space-occupying intracranial lesions that cause clinical signs of brain dysfunction by directly compressing or invading brain tissue and indirectly through secondary effects, such as induction of peritumoral edema, neuroinflammation, obstructive

• **Fig. 31.1** MRI and pathologic phenotypes of canine brain tumors causing multifocal intracranial clinical signs. hydrocephalus, and intracranial hemorrhage.[25] In early stages of tumor growth, compensatory autoregulatory mechanisms, such as decreased cerebrospinal fluid (CSF) production and shifting of CSF into the spinal subarachnoid space, are effective at maintaining the intracranial pressure within physiologic ranges. For some slow-growing tumor types, such as meningiomas, intracranial pressure–volume homeostatic regulatory mechanisms can remain surprisingly intact despite large tumor volumes associated with significant mass effect; however, with progressive increases in tumor volume, autoregulatory mechanisms become overwhelmed and intracranial hypertension (ICH) develops. ICH, and the resulting detrimental decrease in cerebral perfusion pressure, is the common pathophysiologic denominator underlying many of the primary and secondary mechanisms of tumor-associated brain injury. Acute clinical deterioration observed in animals with brain tumors and ICH is often the result of vasogenic or interstitial (i.e., obstructive hydrocephalus) brain edema, abnormalities of cerebral blood flow (ischemia or hemorrhage), brain herniations, or combinations of these mechanisms (Figs. 31.1A, B).[25]

A brain tumor should be considered as a differential diagnosis in any middle-aged or older animal with a clinical history consistent with peracute, acute, or chronic brain dysfunction, especially if clinical signs are progressive. In dogs, seizures are the most common clinical manifestation of intracranial neoplasia and occur in approximately 50% of dogs with forebrain tumors.[2,26–28] The index of suspicion for a brain tumor should increase in dogs that experience a new onset of seizure activity after 5 years of age, especially in at-risk breeds.[26] Significant risk factors for tumor-associated structural epilepsy based on magnetic resonance imaging (MRI) diagnosis include the presence of tumor involving the frontal lobe, falcine or subtentorial brain herniations, and marked contrast enhancement of the tumor.[28] In cats, the overall incidence of tumor-associated epilepsy is lower than dogs, with approximately 25% of cats with brain tumors experiencing seizures.[3,24,29] In one study, seizures were more common in cats with glioma (27%) and lymphoma (26%) than meningioma (15%).[24] Behavioral changes are the most frequently reported clinical sign associated with feline brain tumors, being observed in 16% to 67% of cats.[3,29] Central vestibular dysfunction is the most common clinical manifestation of brain tumors affecting the brainstem.[26,30] Nonspecific complaints (e.g., lethargy, inappetance) were identified in more than 20% of cats with brain tumors and are frequently reported in dogs with pituitary tumors.[3,31]

Tumors involving forebrain structures are more common than those in the brainstem.[1–3,30] In many cases with solitary masses, observed neurologic deficits are reflective of the focal neuroanatomic area involved. However, dogs and cats may present with neurologic deficits indicative of multifocal intracranial disease (see Fig. 31.1).

In 50% of dogs with solitary PBTs, multifocal signs result from the tumor or its secondary effects involving multiple region of the brains.[2] The phenotype of some PBTs, such as butterfly glioblastomas, by definition requires tumor invasion of both cerebral hemispheres.[32] Multiple tumors may also be present, which occurs occasionally in canine meningiomas, but is seen in approximately 20% of cats with meningiomas.[3,33,34] Canine oligodendrogliomas can manifest with multifocal or diffuse leptomeningeal involvement.[35] Rare case reports describing synchronous PBTs of different histologies and synchronous PBTs and SBTs also exist.[36]

VetBooks.ir

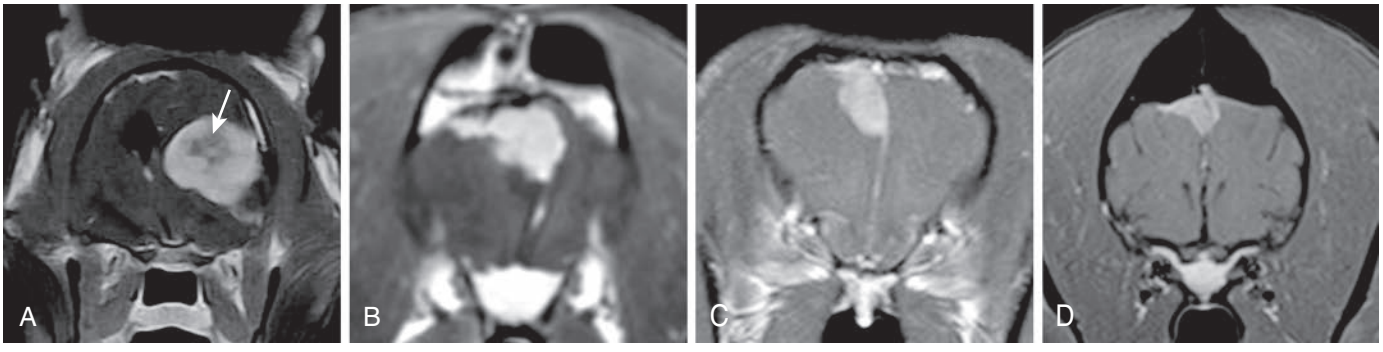
Choroid plexus carcinomas may metastasize within the CNS by a unique mechanism termed *drop metastases* in which cancer cells are exfoliated into the subarachnoid space or ventricular system with eventual distant implantation of tumor foci.[37] Finally, SBTs that spread hematogenously often result in multiple metastases within the brain (see Fig. 31.1).[4]

Diagnosis of Intracranial Tumors

The index of suspicion for a brain tumor as a potential etiology for the observed clinical signs is based upon signalment, history, and neurologic examination findings. In addition to brain tumors, differential diagnoses in dogs and cats with focal intracranial disease include anomalies/malformations, infectious or immune-mediated meningoencephalitis, traumatic brain injury, and stroke. For those animals with a multifocal or diffuse localization, metabolic disorders, neurodegenerative diseases, and meningoencephalitides should be considered. A logical and prioritized diagnostic approach to patients with suspected brain tumors is indicated.

Minimum Database

Laboratory evaluation of health status (complete blood count, serum biochemistry, urinalysis) is important, as anesthesia is recommended for diagnosis of structural brain disease. The at-risk population of middle-aged to older animals with brain tumors may also have significant concurrent disease that affects management.[2,38]



Thoracic radiographs and an abdominal ultrasound (AUS) should be considered in an attempt to identify concurrent unrelated neoplasia or other significant comorbidities. Studies have reported contemporaneous and unrelated neoplasms in 3% to 23% of dogs with PBTs, the majority of which involved the thoracic or abdominal cavities.[2,39] Recent studies have shown that although abnormalities are frequently identified on thoracic radiographs and AUS in dogs with PBT, the results of these procedures uncommonly (1.3%) negatively affected the decision to pursue advanced neurodiagnostics indicated for the neurologic condition of the patient, and significantly altered therapeutic recommendations for the brain tumor in 8.0% of cases.[38,39] For clinically stable patients with a suspected brain tumor and unremarkable general physical examination, the authors do not routinely perform screening radiographs or AUS before MRI, but do recommend these procedures before brain tumor treatment.

Diagnostic Imaging

Computed tomography (CT) and MRI have revolutionized the antemortem clinical diagnosis and management of brain tumors in veterinary medicine.[40–43] MRI is the preferred modality for the evaluation of intracranial disease. Information obtained from imaging such as tumor number, origin within the neuraxis (extra-axial, intraaxia, or intraventricular) and intrinsic signal appearances, often collectively provides characteristic patterns that allow for the presumptive diagnosis of the most frequently encountered PBTs and SBTs. In one investigation, the accuracy of predicting the type of PBT based on MR images of was 70%.[40]

Meningiomas (Fig. 31.2 and see Figs. 31.1A, C) are the most common extraaxial origin tumors in dogs and cats.[3,33–34] Meningiomas typically have a broad-based skull attachment, have distinct tumor margins, and demonstrate marked and often uniform contrast enhancement (see Fig. 31.2). Some meningiomas will also display intratumoral fluid (see Fig. 31.2A), large cystic regions, intratumoral mineralization, calvarial hyperostosis, or a dural tail sign (see Fig. 31.2). Calvarial hyperostosis can result from tumor-induced reactive osseous changes or tumor invasion into bone.[3,44] The dural tail sign is a contrast-enhancing, linear thickening of the dura mater extending from an adjacent extraaxial mass and is not specific for meningioma (see Fig. 31.2) or for neoplastic diseases in general.[45,46] Peritumoral edema is observed in more than 90% of canine meningiomas (see Fig. 31.1A).[20,40,41] In canine studies, reported sensitivities of MRI to correctly identify intracranial meningiomas range between 60% and 100%,[20,40,47] but specific grades and subtypes cannot be distinguished.[20] The MRI sensitivity for meningiomas has been estimated to be 96% in cats.[48] The imaging features of HS, granular cell tumors, and hemangioblastomas share similarities with those of meningiomas (see Fig. 31.2).[41,42,49]

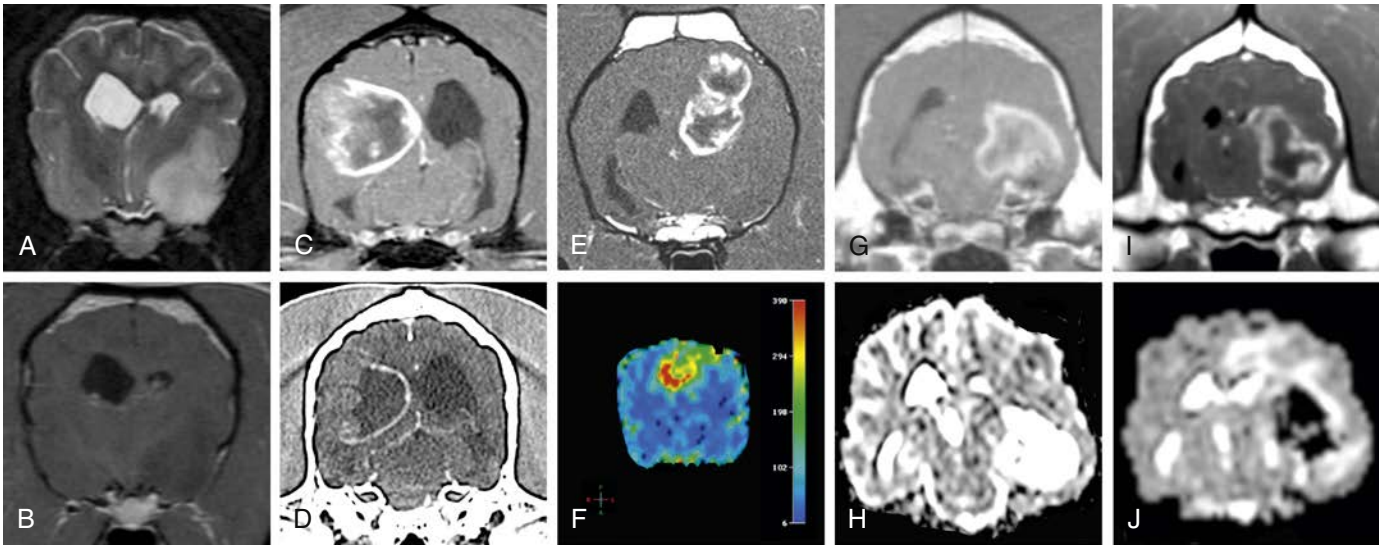
As gliomas originate within and may infiltrate and displace the neuropil, they often appear poorly marginated and may or may not demonstrate contrast enhancement.[40–42,50] Among contrast-enhancing gliomas, the patterns and degree of enhancement seen can be highly variable. A "ring enhancing" pattern, in which a circular ring of contrast enhancement surrounds nonenhancing abnormal tissue, is often associated with gliomas (Fig. 31.3). However, ring enhancement is a nonspecific finding that has been associated with neoplastic, vascular, and inflammatory brain diseases.[51] Currently, using conventional CT or MRI sequences, it is not possible to reliably differentiate types of gliomas (astrocytomas from oligodendrogliomas) or accurately predict the grade of gliomas.[40,50] The considerable overlap that exists in the imaging

• **Fig. 31.2** Postcontrast magnetic resonance image features of intracranial meningioma and its imaging mimics. (A) Feline meningioma, with intratumoral fluid (*arrow*). (B) Canine histiocytic sarcoma. (C) Canine granular cell tumor. (D) Canine parasagittal meningioma. Each of the canine tumors features a dural tail sign.

features of gliomas, cerebrovascular accidents, and inflammatory lesions results in frequent misdiagnosis of these categories of intraaxial lesions.[52,53] The addition of diffusion-weighted, spectroscopic, and perfusion-weighted imaging sequences (see Fig. 31.3) to conventional MRI sequences has shown promise in improving the ability of MRI to discriminate between neoplastic and nonneoplastic lesions, and differentiation of tumor grades.[54,55]

Choroid plexus tumors (see Fig. 31.1F) and ependymomas are the most common tumors found in an intraventricular location, and both of these tumors types often uniformly contrast enhance.[21,56] Other intraventricular tumors that are occasionally or rarely seen include meningiomas arising from the tela choroidea of the third ventricle, oligodendroglioma, PNET, and central neurocytoma.[2,3] The identification of intraventricular or subarachnoid metastatic tumor implants on MRI studies is a reliable means to clinically discriminate grade III choroid plexus carcinomas (CPC) from grade I papillomas (CPP).

Finally, although MRI is sensitive for the detection of intracranial neoplasms, a normal MRI does not rule out a brain tumor. Lymphomatosis and gliomatosis cerebri are notable for their propensity to be occult on imaging studies of the brain.



Tumor Biopsy and Pathology

In practice, it is common to make clinical decisions in patients with presumptively diagnosed tumors based on imaging derived data. However, it is important to recognize the potential consequences that the previously described limitations of imaging can have on individual patients. Histopathologic examination of representative tissue is required for the definitive diagnosis and grading of nervous system tumors. Excisional biopsy performed during curative-intent surgery remains the most frequently employed biopsy technique for PBTs, but these procedures have been historically limited to patients with superficially located, extraaxial forebrain or cerebellar tumors. In cases in which surgical resection may not be a possible or optimal, minimally invasive brain biopsy (MIBB) techniques are a viable alternative.

Several MIBB techniques have been used in dogs and cats with brain tumors including endoscopic-assisted, free-hand, and image-guided procedures.[56–58] When MIBB is performed in animals with brain tumors by operators experienced with contemporary CT and MRI stereotactic systems, diagnostic yields approach 95%, and serious adverse events occur in approximately 5% of cases.[8,58] The histologic classification and grading of anaplastic CNS tumors can be challenging when evaluating the limited sample sizes associated with MIBB, but often can be facilitated with additional immunohistochemical evaluation of tumors.[59,60]

Not surprisingly, as intracranial tumors are more common in dogs, a wider variety of histologic types and subtypes have been described in dogs compared with cats. There are multiple histologic subtypes of grade I meningiomas including angiomatous, meningothelial, transitional, fibroblastic, psammomatous, microcystic, and papillary variants. Meningothelial, transitional, and psammomatous subtypes of meningiomas are the most common in both species.[20,29] The majority of feline meningiomas are grade I tumors.[29] Atypical (grade II) meningiomas account for a significantly higher proportion (40%) of meningiomas in dogs.[20] In addition, all grades of canine meningiomas can display invasion into the neural parenchyma, a mechanism that may contribute to therapeutic failure.[20] Anaplastic (grade III) meningiomas are rare in humans, dogs and cats, and account for about 1% of all canine and feline meningiomas.[20]

The histopathologic features of canine gliomas are remarkably similar to what is seen in humans.[60–64] Their propensity to locally or distantly infiltrate brain tissue contributes to their malignant clinical behavior.[32,60–64] A diverse spectrum of types and grades of astrocytomas, oligodendrogliomas, and oligoastrocytomas that occur in people have been documented in dogs. However, the frequency of glioma types encountered in dogs differs from

• **Fig. 31.3** Comparative magnetic resonance image (MRI) features of canine gliomas and other ring enhancing lesions. Top panels are all transverse, T1-weighted postcontrast images. VetBooks.ir

that seen in humans, with oligodendrogliomas accounting for a significantly higher proportion of all canine gliomas.[1,2,64] Insufficient data currently exist in veterinary medicine to evaluate the effect of glioma grade on clinical outcome.[5] Intracranial gliomas are rare in cats, and oligodendrogliomas are the most common type observed.[3,65,66]

In the dog, approximately 40% of CPTs are grade I CPP, 60% are grade III CPC, and nearly 50% of CPTs occur in the fourth ventricular region.[21] Atypical (grade II) choroid plexus papillomas have not yet been recognized in veterinary medicine.[5,21] The morphology of CPTs usually allows for rapid and accurate cytologic diagnosis of tumor type when performed on surgical or MIBB specimens.[21] In dogs and humans, CPCs frequently demonstrate local invasion and commonly metastasize via the ventricular system.[21]

Although the genetic and epigenetic studies performed to date in canine brain tumors have identified similarities in molecular signatures, differentially expressed genes, and methylation profiles in developmentally regulated genes between human and canine tumors, these studies were performed with fairly limited microarray platforms.[8,10,67–74] It is likely that additional common denominators are shared among canine and human tumors and will be discovered with the use of more robust whole exome sequencing and single nucleotide polymorphism analytical systems.[23] It is also probable that aberrations in key pathways unique to the dog will continue to be revealed.[10]

Cerebrospinal Fluid Analysis

CSF analysis provides data that are complementary to clinical examination and diagnostic imaging results, and helps the clinician refine the list of differential diagnosis. Obtaining CSF when ICH is present carries a risk of causing clinical deterioration. Although this risk is low, it should be critically assessed in each patient and evaluated in context of the likelihood of obtaining a nonspecific test result. Advanced imaging of the brain should always precede CSF collection to best evaluate patient risk.

Although CSF is a sensitive indicator of intracranial disease and is frequently abnormal in patients with brain tumors, white blood cell (WBC) counts, WBC differentials, and total protein concentrations are highly variable and are often nonspecific for neoplasia.[75,76] In one study of CPTs, CSF analysis was helpful for the differentiation of CPCs from CPPs, as observation of a CSF total protein concentration greater than 80 mg/dL was exclusively associated with a diagnosis of CPC.[21] Exfoliated neoplastic cells may be observed in the CSF cytology of patients with any type of brain tumor, but choroid plexus tumors, lymphoma, HS, and cats with caudal brainstem oligodendrogliomas have been the most frequently reported.[2,21,65,77]

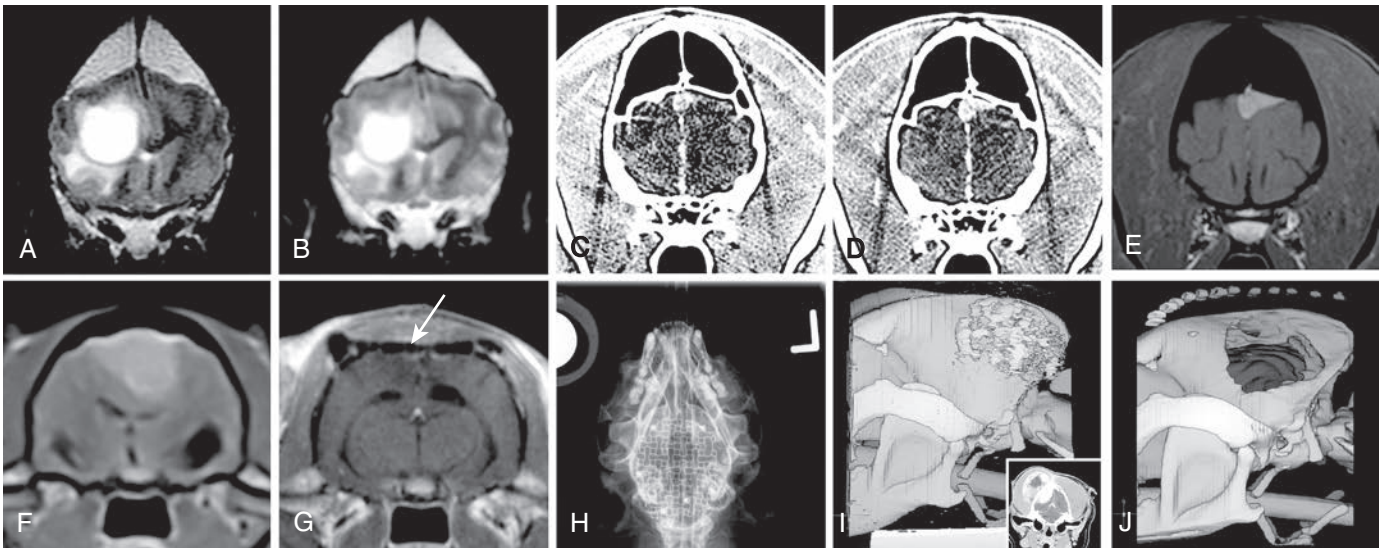
Treatment and Prognosis of Intracranial Tumors

Many veterinary studies regarding the treatment of brain tumors are limited by the inclusion of presumptively diagnosed cases, variable survival definitions and end-points, lack of inclusion or reporting of objective imaging-based criteria of therapeutic response or other unbiased quantitative follow-up metrics, retrospective study designs, and small case numbers[7,9,78] Thus there currently exists a significant void in the literature with respect to meaningful data regarding tumor type-specific therapeutic outcomes for many PBTs, as well as a lack of large and rigorously designed trials comparing treatment modalities.

Palliative Care

The primary palliative therapies administered to brain tumor patients are anticonvulsant drugs (ACD) for tumor-associated structural epilepsy, corticosteroids targeting peritumoral vasogenic edema, and analgesics for signs consistent with somatic, visceral, or neuropathic cancer pain.[7,9,30] Although seizures are one of the most common clinical signs associated with brain tumors, ideal ACD protocols for the treatment of tumor-associated epilepsy are currently unknown.[2,24,27,28] Phenobarbital, levetiracetam, and zonisamide are popular clinical ACD monotherapy choices.[24,28,30] Multidrug ACD protocols are frequently needed to control refractory seizures in brain tumor patients, and the aggressiveness and diligence of the approach to seizure management is often as important to the therapeutic outcome as the tumor response to other treatment modalities.[30]

Animals that have peritumoral vasogenic edema on MRI are more likely to respond favorably to corticosteroid treatment (Figs. 31.4A, B and see Fig. 31.1A) however, animals without significant vasogenic edema may benefit also from the antiinflammatory and euphoric effects of corticosteroids; corticosteroid therapy alone may also transiently reduce the tumor burden in some cases (see Figs. 31.4A, B) or provide modest benefit to animals with tumors causing secondary obstructive hydrocephalus.[7] Polyuria, polydipsia, polyphagia, and sedation are commonly anticipated and reported adverse effects of palliative treatment, but palliative therapies are rarely associated with significant treatment-associated morbidity that necessitates discontinuation of therapy.[9,30,78]



Pain associated with nervous system tumors can arise from compression or stretching of the meninges, nerve roots, or vasculature, tumor-associated meningitis, neuritis, or radiculitis, and tumor infiltration of the periosteum or musculature.[44] Hyperesthesia of the head or neck is frequently observed in dogs with brain tumors, being reported in 12% of dogs with PBTs in one study.[2] Clinical signs consistent with pain often respond to corticosteroid treatment, and additional opioid or neuropathic pain agents can be added if necessary.

Studies published to date indicate that 6% and up to 19% of canine and feline meningiomas, respectively, are identified incidentally.[2,3] Given the increasing clinical usage of serial cross-sectional imaging techniques to manage numerous diseases in veterinary medicine, it is likely that the frequency of identification of incidental brain tumors will increase. Thus objective observation (e.g., watchful monitoring) also represents a reasonable approach to the management of some small and asymptomatic brain tumors (see Figs. 31.4C–E). Further elucidation of the natural disease history for specific brain tumors will be paramount to identifying optimal indications for watchful monitoring, as well as recommended observation intervals and protocols.

Currently, there is no robust information regarding survival associated with palliative care of specific PBT types or grades. Pooled data indicates a median survival time (MST) after palliative care of PBT of approximately 9 weeks, with a range of 1 to 13 weeks.[3,7,9,30,79] Dogs with supratentorial tumors treated palliatively have a better prognosis (MST 25 weeks) than those with infratentorial tumors (MST 4 weeks).[30] The prognosis associated with palliative care of pituitary tumors is more favorable than PBTs, with a MST of 51 weeks reported in one study.[80]

Chemotherapy

Data evaluating the efficacy of chemotherapy for the management of brain tumors is limited by the lack of histologic tumor diagnoses in the vast majority of reported cases, and the preponderance

• **Fig. 31.4** Serial imaging of brain tumors treated with different approaches. (A, B) Grade III oligodendroglioma in the right frontal lobe associated with perilesional vasogenic edema. Compared with the pretreatment (A) image there is improvement in the edema and a decrease in the size of the mass after 3 days of dexamethasone therapy (B). Sequential CT (C, D) and magnetic resonance imaging (E) examinations of an incidental meningioma managed with annual watchful monitoring. There is minimal enlargement of the mass over the depicted 3-year period. Feline parasagittal meningioma with calvarial hyperostosis (F) treated via bilateral radical rostrotentorial craniectomy and reconstructive titanium mesh cranioplasty (G, *arrow*; H). of case reports or small case series examining specific drugs. The most commonly used chemotherapeutics for brain tumors are the alkylating agents lomustine (CCNU), carmustine (BCNU), and temozolomide (TMZ), or the antimetabolite hydroxyurea, all of which penetrate the blood–brain barrier (BBB).[79–81] A small number of case reports have reported objective tumor responses or survival benefits associated with chemotherapy.[82,83] In general, however, chemotherapy appears to have very limited objective efficacy for the treatment of brain tumors, especially when used as a monotherapy in the setting of gross disease. One retrospective study in 71 dogs with presumptively diagnosed brain tumors reported that CCNU-treated dogs (MST 93 days) experienced no survival benefit compared with dogs receiving palliative therapy (MST 60 days).[79] No difference in survival was reported between groups of dogs with predominantly presumptively diagnosed gliomas treated with stereotactic volume modulated arc radiotherapy (VMAT) with (MST 420 days) or without (MST 383 days) TMZ.[81] At the dose intensities reported in the literature, toxicities associated with CCNU, TMZ, and hydroxyurea appear to be uncommon and rarely life-threatening in companion animals with brain tumors.[79,81]

In vitro studies have demonstrated that therapeutic responses to chemotherapeutic agents (such as bleomycin, carboplatin, CCNU, irinotecan, and TMZ), as well as mechanisms of chemoresistance observed in canine glioma cell lines, parallel those seen in human glioma cell lines.[70] Thus it is reasonable to expect that the inclusion of adjuvant chemotherapy in multimodality companion animal brain tumor treatment protocols could result in modest clinical benefits, as is generally seen in humans. Metronomic chemotherapy with chlorambucil in conjunction with surgical resection is currently being evaluated in an early phase trial in dogs with gliomas.[84] The creation of animal patient-derived tumor cell lines will be paramount to efforts necessary to develop and evaluate brain tumor-specific drug protocols, such as high-throughput drug library screening and the identification of biomarkers that predict chemoresponsiveness.

Surgery

Advantages associated with surgical resection of brain tumors include the rapid reduction or elimination of the tumor burden, the secondary beneficial effect this has on reducing intracranial pressure, and definitive histopathologic diagnosis of the tumor. Several variables complicate critical comparisons of studies evaluating the efficacy surgical treatment of specific tumor types including the experience of the surgeon, availability or standardized protocols for usage of a growing number of operating room technologies, and a nearly universal lack of inclusion of quantifiable surrogates of surgical success, such as the extent of resection (EOR) in PBT studies. Given that attainment of wide excision margins of brain tumors is generally not possible, objective evaluation of EOR is currently dependent on MRI-based assessments, which are associated with practical limitations, including expense and difficulties distinguishing residual tumor from surgically induced reactive changes in the acute postoperative period.[85,86]

Cytoreductive surgery is currently the preferred primary mode of therapy for feline supratentorial meningiomas.[3,29,87,88] Feline supratentoral meningiomas are often located over the cerebral convexities, visibly well demarcated, and are not usually infiltrative into the underlying brain parenchyma. These characteristics make them amenable to gross total resection (see Figs. 31.4F, G) with low procedural mortality, even in instances of large tumor burdens, multiple tumor foci, or recurrent tumor.[34] Reconstruction of extensive cranial surgical defects necessary to remove large tumors can be performed using MRI-compatible materials, including fascial or calvarial autografts, or polymethylmethacrylate or titanium mesh cranioplasties (see Figs. 31.4G, H).[89]

VetBooks.ir

Cats with cerebral meningiomas treated surgically often survive in excess of 2 years, with reported MSTs ranging from 23 to 37 months. [3,29,87,88] Approximately 25% of feline meningiomas will recur after surgery, with highly variable times to recurrence ranging from 3 to 69 months.[87,88]

Outcomes associated with surgical management of canine meningiomas are more variable than those of feline meningiomas, reflective of the previously identified operator and technical factors, in addition to the propensity for all grades of canine meningiomas to locally invade brain tissue.[20] Most surgical studies of canine meningiomas have included superficially located cerebral or cerebellar convexity, falcine, parasagittal, or olfactory tumors.[90–94] Surgical treatment of basilar, cerebellopontomedulary angle, foramen magnum, parasellar, and tentorial meningiomas is technically challenging and has not been frequently reported.[90] When standard cytoreductive surgical techniques are used, the MST for canine meningiomas is approximately 7 months.[91–93] Studies describing the use of techniques or technologies that facilitate removal of infiltrative tumor or intraoperative visualization such as cortical resection, extirpation with an ultrasonic aspirator, or endoscopic assisted resection in canine meningiomas report superior MSTs (16–70 months) compared with conventional surgical methods.[90,94] Dogs with meningiomas treated surgically also benefit from the addition of adjunctive radiation therapy (RT), as MSTs associated with multimodal surgery and RT protocols range from 16 to 30 months.[92,95,96]

There is a paucity of data regarding the potential efficacy of surgery as a primary treatment of other PBTs, such as ependymomas, gliomas, and choroid plexus tumors, although a few individual animals with these tumor types experienced prolonged survival times (STs) after surgery or multimodal investigational therapies.[7,21,84,97] Surgical removal of these tumors is seldom attempted because approaching and removing them is technically demanding due to their intraaxial or intraventricular locations. In addition, as high-grade variants of these tumors are poorly delineated and locally invasive, it is inherently more difficult to discriminate the margins of tumor from the neighboring neuropil. Clinician attitudes and abilities with respect to the resection of these tumors types are evolving in parallel with improvements in brain imaging techniques, intraoperative stereotactic and neuronavigational systems, minimally invasive automated tissue resection devices, and "tumor painting" with fluorophores to assist with delineation of tumors from the surrounding brain.[7,84,97,98] The literature also suggests that the prognosis for some tumor types, such as HS, is poor, irrespective of the types of treatment administered.[99]

Surgery also has utility in the management of some SBTs. Transsphenoidal hypophysectomy is an effective technique for the treatment canine and feline pituitary-dependent hyperadrenocorticism (PDH) and feline acromegaly, producing durable endocrinologic and clinical remissions.[100–102] However, microsurgical hypophysectomy has limited value in cases with pituitary macrotumors, is associated with a steep operator learning curve, and is currently only offered at a few centers worldwide.[101,102] Some calvarial SBTs, such as multilobular osteochondrosarcoma can also be managed surgically with good long-term outcomes depending on histologic grade and completeness of excision (see Figs. 31.4I, J).[103]

The frequency of significant adverse events associated surgical treatment of PBTs varies widely between individual studies, ranging from 6% to 100%.[29,78,84,87,88,90–92,98,104,105] If the outlier study with 100% perioperative mortality is excluded from analysis, the average rate of surgical adverse events is approximately 11%.[104] Common causes of morbidity and early perioperative mortality include aspiration pneumonia, intracranial hemorrhage or infarction, pneumocephalus, medically refractory provoked seizures, transient or permanent neurologic disability, electrolyte and osmotic disturbances, and thermoregulatory dysfunction.[78]

Radiation Therapy

RT is beneficial for the treatment of PBTs and SBTs when used as a sole or adjunctive therapeutic modality. As with other treatments, extrapolating meaningful data from the veterinary brain tumor RT literature with respect to the outcomes associated with specific tumor types in confounded by a general lack of histologically diagnosed tumors included in RT studies, grouping of heterogeneous intracranial masses in data analyses, and considerable variability in the RT types and dose prescriptions used. RT equipment and techniques have advanced to current predominantly linear accelerator-based options, including intensity-modulated RT (IMRT) capabilities such as VMAT and tomotherapy, as well as stereotactic RT (SRT).[81] The advantages of IMRT, VMAT, and SRT are improved target volume conformity, particularly in volumes with complex shapes, and improved sparing of normal tissues resulting in reduced risk for toxicities.[81] SRT broadly encompasses treatments that involve the precision delivery of high doses of ionizing radiation to a stereotactically defined anatomic target in a limited number (1–5) of fractions, compared with the 16 to 20 fractions for standard RT protocols.[9]

Studies of cohorts of dogs treated with RT as a sole treatment modality for brain tumors report MSTs ranging from 7 to 23 months when all treated intracranial masses are included.[81,96,106–111] MSTs associated with RT treatment of extraaxial masses, the majority of which were presumptively diagnosed meningiomas, range from 9 to 19 months; and MSTs reported for intraaxial masses ranges from 9 to 13 months.[78, 81,96,106–111] Some RT studies report that extraaxial tumors have a more favorable prognosis than intraaxial tumors.[110] Given the variable outcomes associated with both RT and surgery, there is currently no clearly superior choice between these two modalities when either is used a sole treatment for canine meningiomas.[78]

RT is also useful for the adjunctive therapy of canine meningiomas, with combined surgical and RT therapy producing MSTs of 16 to 30 months.[92,95,96] Selected biomarkers have been shown to have prognostic value in dogs with meningiomas treated with surgery and RT. In one study of 17 dogs treated with surgery and adjunctive hypofractionated RT, survival was negatively correlated with VEGF expression.[8] The MST was 25 months for dogs with tumors with 75% or fewer cells demonstrating immunoreactivity to VEGF compared with 15 months for dogs with tumors with greater than 75% of cell staining for VEGF, and dogs with tumors demonstrating more intense VEGF immunoreactivity also had a significantly shorter MST.[112] Progesterone receptor expression has also been shown to be inversely related to the tumor proliferative index (PF_{PCNA} index), which was predictive of survival in dogs with meningiomas after surgery and postoperative RT. The 2-year progression-free survival rate was 42% for tumors with a PF_{PCNA} index 24% or greater and 91% for tumors with a PF_{PCNA} index less than 24%.[95]

Compared with palliative therapy, RT is effective at reducing tumor size, improving neurologic signs, and providing a survival benefit in dogs and cats with pituitary tumors.[80,108,113–117] RT is the preferred therapeutic modality for pituitary macrotumors.[80,115] In cases of PDH treated with RT, the reported rates of endocrinologic remission are variable, with some studies reporting

VetBooks.ir

persistent hypercortisolinemia for up to a year after RT.[80,113,116] Thus continued medical management and serial endocrinologic evaluations are necessary after RT of PDH. Negative prognostic indicators associated with RT for pituitary masses include severe neurologic dysfunction at presentation and large relative tumor size.[80,115]

SRT is actively being investigated for the treatment of multiple types of brain tumors. SRT offers the distinct advantage of a reduced number of anesthetic episodes required for treatment. However, SRT is associated with limitations as to the size of masses that can be treated (likely several centimeters) and it is not suitable for treating residual microscopic disease after surgery.[9] Preliminary data suggest that SRT results in tumor control that is comparable to standard fractionated RT protocols with potentially fewer short-term adverse effects and, in the case of pituitary tumors, provide results that are similar to those of hypophysectomy.[111,115–117]

Approximately 10% of brain tumor cases treated with RT will experience treatment-related mortality or adverse effects.[78] Frequently reported adverse effects include aspiration pneumonia, pulmonary thromboembolism, acute CNS toxicity which often manifests as a decreased level of consciousness, damage to organs in the treatment field including deafness, cataract formation, and keratitis, and late-onset radiation necrosis.[78] Important radiobiologic considerations when treating brain tumors include the radiation dose per fraction, total radiation dose, and the volume of the brain irradiated. In one study of hypofractionated RT, delivery of a high dose per fraction resulted in the death of nearly of 15% of treated dogs because of suspected delayed radiation side effects.[110] Although significant adverse events associated with SRT have been uncommonly reported in animals to date, the more frequent use of high-dose per fraction prescriptions may eventually influence the incidence of observed toxicity.

Novel Therapeutics

The identification and use of novel animal models that allow for the study of fundamental cancer drug and device development questions would meet a critical and shared need among stakeholders in the cancer research and global healthcare communities. A growing body of evidence indicates that canine brain tumors are clinically, phenotypically, and molecularly similar to their human analogs, thus providing unique avenues for preclinical discovery.[7,9,10,118] Translational studies of investigational agents in tumor-bearing dogs can provide a variety of pharmacokinetic, mechanistic, toxicity, and antitumor activity data in an immunocompetent host, and thus offer numerous opportunities to guide the therapeutic development process to mutually improve the lives of dogs and humans with brain tumors.[118]

The repertoire of agents and techniques that are being investigated in canine brain tumors is rapidly expanding. General areas that capture the efforts of active veterinary neuro-oncology research programs can be summarized into (1) macroscopic tumor targeting or CNS delivery techniques, (2) novel molecular therapeutics targeting tumor-specific markers or aberrant cellular pathways, (3) immunotherapy, and (4) modifications of the dosing or chemistry of existing therapeutics based on new mechanistic discoveries. Reviews of early-phase trials evaluating these approaches in dogs with brain tumors are available.[7,9,119]

The objectives of macroscopic tumor targeting techniques are to facilitate the gross surgical resection of tumors or to overcome therapeutic drug delivery limitations imposed by the BBB. The use of intraoperative microsurgical or stereotactic equipment and neuronavigational systems with various tissue resection devices and techniques are being actively investigated for the surgical biopsy and treatment of canine brain tumors.[7,9,58,84] The safety and feasibility of brain tumor ablation techniques using lasers and pulsed electrical fields have also been demonstrated in canine gliomas.[119] Technologies capable of focally disrupting the BBB to allow for CNS drug delivery, such as transcranial focused ultrasound and irreversible electroporation, are also being used to treat canine brain tumors.[119]

Approaches that bypass the BBB and allow for direct intratumoral delivery of therapeutically relevant concentrations of macromolecular drugs, such as convection-enhanced delivery (CED) of chemotherapeutics and implantation of various biodegradable nanomaterial drug carriers, have also been investigated in dogs. CED of nonselective chemotherapy drugs, such as liposomal CPT-11, and novel agents targeting the overexpression of cell surface EGFR (EGFRvIII-antibody bioconjugated nanoparticles), EphA2, and IL-13RA2 (recombinant bacterial cytotoxins) receptors that occur in canine and human gliomas, have been performed in dogs with glioma.[7,9,67,119–121] These studies have illustrated the safety of the CED procedure and have provided preliminary evidence of efficacy of these investigational agents.

There is a considerable library of targeted agents being develop for and tested in canine brain tumors, and these agents encompass a wide variety of mechanistic approaches including protease-conjugated oncolytic viruses, immunomodulatory microRNAs or small interfering RNAs, immune-checkpoint inhibitors, apoptosis promoters, radiosensitizing agents, and nanoparticular cytotoxic drugs. These compounds have shown promising antitumor effects in vitro or in vivo against non-CNS tumors, the ability to penetrate the BBB when administered systemically, or favorable safety and pharmacokinetic profiles in healthy dogs, and are currently in early phase trials in dogs with tumors.[7,9,122,123] In a proof-of-concept trial, bacterially derived minicells were packaged with doxorubicin, targeted to EGFR using bispecific antibodies to EFGR, and administered intravenously to dogs with brain tumors. Durable and objective tumor responses were seen in 24% of dogs and no significant toxicities were observed.[123]

There has been a paradigm shift away from the brain being considered an immune-privileged organ unfavorable to immunotherapeutic (IT) interventions toward an elucidation and exploitation of the unique mechanisms that characterize immunocompetency and tumor–host interactions within the brain. A diverse array of IT strategies, whose unifying goal is to introduce, stimulate, or otherwise augment the patient's T-cell–mediated immune response against cancer cells, are being explored for use in the treatment of companion animal brain tumors.[7,9,] IT approaches that involve tumor vaccinations with stimulated patient-derived dendritic cells and autologous tumor lysates combined with toll-like receptor ligands have demonstrated the safety, feasibility, and potential efficacy of IT for use in canine glioma and meningioma.[7,9,93,97]

Recent studies have provided data that indicates that novel repurposing approaches using existing drugs are capable of achieving intratumoral drug concentrations that may result in favorable therapeutic and adverse effects profiles compared with traditionally administered doses or other chemotherapy agents with the same mechanism of action.[84] An in vitro study of benzimidazole anthelmintics in canine glioma cell line demonstrated that drug treatment increased depolymerization of tubulin and increased tumor cell apoptosis compared with the controls.[124]

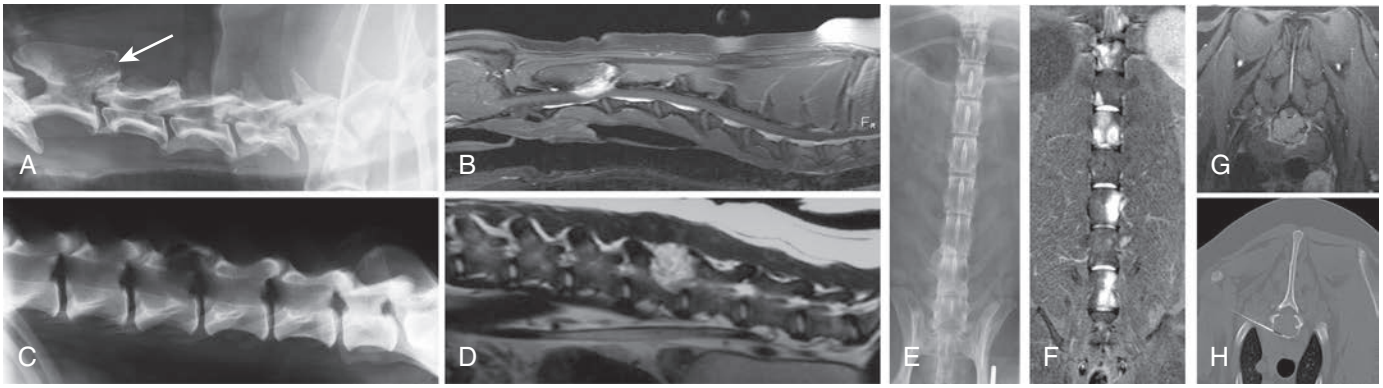
Tumors of the Spinal Cord

Classification and Epidemiology

As with brain tumors, SC neoplasms are classified as primary or secondary according to their tissue of origin. However, a classification scheme based on the tumor location relative to the neuraxis (Table 31.2) is the most commonly used method of clinical classification of tumors affecting the SC in veterinary medicine. The overall incidence in dogs and cats is unknown, but SC tumors appear to be less common than intracranial neoplasms.

Extradural tumors account for approximately 50% of all tumors affecting the SC and frequently arise from the vertebrae. Vertebral tumors such as osteosarcoma (OSA), chondrosarcoma (CSA), plasma cell tumors, fibrosarcoma (FSA), and HSA are commonly encountered extradural tumors (Fig. 31.5; see Table 31.2)[125–133] Intradural-extramedullary (ID-EM) tumors account for 35% of all tumors, and meningiomas are the most common ID-EM tumor (Fig. 31.6) and also the most common primary spinal cord tumor diagnosed in dogs and cats.[125,126,131] Approximately 15% of spinal cord neoplasms are intramedullary (IM), although up to one-third of tumors may involve multiple compartments.[125–127,134,135] In dogs, ependymomas and gliomas are the most frequently diagnosed primary IM tumors, and HSA and transitional cell carcinoma are the most common secondary IM tumors.[135]

In dogs and cats, CNS lymphoma may affect any or all compartments of the SC and may occur as a primary or secondary tumor.[77,136–139] Lymphoma is the second most prevalent SC disease of cats and the most common feline SC tumor, although 85% of cases of SC lymphoma in cats are secondary and part of a multicentric process.[137–139] Older studies report that 80% to 90% of cats with CNS lymphoma were seropositive for FeLV p27 antigen; a more recent reported indicated that only 56% of cats with CNS lymphoma were infected with FeLV.[138,140] This may reflect the decreasing overall prevalence of feline retroviral infections attributable to vaccination and improved management practices, or infer the importance of other factors that contribute to development of CNS lymphomas.[141] Cats with lymphoma are typically younger (median 4 years) at diagnosis than cats with other tumor types affecting the SC (median 9 years).[138]



Large-breed, older dogs are predisposed to the development of vertebral tumors.[129,130] SC tumors such as ependymomas and nephroblastomas are more commonly seen in dogs less than 6 years old.[142,143] Young German shepherd dogs and golden retrievers (<3 years of age) are predisposed to nephroblastoma.[142,143] Boxer dogs were overrepresented in one study of intraspinal meningiomas, and both boxers and other brachycephalic breeds are predisposed to tumors of glial origin.[131,134]

TABLE 31.2 Clinical Classification and Examples of Tumors Affecting the Spinal Cord

Anatomic Location Relative to Spinal Cord		
Extradural	*Intradural-Extramedullary*	*Intramedullary*
Osteosarcoma	Meningioma	Astrocytoma
Chondrosarcoma	Peripheral nerve sheath tumor	Ependymoma
Fibrosarcoma	Nephroblastoma	Oligodendroglioma
Plasmacytoma	Histiocytic sarcoma	Gliomatosis cerebri
Multiple myeloma	Lymphoma	Hemangiosarcoma
Lymphoma		Transitional cell carcinoma
Hemangiosarcoma		Lymphmoma
Various carcinomas		

Pathophysiology, History, and Clinical Signs

Dogs and cats with SC tumors commonly present for progressive myelopathic signs reflecting the neuroanatomic location of the tumor with or without evidence of pain. Tumors in ED or ID-EM locations cause clinical signs of neurologic dysfunction, mainly by compression of the spinal cord or nerve roots by the neoplasm (see Fig. 31.6). IM tumors may cause signs of spinal cord disease by compression, invasion, or destruction of the SC parenchyma, as well as by obstructing CSF flow and inducing

• **Fig. 31.5** Imaging features of extradural vertebral tumors. Lytic and sclerotic lesion in the C2 spinous process (A, *arrow*) and corresponding postcontrast MRI (B) illustrating spinal cord compression from a plasmacytoma. Radiographic lysis in the L4 lamina and pedicle (C), and corresponding sagittal MRI (D) demonstrating chondrosarcoma. VetBooks.ir

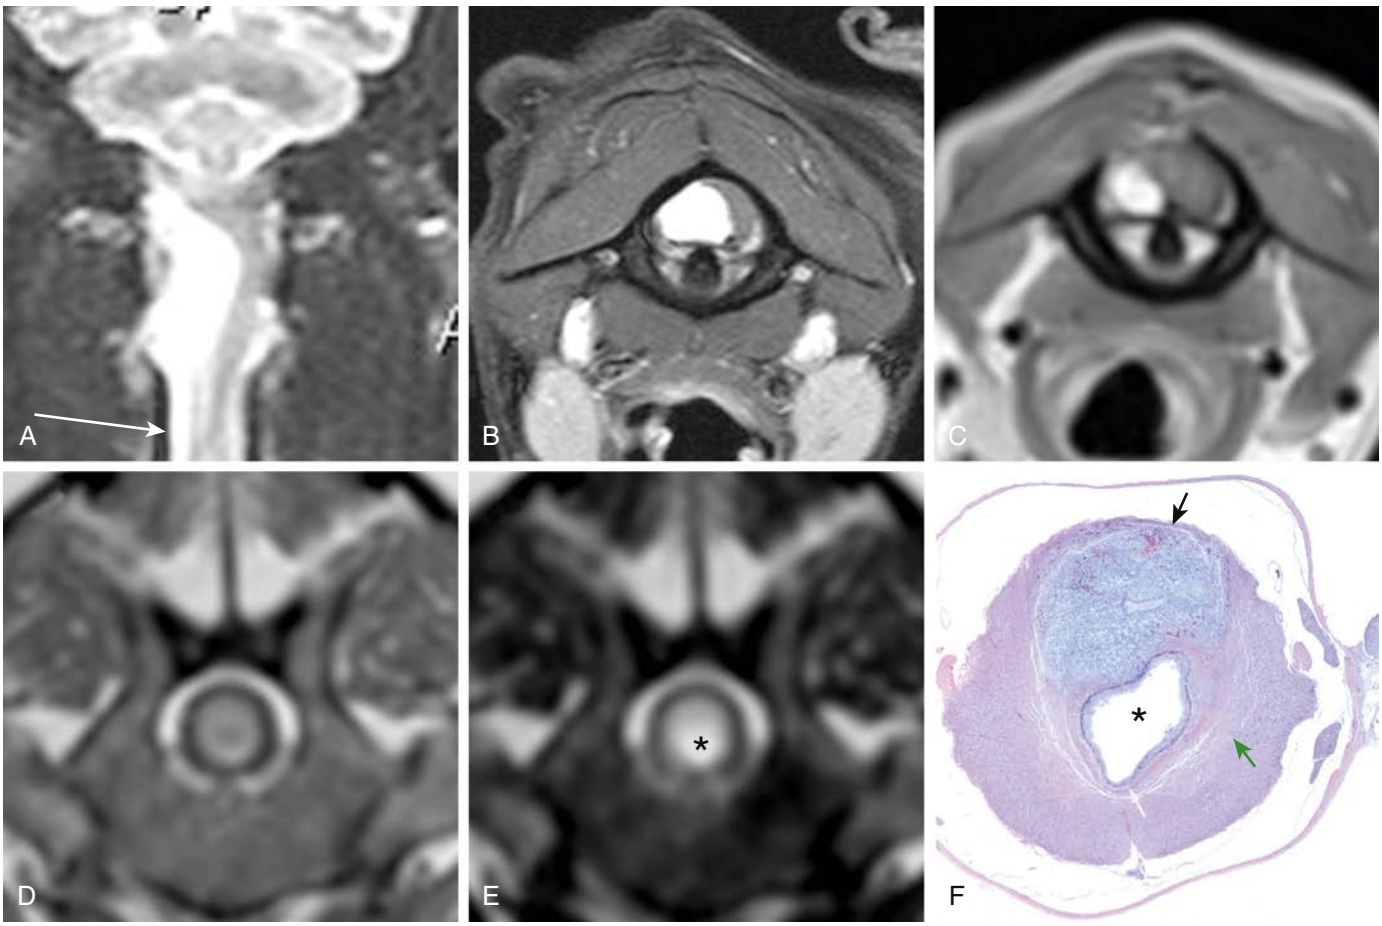
syringomyelic syndrome (see Fig. 31.6).[135] All types of SC tumors can cause numerous secondary changes within the SC including edema, inflammation, gliosis, and hemorrhage. Signs of paraspinal hyperesthesia arise from compression, stretching, inflammation, or invasion of the meninges, nerve roots, periosteum, or paraspinal musculature. Early reports have described IM tumors as nonpainful because of lack of nociceptors in the parenchyma[126,144]; however, in one study that specifically reported on the prevalence of paraspinal hyperpathia, 68% of all dogs with IM tumors displayed paraspinal hyperpathia.[135] Development of hyperpathia in association with IM tumors may be a result of altered neurotransmitter modulation association with destruction of the dorsal horn of the gray matter known as syringomyelic syndrome (see Fig. 31.6D–F).[135] Another theory postulates that intramedullary mass expansion may lead to stretching of meninges and stimulation of nociceptive pathways.

Primary IM tumors have a protracted clinical course compared with metastatic IM neoplasms.[135] Acute decompensation can occur because of pathologic fracture of neoplastic vertebra, hemorrhage in or around the tumor or SC, or necrosis of the tumor itself. Clinical signs of SC disease, rather than primary organ dysfunction, is a frequent chief complaint for animals with secondary SC tumors, occurring in up to 44% of dogs with metastatic tumors.[135,140]



Diagnosis of Spinal Cord Tumors

The minimum database for a patient with a suspected SC neoplasm is identical to that for a brain tumor patient. Although these laboratory tests will seldom provide a definitive answer regarding the etiology of SC neoplasia, they can provide valuable information with respect to hematologic abnormalities, paraneoplastic syndromes, and primary organ dysfunction that is often detected in patients with metastatic cancers such as lymphoma and multiple myeloma.[132,145]

Diagnostic Imaging

Survey radiographs may identify primary vertebral body tumors (see Fig. 31.5A, E), pathologic fractures, osseous metastases, as well as evidence of concurrent malignancy or disease, but are frequently normal (see Fig. 31.5C).[135,145] In cats, radiographically apparent lytic lesions are seen more commonly in nonlymphoid neoplasms.[133,138]

As with brain tumors, MRI is the modality of choice for the evaluation of SC tumors.[130–131,135,146,147] However, CT myelography can be helpful for determination of the longitudinal and axial location of many neoplastic lesions.[147] Irrespective of the imaging modality used, in some cases it can be difficult to distinguish ID-EM from IM origin masses.[146] Similar to what is observed with

VetBooks.ir

intracranial tumors, the commonly encountered vertebral and SC tumors often display characteristic MRI features that allow for presumptive diagnosis, but definitive diagnosis can only be obtained with histopathology, as there exists considerable overlap in the MRI features of specific tumor types with other neoplasms and nonneoplastic lesions.[130,131,135,146,147] Meningiomas usually appear as focal ID-EM masses, often strongly enhancing on postcontrast MRI sequences, and frequently demonstrate a dural tail (see Figs. 31.6A, B).[131] Although spinal lymphoma is commonly described as an extradural mass lesion, especially in cats, it is very often a mixed compartment neoplasm in dogs and involves extraneural tissues in both species.[77,136–139] Plasma cell tumors and lymphoma both cause osteolysis, though the latter typically spares the cortex.[148] Short tau inversion recovery (STIR) MR sequences have been reported to have the most utility for the detection of vertebral (see Figs. 31.5D, 31.6A) or SC tumors involving multiple compartments.[148]

Tumor Biopsy and Pathologys

Biopsy of tumors affecting the vertebrae or SC is required for definitive diagnosis. Biopsy is often achieved at the time of surgical excision, but needle biopsy can be performed using percutaneous, surgical free-hand and image-guided techniques, including ultrasonography and CT (see Fig. 31.5H).[149]

Among ED tumors arising from the vertebra, OSA is the most common followed by CSA and FSA.[125,130,133] A variety of ED (often epidural) tumors that often do not involve the vertebra but arise from adipose tissue have also been reported, including lipomas, infiltrative lipomas, liposarcomas, and myelolipomas. Solitary plasma cell tumors affecting the vertebra are classified as plasmacytomas (see Figs. 31.5A, B) and may precede multiple myeloma.[132] Meningiomas and nerve sheath tumors are the two most common ID-EM neoplasms, with meningiomas predominating. Nephroblastomas also are predominantly ID-EM tumors, and almost always are found between T9 and L2 spinal cord segments because of the embryologic origin of the metanephric blastema from which they arise.[142,143] Approximately 80% of canine nephroblastomas will demonstrate immunoreactivity to WT-1, a human nephroblastoma gene product.[142]

When lymphoma involves the neuraxis in dogs and cats, it is most often a manifestation of multicentric disease.[136,138,139] In cats with SC lymphoma, more than 80% had extraneural organ involvement that commonly included the bone marrow, kidneys, liver, spleen, lymph nodes, and 43% had concurrent brain involvement.[138] Immunophenotypic characterizations of the vast majority of canine and feline cases of nervous system lymphomas have not been performed, but both B- and T-cell lymphomas have been reported.[136,139] In a recent report of canine lymphoma, the only case of primary CNS lymphoma identified in the patient cohort was restricted to the SC, and was a diffuse large B-cell lymphoma characterized by CD79a staining.[136] Among the 36 cases of metastatic canine CNS lymphomas in this series, 55% were B-cell lymphomas and 45% were of T-cell lineage.[136]

Cerebrospinal Fluid Analysis

CSF analysis is frequently done in combination with cross-sectional imaging and is a sensitive but nonspecific test that does not usually provide a diagnosis, with the exception of lymphoma. In 68% of dogs with CNS lymphoma in one series, a diagnosis was made using CSF analysis, and a diagnostic CSF was more likely when infiltrative meningeal lesions were seen on MRI.[136]

Treatment and Prognosis for Tumors Affecting the Spinal Cord

There is limited information on the results of treatment of vertebral or SC tumors in veterinary medicine; however, treatment options parallel those available for brain tumor management. The principles and outcomes associated with palliative treatment of SC tumors are also generally similar those of brain tumors, with the major exception of the more intensive and multimodal pain and urinary bladder management plans that are often required in animals with SC tumors. Palliative treatment of vertebral and SC tumors rarely results in prolonged STs or satisfactory functional outcomes, with MST ranging from 0 to 105 days.[128,129,134,135] In general, despite the type of treatments currently administered, many dogs and cats with vertebral and SC tumors die or are euthanized because of tumor-related causes, which often present as a recurrence or progression of neurologic signs.[126,128,130,131] Thus presumed and confirmed local treatment failures remain a significant source of morbidity and mortality in animals with vertebral and SC tumors (see Figs. 31.6A–C).

Chemotherapy

Chemotherapy may be used as an effective primary treatment modality in cases of vertebral plasma cell tumors, multiple myeloma, or lymphoma.[132,138,140] Dogs with vertebral plasmacytomas and multiple myeloma may have favorable and durable responses to melphalan and prednisone chemotherapy, even in the face of multiple or diffuse vertebral lesions and signs of moderate SC dysfunction.[132] Although there exist numerous reports on SC lymphoma in dogs in cats, there is limited information on specific chemotherapy protocols used and the results of treatment, specifically with respect to survival and neurologic functional endpoints.[138,140] Six cats with lymphoma treated with a combination of vincristine, cyclophosphamide, and prednisone had a complete remission rate of 50% and the median duration of remission was 14 weeks.[150] Platinum-based chemotherapeutic agents are often use as adjunctive treatment in cases of vertebral OSA.[129]

Surgery and Radiation Therapy

In addition to providing a histopathologic diagnosis, cytoreductive surgery often results in a significant acute clinical benefit from SC decompression.[128,129,131,133] Depending on the tumor type, surgery alone may convey sustained improvement in neurologic function.

Meningiomas can be treated effectively with surgery, with or without postoperative RT.[131,133] The MSTs for dogs with intraspinal meningioma treated with surgery alone vary widely and range from 6 to 47 months.[129,131,151,152] Serious surgical adverse events are more common with treatment of cranial cervical meningiomas because of compromise of critical respiratory or vascular structures.[131] The addition of postoperative RT in dogs with meningiomas increased the MST to approximately 45 months; dogs receiving RT took significantly longer to neurologically decline than dogs that did not, thus delaying the period to clinical deterioration because of local treatment failure.[131] In cats with spinal meningiomas treated surgically, reported MSTs are 6 to 17 months.[133,144]

Vertebral tumors in dogs and cats are frequently treated with multimodal therapy consisting of surgery, RT, and/or chemotherapy. The long-term prognosis associated with vertebral tumors is guarded, with one study reporting an overall MST of 4.5 months in dogs with a variety of vertebral tumors.[129] In this

VetBooks.ir

study, the posttreatment neurologic status was the only significant prognostic factor where a nonambulatory status was significantly associated with shorter STs.[129] Two dogs with CSAs treated with surgery alone both had a recurrence of clinical signs because of imaging confirmed tumor recurrence within 5 months of surgery.[130]

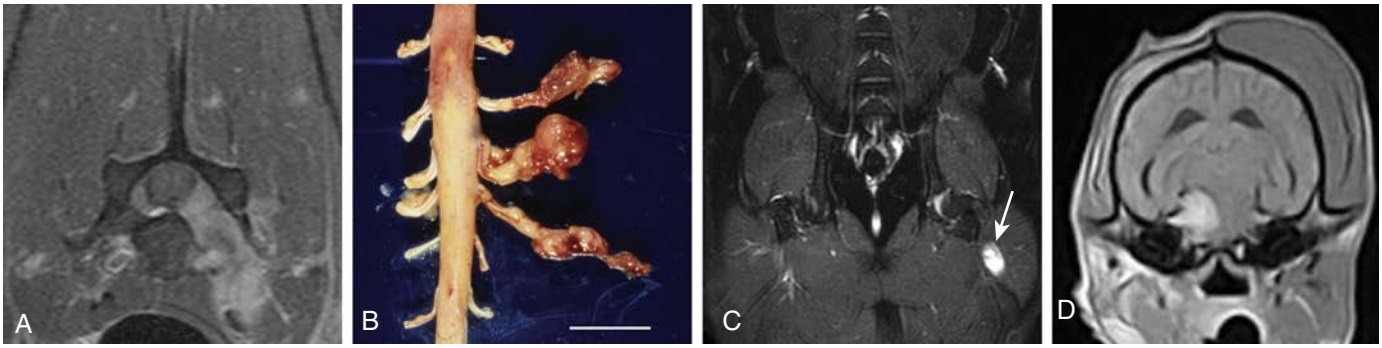
Cats with malignant vertebral tumors also have a guarded to poor long-term prognosis with surgical treatment, with a reported MST of 3.7 months in one study.[133] The literature indicates that common contemporary veterinary neurosurgical techniques are generally insufficient to attain the goal of en bloc surgical excision of vertebral tumors, which is critical to the therapeutic outcome in humans.[129,130,133] Thus, although currently largely unexplored in veterinary medicine, aggressive surgical techniques, including vertebrectomy with vertebral stabilization, will likely become an important component of advancing the surgical treatment of vertebral and SC tumors.[153]

Currently, there is insufficient information to clearly identify the superior method of treatment of solitary vertebral plasma cell tumors in dogs and cats. Solitary plasmacytomas have been treated successfully with surgery, RT, and various combinations of these modalities.[132,154]

Dogs with nephroblastomas treated with surgery and RT may also experience improved functional outcomes and STs compared with those not treated surgically, although reported MSTs vary widely.[142,143] In one study, MST for dogs that were not treated surgically was 1 day compared with 71 days for dogs that underwent cytoreductive surgery.[142] Another investigation reported that dogs with nephroblastoma treated with cytoreductive surgery or RT survived longer (MST 374 days) than dogs treated palliatively (MST 55 days).[143] Tumors confined to an ID-EM location were associated with superior STs (MST 380 days) than tumors with IM involvement (MST 140 days).[143] As nephroblastoma affects young dogs, the literature suggests that the majority of dogs will experience life-limiting local tumor recurrence or treatment complications regardless of treatment type.[142,143]

The outcomes associated with other specific types of SC tumors are unknown owing to very limited numbers of reported cases that received treatment, and in some instances, cases received RT treatment without histologic confirmation of the type of lesion being treated.[155] A few case reports suggest that primary IM neuroepithelial neoplasms may be resected if well-demarcated and that long-term successful outcomes are possible with combinations of surgery, with and without RT.[156] However, most animals with IM tumors are euthanized at or near the time of diagnosis because of poor prognosis or failure to respond to palliative therapy.[134,135]

Tumors of Cranial, Paraspinal, and Peripheral Nerves



Classification, Epidemiology, and Comparative Pathology

Peripheral nerve tumors (often collectively called *peripheral nerve sheath tumors* [PNSTs]) are uncommon in dogs and rare in cats. PNSTs may arise from Schwann cells, perineurial cells, or intraneural fibroblasts. Descriptive terminology that reflects the cellular origin of these tumors (schwannoma, neurofibroma, neurofibrosarcoma) is not routinely used because of the inherent level of difficulty in determining the tissue of origin of these tumors in veterinary medicine. Instead, PNSTs are divided into benign peripheral nerve sheath tumors (BPNSTs) or malignant peripheral nerve sheath tumors (MPNSTs) based on microscopic evidence of malignancy.[157–159] This latter classification scheme is more useful from a clinical standpoint, as the majority of reported PNSTs in dogs are histologically and biologically aggressive tumors. Cats have a higher proportion of BPNSTs compared with dogs.[158]

PNSTs may arise in any cranial nerve, spinal nerve root, or somatic or autonomic peripheral nerve.[157–160] PNSTs occur most commonly in middle-aged to older dogs of medium and large breeds. No breed or sex predilection has been noted. The most frequently affected cranial nerve is the trigeminal nerve, and the most common spinal nerve roots affected are in the caudal cervical region (C6–T2) followed by nerves of the lumbar intumescence (Fig. 31.7).[157–160] Metastasis is rare. Secondary tumors, such as lymphoma, malignant sarcomas, HS, and hamartomas, can occasionally involve peripheral nerves.[136,138,139] In cats, diffuse infiltrative peripheral nerve lymphoma (neurolymphomatosis) is usually B-cell origin, but one case of peripheral T-cell lymphoma in an FeLV-positive cat has been reported.[161,162] In dogs, peripheral nerve lymphoma is typically of T-cell origin.[136]

Pathophysiology, History, and Clinical Signs

As with brain and spinal tumors, the clinical signs of PNSTs reflect the location of the tumor. As the majority of reported canine PNSTs involve the nerve roots and/or nerves of the brachial and

• **Fig. 31.7** MRI and pathologic features of PNST. (A) Postcontrast MRI of C7 MPNST manifesting as thickening and contrast enhancement of the affected nerve, as well as intradural invasion. (B) At necropsy, a MPNST appears as nodular masses on the C7, C8, and T1 nerves. Bar = 1.5 cm. (C) Dorsal MRI image of a sciatic PNST causing enlargement of hyperintensity of the affected nerve (*arrow*). (D) MRI of a trigeminal PNST with compression of the midbrain and atrophy of the muscles of mastication ipsilateral to the tumor.

VetBooks.ir

lumbar plexi, the classic clinical scenario is one of chronic lameness without identifiable orthopedic abnormalities.[163,164] The etiology of the observed clinical signs may remain elusive for months and may not be appreciated until signs progress to monoparesis with neurogenic atrophy or signs of spinal cord disease appear. Signs of myelopathy are often asymmetric and occur when the mass invades the vertebral canal and compresses or invades the SC. Clinical signs of pain on palpation or paresthesia are also common.

Trigeminal PNSTs cause signs of severe, unilateral masticatory muscular atrophy, diminished jaw tone, decreased facial sensation, and Horner's syndrome.[160] Brainstem involvement may result in other regional cranial nerve deficits and long tract signs depending on size and invasiveness of the mass (see Fig. 31.7D). Peripheral nerve lymphoma may present with a clinical history similar to PNST or with neurolymphomatosis. In the latter scenario, flaccid tetraparesis and hyporeflexia can reflect the diffuse neoplastic infiltrative neuropathy.[161]

Diagnosis of PNSTs

Approximately 33% of cases with PNST affecting the brachial plexus will have a palpable mass on physical examination.[157,163,165] Ultrasound of the axillary region appears to be more sensitive for the detection of mass lesions than palpation, but not as useful as MRI.[166]

PNST can be challenging to diagnose, and exploratory surgery and biopsy is sometimes required. The most useful imaging tool for diagnosing PNST and discriminating other etiologies of the observed clinical signs is MRI, whether the lesion involves a plexus, the SC, or a cranial nerve, although CT-myelography is described.[160,166] To facilitate the diagnosis of PNST, cross-sectional imaging should include sequences with a wide field of view to incorporate the plexi and limb structures (see Fig. 31.7C). On MRI examinations of PNST cases, up to 50% of patients display only nerve thickening rather than a discrete mass (see Fig. 31.7A).[160,166,167] Postcontrast sequences are particularly helpful in the identification of subtle tumors. Idiopathic neuritis, hypertrophic ganglioneuritis, and peripheral nerve lymphomas may have an identical appearance on MRI to PNST.[166,168]

Treatment and Prognosis of PNSTs

Surgery is the preferred treatment of PNSTs in dogs and cats.[157,158] The prognosis for paraspinal or plexus PNSTs depends in part on tumor location and whether or not the tumor is amenable to complete resection using amputation, compartmental resection with limb sparing, laminectomy, or combinations of techniques.[157,158,169] Proximity to and invasion into the vertebral canal, which occurs in 45% of dogs, and the presence of tumor infiltrated margins after compartmental resection are negative prognostic indicators.[157,169] In dogs, the overall prognosis historically is considered guarded to poor, with MSTs of approximately 6 months for dogs with paraspinal and plexus PNST, reflecting the more malignant biologic behavior of canine PNST. Long-term survival is possible after complete resection of tumors,[163] including the use of limb sparing techniques (MST 1303 days).[169] Recently, a study investigating VMAT radiotherapy for the treatment of canine PNST reported outcomes that were superior to earlier reports of surgically treated dogs with evidence of nerve root and vertebral canal invasion, with a mean progression-free ST of 8 months.[170] The prognosis for cats is more favorable. In one study of 45 surgically treated cats, 31% (5/16) of MPNST recurred compared with 14% (4/43) of BPNST.[158] Treatment failures typically manifest as neurologic signs attributed to local recurrence.

Canine trigeminal PNST may have an insidious clinical course, with some untreated dogs experiencing STs in excess of 18 months without significant clinical progression.[160,167,171] Trigeminal PNSTs may be surgically removed or irradiated and successful outcomes have been reported for both treatment modalities.[160,167,171] The MSTs for dogs with trigeminal PNST treated with SRS or SRT is reported as 745 days[167] and 441 days.[171] RT may be superior to palliative and surgical treatment, particularly with respect to resolving neurologic signs in cases with clinical and imaging evidence of brainstem involvement.[111,167,171] Peripheral nerve lymphomas, which may be indistinguishable from PNST, may respond to radiation or chemotherapy, although no current literature provides specific treatment recommendations or outcomes of dogs or cats with peripheral nerve lymphoma or neurolymphomatosis.

32 Ocular Tumors

PAUL E. MILLER AND LEANDRO B.C. TEIXEIRA

Tumors of the eye, orbit, or adnexa can have devastating consequences for an animal's vision, appearance, and comfort and may be harbingers of potentially life-threatening disease elsewhere in the body. By virtue of their location, even benign ocular tumors may cause blindness and loss of the eye. Although these tumors reportedly affected only 0.87% of all dogs and 0.34% of all cats recorded in the Veterinary Medical Database (VMDB) over a 10-year period, their actual frequency is undoubtedly greater because many presumably benign ocular tumors are not histologically examined. Additional insights into the relative frequency of ocular tumors can also be gained by reviewing submissions over several decades to the large ophthalmic pathology database compiled by the Comparative Ocular Pathology Laboratory of Wisconsin (COPLOW) (Fig. 32.1). This chapter describes the more common ocular tumors in small animals and also uses the database of the COPLOW laboratory to estimate the relative frequency of various ocular tumors.

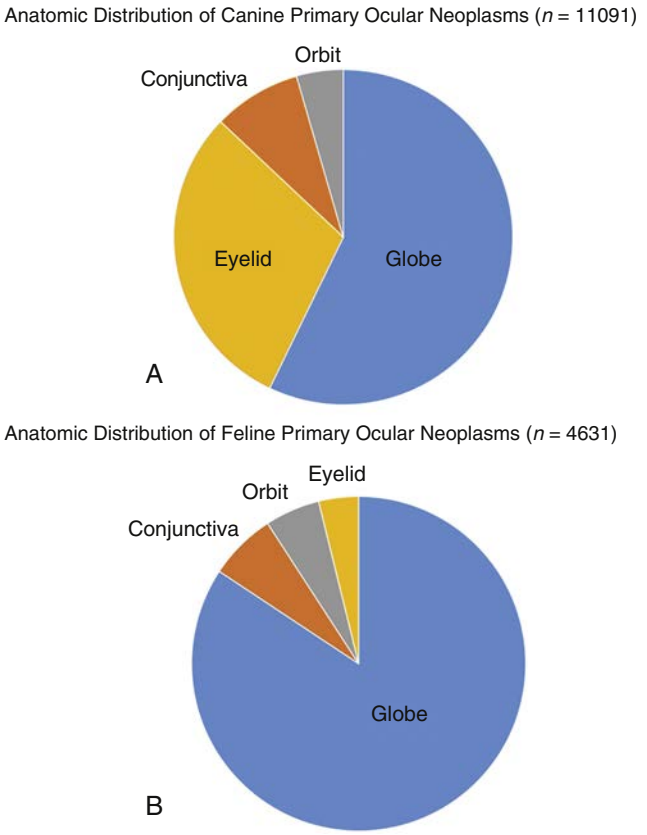
Tumors of the Eyelids, Third Eyelid, Conjunctiva, and Ocular Surface

Incidence and Risk Factors

Benign adenomas and melanomas of the haired skin or eyelid margin make up 76% of canine eyelid tumors in the COPLOW database and tend to affect old dogs. One study suggests Boxers, collies, Weimaraners, cocker spaniels, and springer spaniels are at greater risk for eyelid neoplasia than the general hospital population,[1] and another study suggests that beagles, Siberian huskies, and English setters are at greater risk than mixed-breed dogs.[2] Canine juvenile histiocytomas affect the eyelid skin of young to middle-aged dogs[1,2] but are relatively uncommon, comprising only 3% of eyelid biopsy samples submitted to COPLOW. Squamous cell carcinoma (SCC) comprises up to two-thirds of feline eyelid and third eyelid tumors and has a predilection for the lower eyelid and medial canthus of white cats.[3] Ocular SCC is less frequent in dogs, but in both cats and dogs increased exposure to solar radiation, lack of adnexal pigmentation, and possibly chronic ocular surface irritation are believed to be predisposing factors (Fig. 32.2).[1,4,5]

Vascular endothelial cell tumors of the lateral limbus or the leading edge of the third eyelid constitute 25% of conjunctival tumors in dogs and tend to occur in the nonpigmented conjunctiva in Bassett hounds, springer spaniels, and beagles (Fig. 32.3). Melanomas often occur in dogs with a pigmented conjunctiva and are the most common malignant tumor of the canine conjunctiva, making up 16% of conjunctival tumor biopsies. Older (mean = 11 years), female, Weimaraner, and possibly German shepherd/large-breed dogs may be predisposed to conjunctival melanomas.[6] Melanomas also have a propensity for the nictitating membrane and superior palpebral conjunctiva.[6,7] Ocular viral papillomas compose about 3% of conjunctival tumors and tend to occur in young dogs and are believed to have a papillomavirus etiology (perhaps canine oral papillomavirus).[8] However, one study failed to identify papillomaviral genetic material in older dogs with smaller solitary lesions, suggesting that the cause of ocular surface papillomas in dogs may be heterogeneous.[9] Canine squamous papilloma is a benign papillary tumor of unknown etiology and makes up 9% of conjunctival tumor biopsies. Reactive papilloma is seen secondary to other conditions such as meibomian tumors, but they make up 18% of conjunctival tumor biopsies. Corneal tumors have a predilection for the limbus.

Pathology and Natural Behavior



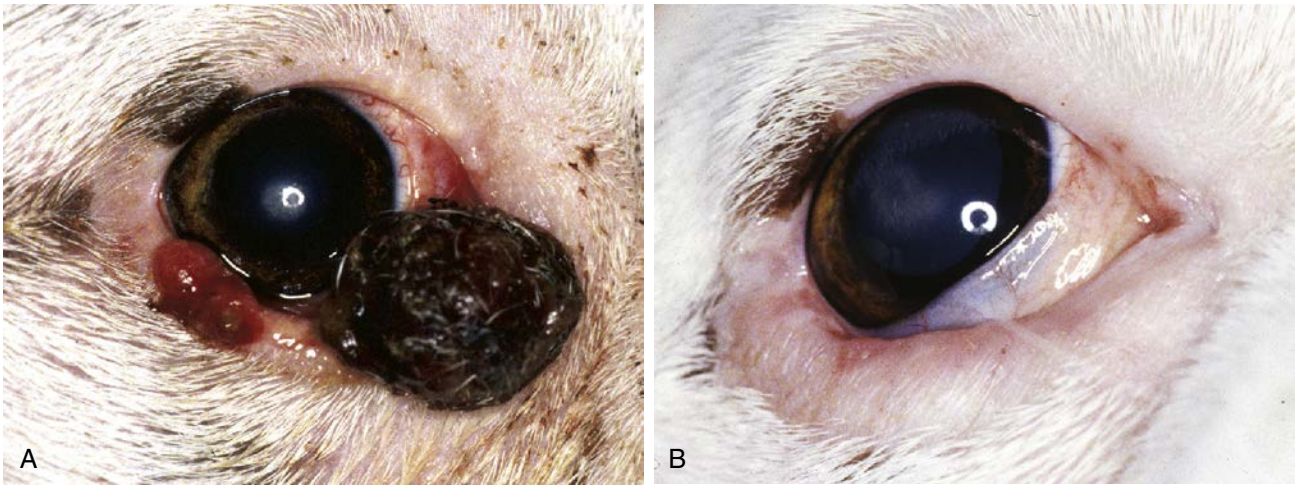
Sebaceous or meibomian gland adenomas and epitheliomas, papillomas, and melanomas comprise more than 80% of canine eyelid and conjunctival neoplasms, and a substantial majority of these tumors are histologically benign.[1,2] Even histologically malignant eyelid tumors in dogs rarely metastasize, although they are more likely to be locally invasive and recur after surgery.[1,2] In contrast, most feline eyelid and ocular surface tumors such as SCC are malignant.[3]

Viral papillomas tend to be well demarcated and superficial, minimally altering deeper tissues. Surgical manipulation has occasionally been associated with dispersal of papillomas throughout the ocular surface.[10,11] Papillomas, like histiocytomas, often spontaneously regress in young dogs, although they may persist in the older dog where they may not be of viral origin. SCC may also develop superficially, but after malignant transformation the preinvasive actinic plaque can invade deeper tissues. SCC may spread to regional lymph nodes late in the course of the disease and uncommonly distantly metastasize. SCC of the third eyelid may more readily invade the orbit than corneal or eyelid SCC. Primary corneal SCC is more common in brachycephalic dogs and has been reported to be associated with chronic keratitis and topical immunosuppressive therapy.[12]

Adenocarcinomas of the gland of the third eyelid constitute 12% of conjunctival tumors in dogs and approximately 85% of

VetBooks.ir

all third eyelid tumors in dogs and cats.[13] They are variable in morphology and often show moderate infiltrative growth.[13] They may mimic prolapse of the gland of the nictitans ("cherry eye") by appearing as localized, firm, smooth, pink swellings on the posterior surface of the nictitans, but a key differentiating feature is their occurrence in much older dogs (10–16 years). Although excision of the grossly visible tumor may initially appear adequate, recurrence is common if the entire gland is not removed, and metastasis, especially to the regional lymph nodes and orbit, is possible.[13–15] Adenomas of the gland of the third eyelid are less frequently reported in dogs (approximately 14% of all third eyelid tumors) as are SCC (approximately 1% of all canine and 16% of all feline third eyelid tumors).[13]



• **Fig. 32.1** The distribution of canine (A) and feline (B) ocular tumors submitted to the Comparative Ocular Pathology Laboratory of Wisconsin.

The natural behavior of conjunctival vascular, melanocytic, and mast cell tumors (MCTs) is poorly understood, in part because they are uncommon. Conjunctival hemangiomas and hemangiosarcomas tend to remain relatively superficial but may recur after simple excision.[15–19] Hemangiosarcomas may exhibit a more aggressive course and a primary ocular hemangiosarcoma must be differentiated from a metastatic lesion. However, metastasis of primary conjunctival vascular tumors, even when classified as hemangiosarcomas, appears to be rare.[15–19]

Feline conjunctival melanomas originate on the bulbar conjunctiva and invade the eyelid.[20,21] Melanoma of the conjunctiva in dogs is most often morphologically malignant, but metastatic disease is not common. As in cats, canine conjunctival melanomas have been reported to recur locally after surgical excision in 55% of cases, and at least 17% of the dogs experienced orbital invasion or spread to the regional lymph nodes or lungs.[6] Melanomas originating from the palpebral conjunctiva may have greater metastatic potential.[6] Mitotic index, cell type, and degree of pigmentation are not useful predictors of malignancy for canine conjunctival melanomas.[6] Conjunctival (subconjunctival) MCTs make up 4% of conjunctival tumors, but their natural history is poorly understood in part because they are uncommon. Nevertheless, they have been suggested to have a relatively benign course in dogs, even with incomplete excision and if the tumors present more malignant histologic features.[22,23] Conjunctival MCTs are not typically graded as the grading system was developed for cutaneous tumors and the criteria are not applicable to conjunctival tissues. In the largest review to date, local recurrence was observed in only 2 of 32 dogs, even though residual tumor was histologically present in 25 dogs.[23] In addition, none of the 32 dogs died of conjunctival MCT-related disease.[23]

History and Clinical Signs

Vascular tumors are often focal, raised, soft, red masses with visible feeder vessels arising from the surface of the conjunctiva or third eyelid.[15–19] SCC of the eyelid, third eyelid, or ocular surface

• **Fig. 32.2** (A) Squamous cell carcinoma affecting the lower eyelids of a boxer. (B) Same dog after cryosurgical ablation of the tumor. Lid function is spared.

VetBooks.ir

may appear as a focally thickened, roughened, and usually pink-to-red lesion in older animals or, more commonly, as an ulcerated lesion with a protracted course.[3–5] In contrast, papillomas in young dogs appear verrucous and usually progress rapidly over weeks to a few months whereas they tend to be solitary and slowly progressive in older dogs. Conjunctival MCTs often have smooth surfaces and appear tan or red in color. Nonneoplastic conditions such as nodular granulomatous episcleritis, which is an inflammatory disorder, can be mistaken for neoplasia.

In addition to a mass lesion, other clinical signs of eyelid or ocular surface tumors may include epiphora, conjunctival vascular injection, mucopurulent ocular discharge, protrusion of the third eyelid, conjunctival/corneal roughening or ulceration, and corneal neovascularization or pigmentation. Occasionally, palpebral conjunctival masses protrude only when their bulk no longer can be accommodated by the space between the eyelid and globe, and very advanced tumors may create exophthalmia or enophthalmia if the orbit is invaded. Large tumors and sebaceous adenomas often have a substantial inflammatory component and may be secondarily infected. Mesenchymal hamartoma appears to have a predisposition for the skin of lateral canthus of dogs.[24]

Diagnostic Techniques and Workup

In addition to fluorescein staining and examination of the ocular surface with a cobalt filter or black light, the extent of involvement of the bulbar and palpebral conjunctiva should be determined by everting the eyelid (and third eyelid if affected). Careful palpation of the lesion by inserting a lubricated finger in the conjunctival cul-de-sac can be invaluable for determining the full extent of the tumor and whether bony involvement has occurred. Nasolacrimal lavage and possibly positive contrast dacryocystorhinography may help characterize medial canthal masses. In general, small eyelid and ocular surface tumors are best diagnosed and treated by excisional biopsy. Fine-needle aspiration (FNA) or incisional biopsies of larger tumors aid in determining prognosis and planning definitive therapy. Occasionally, orbital ultrasound, skull radiographs, computed tomography (CT), magnetic resonance imaging (MRI), regional lymph node cytology, and thoracic radiographs are required to localize or clinically stage potentially malignant tumors such as SCC, MCTs, adenocarcinomas of the third eyelid, and conjunctival melanomas.

• **Fig. 32.3** Hemangiosarcoma of the third eyelid in a dog.

Therapy

Specific therapy varies with the type of tumor; its location, size, and extent; whether the eye still has useful vision; the animal's expected lifespan; the degree of discomfort the mass is creating; and the owner's financial limitations. All eyelid tumors, whether benign or malignant, have the potential to affect vision or ocular comfort. Indications for tumor removal include any eyelid tumor in a cat, rapid growth, ocular surface irritation, impaired eyelid function, owner concern, or an unappealing appearance. In young dogs, observation of nonirritating papillomas or histiocytomas, even if quite large, may be appropriate as spontaneous regression is common.

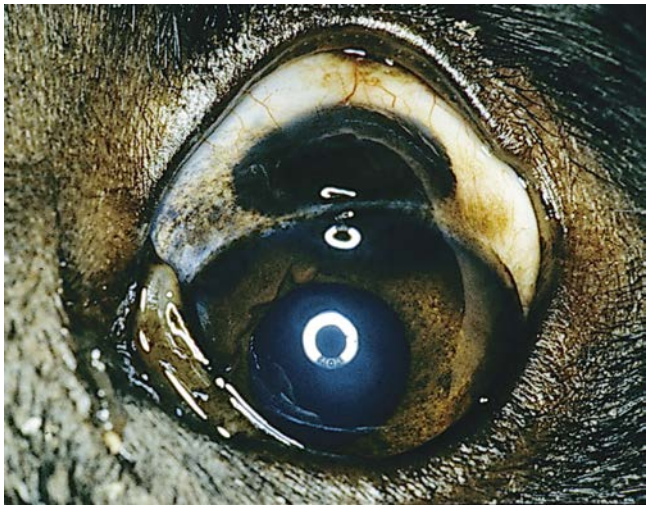
Tumors involving less than one-fourth to one-third of the length of the eyelid are best treated by a V-plasty (wedge) or four-sided excision.[25] The latter technique affords superior apposition of the eyelid margins and wound stability, especially in tumors approaching the one-fourth to one-third limit, because the initial incision is made perpendicular to the eyelid margin rather than obliquely. In general, only one-third to one-fourth of the eyelid in dogs and one-fourth of the eyelid in cats can be removed with these techniques. Antibiotic or antiinflammatory therapy may reduce the size of large tumors that are infected or inflamed so that a wedge or four-sided excision becomes possible. Electrosurgical excision should be avoided because it may result in substantial scarring of the eyelids. Carbon dioxide (CO_2) laser ablation may be appropriate for some tumors.[26]

Tumors greater than one-fourth to one-third of the eyelid typically require more advanced reconstructive blepharoplasty or use of other therapeutic modalities. Some tumors may be responsive to systemic chemotherapy (e.g., lymphoma, MCTs), local infiltration with chemotherapeutic agents such as cisplatin (e.g., SCC),[27] and/or local radiation therapy (RT; e.g., SCC). In some cases, these modalities will completely eliminate the tumor or shrink it to the point in which a less extensive surgical procedure can be performed. Reconstructive blepharoplasty, however, is the procedure of choice if surgical cure is a possibility and these other modalities have failed or are unlikely to substantially affect the tumor or if the nature of the tumor indicates extensive margins are required.

Cryosurgery is an attractive alternative to extensive blepharoplasty and has been reported to be effective in several canine eyelid tumor types (see Fig. 32.2; see also Chapter 10).[2,28] It is quick, less technically demanding than reconstructive blepharoplasty, and usually permits preservation of the nasolacrimal puncta and canaliculus. In many old or debilitated patients, cryosurgery can be accomplished with only sedation or local/topical anesthesia. After pretreatment with dexamethasone (0.1 mg/kg intravenous [IV]), the mass is isolated with a chalazion forceps (if possible) and debulked flush with the lid margin. Using liquid nitrogen and a closed probe that approximates the diameter of the mass as much as possible, a double freeze-thaw is performed so that the ice ball extends 3 to 5 mm beyond the visible margins of the mass. Ice balls should overlap in large tumors. Freezing may be repeated a

second or third time if complete regression is not achieved after the first session. Substantial postoperative swelling and usually transient depigmentation of the frozen tissue are to be expected.

Tumors involving the conjunctiva and third eyelid (especially conjunctival hemangiosarcomas, melanomas, and nictitans adenocarcinomas) are most effectively treated by surgical excision, occasionally to the point of exenterating the orbit. If the globe is to be spared, however, excision of the entire nictitans should not be taken lightly because undesirable sequelae such as ocular drying and chronic keratitis frequently result. Bulbar conjunctival tumors move freely and, if small, are generally amenable to excision under only topical anesthesia and perhaps sedation. Cryosurgery may permit the nictitans to be spared in the cases of papillomas and early SCC, or it can be used as an adjunct to excision in advanced canine conjunctival melanomas and SCC.[6,28]



Superficial keratectomy/sclerectomy is preferred for many corneal and scleral tumors, although some tumors require a full-thickness resection of the cornea or sclera. In the latter case, corneal or scleral allografts or autologous tissue grafts should be used to maintain ocular structural integrity. Limbal SCC and epibulbar melanoma may also be amenable to cryosurgery, although the ice ball should be carefully monitored to avoid unnecessary freezing of intraocular structures.

Prognosis

The prognosis for most canine primary eyelid tumors is excellent, whether treated by excision or cryosurgery. Metastasis is rare, even in histologically malignant primary lid tumors, and recurrence rates are low (approximately 10%–15%).[2] New primary eyelid tumors are not uncommon and must be distinguished from recurrence. Because most eyelid tumors in cats are malignant, the prognosis is not as good as that for dogs, but it is unclear how prognosis correlates with the histologic features. Conjunctival melanomas and nictitans adenocarcinomas frequently recur after partial excision of the nictitans, even if all the clinically visible tumor has been removed.[6] Conjunctival hemangiosarcomas appear to have a good prognosis because total excision may be curative, although recurrence and loss of the eye is still possible.[15–19] Conjunctival MCTs also appear to have a good prognosis.[23]

Limbal (Epibulbar) Melanomas

Limbal melanomas are typically benign, slightly raised, heavily pigmented masses originating from melanocytes in the sclera or subconjunctival connective tissue (Fig. 32.4).[29–35] They comprise 3.5% of all canine ocular tumors and 1% of feline ocular tumor submissions to COPLOW. The majority of these slow-growing tumors originate in the superior limbal region, suggesting exposure to solar radiation may be a risk factor.[15] Affected dogs average 5 to 6 years old (cats 8+ years), and a female sex and German shepherd, golden retriever and Labrador retriever breed predilection has been inconsistently reported.[29–35] Confirmed metastasis has not been reported in dogs or cats and mitotic figures are rarely encountered; although in one study, two of four cats also had feline leukemia virus (FeLV)-associated lymphoma or leukemia, and a third cat had a second intraocular pigmented mass unassociated with the limbal tumor.[34] Lightly pigmented spindle cells capable of division are seen histologically, but the dominant cell is presumably a hypermature spindle cell that is large, round, pigment laden, and benign.[30] These masses are often only incidentally noted and the clinical signs are typically minimal, although

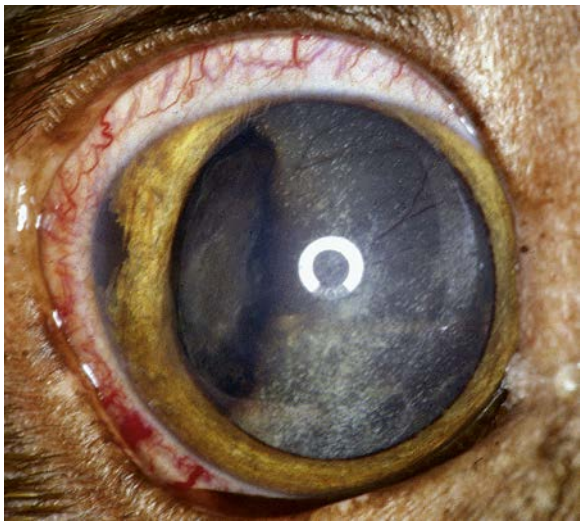
• **Fig. 32.4** Epibulbar melanomas typically originate from the superior limbal region of the globe. (Image courtesy Dr. Elizabeth Adkins.)

local corneal invasion, epiphora, and mild conjunctival irritation may be seen.[32,33] Differential diagnoses include conjunctival melanoma, invasive uveal melanoma, metastatic melanoma, and staphyloma or coloboma. Gonioscopy aids in differentiating invasive intraocular tumors from limbal melanomas.

Therapy should be considered if the tumor has invaded the eye or if growth is rapid. Given its benign nature and usually slow growth rate (imperceptible growth over 18 months has been described), observation alone may be appropriate in older dogs. If intervention is required, lamellar keratectomy/sclerectomy with graft placement is often curative.[36–38] Beta-irradiation and cryosurgery have been used as adjuncts to surgery.[36,39] Cryosurgery alone or laser photocoagulation[35] has also been described as effective means of treatment. Regrowth after local surgical excision occurs in approximately 30% of patients, but 2 to 3 years may pass before the anterior chamber is invaded and enucleation is required.[30,32,33] The addition of adjunctive therapy such as cryotherapy or beta-irradiation substantially reduces the risk of recurrence after local excision.[36,39] Enucleation is curative and indicated if painful intraocular disease is present.[30]

Primary Ocular Tumors

Canine Anterior Uveal Melanomas



Incidence and Risk Factors

In one review of data from the Armed Forces Institute of Pathology, intraocular melanomas, other primary intraocular tumors, and metastatic intraocular neoplasms constituted 12%, 14%, and 9%, respectively, of canine ophthalmic/orbital/adnexal tumors.[40] In the COPLOW archive, uveal melanocytic tumors make up 25% of all ocular tumor submissions. Any age is at risk, but most affected dogs are older than 7 years of age, and breed or sex predilections are inconsistent.[30]

Pathology and Natural Behavior

Approximately 75% of canine intraocular melanomas are benign, and 95% arise from the iris or ciliary body (Fig. 32.5).[30,32,41] The most clinically useful classification scheme classifies these tumors simply as melanocytoma (benign) and melanoma (potentially malignant) based on nuclear features of the tumor cells, with

VetBooks.ir

• **Fig. 32.5** Most anterior uveal melanomas originate from the iris or ciliary body and are benign.

mitotic rate being the most important.[30,31] Benign tumors have fewer than two to four mitotic figures/10 HPFs (mitotic index), and malignant tumors demonstrate nuclear pleomorphism and a mitotic index of at least four and often more than 30. Destruction of the eye is not by itself sufficient for a diagnosis of malignancy.[30] The overall rate of metastasis of intraocular melanomas is approximately 4%[41] and usually occurs via the hematogenous route. Local spread along ocular vessels and nerves or via direct penetration of the sclera or cornea also occurs. Benign tumors tend to be smaller, more darkly pigmented and have a lower mitotic index than malignant tumors.[30,31]

Circumscribed, nevus-like pigmented iridal growths have been described in young dogs (7 months to 2 years old).[32] The natural history of these lesions is variable because enlargement may not occur over several years.[32,40] Some, however, are capable of rapid growth, but to date all are clinically and histologically benign.

Ocular melanosis of Cairn terriers resembles feline diffuse iris melanoma in some respects.[42] This disorder is probably an autosomal-dominant condition with a variable age of onset and rate of progression. It results in a thickening and pigmentation of the iris, release of pigment into the aqueous, pigment deposition in the sclera/episclera, and to a lesser extent posterior segment pigment deposition. Secondary glaucoma is common, and overt uveal melanocytic neoplasia occurs in a small percentage of dogs.[42]

History and Clinical Signs

Common presentations of intraocular tumors include a visible intraocular or scleral mass, glaucoma, hyphema, anterior uveitis, or extrabulbar spread, or they can be an incidental finding during an ophthalmic examination.[30,41] Because glaucoma or hyphema are often the only overtly visible clinical signs,[30,41] intraocular neoplasia should always be considered in animals with hyphema, glaucoma, or both when there is no history of trauma or coagulopathy. Small masses frequently create few symptoms other than pupillary distortion. Pigmentation is variable and not a reliable indicator of tumor type.

Diagnostic Techniques and Workup

Usually, the clinical or ultrasonographic appearance (if the media are opaque) is strongly suggestive of intraocular neoplasia, although it may be difficult to arrive at a definitive diagnosis without invading the eye or removing it because organizing blood clots are not always distinguishable from neoplastic mass lesions. Because most anterior uveal brown or black masses are cystic and not neoplastic, transillumination should be attempted before more invasive procedures. Uveal cysts typically permit bright light to pass through them, are roughly spherical, and may be attached to the ciliary body or free-floating in the anterior chamber. Once suspected, most primary canine intraocular tumors are observed for progression, although occasionally FNA (with its risks of inflammation, infection, and hemorrhage) or attempts at intraocular resection or enucleation are used for diagnostic purposes. The possibility of metastasis from another primary site (i.e., oral cavity or nail bed) to the eye or from the eye to other organs should be eliminated.

Therapy

Canine primary intraocular tumors are often carefully observed, although surgical intervention (sector iridectomy/cyclectomy, laser ablation, enucleation) should also be considered. Digital photographs are a valuable aid in assessing progression. Enucleation is advised if there is concern about malignancy or if complications such as intractable uveitis, chronic hyphema or secondary glaucoma occur.[43] In the COPLOW collection, 14% of canine globes with glaucoma that are removed also had melanoma. The low risk of metastasis and unproved efficacy of enucleation at preventing metastasis in the few malignant tumors that have been reported make it difficult to automatically advise enucleation of normotensive, noninflamed, visual eyes.[30] Isolated primary masses involving only the iris or a portion of the ciliary body may be amenable to local resection by sector iridectomy/cyclectomy to preserve the eye and vision.[32,40] These intraocular procedures, however, require an accomplished ophthalmic surgeon and often have unsatisfactory long-term results. Transscleral and transcorneal Nd:YAG or diode laser therapy has induced remission in some small- to moderate-sized primary intraocular tumors.[43,44] Specialized goniolenses may also allow laser treatment of masses that have invaded into the iridocorneal angle. Although the results were variable, perhaps because these tumors varied histologically in nature, laser therapy holds promise for the palliation or potential cure of a number of intraocular tumor types while also preserving vision. Metastasis was not observed after this procedure, although this obviously remains a risk when the tumor is malignant.[43]

Prognosis

Although the data in most studies are heavily "censored," the prognosis for histologically benign melanomas appears to be excellent. Enucleation is curative, but attempts at local excision or laser photoablation may be only palliative, especially if the ciliary body or trabecular meshwork is involved. The presence of black, nonsolid material within the orbit after the enucleation of benign melanomas with scleral invasion apparently does not affect prognosis because these cells appear incapable of continued growth.[32] In one study, approximately 25% of histologically malignant melanomas demonstrated metastasis, typically within 3 months of enucleation, and most dogs with metastasis were euthanatized within 6 months of enucleation.[30] This surprisingly poor prognosis has not been the experience of cases followed recently in the COPLOW data set, and in a larger study, dogs with tumors classified as malignant were reported to have only a somewhat decreased survival time compared with dogs with melanocytoma and dogs from a control population.[45]

VetBooks.ir

Choroidal Melanomas

Choroidal melanomas are rare intraocular melanocytic tumors, comprising only 4% to 7% of canine uveal melanomas, with no clear breed or sex predisposition.[46] Middle-aged (6–7 years), medium- to large-breed dogs predominate.[46] Generally, these tumors are well-delineated, raised subretinal pigmented masses with tapering margins, bulging centers, and a propensity for the peripapillary region and optic nerve.[46,47] In some cases, the tumor may remain virtually static for many years, whereas others exhibit infiltration into the overlying retina, through the sclera, up the optic nerve, and into the orbit.[46] Nuclear anaplasia is minimal and generally mitotic figures are absent.[47] Despite these benign cytologic features, metastasis has been described in one dog 21 months after exenteration, and follow-up in most studies is incomplete.[48] In general, however, these tumors appear to be benign in the vast majority of dogs. Most dogs with tumors involving a limited portion of the choroid are asymptomatic, and the mass is noted incidentally on ophthalmoscopy. Larger tumors frequently present with chronic uveitis, secondary glaucoma, retinal detachment, intraocular hemorrhage, or blindness.[46,47] Extension into the orbit can occur, and documentation of this is important in planning for enucleation surgery. Ocular ultrasonography may demonstrate mass lesions if anterior segment changes or retinal detachment obscures an underlying mass. Therapy usually consists of enucleation once progression has been documented or if the eye is painful. Diode laser ablation may offer an alternative to enucleation if the lesion is small and does not involve the optic nerve. Optic nerve or scleral invasion may warrant a more cautious prognosis.

Feline Primary Intraocular Melanomas (Feline Diffuse Iris Melanoma)

Incidence and Risk Factors

Anterior uveal melanomas are the most common primary intraocular tumor in cats (Fig. 32.6).[49] They account for 55% of all neoplastic submissions to the COPLOW in cats. There appears to be no breed or sex predisposition, and most cats are more than 9 years of age at the time of diagnosis,[49,50] although the prodromal period for many of these tumors may be quite long.

Pathology and Natural Behavior

In the malignant form of uveal melanoma, the rate of metastasis (frequently to the liver and lungs) has been reported to vary from 55% to 66% or higher.[49–52] Iridal hyperpigmentation, however, frequently takes months to years to progress to the extent to which the eye must be enucleated, and an additional 1 to 3 years after enucleation are required before metastatic disease may become evident.[49,50,52,53] No single morphologic feature is predictive of outcome, but in some studies metastasis has been linked to a greater mitotic index, larger tumors, and extension through the iris into the ciliary body stroma and involvement of the scleral venous plexus.[49,50] In a recent study,[54] an increased risk for metastasis was found if there was extrascleral extension, necrosis within the neoplasm, a mitotic index of more than seven mitoses in 10 high-power (×400) fields, choroidal invasion, increased labeling for E-cadherin (a transmembrane protein responsible for cell adhesion) or melan-A (an antigen expressed by melanocytes) label intensity. PNL2 label homogeneity was associated with a decreased rate of metastasis.[54] PNL2 is an antibody directed against an unidentified antigen expressed by normal and neoplastic melanocytes.

• **Fig. 32.6** Diffuse iris melanomas may first appear as multifocal to diffuse pigmentary changes, as seen in the coalescing darker regions of the iris in this cat.

Most ophthalmologists have noted unilateral or occasionally bilateral slowly progressive iridal pigmentary changes (especially in older orange cats) over many years to a decade or more that apparently do not lead to disease beyond the pigmentation, although eventual removal of these eyes can show melanoma. It is possible in some cats that these initially benign-appearing accumulations of small, angular pigmented cells on the anterior iridal surface undergo transformation to the larger, rounded cells typical of the potentially malignant diffuse iris melanoma. Of concern to the clinician waiting to document progression before advising treatment, however, is that malignant transformation is not readily observable clinically and that these cells, once transformed, appear to be capable of quickly dropping off into the anterior chamber and entering the drainage apparatus and vasculature.[50]

History, Clinical Signs, Diagnostic Techniques, and Workup

Slowly progressive, diffuse iridal hyperpigmentation is the most common clinical sign, although occasionally a pigmented iridal nodule or amelanotic mass is seen. Secondary glaucoma will eventually occur, and the diffuse form may be mistaken for chronic anterior uveitis with iridal hyperpigmentation.

The diagnosis of melanoma, generally made clinically, requires demonstration of progression and iridal thickening or irregularity of the iris surface or pupil. The prognostic and diagnostic value of FNAs of the iridal surface or iridal biopsies is unclear and worthy of further study. A recent report described multiple cases of darkly pigmented iridociliary cysts in cats that were erroneously diagnosed as iris melanomas.[55] These cases presented single to multiple cysts that failed to transilluminate and caused distortion and discoloration of the iris, leading to enucleation of the globe. The presence of bilateral masses protruding through the pupil may help distinguish iridociliary cysts from melanomas and should prompt the clinician to pursue additional diagnostic imaging, such as high-resolution ultrasound.

Therapy

The treatment of feline uveal melanomas is controversial. Ideally, enucleation would be delayed until just *before* malignant transformation, invasion into other ocular structures, secondary glaucoma,

VetBooks.ir

or metastasis. Such precise timing, however, is seldom attainable in a clinical setting, and enucleation is commonly performed if iridal pigment changes have been demonstrated to progressively increase to the point that virtually the entire iridal surface is involved, pigmented cells are present in the trabecular meshwork, the pupil is distorted (indicating iridal invasion), ciliary body or scleral invasion is threatened, uveitis is present, or glaucoma is impending. Although it would seem logical that early enucleation would optimize survival, this is unproved. In one study, enucleation has been shown to markedly enhance the rate of metastasis in cats with feline sarcoma virus–induced uveal melanomas.[56] The applicability of this experimental model to spontaneous disease, however, is unclear and neither feline sarcoma virus nor FeLV were found in a study of 10 eyes with spontaneous diffuse iris melanoma.[57] Some ophthalmologists have attempted to ablate small, focal, hyperpigmented foci on the iris of cats with a diode laser, thereby preserving vision and the eye. The long-term success rate and side effects of this procedure, however, are not known. Finally, most slowly progressing lesions are simply monitored, ideally by comparison to baseline photographs. This option is particularly suitable for older cats with other diseases that limit their expected lifespan. In many cats, progression may be so slow as to permit the patient to be followed for many years to a decade or more without apparent metastasis.

Prognosis

The metastatic potential of feline uveal melanomas has been correlated with the extent of ocular involvement seen histologically.[50,54] Because the tumor is relatively slow-growing, however, the period until metastatic disease becomes apparent may be measured in years, and even then, substantial additional time may elapse before the metastasis is life threatening. Cats with tumors confined to iris stroma and trabecular meshwork at the time of enucleation have survival times comparable to those of age-matched controls. Enucleation after the tumor has invaded into the ciliary body but not the sclera warrants a poorer prognosis, but the median survival time (MST) is still approximately 5 years.[50] Enucleation after the tumor has invaded into the ciliary body and the sclera merits an even poorer prognosis, with an MST of approximately 1.5 years.[50] The MST is also reduced if secondary glaucoma has occurred.[50] In one study of 47 cats enucleated for diffuse iris melanoma, confirmed or suspected metastasis occurred in nine cases.[54] However, cats being enucleated for diffuse iris melanoma most likely reflect the more extensive form of the disease and the rate of metastasis in cats with all forms of diffuse iris melanoma is likely substantially lower.

Feline Ocular Posttraumatic Sarcoma

Sarcomas after ocular trauma, although uncommon, are second only to melanomas in frequency as a primary ocular tumor of cats (Fig. 32.7).[58–61] In the COPLOW collection, 8% of feline ocular tumors are posttraumatic sarcoma. These tumors are subdivided into three morphologic subtypes: spindle cell sarcoma (the most common), round cell sarcoma (posttraumatic lymphoma), and osteosarcoma/chondrosarcoma. All three have similar histories leading up to tumor presentation. Cats that are 7 to 15 years of age are most commonly affected, the latency period after trauma averages 5 years,[59] and 67% of affected cats are males or neutered males. Damage to the lens and chronic uveitis may be risk factors.[58–60] Ciliary body ablation with gentamicin for glaucoma may also be a risk factor.[62]

• **Fig. 32.7** Posttraumatic sarcoma in a cat. (Image courtesy Dr. Elizabeth Adkins.)

Because of the risk of posttraumatic sarcoma, many clinicians are cautious about cataract surgery, intravitreous injections of gentamicin for the treatment of glaucoma or the use of an intrascleral prosthesis in cats. The cell of origin varies and is not definitively known for all three subtypes. There is good evidence that the spindle cell variant originates from the lens epithelial cell, and that the initial pathogenesis of the tumor is related to lens capsule rupture, release, and proliferation of the lens epithelial cells and epithelial-to-mesenchymal transition, leading to the sarcoma phenotype of the tumor.[63,64] Neoplastic cells of the round cell variant are positive on immunohistochemistry for CD79a (a B-lymphocyte marker) and this variant likely represents a form of anaplastic, primary ocular, B-cell lymphoma.[65] Chronic inflammation may support neoplastic transformation of a pluripotent cell.[58–60] These tumors, often within the same eye, exhibit a spectrum of changes ranging from granulation tissue to fibrosarcoma, osteosarcoma, and anaplastic spindle cell sarcoma.[59,60] All of these tumors tend to circumferentially line the choroid and quickly infiltrate the retina and optic nerve.[59,60] The round cell variant tends to infiltrate the retina early.[65,66] White or pinkish discoloration of the affected eye or change in the shape or consistency of the globe are the most common presenting signs. Skull radiographs may demonstrate bone involvement or metallic foreign bodies.[61]

Because this tumor is uncommon, many ophthalmologists will not remove a comfortable phthisical feline eye unless it changes appearance. The advanced stage at which many of these tumors are first identified, however, and the propensity for early optic nerve involvement indicate that enucleation at this point may be only palliative and not prolong life. This has led some authors to advocate prophylactic enucleation of phthisical feline eyes or of feline eyes that are blind and have been severely traumatized or are chronically inflamed.[58,61] Further support for this approach comes from the observation that approximately 7.5% of globes removed prophylactically in the COPLOW collection already have tumors. Extension beyond the sclera or into the optic nerve may occur and are poor prognostic indicators, further supporting the concept of early enucleation. As much of the optic nerve as possible should be removed during enucleation for confirmed or suspected ocular sarcoma so that the extent of infiltrative disease

and prognosis may be accurately determined. There is reason to believe that the prognosis is considerably better if enucleation is performed before the tumor invades the optic nerve or extends beyond the sclera.[67] To date, there have been no reports of treatment by RT or chemotherapy.

Extraocular extension is common, as is recurrence after orbital exenteration.[58,61] Continued growth up the remainder of the optic nerve into the chiasm and brain, with vision loss or other neurologic signs, involvement of regional lymph nodes, and distant metastasis, has been reported.[47,59] The vast majority of animals die of local invasion and recurrence, typically within several months of enucleation.[58,61]

Spindle Cell Tumors (Uveal Schwannoma) of Blue-Eyed Dogs

Dogs with a blue, or partially blue, iris appear to be at risk of developing a spindle cell sarcoma in the uvea.[68,69] These tumors usually involve the iris but can originate or extend into the ciliary body, choroid, and even the vitreous. Breeds that commonly have blue irides are more likely to develop an iridal spindle cell sarcoma, but any dog with any blue in its iris appears to be at risk. The origin of these tumors is thought to be Schwann cells of nonmyelinated peripheral nerves and the term "uveal Schwannoma of blue-eyed dogs" has been proposed.[69,70] The cells stain positive with glial fibrillary acidic protein (GFAP), as do the Schwann cells of nonmyelinating nerves. In a case series involving 11 dogs, more than half of the tumors were not clinically recognized and the diagnosis of neoplasia was not made until histopathology was performed. Metastatic disease appears uncommon, although one case has been reported and local recurrence within the scleral shell was seen in another dog that had been treated by evisceration and placement of an intrascleral prosthesis.[68,70]

Iridociliary Epithelial Tumors

Primary iridociliary epithelial tumors (ciliary body adenomas, adenocarcinomas, pleomorphic adenocarcinoma, and less commonly, medulloepitheliomas and other primitive neuroectodermal tumors [PNETs]) are the second most common primary intraocular tumors in dogs after melanocytic neoplasms and the third most common in cats.[71,72] They account for 12% of all canine and 3.5% of all feline tumors in the COPLOW database. The two main histologic forms of iridociliary adenomas/carcinomas that have been described are papillary (57% of cases in one study) and solid tumors (43%).[71] In the authors' experience, these tumors often appear nonpigmented clinically, but histologically at least some pigmented cells are present in approximately one-half of cases. Pigmented tumors of the ciliary body may be grossly indistinguishable from anterior uveal melanomas. Middle-aged to older dogs are the most commonly affected and golden and Labrador retrievers may be predisposed, for they comprised 27% of dogs with iridociliary epithelial tumors in one survey.[71] Most of these tumors appear to be benign, fairly well-delineated, sometimes pedunculated, slow-growing masses that originate in the pars plicata of the ciliary body or the iris epithelium.[71–73] Although approximately 60% invade the uveal tract, only 21% invade the sclera.[71] Tumors that invade the sclera are typically classified as adenocarcinomas and have anaplastic features, but metastasis is uncommon and occurs late in the course of the disease, if at all.[71–75] A small series of truly malignant pleomorphic adenocarcinomas with potentially fatal metastasis has been described in dogs.[76,77] These tumors are rare (0.2% of COPLOW's canine tumors) and affected dogs usually have long-standing disease thought to be inflammatory or traumatic. One retrospective study reported that 13% of cases had a history of known or suspected ocular trauma and 33% received an intravitreous gentamicin injection for the treatment of glaucoma.[77]

Clinical signs include a retroiridal mass that may displace the iris or lens by expansive growth, and if the tumor is large, secondary glaucoma, ocular pain, and intraocular hemorrhage may be noted.[74] The diagnostic workup and differential diagnosis are similar to that of anterior uveal melanomas. Given the high frequency of ciliary body cysts in some predisposed breeds (especially the golden retriever), it is essential to differentiate ciliary body tumors from a benign cystic lesion before enucleation. Cystic lesions, which rarely require any intervention, are usually seen as lightly pigmented, ovoid, retroiridal masses that can be shown to be hollow by transillumination or hypoechoic by ultrasonography. Early enucleation of ciliary body tumors has been recommended, although benign adenomas may remain static for years, making enucleation controversial for small tumors unassociated with secondary ocular disease. Local intraocular resection or laser photoablation may permit vision and ocular comfort to be maintained for at least some period of time.[43] However, in one study,[72] the vast majority of local excisional biopsies for iridociliary epithelial tumors had "dirty" margins and of the 19 dogs with follow-up only four did not have recurrence (which occurred an average of 23 months postbiopsy). In that study, adenomas were indistinguishable from adenocarcinomas on the basis of biopsy alone, although adenocarcinomas seldom metastasize. Complications of excisional biopsy include tumor recurrence, intraocular hemorrhage, chronic uveitis, cataract, glaucoma, lens displacement and retinal detachment. Systemic administration of 5-fluorouracil (5-FU) has been described as an adjunct to local resection of ciliary body tumors, but the efficacy of this therapy is unknown.[75]

Secondary Uveal Neoplasms

Numerous malignant tumors, especially adenocarcinomas, have been reported to metastasize to the highly vascular uveal tract. Metastatic tumors to the eye in dogs account for approximately 5% of all tumor submissions in the COPLOW database. Of those, the most common tumors in descending order are lymphomas, histiocytic sarcomas, hemangiosarcomas, respiratory (nasal and pulmonary) carcinomas, digital and oral melanomas, osteosarcomas and SCC.[78] In cats, the most common metastatic tumors to the eye are lymphomas, respiratory (nasal and pulmonary) carcinomas and SCC.

Lymphoma is the most common secondary intraocular tumor in the dog and cat, and ocular lesions are present in approximately one-third of dogs with the disease.[74,79–81] Ocular lymphomas are typically thought to be associated with systemic disease; however, a recent study found that, 60% of dogs with ocular lymphomas are free of systemic disease at the time of enucleation and hence were classified as presumed solitary ocular lymphoma (PSOL).[82] In this study, dogs with PSOL experienced a longer median survival time (MST, 769 days) than dogs with known systemic involvement (MST of 103 days). Histiocytic sarcomas account for 1.5% of all canine tumor submissions in the COPLOW database. In dogs, the diagnosis of ocular histiocytic sarcomas carries a poor prognosis with rapid progression of systemic disease and

clinical decline. Unpublished data from the COPLOW laboratory indicates that dogs diagnosed with histiocytic sarcoma in the eye have an average survival time of 3 months. Common presentations include severe uveitis, glaucoma, retinal hemorrhages, hyphema, conjunctivitis, and keratitis characterized by corneal infiltrates, edema, vascularization, and intrastromal hemorrhage.[74,79–81] Exophthalmia resulting from orbital invasion by the tumor and vision loss due to optic nerve or central nervous system (CNS) disease may also be present. Posterior segment lesions may include retinal vascular tortuosity, papilledema, multiple intraretinal hemorrhages, and retinal detachment. In one study, the lifespan of dogs with intraocular lymphoma was only 60% to 70% as long as dogs without ocular involvement when treated with cyclophosphamide, vincristine, and prednisolone (COP), or with doxorubicin.[80] Topical or systemic corticosteroid therapy or enucleation is palliative. (See Chapter 33 for the definitive therapy of lymphoma.) Ophthalmic disease, especially intraocular or retinal hemorrhage, may also be the presenting complaint in animals with multiple myeloma.[83]

Tumors of the Orbit and Optic Nerve

Incidence and Risk Factors

Risk factors other than middle to old age, possibly large-breed dogs,[84] and possibly sex (female dogs, male cats) have not been described.[84–92] Tumors involving the optic nerve are rare, although secondary invasion occurs in feline posttraumatic sarcomas, feline SCC, and canine choroidal melanomas. Canine orbital meningioma is the most common tumor of the optic nerve but comprises only 3% of all meningiomas in dogs.[88,90] Orbital rhabdomyosarcoma is a relatively rare but highly malignant neoplasm in juvenile dogs that accounts for 0.2% of all canine tumor submissions in the COPLOW database.[93] Lobular adenomas of unspecified glandular origin have been recently reported to involve the anterior orbit in dogs.[89]

Pathology and Natural Behavior

Orbital neoplasia may be primary (most common in dogs), secondary to extension of adjacent tumors into the orbit (most common in cats), or the result of distant metastasis. In cats and dogs, more than 90% of orbital tumors are malignant, and regional infiltration (including into the CNS) or distant metastasis is common.[84–87] At least 26 types of orbital tumors, roughly equally divided among connective tissue, bone, epithelial, and hemolymphatic origins, have been reported in dogs.[87] Osteosarcomas, MCTs, histiocytic sarcomas, fibrosarcomas, and neurofibrosarcomas are the most common canine primary orbital tumors.[87] More than two-thirds of feline orbital tumors are epithelial in origin, with SCC being the most common,[86] but at least 15 other tumor types have been described in cats.

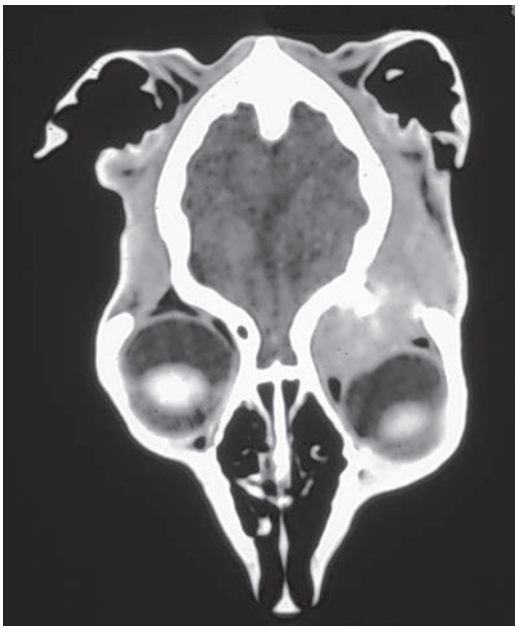
Canine orbital meningiomas exhibit predictable biologic behavior. They are slowly progressive and rarely metastasize; they may be osteolytic and invade surrounding tissues, including the CNS via the optic foramen.[87,89,90] Primary optic nerve tumors in dogs include glioma and meningioma.[87,88,90,91] Retinal and optic nerve gliomas may be considered as differential diagnoses of intraocular and orbital masses. The metastatic potential of gliomas appears to be low, but ascending invasion into the ventral aspect of the brain is possible.[92]

Canine orbital rhabdomyosarcomas (COR) are embryonal tumors that usually exhibit an aggressive biologic behavior. A recent case series reported that the age of the patient had a direct effect on the prognosis of the disease.[93] Dogs younger than 4 years old diagnosed with COR had high rates of recurrence and/or metastasis and were euthanized within 6 months (median 2.5 months). On the other hand, COR in dogs 6 years of age or older had a less aggressive biologic behavior with no clinical signs of recurrence or metastasis 8 to 13 months postdiagnosis.

Lobular orbital adenomas are made up of multiple soft friable lobules in the anterior orbit, making complete surgical excision difficult.[89] We have noted that for this tumor, excision of the multiple soft masses is possible with a large diameter surgical suction tip or a Sims Connector. This increases the ability to completely remove the tumor and limits the surgical exposure required.

History and Clinical Signs

Slowly progressive exophthalmia, absent to minimal pain on opening the mouth, difficulty in retropulsing the eye, and deviation of the globe typify orbital neoplasia. Sudden erosion of nasal or sinus tumors into the orbit occasionally results in acute exophthalmia and substantial orbital pain. Enophthalmia may occur if the mass is anterior to the equator of the globe. Lobular adenomas may present as soft, raised, subconjunctival masses and create either enophthalmia or exophthalmia. Chronic epiphora secondary to obstruction of the nasolacrimal duct, exposure keratoconjunctivitis, palpable orbital masses after enucleation, or unexplained orbital pain also suggests orbital neoplasia.[84–87] Measurement of corneal diameters and intraocular pressure (IOP) aids in differentiating glaucomatous ocular enlargement (large corneal diameter, high IOP) from exophthalmia (normal corneal diameter and IOP).



Optic nerve lesions may result in unilateral or bilateral blindness (the latter if the optic chiasm is affected), optic nerve head pallor, papilledema, or marked protrusion and congestion of the optic disc on ophthalmoscopy. A relatively mild degree of exophthalmia with vision loss suggests optic nerve neoplasia because tumors of other orbital tissues typically cause profound exophthalmos before visual loss. Tumors affecting the retrobulbar, intracanalicular, or chiasmal portions of the optic nerve may not result in exophthalmia or a visible change in the optic nerve head.

Diagnostic Techniques and Workup

It is essential to differentiate nonneoplastic orbital inflammatory diseases (granulomas, cellulitis, abscesses, myositis of the extraocular and masticatory muscles) from neoplasia. Animals with inflammatory disease typically exhibit significant pain on opening the mouth. The location of an orbital mass can usually be determined by careful physical examination, including retropulsion of the globe, oral examination caudal to the last molar, and determination of the direction of malposition of the eye.

In addition to physical examination, cytology of regional lymph nodes, orbital ultrasound, orbital and thoracic radiographs and orbital CT/MRI imaging should be considered. In one study of cats with orbital neoplasia, 59% had radiographic signs of orbital bone lesions and 15% had evidence of metastasis on thoracic radiographs.[86] CT or MRI offer superior depictions of the orbit and facilitate planning of either radiation or surgical therapy (Fig. 32.8). Histologic characterization by FNA or needle core biopsies (performed via the mouth or through the orbital skin), with ultrasound or CT guidance if necessary, are helpful in arriving at a definitive diagnosis. The globe, major orbital blood vessels, and optic nerve should be avoided. Because 50% of orbital tumors

VetBooks.ir

• **Fig. 32.8** CT (dorsal view) provides detailed information about the location and extent of orbital tumors, as in this 17-year-old cat with orbital osteosarcoma.

may have a nondiagnostic FNA, especially in cases of SCC,[86] exploratory orbitotomy via a number of approaches[94–99] or exenteration may be required to characterize the mass and resect it if possible. Cerebrospinal fluid taps may aid in distinguishing optic nerve neoplasia from optic neuritis.

Therapy

Primary orbital and optic nerve tumors that lack metastasis or regional lymph node involvement may be amenable to surgical excision. If bony involvement is not present, orbital exenteration by widely dissecting around the mass (stripping periorbita if necessary) is usually the preferred procedure, as the advanced stage of the tumor at the time of diagnosis typically makes it impossible to excise the mass completely and preserve a functional or comfortable eye. If periorbital bones are involved, radical "orbitectomy," which resects the affected orbital tissues and surrounding bones, should be considered.[96] When treating optic nerve tumors, as much of the ipsilateral optic nerve as possible should be removed in an attempt to obtain complete excision.[87]

If preservation of a comfortable eye and vision appears possible, a variety of orbitotomy/partial orbitectomy techniques, ranging from small incisions through the eyelid or mouth to reflection of the zygomatic arch, temporalis muscle elevation, zygomatic process osteotomy and ostectomy of a variety of orbital bony structures have been described.[94–99] Recently orbital reconstruction techniques have also been described which improve the tectonic, cosmetic and functional results of the procedure.[99] Postoperative complications are common and may include secondary enophthalmia with entropion and possibly diplopia (double vision). Surgical debulking as an alternative to "radical orbitectomy" can be palliative, and some dogs may survive a year or more with minimal therapy.

The role of chemotherapy and RT, either alone or as an adjunct to surgery, is yet to be defined in the treatment of orbital tumors, although chemotherapy for orbital lymphoma may be effective. Systemic corticosteroids may permit some patients with optic nerve meningioma to maintain vision for several weeks to months. RT may be helpful in the case of nasal tumors with orbital extension, in subtotally excised or recurrent meningiomas, and in other select cases.

Prognosis

With conservative treatment, the prognosis for most tumors involving the orbit and optic nerve is poor,[86,87] especially if there is bony involvement on skull radiographs. Recurrence at the primary site and involvement of adjacent or distant sites are common, often occurring within weeks to a few months. Even benign-appearing tumors such as lobular orbital adenomas and orbital meningiomas may be locally invasive and have a propensity for recurrence after wide excison.[84–90,96] In one study, however, radical orbitectomy (with or without chemotherapy or RT) provided a local disease-free interval of more than 1 year in more than 50% of patients and a 70% survival rate for the first year.[96] In another study, the mean survival time for cats with orbital tumors treated by RT, chemotherapy, or surgery that included resection of affected orbital bones was only 4.3 months.[86] In a study of 23 dogs with orbital tumors, most of which were treated by exenteration with or without adjunct therapy, only three survived 3 years or longer.[87] The majority of these animals died as a direct result of the tumor or were euthanatized at the time of diagnosis.[84–87]

Ocular Effects of Cancer Therapeutic Modalities

The ocular effect of external-beam RT for nasal and periocular tumors can have a substantial effect on an animal's quality of life. Common complications include chronic keratoconjunctivitis, corneal ulceration, "dry eye," enophthalmia, entropion, cataracts, retinal hemorrhages, retinal detachments, and blindness.[100–103] Many of these conditions respond poorly to treatment, and vigorous attempts at prevention should be made to avoid chronic ocular pain and blindness. Recently intensity-modulated RT (IMRT), which uses conformal avoidance, has been shown to significantly decrease the ocular toxicity seen in dogs treated by RT for spontaneous sinonasal tumors.[102,103]

In humans, blurred vision, partial visual field defects, loss of color vision, and diplopia have been associated with several antineoplastic drugs.[104–107] Similar effects probably occur in animals but would be difficult to detect. In addition, in humans, the bacillus Calmette-Guérin (BCG) has been associated with uveitis; cyclophosphamide has been associated with dry eye; cisplatin has been associated with neuroretinal toxicity; doxorubicin has been associated with excessive lacrimation and conjunctivitis; 5-FU has been associated with blurred vision, excessive lacrimation, blepharitis, conjunctivitis, and keratitis; and vincristine has been associated with cranial nerve palsies, optic neuropathy, and cortical and night blindness.[104] Monoclonal antibodies directed at the vasculature supporting the tumor also have been associated with uveitis.[105] Antibody–drug conjugates have been associated with blurred vision, dry eye, and corneal abnormalities including microcystic corneal disease.[106]

Comparative Aspects

Malignant melanoma of the choroid is the most common primary ocular malignancy in adult humans. Initially, it was believed that enucleation of these patients may enhance the risk of metastasis;

thus a large randomized clinical trial (the Collaborative Ocular Melanoma Study) was conducted comparing enucleation with iodine-125 brachytherapy, which left the globe intact.[108,109] Both treatment modalities yielded similar results, although many patients still died from metastatic melanoma, and it appears that significant improvement in survival rates will depend on developing effective systemic therapeutic modalities for melanoma.[108,109]

Retinoblastoma is the most common malignant intraocular tumor of children and has a genetic basis. No cases of retinoblastoma have been described in nonhuman primates, and only one case of retinoblastoma has been described in a dog.[110] With therapy, long-term survival in children is over 85%, but many patients develop second tumors, especially osteosarcoma.[111] Cancer-associated retinopathy is an uncommon, immune-mediated paraneoplastic phenomenon in humans in which antibodies are directed against specific retinal autoantigens, such as recoverin.[112–114] In this condition, patients with small-cell lung carcinoma and other tumors may develop blurred vision, impaired color vision, substantial visual field defects, or complete blindness as tumor antigens cross-react with specific retinal components.[112–114] Treatment with IV immunoglobulin has been reported to return vision to some patients.[112] Although cancer-associated retinopathy has been suggested to occur in dogs, especially those with sudden acquired retinal degeneration syndrome (SARDS), definitive proof is lacking and one study did not identify antibody activity against retinal proteins or evidence of neoplasia in dogs with SARDS.[115]

Hematopoietic Tumors

SECTION A: CANINE LYMPHOMA AND LYMPHOCYTIC LEUKEMIAS

DAVID M. VAIL, MARIE PINKERTON, AND KAREN M. YOUNG

Lymphoma

Lymphoma (malignant lymphoma or lymphosarcoma) comprises a diverse group of neoplasms that have in common their origin from lymphocytes. The neoplasms usually arise in lymphoid tissues such as lymph nodes (LNs), spleen, and bone marrow; however, they may arise in almost any tissue in the body. Although the annual incidence of lymphoma is difficult to predict in the absence of a national canine tumor registry, it is clear that it represents one of the most common neoplasms seen in the dog. The annual incidence has been estimated to range between 13 and 114 per 100,000 dogs at risk. The rates at specific ages are estimated to be 1.5 per 100,000 for dogs less than 1 year of age and 84 per 100,000 for dogs 10 to 11 years old.[1–4] Lymphoma comprises approximately 7% to 24% of all canine neoplasias and 83% of all canine hematopoietic malignancies.[5,6] In a review of the Veterinary Medical Database Program (VMDP) at Purdue University from 1987 to 1997, the frequency of dogs presented with lymphoma to 20 veterinary institutions increased from 0.75% to 2.0% of total case load, and it appears the frequency is continuing to increase. A similar trend is present in physician-based oncology; non-Hodgkin's lymphoma (NHL) represents 5% of all new cancer cases, the fifth leading cause of cancer death, and the second fastest growing cancer in terms of mortality in humans.[7] Middle-aged to older (median age of 6–9 years) dogs are primarily affected, although dogs with T-cell lymphoma tend to be younger.[8] A decreased risk for lymphoma is reported for intact females.[9] Breeds reported to have a higher incidence include boxers, bullmastiffs, basset hounds, St. Bernards, Scottish terriers, Airedales, pitbulls, Briards, Irish setters, Rottweilers, and bulldogs; breeds at lower risk include dachshunds and Pomeranians.[8,10,11] See Box 33.1.

Etiology

The etiology of canine lymphoma is likely multifactorial and largely unknown; however, investigations are currently shedding significant light on the subject.

Genetic and Molecular Factors

Advances in molecular cytogenetics (see Chapter 1, Section A), including array-comparative genomic hybridization and chromosome painting, have been and are currently being applied to investigations of chromosomal aberrations in dogs with lymphoma.[12–18] Publication of the canine genome and commercial availability of canine gene microarrays (GeneChip Canine Genome 2.0 Array, Affymetrix, Inc.) have led to advances in our understanding of deregulations of gene expression occurring in lymphoma.[19] Gains of canine chromosomes 13 and 31 and loss of chromosome 14 have been documented as the most common aberrations in a group of 25 cases analyzed.[17] Chromosomal aberrations have also been associated with prognosis in dogs with lymphoma. A study of 61 dogs with lymphoma demonstrated a prognostic advantage in dogs with trisomy of chromosome 13 (25% of the dogs studied), as evidenced by increase in duration of first remission and overall survival time (ST).[20] Germline and somatic genetic mutations and altered oncogene/tumor suppressor gene expression, epigenetic changes (e.g., DNA hypomethylation), signal transduction, and death-pathway alterations (e.g., *Bcl-2* family) are common in human lymphomas and have been reported in the dog as well (see Chapter 1, Section A, and Chapter 15, Section B).[21–25] These include N-*ras, p53, Rb,* p16 cyclin-dependent kinase, telomerase, and NF-κB among others.[22,26–31] Somatic mutations, as determined by exome sequencing, have shown much overlap in canine breeds with respect to B-cell lymphoma, specifically mutations in TRAF3-MAP3K14, FBXW7, and POT1, but little overlap in somatic mutations among breeds with T-cell lymphoma.[21] In addition, differences in the prevalence of immunophenotypic subtypes of lymphoma among different breeds indicate heritable risks.[32] Telomerase activity (see Chapter 2) has also been documented in canine lymphoma tissues.[33–35] As somatic mutations are often implicated, it is not surprising that alterations or deficiencies in DNA repair mechanisms would also be implicated, as has been demonstrated in golden retrievers with lymphoma.[36]

Infectious Factors

The hypothesis that a retrovirus may be involved in the pathogenesis of canine lymphoma has not been confirmed. Epstein–Barr virus, a gammaherpesvirus linked to some forms of lymphoma in humans, has also been investigated in canine lymphoma; however, there was no association between serologic or molecular detection of gammaherpesvirus and development of lymphoma.[37,38]

In humans, a direct association between *Helicobacter* sp. infections and development of gastric lymphoma has been made.[39] Although this has not been definitively shown in dogs, there is

VetBooks.ir

• BOX 33.1 Key Clinical Summary Points: Canine Lymphoma

- Lymphoma is a catch-all term for approximately two dozen lymphocyte cancer subtypes (Table 33.1).
- Most are intermediate or high grade, but indolent forms exist.
- Dogs with lymphoma most commonly have peripheral lymphadenopathy, although varied anatomic locations can be affected (Box 33.2).
- For nodal disease, needle aspirate cytology is a good first screening step; ancillary diagnostics are required to subtype for prognosis or to confirm diagnosis in equivocal cases (Figs. 33.3, 33.8).
- Many treatment protocols exist, but most involve CHOP-based combination chemotherapy (Table 33.4).
- Initially gratifying to treat, as response rates are high and often durable (>6 months); however, cures are rare (<10%) and it is ultimately a uniformly fatal disease.
- Dogs with indolent subtypes may live years, often without therapeutic intervention.
- A veterinary oncology specialist should be consulted on individual cases, as the clinical, diagnostic, and therapeutic landscape changes rapidly.

evidence of *Helicobacter* sp. infection in laboratory beagle dogs resulting in gastric lymphoid follicle formation that is considered a precursor of mucosa-associated lymphoid tissue (MALT) lymphoma in humans.[40]

Alterations in the gut microbiome have been implicated as playing a role in susceptibility to certain tumors. Fecal microbiota of dogs with lymphoma have been shown to be significantly different than control dogs, although a cause–effect relationship is unclear.[41]

Environmental Factors

In humans, evidence has accumulated implicating phenoxyacetic acid herbicides, in particular 2,4-dichlorophenoxyacetic acid (2, 4-D), in the development of NHL. Some epidemiologic evidence also implicates lawn herbicide use and occurrence of lymphoma incidence in dogs.[42–45] In one case-control study, the risk of canine lymphoma was reported to rise two-fold (odds ratio [OR] = 1.3) with four or more yearly owner applications of 2,4-D. The results of this study have come under criticism, and three additional follow-up investigations have not validated this increased risk.[46–48] In another study, dogs exposed to lawn treatment within 7 days of application were greater than 50 times more likely to have 2,4-D urinary levels of 50 µg/L or higher.[45] In an environmental case-control study performed in Europe, two variables, residency in industrial areas and use of chemicals (defined as paints or solvents) by owners, modestly increased the risk of developing lymphoma; however, no link was found with pesticide use.[49] A more recent epidemiologic study investigating multiple environmental factors showed increased risk of canine lymphoma with use of lawn care products, in particular professionally applied pesticides.[43] This study did not find an association with flea and tick control products.

A weak association between lymphoma in dogs and exposure to strong magnetic fields was observed in a preliminary epidemiologic study.[50] In this hospital-based case-control study, the risk of developing lymphoma with high or very high exposure was increased (OR = 1.8). More thorough studies are necessary to evaluate this association further. Proximity to environmental waste was implicated in two European studies; however, it was felt to be a risk indicator rather than a risk factor and would require further case-control investigations.[51,52] Exposure to tobacco smoke was also implicated in one study.[53]

Immunologic Factors

Impaired immune function has also been implicated in dogs with lymphoma. Immune system alterations, such as immune-mediated thrombocytopenia, independent of age and sex, have been associated with a higher risk of subsequently developing lymphoma compared with the normal population.[54,55] Additional evidence comes from observations in human and feline transplantation patients.[56–58] In a case-control study of cats undergoing renal transplant, 24% of cases developed cancer (36% of those were lymphoma) while on cyclosporine immunosuppressive therapy compared with 5.1% of control cats, none of which developed lymphoma (OR, 6.1; $p = 0.001$).[58] A case of lymphoma developing in a dog after treatment with cyclosporine also exists.[57] One report suggests an association between the immunodysregulation observed in dogs with atopic dermatitis and the risk of developing epitheliotropic T-cell lymphoma; whether lymphoma is associated with the primary disease or the immunomodulatory treatments commonly applied is unknown.[59]

Classification and Pathology

Classification of malignant lymphoma in dogs is based on anatomic location, histologic criteria, and immunophenotypic characteristics. The most common anatomic forms of lymphoma, in order of decreasing prevalence, are multicentric, gastrointestinal (GI), mediastinal, and cutaneous forms.[60] Primary extranodal forms, which can occur in any location outside the lymphatic system, include the eyes, skin, central nervous system (CNS), bone marrow, bladder, heart, and nasal cavity. The pathologic characteristics of the various anatomic classifications will be discussed in this section and clinical characteristics will be described in subsequent sections.

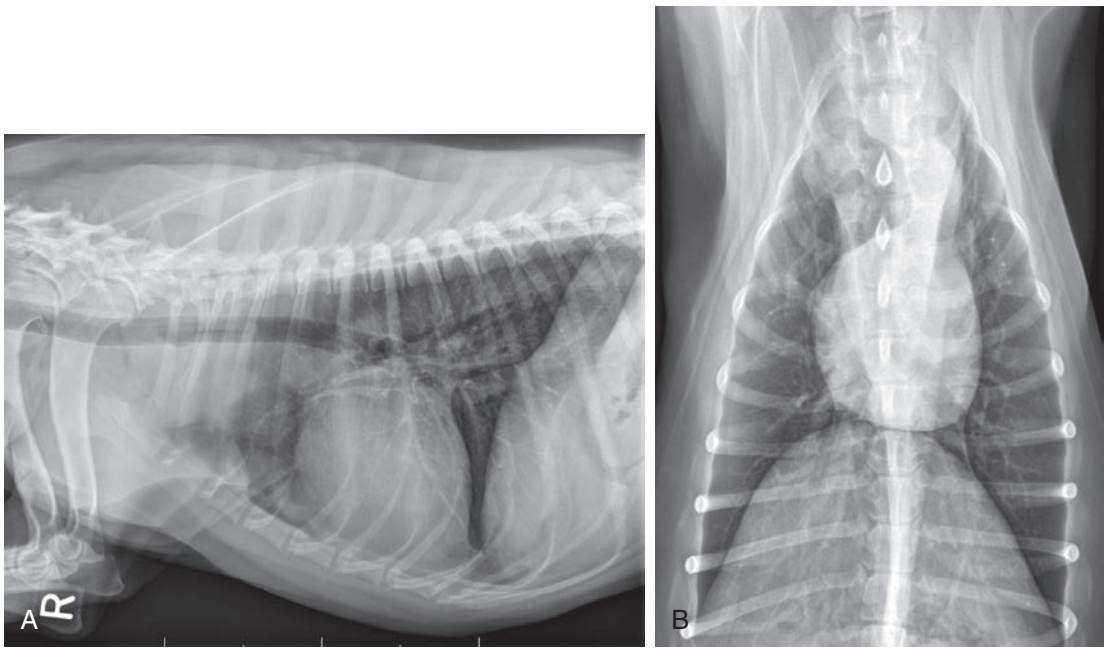
More than 80% of dogs with lymphoma are presented with the multicentric form, which is usually characterized by the presence of peripheral lymphadenopathy (Fig. 33.1).[60] The alimentary form of lymphoma is much less common, accounting for 5% to 7% of all canine lymphomas. Primary GI lymphoma in dogs may occur focally, but more often affects multiple segments with thickening of the wall, narrowing of the lumen, and frequently mucosal ulceration.[61,62] Histologically, there is infiltration of neoplastic lymphocytes throughout the mucosa and submucosa with occasional transmural infiltration. Liver and local LNs are often secondarily involved. Lymphocytic-plasmacytic inflammatory bowel disease (LP-IBD) can be seen adjacent to or distant from the primary tumor. Pathologically, some of these neoplasms may resemble plasma cell tumors and aberrant production of immunoglobulins may occur. Histologically, distinguishing between GI lymphoma and LP-IBD can be difficult. Some have suggested that LP-IBD may be a prelymphomatous change in the GI tract. A syndrome of immunoproliferative intestinal disease characterized by LP-IBD has been described in Basenjis, which subsequently develop GI lymphoma.[63] In addition, plasma cell–rich areas with heterogeneous lymphomatous infiltration may resemble lesions of LP-IBD. Only a few reports specifically identify the immunophenotype of the lymphocyte subpopulations in GI lymphoma in dogs. Historically, it was presumed that they most likely originate from B cells; however, recent evidence suggests that most GI lymphomas in dogs arise from T cells and often exhibit epitheliotropism.[62,64,65] The boxer and Shar-pei breeds may be overrepresented in cases of alimentary lymphoma.[65,66]

The mediastinal form of the disease occurs in approximately 5% of cases.[60] This form is characterized by enlargement of the

VetBooks.ir

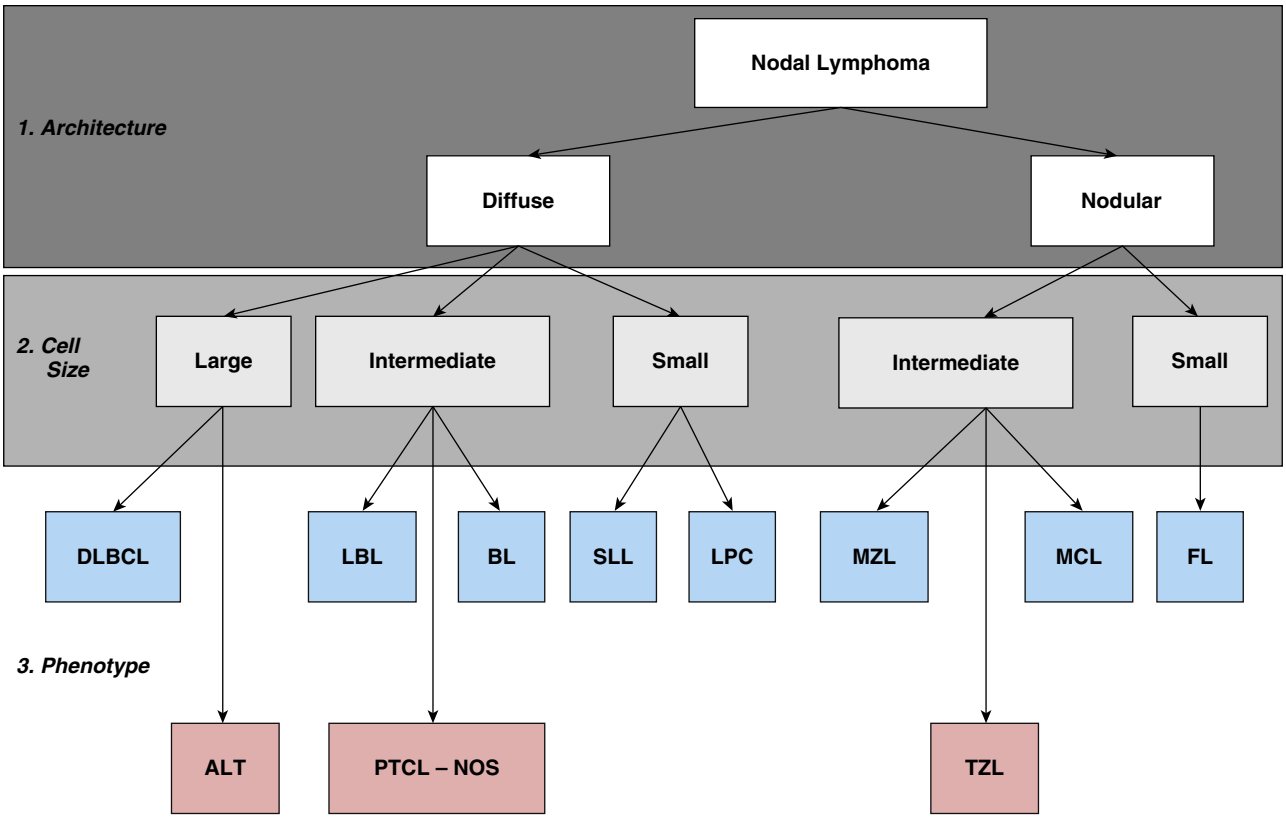
cranial mediastinal LNs, thymus, or both (Fig. 33.2). Hypercalcemia is reported to occur in 10% to 40% of dogs with lymphoma and is most common with the mediastinal form. In a study of 37 dogs with lymphoma and hypercalcemia, 16 (43%) had mediastinal lymphoma.[67] The mediastinal form in dogs is most commonly associated with a T-cell phenotype.[68,69] A single case of mediastinal γδT-cell lymphoma with large granular lymphocyte morphology has been reported.[70]

Cutaneous lymphoma can be solitary or more generalized and is usually classified as epitheliotropic (mycosis fungoides) or nonepitheliotropic.[71,72] Canine epitheliotropic cutaneous lymphoma originates from T cells,[73–77] similar to the case in humans. In dogs, these more commonly represent $CD8^+$ cells, whereas in humans they are typically $CD4^+$ cells.[76] A rare form of cutaneous T-cell lymphoma, characterized by skin involvement with evidence of peripherally circulating large (15–20 μm in diameter) malignant T cells with folded, grooved nuclei, has been described. In humans, this is referred to as Sézary syndrome and has been reported in both dogs and cats.[78–80] Nonepitheliotropic cutaneous lymphomas form single or multiple dermal or subcutaneous nodules or plaques; histologically, they spare the epidermis and papillary dermis and affect the middle and deep portions of the dermis and subcutis.[72] An inflamed form of nonepitheliotropic cutaneous T-cell lymphoma (NE-CTCL) is more pleocellular and can be difficult to differentiate from reactive histiocytosis.[71]



• **Fig. 33.1** A dog with obvious mandibular lymphadenopathy resulting from multicentric lymphoma.

Atypical Anatomic Forms of Lymphoma



Hepatosplenic lymphoma is a relatively uncommon, distinct presentation in the dog marked by a lack of significant peripheral lymphadenopathy in the face of hepatic, splenic, and bone marrow infiltration with malignant lymphocytes, usually of T-cell origin.[81–83] Biologically, this form of lymphoma is extremely aggressive and poorly responsive to therapy. In humans and dogs, the tumor usually is composed of γδT cells (i.e., T cells that express the γδT-cell receptor).[81,82]

Intravascular (angiotropic, angioendotheliomatosis) lymphoma is a distinct form of lymphoma defined as proliferations of neoplastic lymphocytes within the lumen and wall of blood vessels in the absence of a primary extravascular mass or leukemia. It has been reported several times in the veterinary literature and often involves the CNS and peripheral nervous system (PNS), including the eye.[84–89] The B-cell immunophenotype is most common in humans; however, in most reported cases in dogs, the origin is either T cell or null cell (neither B nor T cell), although one case of a B-cell phenotype has been reported.

Pulmonary lymphomatoid granulomatosis (PLG), also termed angiocentric B-cell lymphoma, is a rare neoplasm of the lung and

• **Fig. 33.3** The histologic approach toward the classification of canine nodal lymphoma. Using excisional lymph node sections, lymphoma is initially divided into diffuse (effacing) or nodular (noneffacing) forms of the disease. Next, using a red blood cell or a small lymphocyte as a guideline, the neoplastic population is divided into large, small, and intermediate forms of the disease. Finally, using knowledge of additional cellular and nuclear features, including mitotic rate and immunophenotype (B cell, blue boxes; T cell, red boxes), a final diagnosis is established. *ALT*, Anaplastic large cell T-cell lymphoma; *BL*, Burkitt lymphoma; *DLBCL*, diffuse large B-cell lymphoma; *FL*, follicular lymphoma; *LBL*, lymphoblastic lymphoma; *LPC*, lymphoplasmacytoid lymphoma; *MCL*, mantle cell lymphoma; *MZL*, marginal zone lymphoma; *PTCL, NOS*, peripheral T-cell lymphoma, not otherwise specified; *SLL*, small lymphocytic lymphoma; *TZL*, T-zone lymphoma. occasionally other tissues, characterized by a heterogeneous accumulation of lymphocytes (both B and T cell), neutrophils, plasma cells, and macrophages, often arranged angiocentrically.[90–94] Clinical signs are related to respiratory compromise, and various chemotherapeutic protocols have been used with reported results varying from rapid progression to long-term clinical remissions.

Histologic Classification Systems

Lymphomas arise from clonal expansion of lymphocytes with distinctive morphologic and immunophenotypic features. Many histologic systems have been used to classify NHL in humans, and some of these have been applied to lymphoma in the dog and other species. Histologic classification of lymphoma currently follows the Revised European American Lymphoma/World Health Organization (REAL/WHO) system, which incorporates anatomic, morphologic (cytology and histology), and immunophenotypic criteria (B- and T-cell immunophenotype), with the goal of enabling accurate and reproducible diagnosis of specific neoplastic entities.[90,95,96] Fig. 33.3 represents an overall histologic approach to the classification of various subtypes in the dog as reviewed by Seelig et al.[96,97] This theoretically should assist in better tailoring of treatment protocols, better correlation of prognosis with subtype, and better comparative capabilities once larger data sets with correlate outcomes are generated. Table 33.1 shows some of the WHO categories in three different surveys, including a 2-year survey (2008–2009) of canine necropsy and biopsy cases at the University of Wisconsin–Madison Veterinary Care Hospital[29,95,96,98]; some of the less common categories in the REAL/WHO system were not represented and are not listed. Most canine lymphomas fall into the following categories, in decreasing frequency: diffuse large B-cell lymphoma (DLBCL), peripheral T-cell lymphoma not otherwise specified (PTCL-NOS), T-zone lymphoma (TZL), T-lymphoblastic lymphoma (also called "precursor T-cell neoplasia"), and marginal zone lymphoma (MZL).[90] The REAL/WHO system provides accurate and consistent reproducible diagnostic results similar to the system used in human pathology; agreement among a group of pathologists examining 300 cases was 83%, and accuracy in evaluating the six most common diagnoses (80% of the cases) was 87%.[99] It is clear that lymphoma is not a single disease, and classification by subtype will become increasingly important as clinical studies are performed to correlate the various categories of disease with biologic behavior, response to treatment, and

TABLE 33.1 World Health Organization Classification System for Canine Lymphoma

Category	PERCENTAGE		
	Seelig et al[96] (*n* = 3 data sets)	Vezzali et al[98] (*n* = 123)	University of Wisconsin (*n* = 122)
B-Cell Neoplasms	69	78.9	59.0
Precursor B lymphoblastic leukemia/lymphoma[a]	—	2.4	8.2
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	—	2.4	0.8
Lymphocytic lymphoma—intermediate type	—	0.8	—
Lymphoplasmacytic lymphoma	—	3.3	0.8
Mantle cell lymphoma	2	1.6	—
Follicular center cell lymphomas	—	2.4	—
Marginal zone lymphoma (splenic, nodal, mucosa-associated lymphoid tissue)	8	3.3	2.5
Plasma cell myeloma/plasmacytoma	—	16.3	9.8
Diffuse large cell lymphoma	52	33.3	24.6
T-cell–rich, B-cell lymphoma	—	0.8	—
Large cell immunoblastic lymphoma	—	10.6	10.7
Mediastinal (thymic) large B-cell lymphoma	—	0.8	—
Burkitt's lymphoma/leukemia	—	0.8	1.6
Other B cell	8[d]	—	—
T-Cell and Natural Killer (NK[b]) Cell Lymphomas	31	21.1	41.0
Precursor T lymphoblastic lymphoma/leukemia[a]	3	6.5	9.8
T-cell chronic lymphocytic leukemia (CLL)	—	3.3	0.8
Intestinal T-cell lymphoma	—	4.1	4.1
Mycosis fungoides/Sézary syndrome	—	1.6	11.5
Cutaneous nonepitheliotropic lymphoma	—	3.3	—
Anaplastic large cell lymphoma	—	—	0.8
Peripheral T-cell lymphoma-not otherwise specified	15	2.4	13.1[c]
T-zone lymphoma	4		
Other T cell	7[d]	—	—
Other	3[d]		

[a]Acute leukemias and lymphoblastic lymphomas of both B and T derivation are also classified as lymphoid "precursor neoplasms."

[b]Non-B, non-T lymphomas.

[c]Includes T-zone lymphoma in this data set.

[d]Other in Seelig include those not otherwise subclassified.

prognosis. Preliminary results indicate that dogs with indolent lymphoma (e.g., MZL, follicular lymphoma, B- or T-cell small cell lymphoma, T-cell–rich B-cell lymphoma, and TZL) maintain normal activity and appetite levels even during advanced stages of disease and experience long-term survival even with limited or no therapy.[90,99–102]

Other classification systems that have been used include the National Cancer Institute Working Formulation (WF)[103] and the updated Kiel system.[104] The WF was developed to allow investigators to "translate" among the numerous classification systems so that clinical trials could be compared in humans. Most of the larger compilations agree that most canine lymphomas are intermediate or high grade. The WF categorizes tumors according to pattern (diffuse or follicular) and cell type (e.g., small cleaved cell, large cell, immunoblastic), but it does not include information about the immunophenotype of the tumor.[103] The WF subtypes are related to the biology of the tumor and patient survival. The updated Kiel classification includes the architectural pattern,

morphology (centroblastic, centrocytic, or immunoblastic), and immunophenotype (B or T cell) of the tumor cells.[104] In both systems, the tumors can then be categorized as low-grade, intermediate-grade, or high-grade malignancies. Low-grade lymphomas composed of small cells with a low mitotic rate typically progress slowly and are associated with long STs, but are ultimately incurable. High-grade lymphomas with a high mitotic rate progress rapidly, but are more likely to respond initially to chemotherapy and, in humans, are potentially curable. In the REAL/WHO system, each subtype of lymphoma is classified as a distinct disease based on characteristics that include biologic behavior (indolent versus aggressive, response to treatment).[90]

Several features of canine lymphomas become apparent when these classification systems are applied. The most striking difference between canine and human lymphomas is the scarcity of follicular lymphomas in the dog. The most common form of canine lymphoma is DLBCL, a high-grade tumor.[90,98,99,105] A small percentage of canine lymphomas (5.3%–29%) are considered low-grade.

A documented difference exists in the prevalence of the various immunophenotypes based on breed.[32,106,107] For example, cocker spaniels and Doberman pinschers are more likely to develop B-cell lymphoma, boxers are more likely to have T-cell lymphoma, and golden retrievers appear to have an equal likelihood of B- and T-cell tumors.

To be clinically useful, these classification systems in the end must yield information about response to therapy, maintenance of remission, and survival. In most studies, high-grade lymphomas achieve a complete response (CR) to chemotherapy significantly more often than low-grade tumors. However, dogs with low-grade tumors may live years without aggressive chemotherapy.[100–102,108–111] Dogs with T-cell lymphomas have shown a lower rate of CR to chemotherapy and shorter remission and STs than dogs with B-cell tumors (with the exception of low-grade T-cell subtypes).[68,69,112,113] Furthermore, T-cell lymphomas are more commonly associated with hypercalcemia.[8,114,115]

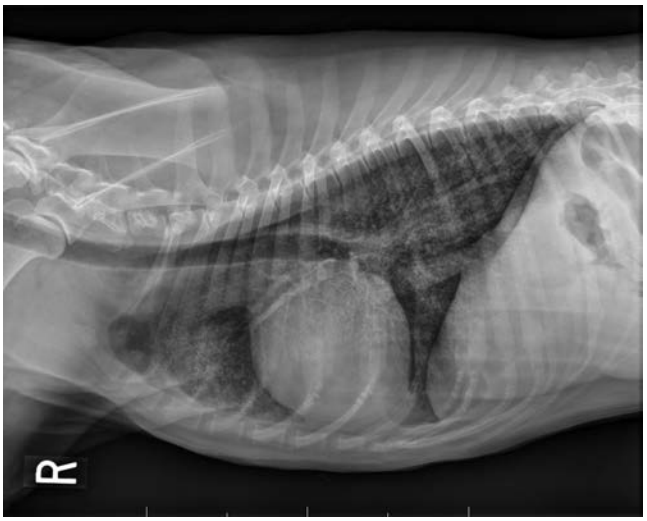
In the veterinary literature, 60% to 80% of canine lymphomas are of B-cell origin; T-cell lymphomas account for 10% to 38%; mixed B- and T-cell lymphomas account for as many as 22%; and null-cell tumors represent fewer than 5%.[8,68,69,116–118] The development of monoclonal antibodies to detect specific markers on canine lymphocytes has made immunophenotyping of tumors in dogs routinely available in many commercial laboratories. Such techniques can be performed on paraffin-embedded samples, from tissue microarrays, on cytologic specimens obtained by fine-needle aspiration (FNA) of lesions, or by flow cytometric analysis of cellular fluid samples (e.g., peripheral blood, effusions) and lesion aspirates.

One criticism of the Kiel and WF classification systems is that they fail to include extranodal lymphomas as a separate category. The REAL/WHO system does include anatomic location as a factor in determining certain categories. Although differences between nodal and extranodal tumors in biologic behavior and prognosis are well recognized, comparative information about the histogenesis of these tumors is lacking. For example, in humans, small-cell lymphomas arising from MALT are composed of cells with a different immunophenotype than that of other small-cell lymphomas (i.e., MALT lymphomas typically are negative for both CD5 and CD10). With the exception of cutaneous lymphoid neoplasms, detailed characterization of extranodal lymphomas in dogs has not been done. Although cutaneous lymphoma is a heterogeneous group of neoplasms that includes an epitheliotropic form resembling mycosis fungoides and a nonepitheliotropic form, most cutaneous lymphomas have a T-cell phenotype.[119]

• BOX 33.2 World Health Organization's Clinical Staging System for Lymphoma in Domestic Animals

1. Anatomic site
   - A. Generalized
   - B. Alimentary
   - C. Thymic
   - D. Skin
   - E. Leukemia (true)[a]
   - F. Others (including solitary renal)
2. Stage (to include anatomic site)
   - I. Involvement limited to a single node or lymphoid tissue in a single organ[b]
   - II. Involvement of many lymph nodes in a regional area (± tonsils)
   - III. Generalized lymph node involvement
   - IV. Liver and/or spleen involvement (± Stage III)
   - V. Manifestation in the blood and involvement of bone marrow and/or other organ systems (± Stage I–IV)

Each stage is subclassified into:



a. Without systemic signs
b. With systemic signs

[a]Only blood and bone marrow involved.
[b]Excluding bone marrow.

To summarize, it is important to determine the histologic grade of canine lymphomas as low (small lymphocytic or centrocytic lymphomas), intermediate, or high (diffuse large cell, centroblastic, and immunoblastic lymphomas), and the architecture as diffuse or nodular/follicular. Furthermore, determining the immunophenotype of the tumor provides useful information and is essential to accurately subtype lymphoma. Response rates to chemotherapy are, in general, better in animals with B-cell tumors and intermediate- to high-grade lymphomas. Dogs with low-grade indolent lymphomas can have long STs without aggressive therapy.

History and Clinical Signs

The clinical signs associated with canine lymphoma are variable and depend on the extent and location of the tumor. Multicentric lymphoma, the most common form, is usually distinguished by the presence of generalized peripheral lymphadenopathy (see Fig. 33.1). Enlarged LNs are usually painless, rubbery, and discrete. In addition, hepatosplenomegaly and bone marrow involvement can be associated with generalized lymphadenopathy. Most dogs with multicentric lymphoma are presented without dramatic signs of systemic illness (WHO substage *a*) (Box 33.2); however, a diversity of nonspecific signs such as anorexia, weight loss, vomiting, diarrhea, emaciation, ascites, dyspnea, polydipsia, polyuria, and fever can occur (WHO substage *b*). Dogs with T-cell lymphoma are more likely to have constitutional (i.e., substage *b*) signs. Most veterinary oncologists consider mild-moderate severity of clinical signs sufficient for a substage *b* designation.[120] Polydipsia and polyuria are often evident in dogs with hypercalcemia of malignancy. Dogs may also be presented with clinical signs related to blood dyscrasias secondary to marked tumor infiltration of bone marrow (myelophthisis) or paraneoplastic anemia, thrombocytopenia, or neutropenia. These could include fever, sepsis, anemia, and hemorrhage. Diffuse pulmonary infiltration, as detected by radiographic changes, is seen in 27% to 34% of dogs with the multicentric form (Fig. 33.4).[121,122] Based on bronchoalveolar lavage, the actual incidence of lung involvement may be higher.[123,124]

• **Fig. 33.4** Lateral projection of a thoracic radiograph of a dog with diffuse interstitial infiltration with lymphoma secondary to multicentric lymphoma.

Dogs with GI lymphoma usually present with nonspecific GI signs, such as vomiting, diarrhea, weight loss, and malabsorption.[61,64,125–128] Mesenteric LNs, spleen, and liver may be involved.

The mediastinal form of lymphoma is characterized by enlargement of the cranial mediastinal structures and/or thymus (see Fig. 33.2), and clinical signs are associated with the extent of disease with resulting respiratory compromise or polydipsia/polyuria from hypercalcemia. In advanced cases, dogs present with respiratory distress caused by a space-occupying mass and pleural effusion, exercise intolerance, and possibly regurgitation. In addition, dogs with mediastinal lymphoma may have precaval syndrome, characterized by pitting edema of the head, neck, and forelimbs secondary to tumor compression or invasion of the cranial vena cava (Fig. 33.5).

Clinical signs in dogs with extranodal lymphoma depend on the specific organ involved. Cutaneous lymphoma can be mucocutaneous, cutaneous, or both. Lesions can be solitary, generalized, or multifocal.[71,74–76,129–132] Tumors occur as nodules, plaques, ulcers, and erythemic or exfoliative dermatitis with focal

• **Fig. 33.5** (A) Facial edema in a dog with precaval syndrome secondary to mediastinal lymphoma. (B) Forelimb edema in a dog with precaval syndrome secondary to mediastinal lymphoma. • **Fig. 33.6** (A) Early epitheliotropic cutaneous lymphoma in the scaly, plaque stage in a dog. (B) Advanced epitheliotropic cutaneous lymphoma in the nodular stage in a dog. (C) Oral mucosal epitheliotropic cutaneous lymphoma in a dog.

hypopigmentation and alopecia. Epitheliotropic T-cell lymphoma (e.g., mycosis fungoides) typically has a clinical course with three apparent clinical stages. Initially, there will be scaling, alopecia, and pruritus (Fig. 33.6A), which can mimic a variety of other skin conditions. As the disease progresses, the skin becomes more erythematous, thickened, ulcerated, and exudative. The final stage is characterized by proliferative plaques and nodules with progressive ulceration (Fig. 33.6B). Oral mucocutaneous involvement may also occur and this can appear as multicentric erythematous plaque-like hypopigmented lesions or nodules associated with the gum and lips (Fig. 33.6C). Extracutaneous involvement can also occur, most often in the LNs, spleen, liver, and bone marrow/peripheral blood. Nonepitheliotropic cutaneous lymphomas are also quite variable in appearance and can form single or multiple dermal or subcutaneous nodules or plaques that may be nonpuritic, ulcerated, or alopecic with crusts.[71] The face (lips, nasal planum, eyelids), lower extremities (paws, interdigital folds), neck, and trunk are often affected.

Dogs with CNS lymphoma may be presented with either multifocal or solitary involvement.[133–135] The majority of cases involve secondary extension into the CNS. Most have a B-cell immunophenotype and have meningeal, perivascular, and periventricular locations, whereas T-cell varieties are more likely to involve the peripheral nerves.[136] Seizures, paralysis, and paresis may be noted.

Ocular lymphoma is characterized by infiltration and thickening of the iris, uveitis, hypopyon, hyphema, posterior synechia, and glaucoma, and is discussed in more detail in Chapter 32.[137–139] Although it is often secondary to multicentric systemic lymphoma, in a compilation of 100 cases, 61% were presumed solitary ocular lymphoma (PSOL) without systemic involvement at diagnosis and no progression postenucleation.[137] Peripheral T-cell lymphoma and DLBCL are the most common subtypes. Importantly, dogs with PSOL had median survival times (MSTs) of 769 days versus 103 days for dogs having systemic involvement at diagnosis. In one study of 94 cases of canine multicentric lymphoma, 37% had ocular changes consistent with lymphoma; and, in a series of 102 cases of uveitis in dogs, 17% were secondary to lymphoma.[139] Anterior uveitis was most commonly seen in the advanced stage of disease (stage V).

VetBooks.ir

Dogs with intravascular lymphoma usually present with signs related to CNS, PNS, or ocular involvement,[84–88] including paraparesis, ataxia, hyperesthesia, seizures, blindness, lethargy, anorexia, weight loss, diarrhea, polyuria, polydipsia, and intermittent fever. Finally, dogs with pure hepatosplenic lymphoma usually present with nonspecific signs of lethargy, inappetence and weakness, and often are icteric.[81–83]

Canine lymphoma also may be associated with paraneoplastic syndromes (see Chapter 5). Anemia is the most common lymphoma-related paraneoplastic syndrome.[140] Paraneoplastic hypercalcemia is also common and is characterized clinically by anorexia, weight loss, muscle weakness, lethargy, polyuria, polydipsia, and, rarely, CNS depression and coma. Lymphoma-induced hypercalcemia in most cases results from parathyroid hormone–related peptide (PTHrP), elaborated by neoplastic cells; however, it can also be related to the production of several other humoral factors, including interleukin-1 (IL-1), tumor necrosis factor-alpha (TNF-α), transforming growth factor-beta (TGF-β), and vitamin D analogs (e.g., 1,25-dihydroxyvitamin D).[114,115,141–143] As previously discussed, hypercalcemia is most commonly associated with the T-cell immunophenotype. Other paraneoplastic syndromes that may be encountered include monoclonal gammopathies, neuropathies, and cancer cachexia.

Diagnostics

For dogs with suspected lymphoma, the diagnostic evaluation should include a thorough physical examination; complete blood count (CBC), including differential leukocyte and platelet counts; a serum biochemical profile; and urinalysis. Optimally, plasma ionized calcium concentration should be measured. Ultimately, obtaining tissue or cytologic specimens (or both) for a definitive diagnosis is essential. The differential diagnosis of lymphadenopathy depends on the travel history of the dog (i.e., relative to infectious disease) and the size, consistency, and location of affected LNs. Other causes of lymphadenopathy include infections caused by bacteria, viruses, protozoa (*Toxoplasma* sp., *Leishmania* sp.), rickettsial organisms (salmon poisoning, *Ehrlichia* sp.), and fungal agents (*Blastomyces* and *Histoplasma* sp.). The potential for hypercalcemia to accompany systemic fungal diseases may further complicate differentiation from lymphoma. Discrete, hard, asymmetric LNs, particularly if they are fixed to underlying tissues, may indicate metastatic tumors such as mast cell tumor or carcinoma. Immune-mediated diseases (e.g., pemphigus, systemic lupus erythematosus, and immune-mediated polyarthropathy) also may result in mildly to moderately enlarged LNs. The various differential diseases or conditions that can resemble canine lymphoma are listed in Table 33.2.

TABLE 33.2 Differential Diseases or Conditions That Can Resemble Canine Lymphoma

Form of Lymphoma	Other Disorders
Multicentric	Disseminated infections: bacterial, viral, rickettsial, parasitic, fungal Immune-mediated disorders: dermatopathies, vasculitis, polyarthritis, lupus erythematosus Tumors metastatic to nodes Other hematopoietic tumors: leukemia, multiple myeloma, malignant or systemic histiocytosis
Mediastinal	Other tumors: thymoma, chemodectoma, ultimobranchial cyst, ectopic thyroid carcinoma, pleural carcinomatosis, pulmonary lymphomatoid granulomatosis[a] Infectious disease: granulomatous disease, pyothorax Miscellaneous: congestive heart failure, chylothorax, hemothorax
Alimentary	Other gastrointestinal tumors, foreign body, lymphangiectasia, lymphocytic-plasmacytic enteritis, systemic mycosis, gastroduodenal ulceration
Cutaneous	Infectious dermatitis: advanced pyoderma Immune-mediated dermatitis: pemphigus Other cutaneous neoplasms (in particular histiocytic disorders)
Extranodal	Variable, depending on organ/system involved

[a]The existence of this disease is controversial; in most cases the disease has been reclassified as a lymphoid neoplasm.

Physical Examination

A thorough physical examination should include palpation of all assessable LNs and rectal examination, as in the authors' experience, a significant proportion of dogs will have rectal polyps consisting of aggregates of neoplastic lymphocytes. Inspection of mucous membranes for pallor, icterus, petechiae, and ulceration should be undertaken as these signs may indicate anemia or thrombocytopenia secondary to myelophthisis or immune-mediated disease or may be evidence of major organ failure or uremia. Abdominal palpation may reveal organomegaly, intestinal wall thickening (if marked), or mesenteric lymphadenopathy. The presence of a mediastinal mass and/or pleural effusion can be suspected after thoracic auscultation. Ocular examination, including funduscopic assessment, may reveal abnormalities (e.g., uveitis, retinal hemorrhage, ocular infiltration, glaucoma) in approximately one-third to one-half of dogs with lymphoma.[139,144]

Complete Blood Count, Biochemical Profile, and Urinalysis

Anemia, the most common lymphoma-related hematologic abnormality, is usually normochromic and normocytic (nonregenerative), consistent with anemia of chronic disease[140]; however, hemorrhagic and hemolytic anemias may also occur, and regenerative anemias may reflect concomitant blood loss or hemolysis. In addition, if significant myelophthisis is present, anemia may be accompanied by thrombocytopenia and leukopenia.[145,146] In animals with anemia or evidence of bleeding, in addition to a platelet count, a reticulocyte count and coagulation testing may be indicated. Thrombocytopenia occurs in 30% to 50% of cases, but bleeding is seldom a clinical problem. Neutrophilia occurs in 25% to 40% of dogs and lymphocytosis occurs in approximately 20% of affected dogs. Circulating atypical lymphocytes may be indicative of bone marrow involvement and leukemia. It is important to differentiate multicentric lymphoma with bone marrow involvement (i.e., stage V disease) from primary lymphocytic leukemia because the prognosis for each may be different. Hypoproteinemia is observed more frequently in animals with alimentary lymphoma. In dogs with a high total protein concentration or evidence of an increased globulin fraction on a biochemical profile,

VetBooks.ir

serum proteins may be evaluated by serum protein electrophoresis. Monoclonal gammopathies have been reported to occur in approximately 6% of dogs with lymphoma.[147]

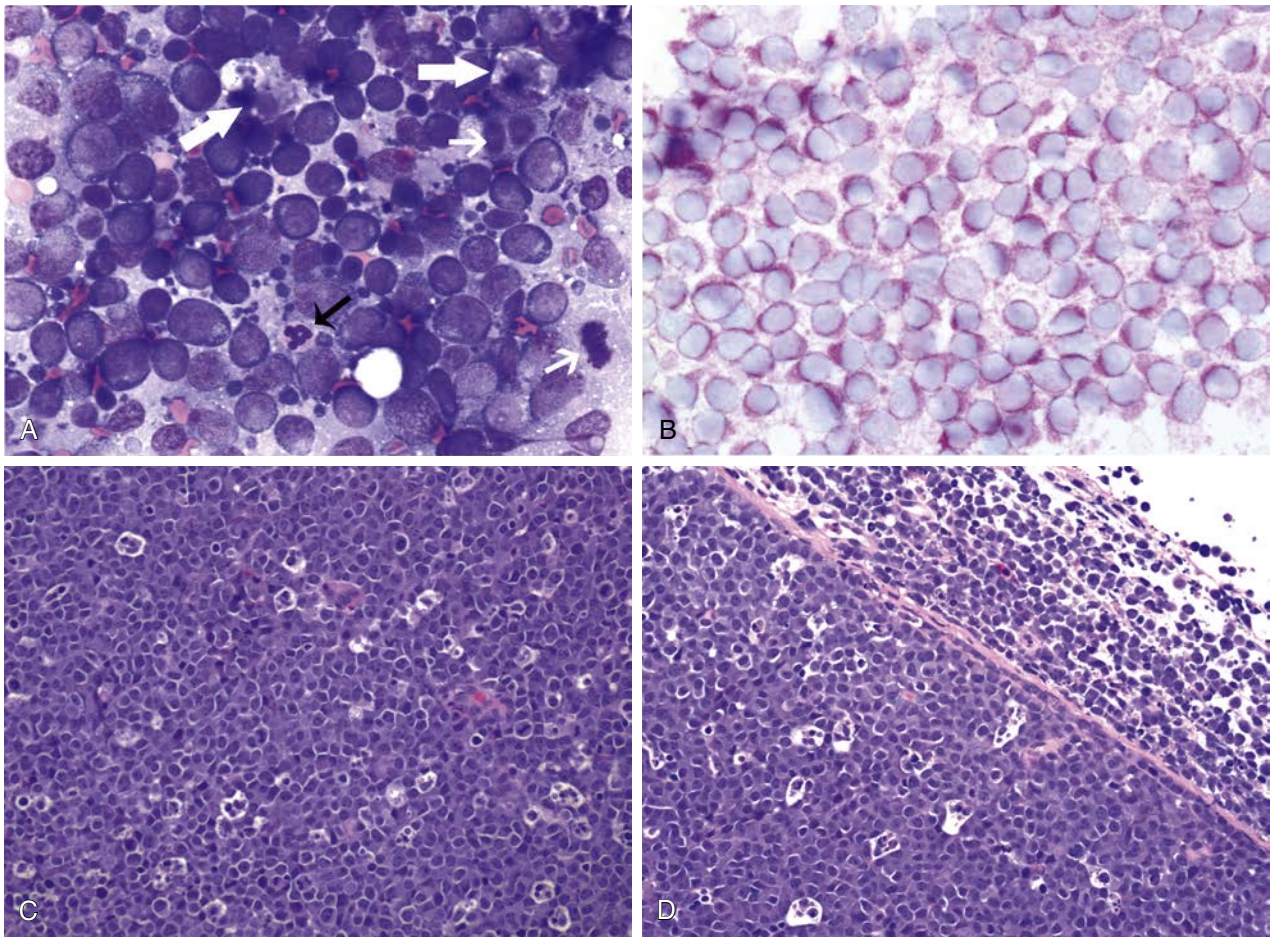
Serum biochemical abnormalities often reflect the anatomic site involved as well as paraneoplastic syndromes, such as hypercalcemia. In dogs with lymphoma, ionized calcium concentrations should be obtained, as they may be increased even if the total calcium concentration is within the reference interval. In cases of hypercalcemia of unknown origin, lymphoma should always be considered high on the differential disease list and diagnostic testing directed at this possibility should be undertaken (see Chapter 5). In addition, the presence of hypercalcemia can serve as a biomarker for response to therapy and relapse. Increased urea nitrogen and creatinine concentrations can occur secondary to renal infiltration with tumor, hypercalcemic nephrosis, or prerenal azotemia from dehydration. Increases in liver-specific enzyme activities or bilirubin concentrations may result from hepatic parenchymal infiltration. Increased serum globulin concentrations, usually monoclonal, occur infrequently with B-cell lymphoma.

Urinalysis is part of the minimum database used to assess renal function and the urinary tract. For example, isosthenuria and proteinuria in the absence of an active sediment may indicate renal disease, and hematuria may result from a hemostatic abnormality. It is important to note that isosthenuria in hypercalcemic dogs is not necessarily indicative of renal disease, as high calcium concentrations interfere with tubular concentrating capabilities through impairment of response to antidiuretic hormone; however, clinicians should be aware that there is a risk of renal calcification and subsequent failure with sustained high calcium concentrations.

Histologic and Cytologic Evaluation of Lymph Nodes

Morphologic and phenotypic examination of the tissue and cells that constitute the tumor is essential to the diagnosis and subtyping of lymphoma. In humans, a combination of histologic, immunophenotypic, clinical, and genetic features are used in the diagnosis and subtyping of NHL. An excellent review of the morphologic and immunophenotypic diagnostic features of canine lymphoma has recently been published.[96] In veterinary medicine, care should be taken to avoid sampling LNs from reactive areas (e.g., mandibular LNs), unless those nodes are the only ones enlarged; the prescapular or popliteal LNs are preferable if also involved. Also, lymphocytes are fragile, and in preparing smears of aspirated material only gentle pressure should be applied in spreading material on the slides. As the majority of dogs with nodal lymphomas are presented with multicentric effacement of peripheral LNs by intermediate or large lymphocytes, cytologic examination of FNAs of affected LNs or other tissues is a highly sensitive and specific first-line or screening diagnostic step.[96] Typically, most of the cells are large lymphocytes (>2 times the diameter of a red blood cell or larger than a neutrophil), and they may have visible nucleoli and basophilic cytoplasm with or without paranuclear clear zones (Fig. 33.7A) or fine chromatin with indistinct nucleoli. Because tissue architecture is not maintained in cytologic specimens, effacement of the node or capsular disruption cannot be detected. Therefore marked reactive hyperplasia characterized by increased numbers of large lymphocytes may be difficult to distinguish from lymphoma. In some forms of lymphoma, intermediate lymphocytes that are similar in diameter to neutrophils predominate; these specimens can be more challenging for novice cytopathologists. Small-cell lymphomas may have few cytologic clues that point to malignancy. Therefore classification of lymphoma into subtypes that make up the low-, intermediate-, and high-grade forms can be attempted using cytologic appearance and immunophenotypic analysis of cytologic specimens (Fig. 33.7B),[96,148–150] but is performed most accurately on histologic sections. Although cytologic findings identified by an experienced cytopathologist may suggest a particular subtype of lymphoma, subsequent analysis that may include flow cytometry, immunocytochemistry, biopsy for histologic examination, clonality assays, and cytogenetic analysis are required to further subtype the lymphoma or to confirm or establish a diagnosis in equivocal cases. Fig. 33.8 presents a diagnostic algorithm for assessing peripheral lymphadenopathy in dogs applying these techniques, beginning with initial screening by cytologic examination.

For accurate histopathologic evaluation, an entire LN, including the capsule, should be removed, placed in buffered formalin, and submitted to a pathologist. Needle-core biopsies are generally inadequate to evaluate nodal morphology. Effacement of normal nodal architecture by neoplastic lymphocytes and capsular disruption are characteristic findings (Fig. 33.7C, D).



Histologic and Cytologic Evaluation of Extranodal Sites

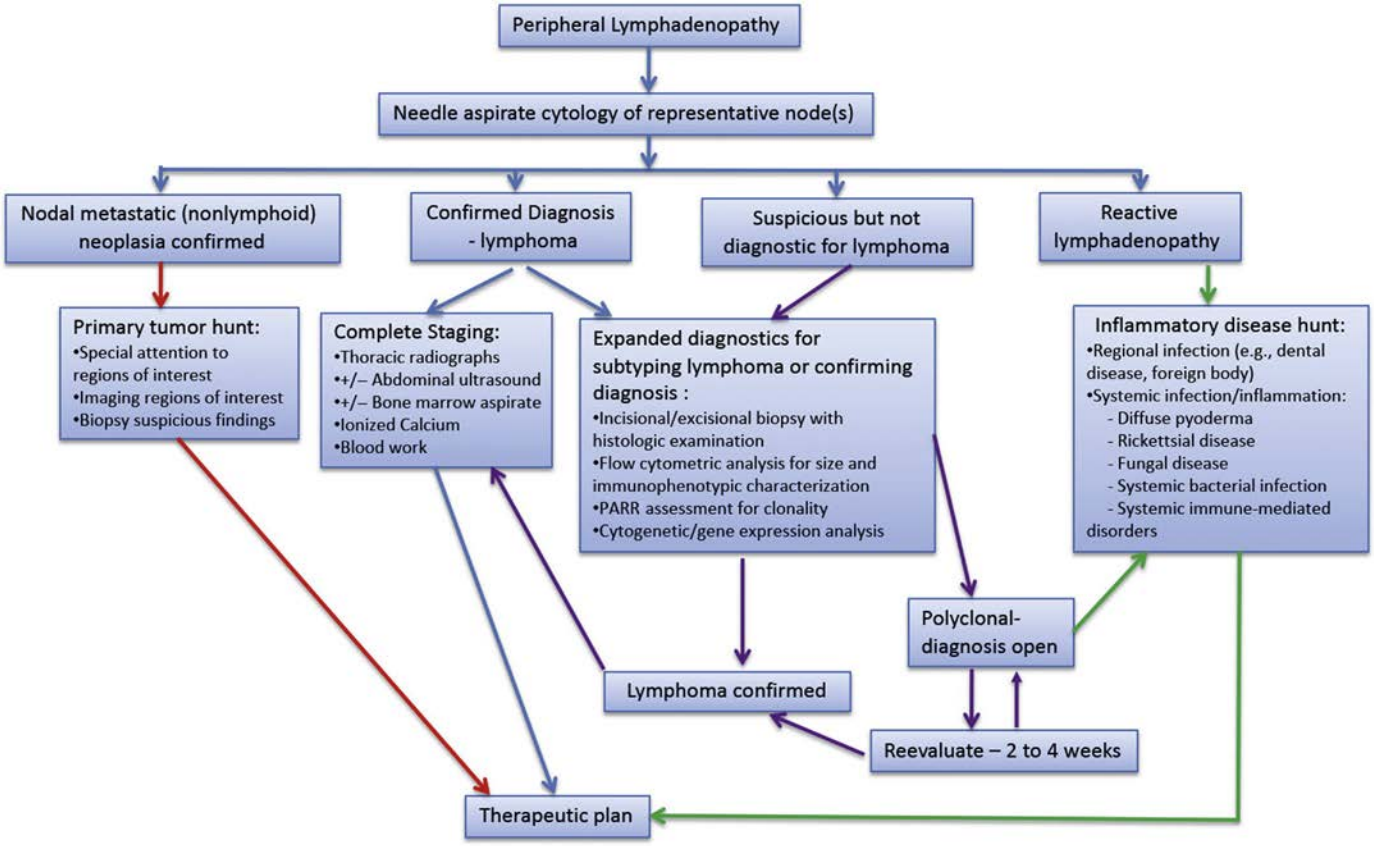
Diagnostic ultrasonography and ultrasound-guided FNA or needle biopsy have been useful for evaluation of involvement of the liver, spleen, or abdominal LNs.[151–153] Aspiration of ultrasonographically normal splenic tissue is rarely contributory to a diagnosis. If possible, the diagnosis should be made by sampling peripheral nodes, avoiding percutaneous biopsies of the liver and spleen. However, if there is no peripheral node involvement, it is appropriate to biopsy affected tissues in the abdominal cavity.

When GI lymphoma is suspected, an open surgical wedge biopsy of the intestine is preferred in most cases to differentiate lymphoma from lymphocytic enteritis. If associated abdominal LNs also appear involved, image-guided biopsies may be obtained with less morbidity than intestinal biopsies. Multiple samples may be necessary to accurately diagnose segmental disease. Endoscopic biopsies may be inadequate as only a superficial specimen is obtained; however, more aggressive endoscopic biopsy techniques combined with more accurate histopathologic, immunophenotypic, and molecular assessments are improving the diagnostic yield of these less invasive techniques.[125,126,154–162] In many dogs with primary GI lymphoma, an inflammatory nonneoplastic infiltrate (i.e., LP-IBD) may be misdiagnosed on biopsy specimens that are too superficial. The application of assays for clonal expansion (e.g., receptor gene rearrangement [PARR]) does not appear as yet to be as accurate for endoscopically derived intestinal biopsies as it is for other solid lymphoid tumors in dogs.

Cytologic examination of cerebrospinal fluid (CSF), thoracic fluid, or mass aspirates is indicated in animals with CNS disease, pleural effusion, or an intrathoracic mass, respectively. In two studies, CSF analysis was diagnostic of lymphoma in 74% of 27 samples.[133,136] Characteristics of the CSF in one study included an increased nucleated cell count in seven dogs with 95% to 100% of the cells comprising atypical lymphocytes.[133] CSF protein concentration was increased in five of the dogs, ranging from 34 to 310 mg/dL (reference interval <25 mg/dL). Flow cytometric and molecular diagnostic procedures may also be applied to CSF samples,[136] although cell counts may be a limiting factor as some of these assays require at least 10,000 cells.

For cutaneous lymphoma, dermal punch biopsies (4–8 mm) should be taken from the most representative and infiltrative, but not secondarily infected, skin lesions. Application of

• **Fig. 33.7** Lymph nodes from dogs with lymphoma. (A) Fine-needle aspirate. Note the homogeneous population of large lymphoid cells with prominent nucleoli and basophilic cytoplasm. These cells are larger than the neutrophil *(black arrow)* in the field. Mitotic figures *(thin white arrows)* and tingible-body macrophages *(thick white arrows)* also are present. (Wright's stain, ×60 objective.) (B) Fine-needle aspirate stained for immunoreactivity for CD79a. Note that nearly all of the lymphocytes express CD79a. The diagnosis was B-cell lymphoma. (Alkaline phosphatase/Fast Red, ×60 objective.) (C) Histologic section. Note effacement of normal architecture. The white spaces are macrophages, giving a "starry sky" appearance to the lymph node. (H&E, ×20 objective.) (D) Histologic section. Note the presence of tumor cells outside the capsule of the lymph node. (H&E, ×20 objective.)



immunophenotypic and clonality assessments of cutaneous biopsies can aid in differentiating lymphoma from benign lymphocytic lesions.[71,75,77,163]

Molecular Diagnostic Techniques

Molecular techniques can be used to establish a diagnosis of lymphoma, but are best used to further characterize the tumor after the initial diagnosis is made. Indeed, in people, genetic characterization of NHL are often used in diagnosis and subtyping.[96] Tissues and cells from peripheral blood, LNs, nonlymphoid sites, and effusions can be analyzed by various molecular and cytogenetic means to aid in categorization of subtypes and in cases that represent a more difficult diagnostic challenge, particularly in cases where reactive lymphocytosis and lymphoma are both possible based on standard histologic or cytologic assessment. These include histochemical and cytochemical, immunohistochemical (IHC) and immunocytochemical, flow cytometric, polymerase chain reaction (PCR), and cytogenetic techniques. For example, the immunophenotype (B vs T cell),[118,164–171] proliferation rate (e.g., expression of Ki67, proliferating cell nuclear antigen expression, argyrophilic nucleolar organizer regions [AgNOR]),[68,74,101,154,171–177] and clonality (PCR for antigen PARR)[81,160,178–187] of the tumor can be determined. Genetic characterizations of canine lymphoma samples have been investigated and are showing potential for both diagnostic and prognostic utility, but are not widely applied and clinical correlates are currently preliminary.[21,22,24,178,179,188,189] The availability of molecular and genetic analyses is increasing in veterinary oncology; however, at present, only immunophenotype and PARR clonality assays are routinely used in dogs to inform clinical decision making.

Immunophenotyping

Immunophenotyping is used to determine the type of cells that comprise the tumor, but this technique also can be helpful for making the initial diagnosis and predicting outcome.[96,164,166–171,190,191] When a heterogeneous population of lymphocytes is expected in a tissue, documentation of a homogeneous population of the same immunophenotype is supportive of a neoplastic process. The immunophenotype of a lymphocyte

• **Fig. 33.8** Diagnostic algorithm for peripheral lymphadenopathy in dogs. *PARR*, polymerase chain reaction for receptor gene rearrangement.

is identified by determining the expression of molecules specific for B cells (e.g., CD79a, CD20) and T cells (e.g., CD3), and have been recently reviewed.[96] Although tumor cells sometimes have morphologic characteristics that typify a particular immunophenotype, exceptions occur and morphologic appearance cannot be used as the sole determinant of immunophenotype. For example, in a series of nine high-grade T-cell lymphomas and leukemias in dogs, the cells had a plasmacytoid appearance typically associated with B-cell lymphoma.[123,192] Similarly, anatomic location does not always predict the immunophenotype.

For accurate determination of immunophenotype, antibodies against lymphocyte markers are applied to tissue sections (IHC), cytologic specimens (immunocytochemistry), or individual cells in a fluid medium (flow cytometry). Flow cytometric evaluation of cells obtained by needle aspiration is also feasible. For T cells, markers include CD3 (pan T), CD4 (helper T), and CD8 (cytotoxic T); for B cells, the markers are CD79a (see Fig. 33.7B), CD20, and CD21, although dogs with indolent TZL can express CD21.[178] Increasingly, aberrant expression of CD molecules has been reported in canine lymphoma. In a study of 59 dogs with lymphoma, tumor cells from six dogs were positive for both T- and B-cell markers; however, a clonality assay revealed clonality either of the T-cell or the immunoglobulin receptor, but not both. This indicates that, in some cases, the malignant cells may coexpress B- and T-cell markers.[118] Antibodies against these molecules are used to determine the immunophenotype; however, they also have potential utility as a therapeutic modality if tumor cells could be targeted using these antibodies. Table 33.3 presents the histologic and immunophenotypic characteristics of the more common lymphoma subtypes in dogs.

Clonality Assays

Information about the clinical presentation and morphologic and immunophenotypic characteristics of the lymphocytes, obtained by IHC or flow cytometric analysis, must be integrated to select appropriate targets for clonality testing and to interpret results accurately.[193] Occasionally, diagnosis of lymphoma and differentiation of malignant versus benign proliferation of lymphocytes are not possible based on standard histologic and cytologic criteria. In these cases, advanced molecular analyses may be helpful to confirm a diagnosis. Clonality is the hallmark of malignancy; that is, the malignant cell population theoretically should be derived from expansion of a single malignant clone characterized by a particular DNA region unique to that tumor. For example, in a dog with T-cell lymphoma, all the malignant cells theoretically should have the same DNA sequence for the variable region of the T-cell receptor gene. Likewise, in a dog with B-cell lymphoma, the tumor cells should have identical DNA sequences in the variable region of the immunoglobulin (Ig) receptor gene. Conversely, in reactive lymphocytosis, the cells are polyclonal for their antigen receptors. Using this knowledge, investigators have used PCR technology to amplify the variable regions of the T-cell and immunoglobulin receptor genes to detect the presence of clonal lymphocyte populations in dogs (see Fig. 8.3 of Chapter 8). These techniques are reviewed in Chapter 8 and elsewhere.[158,180,193–195] In physician-based medicine, such assays of clonality are approximately 70% to 90% sensitive and have a false-positive rate of approximately 5%, and recent studies report similar rates in dogs. False-negative and false-positive

TABLE 33.3 Histologic and Immunophenotypic Characteristics of Common Canine Non-Hodgkin's Lymphomas in Relative Order of Frequency

Subtype	Typical Location	Histologic Architecture	Cellular Features	Immunophenotype
Diffuse large B-cell (DLBCL)	Usually multicentric lymphadenopathy	Diffuse	Large cells; round nuclei; one (central) or multiple nucleoli; high mitotic rate; "starry sky" appearance	$CD1^+$, $CD20^+$, $CD21^+$, $CD45^+$, $CD79a^+$, $Pax5^+$, $MHCII^+$, $CD18^{low}$
Peripheral T-cell lymphoma-not otherwise specified (PTCL-NOS)	Usually multicentric lymphadenopathy	Diffuse	Variable size (small to large); irregular nuclei, variable chromatin, prominent nucleoli; varied mitotic activity	$CD3^+$, $CD79a^-$, $CD21^-$, $CD45^+$, $CD5^+$, $CD4^{+/-}$, $CD8^{+/-}$, $CD18^{high}$, $TCR\alpha\beta$
Marginal zone lymphoma (MZL)	Nodal (nMZL) or splenic (sMZL) or extranodal mucosal	Nodular/ follicular	Mostly intermediate- sized cells-abundant pale cytoplasm; irregular nuclei with peripheralized chromatin and a single central nucleolus; rare mitotic figures (except nMZL)	$CD1^+$, $CD20^+$, $CD21^+$, $CD45^+$, $CD79a^+$, $MHCII^+$, $CD18^{intermediate}$
T-zone lymphoma (TZL)	Usually multicentric Lymphadenopathy	Nodular, paracortical, progressing to diffuse	Small to intermediate- sized cells; moderate amount of pale cytoplasm; oval to elliptical nuclei with sharp, shallow indentations; nucleoli and mitotic figures are sparse	$CD45^-$, $CD3^+$, $CD5^+$, $CD21^+$, $CD4^{+/-}$, $CD8^{+/-}$
Precursor lymphoma[a]	Multicentric and/or leukemia	Diffuse and/or leukemia	Intermediate-sized cells; round nuclei; scant Cytoplasm; high mitotic rate	**If T-cell:** $CD45^+$, $CD34^{+/-}$, $CD5^{+/-}$, $CD3^{+/-}$, $CD4^{+/-}$, $CD8^-$ **If B-cell:** $CD45^+$, $CD18^+$, $CD34^{+/-}$, $CD79a^+$, $CD21^{+/-}$, $CD20^{+/-}$
Mantle cell lymphoma (MCL)	Splenic white pulp	Nodular/ follicular	Small to intermediate- sized cells; scant cytoplasm; round nuclei with dense chromatin, inconspicuous nucleoli; varied mitotic rate	$CD20^+$, $CD21^+$, $CD45^+$, $CD79a^+$, $MHCII^+$
Follicular lymphoma	Lymphadenopathy, solitary or multiple	Nodular/ follicular	Mixed—mostly small cells with clear cytoplasm, pale chromatin, and inconspicuous nucleoli (centrocytes) with fewer large cells with dark blue cytoplasm, vesicular nuclei, and 1–3 nucleoli (centroblasts)	$CD20^+$, $CD21^+$, $CD45^+$, $CD79a^+$, $MHCII^+$

[a]Precursor lymphoma includes lymphoblastic B- or T-cell lymphomas and B- or T-cell acute leukemias.

The comparative diagnostic features of canine and human lymphoma. *Vet Sci.* 2016;3: Epub ahead of print. https://doi.org/10.3390/vetsci3020011; and Burkhard MJ, Bienzle D. Making sense of lymphoma diagnostics in small animal patients. *Vet Clin North Am Small Anim Pract.* 2013;43:1331-1347.

results can occur with clonality assays. For example, cells from a dog with lymphoma may be negative for clonality if the clonal segment of DNA is not detected with the PCR primers used, mutation of the primer site has occurred, there are background nonneoplastic lymphocytes (noise) within the tumor, the malignant cells are natural killer (NK) cells (rare), or the malignant cells are present in too low a frequency to be detected. False positives occur rarely in some infectious diseases (e.g., ehrlichiosis and leishmaniasis). In these cases, a diagnosis should be made only after considering the results of all the diagnostic tests, including histologic/cytologic evaluation, immunophenotyping, and clonality studies in conjunction with signalment and physical examination findings. These molecular techniques, although helpful for diagnosis, could also have utility in detecting relapse and in determining more accurate clinical stage and so-called "molecular remission rates" because they are more sensitive than standard cytologic assessment of peripheral blood, bone marrow, or LNs.

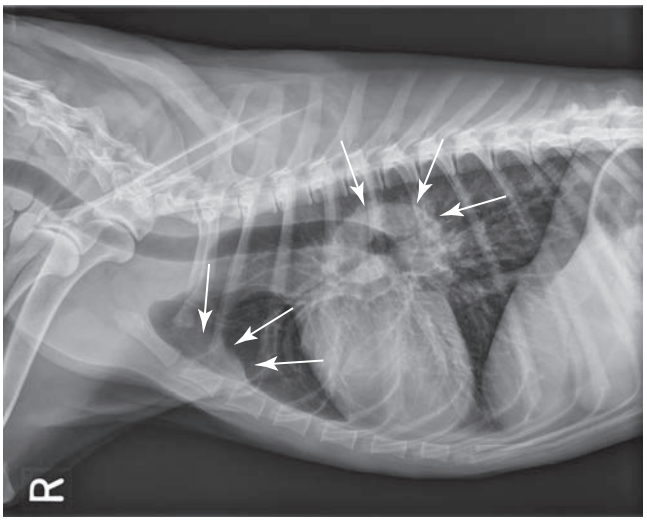
Other Immunohistochemical and Immunocytochemical Assessments

Assessments of several markers of multidrug resistance and apoptotic pathways (e.g., P-glycoprotein, p53, Bcl-2 proteins) have been evaluated in dogs with lymphoma[29,30,174,196,197]; however, their clinical significance and utility have not been established.

VetBooks.ir

Proteomics and Serum Biomarkers

Proteomics comprises, simplistically, methodologies that analyze the entire protein component or protein signature of cells (the proteome). Protein components of a cell (normal or malignant) change over time with upregulation and downregulation of gene expression in response to varied stimuli (e.g., growth factors, environmental cues). It may therefore be possible to use the field of proteomics to identify serum biomarkers of malignancy (i.e., cancer-specific protein markers) and to further analyze response to therapy or even to predict which therapies are appropriate for an individual patient's tumor. Although in its infancy in veterinary oncology, preliminary investigations of the proteome of dogs with lymphoma have been reported[198–201]; however, they have yet to reach the level of sophistication in which useful output would have a significant effect on clinical decision making.



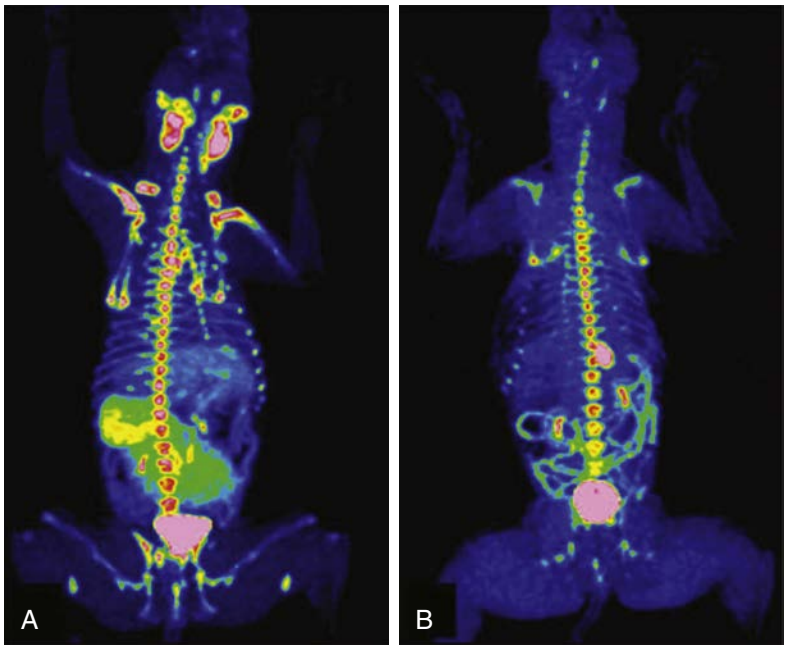
Several analytes in serum have been explored as biomarkers of lymphoma in the dog and have been reviewed.[202] These include tumor and metabolic products, cytokines, cellular leakage enzymes, and serum proteins. Examples include thymidine kinase 1, C-reactive protein, alpha-fetoprotein, alpha-1 glycoprotein levels, zinc, chromium, iron, endostatin, vascular endothelial growth factor (VEGF), lactate dehydrogenase, haptoglobin, and antioxidants/oxidative stress markers.[203–214] Although some have been grouped and commercialized (e.g., TK Canine Cancer Panel [VDI Labs, Simi Valley, CA, USA], Canine Lymphoma Blood Test [cLBT; Avacta Animal Health, Whetherby, UK]), the clinical, biologic, and prognostic significance of these assays has yet to be definitively characterized. Intuitively, use of biomarkers to detect early relapse would have clinical utility if meaningful therapeutic decisions and options were identified that would result in enhancement of quantity and quality of life. Currently, the lead-time provided over standard clinical diagnosis of relapse is relatively short, limiting their routine utility; definitive studies to support their application in larger and more varied general populations of dogs with lymphoma are currently lacking.

Clinical Staging

After a diagnosis has been established, the extent of disease should be determined and categorized by clinical staging. The WHO staging system routinely used to stage dogs with lymphoma is presented in Box 33.2. Most dogs (>80%) are presented in advanced stages (III–IV). Diagnostic imaging and assessment of bone marrow involvement may be indicated for staging. The degree to which thorough staging is implemented depends on whether the result will alter the treatment plan, whether relevant prognostic information is gleaned, and whether the clients need to know the stage before initiating (or declining) a treatment plan. In addition, when comparing different treatment protocols with respect to efficacy, consistent and similar staging diagnostics should be used to avoid so-called "stage migration," which results when one staging methodology is more accurate than another.[215] The effect of stage migration on prognosis should be considered when comparing different published outcomes.

Bone Marrow Evaluation

A bone marrow aspirate or core biopsy (from the proximal humerus or iliac crest) is recommended for complete staging and prognostication and may be indicated in dogs with anemia, lymphocytosis, circulating atypical lymphocytes, or other peripheral cytopenias. In one study of 53 dogs with lymphoma, 28% had circulating malignant cells and were considered leukemic, whereas bone marrow examination indicated involvement in 57% of the dogs.[216] The presence of a few prolymphocytes and large lymphocytes with nucleoli in the circulation of dogs with lymphoma may indicate bone marrow involvement. It is important to remember these cells also can be seen with immune-mediated and inflammatory/infectious diseases. As discussed previously, tumor cells within the peripheral and bone marrow compartments can also be identified using clonality assays (PARR) that are more sensitive than routine microscopic examination in detecting malignant cells; however, the prognostic significance of the knowledge gained with more sensitive staging methodologies has yet to be determined.[216–218] Although bone marrow evaluation may offer prognostically valuable information, it is not necessary to perform the procedure if the client is committed to treat regardless of stage.



• **Fig. 33.9** Lateral radiographic projection of a dog with sternal and hylar lymphadenopathy due to lymphoma.

Imaging

Evaluation of thoracic and abdominal radiographs may be important in determining the extent of internal involvement (Fig. 33.9).[121,219] Approximately 60% to 75% of dogs with multicentric lymphoma have abnormalities on thoracic radiographs, with one-third having evidence of pulmonary infiltrates (see Fig. 33.4) and two-thirds having thoracic lymphadenopathy (sternal and tracheobronchial LNs [see Fig. 33.9]) and widening of the cranial mediastinum (see Fig. 33.2).[121,122] Pulmonary infiltrates usually are represented by an interstitial and/or alveolar pattern; however, nodules (rarely) and bronchial infiltrates can also occur.[220] Pleural effusion may also be present. Cranial mediastinal lymphadenopathy is detected in 20% of dogs with lymphoma.[122,220] Abdominal radiographs reveal evidence of involvement of medial iliac (sublumbar) and/or mesenteric LNs, spleen, or liver in approximately 50% of cases. In the authors' practice, for the typical cases of canine multicentric lymphoma, imaging is limited to thoracic radiographs as there is no prognostic difference between dogs with stage III and IV disease (i.e., liver/spleen involvement); however, cranial mediastinal lymphadenopathy is of prognostic significance. If there are

• **Fig. 33.10** (A) FLT-PET/CT image of a 3-year-old MN Hound cross illustrating FLT uptake in the peripheral nodes, bone marrow, kidneys bladder and spleen. (B) FLT-PET/CT image of the same dog 3 weeks after his final dose of chemotherapy. The lymph nodes were small on CT with minimal FLT uptake on PET images. Note the persistent uptake in the bone marrow, kidneys, and bladder. (Reprinted with permission from Lawrence J, Vanderhoek M, Barbee D, et al Use of 3′-deoxy-3′-[^{18}F]fluorothymidine PET/CT for evaluating response to cytotoxic chemotherapy in dogs with non-Hodgkin's lymphoma. *Vet Radiol Ultrasound*. 2009;50:660–668.)

clinical signs attributable to abdominal disease, if complete staging is necessary (e.g., for clinical trial inclusion), or if peripheral lymphadenopathy is not part of the presentation, further imaging of the abdomen is warranted. Abdominal ultrasonography can be important for obtaining ultrasound-guided intraabdominal samples for diagnosis if more peripheral lesions are not evident (e.g., GI, abdominal nodal, and hepatosplenic lymphoma) or if complete clinical staging is required.[152] Ultrasonographic (including Doppler ultrasound) assessment of peripheral LNs has also been explored[153]; however, its clinical applicability is questionable because cytologic assessment of peripheral nodes is easy, inexpensive, and of higher diagnostic utility.

Advanced imaging modalities, including computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), or PET/CT and PET/MR imaging, are becoming more commonplace in veterinary practice and their utility is only now being determined.[221–226] PET/CT imaging is the current standard of care for following and predicting durability of treatment response in human patients with lymphoma, and both [^{18}F]fluorothymidine (^{18}FLT) PET/CT and [^{18}F]fluoro-D-glucose (^{18}FDG) PET imaging have been reported in dogs with lymphoma.[224–226] ^{18}FLT-PET/CT functional and anatomic imaging shows promise for the evaluation of response to cytotoxic chemotherapy in dogs with lymphoma and for predicting relapse before standard clinical and clinicopathologic confirmation (Fig. 33.10).

Treatment of Multicentric Lymphoma

The therapeutic approach to a particular patient with lymphoma is determined by the subtype, stage, and substage of disease, the presence or absence of paraneoplastic disease, the overall physiologic status of the patient, financial and time commitment of the clients, and their level of comfort with respect to likelihood of treatment-related success and/or side effects. Without treatment, most dogs with intermediate- or high-grade lymphoma will die of their disease within 4 to 6 weeks of diagnosis, although significant variability exists.[147] With few exceptions, canine lymphoma is considered a systemic disease and therefore requires systemic therapy to achieve remission and prolong survival. The majority of canine multicentric lymphomas are intermediate- to high-grade, and, currently, histologic and immunophenotypic characterization does not play a significant role in determining the initial treatment protocol unless a diagnosis of indolent or low-grade lymphoma is confirmed. It is hoped that in the near future, as more clinically correlative information on the significance of the various subclassifications of lymphoma in dogs is acquired, more tailored therapeutic approaches may become available.

Systemic multiagent chemotherapy continues to be the therapy of choice for canine intermediate- and high-grade lymphoma. In general, combination chemotherapy protocols are superior in efficacy to single-agent protocols. In rare cases in which lymphoma is limited to one site (especially an extranodal site), the animal can be treated with a local modality such as surgery or radiation therapy (RT) as long as the client and clinician are committed to diligent reevaluation (active surveillance) to document subsequent progression to systemic involvement, should it occur.

Multidrug Combination Protocols

Many chemotherapeutic protocols for dogs with lymphoma have been developed over the past 30 years (Table 33.4).[116,227–251] Significant limitations arise when comparing efficacy studies in the veterinary literature for the various published protocols. Few of

• **Fig. 33.11** (A) Kaplan–Meier survival duration estimates for a group of 55 dogs with lymphoma treated with an identical CHOP-based combination chemotherapy protocol. Dogs with CD3 immunoreactive (T-cell) lymphoma had significantly shorter survival durations. (B) Kaplan–Meier survival duration estimates for a group of 55 dogs with lymphoma treated with an identical CHOP based combination chemotherapy protocol at the University of Wisconsin. Dogs with substage *b* disease (i.e., clinically ill) had significantly shorter survival durations. (From Vail DM. Hematopoietic tumors. In Ettinger SJ, Feldman EC, eds. *Textbook of Veterinary Internal Medicine*. 6th ed. St. Louis: Elsevier; 2005.)

these studies include sufficient numbers of dogs for adequate statistical power and even fewer compare treatment protocols in a randomized prospective fashion. In addition, staging, inclusion, and response criteria vary considerably among reports. Therefore evaluations of efficacy among various protocols are subject to substantial bias, making direct comparisons difficult and indeed precarious. A recurring theme in the concluding statement in most of these published protocols is some variation of "prospective randomized trials will be required to confirm these suggestive findings." Despite the plethora of available combination protocols, most are modifications of CHOP protocols initially designed for human oncologic use, and currently randomized prospective evidence does not exist in dogs to clearly recommend one over the other as long as the basic CHOP components are present. CHOP represents combinations of cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin), vincristine (O, Oncovin), and prednisone (P). In the 1980s and early 1990s, physicians treating human patients with advanced, intermediate- or high-grade lymphoma faced a similar dilemma in that many different variations of CHOP existed and no randomized data were available to determine which protocols were superior. Eventually, a national randomized trial involving more than 1000 people with intermediate/high grade NHL was conducted comparing the plethora of protocols available, and the results indicated that CHOP was as effective as any of the more complicated protocols and had the safest adverse event profile.[252] CHOP subsequently became (and remains, with the addition of monoclonal antibody therapy) the standard of care for people with intermediate-/high-grade NHL.

Conventional CHOP-based chemotherapy induces remission in approximately 80% to 95% of dogs, with overall MSTs of 10 to 12 months. Approximately 20% to 25% of treated dogs will be alive 2 years after initiation of these protocols (Fig. 33.11). Response rates and durations of response vary according to the presence or absence of prognostic factors discussed in the text that follows. The relative cost of the various protocols to the client depends on the drug(s) selected, the size of the animal, the frequency of administration, and the laboratory tests required to monitor adverse events and response.

In an attempt to better standardize response criteria and outcome reporting of future trials, the Veterinary Cooperative Oncology Group (VCOG) published response evaluation criteria (v1.0)[253] that can be applied in the routine practice setting. The greatest obstacle to performance of prospective randomized comparative lymphoma trials in veterinary oncology is financial; that is, clinical trials are inherently costly, and because most of the known effective drugs are unregistered off-label human generic (i.e., off-patent) drugs, the incentive for pharmaceutical-funded, sufficiently powered, randomized field trials is low, resulting in a general lack of comparative data.

Dogs responding to chemotherapy and undergoing complete "clinical" remission are usually free of clinical signs associated with lymphoma and subsequently return to a very good quality of life, making the treatment of dogs with lymphoma initially gratifying. Most dogs tolerate chemotherapy well, and although dose reductions and treatment breaks ("treatment holidays") are sometimes required in individual cases, only a minority of dogs develop significant adverse events requiring hospitalization.[254,255] Studies assessing client perceptions of medical treatment for cancer in general and lymphoma in particular report a positive experience; most owners feel treatment was worthwhile, that it resulted in improvement in the well-being of their pet, and that quality of life during treatment was good.[256,257] Very few clients express regret about treating lymphoma using a multidrug protocol.

Importantly, it must be realized that cures are rare, and though complete clinical remissions are the norm, complete molecular remissions (iCR), which can be documented only with molecular techniques, are rarely achieved in dogs; thus the utility of documenting iCR, in the absence of meaningful therapeutic options, is limited to investigative trials striving to achieve them.

With lymphoma, the fundamental goals of chemotherapy are to induce a complete durable (>6 months) first remission (termed *induction*), to reinduce a remission when the tumor recrudesces

VetBooks.ir

(the patient relapses) after achievement of a remission (termed *reinduction*), and, finally, to induce remissions when the cancer fails to respond to induction or reinduction using drugs not present in the initial protocols (termed *rescue*).

An unanswered question in the treatment of lymphoma has been whether long-term maintenance chemotherapy is useful after an initial course of aggressive induction chemotherapy lasting 6 months or less. Long-term maintenance chemotherapy has not been shown to be of significant value in humans with most aggressive forms of NHL; however, in humans, the initial induction course of chemotherapy is much more aggressive than that used in veterinary patients. Although no randomized prospective studies have been performed to address the therapeutic benefit of long-term maintenance chemotherapy in dogs, most comparisons of dogs treated with CHOP-based protocols do not show any clear advantage for a maintenance or consolidation phase after induction therapy.[229,231,232,234,240,242–245,247,258–262] Indeed, in most reports, dogs receiving shorter, less costly protocols that do not include a prolonged maintenance phase have comparable remission and progression-free survival (PFS) durations and appear to more readily achieve second remissions when they relapse after completion of chemotherapy than their counterparts receiving long-term maintenance. These data, taken together, suggest that maintenance therapy is not beneficial for most dogs with lymphoma. Until well-designed randomized prospective trials indicate otherwise, the author (DMV) prefers protocols that utilize an aggressive induction without maintenance.

Single-Agent Chemotherapy with Known Activity for Dogs with Lymphoma

The most effective currently available chemotherapeutic agents for canine lymphoma include doxorubicin (DOX), L-asparaginase, vincristine, cyclophosphamide, and prednisone, most of which are represented to one degree or another in most first-line multiagent chemotherapy protocols. Other drugs that have documented activity are often considered second-line agents and include rabacfosadine (Tanovea-CA1), lomustine, vinblastine, actinomycin-D, mitoxantrone, mustargen, chlorambucil, methotrexate, dacarbazine (DTIC), 9-aminocamptothecin, ifosfamide, cytosine arabinoside, procarbazine, bleomycin, and gemcitabine. Of these, cytosine arabinoside,[263] ifosfamide,[264] bleomycin,[265] and gemcitabine[266] appear to have minimal activity. With the exception of DOX, single-agent induction therapy does not typically result in durable remission durations compared with standard combination protocols. Incorporation of other standard cytotoxic drugs with single-agent activity into standard CHOP-based protocols has not resulted in significant gains or has not been adequately evaluated, and most are reserved for subsequent rescue settings.

The use of rabacfosadine (Tanovea-CA1) warrants a brief discussion as it is the only chemotherapy agent currently approved, albeit conditionally, by the US Food and Drug Administration (FDA) for the treatment of dogs with lymphoma (see Chapter 12 for a specific discussion of rabacfosadine). Rabacfosadine has been evaluated in hundreds of dogs with lymphoma and activity has been documented as a single-agent for treatment of cutaneous lymphoma, multiple myeloma, and naïve and relapsed multicentric lymphoma, as well as in combination with DOX for lymphoma.[226,230,267–270] Currently, rabacfosadine is most commonly used as a rescue agent at relapse or as a first-line treatment in combination with DOX owing to a less intense treatment protocol while maintaining similar remission durations compared with CHOP in a nonrandomized fashion.[230]

• BOX 33.3 Current Canine Lymphoma Protocol (UW-Madison-19)

Week 1: Vincristine, 0.7 mg/m^2 IV
Prednisone, 2 mg/kg, PO, daily
Week 2: Cyclophosphamide,[a] 250 mg/m^2 IV or PO
Prednisone, 1.5 mg/kg, PO, daily
Week 3: Vincristine, 0.7 mg/m^2 IV
Prednisone, 1.0 mg/kg, PO, daily
Week 4: Doxorubicin,[b] 30 mg/m^2 IV
Prednisone, 0.5 mg/kg, PO, daily
Week 6: Vincristine, 0.7 mg/m^2 IV
Week 7: Cyclophosphamide,[a] 250 mg/m^2 IV or PO
Week 8: Vincristine, 0.7 mg/m^2 IV
Week 9: Doxorubicin,[b] 30 mg/m^2 IV
Week 11: Vincristine, 0.7 mg/m^2 IV
Week 12: Cyclophosphamide,[a] 250 mg/m^2 IV or PO
Week 13: Vincristine, 0.7 mg/m^2 IV
Week 14: Doxorubicin,[b] 30 mg/m^2 IV
Week 16: Vincristine, 0.7 mg/m^2 IV
Week 17: Cyclophosphamide,[a] 250 mg/m^2 IV or PO
Week 18: Vincristine, 0.7 mg/m^2 IV
Week 19: Doxorubicin,[b] 30 mg/m^2 IV

1. All treatments are discontinued after week 19 if in complete remission.
2. A complete blood count (CBC) should be performed before each chemotherapy. If neutrophil count is <1500 wait 5 to 7 days and repeat CBC.
3. If sterile hemorrhagic cystitis occurs on cyclophosphamide, discontinue and substitute chlorambucil (1.4 mg/kg PO) for subsequently scheduled cyclophosphamide treatments.
4. For acute lymphocytic leukemia (ALL)–administer L-asparaginase 400 IU/kg SQ with each vincristine injection, until a complete response is achieved.

[a]Furosemide (1–2 mg/kg) is given IV or PO, concurrent with cyclophosphamide to lessen the incidence of sterile hemorrhagic cystitis.
[b]In dogs less than 15 kg in body weight, a doxorubicin dose of 1 mg/kg is substituted for 30 mg/m^2

Overall Chemotherapy Recommendations for Multicentric Lymphoma (Author [DMV] Preference)

Several factors should be considered and discussed with caregivers on a case-by-case basis when choosing the treatment protocol. These factors include cost, time commitment involved, efficacy, adverse event profiles, and experience of the clinician with the protocols under consideration.

Induction in Treatment-Naïve Patients

It is now clearly established that "standard-of-care" combination protocols used in dogs with intermediate- and high-grade lymphoma are essentially variations of CHOP protocols (see Table 33.4). Specific details regarding dose and timing of the CHOP protocol currently preferred by the author (DMV) are outlined in Box 33.3. This protocol does not have a maintenance component and all treatments cease at 19 weeks, provided the animal is in complete clinical remission. Although several other CHOP-based protocols include L-asparaginase either at initiation or at varying times throughout the protocol, several studies suggest this does not result in clinically relevant increases in remission rate, speed of attaining remission, or first-remission duration, and therefore the author reserves its use for rescue situations.[246,260,271,272]

If client or other considerations preclude a CHOP-based protocol, single-agent DOX (30 mg/m^2, intravenous [IV], every 3 weeks for five total treatments) is offered along with a 4-week

VetBooks.ir

tapering oral prednisone regimen (same prednisone regimen in Box 33.3) as a less aggressive, less time-consuming, and less costly approach. The expected CR rate for the single-agent DOX protocol will range from 50% to 75%, with an anticipated MST of 6 to 8 months.[246,250,273,274] The addition of oral cyclophosphamide (50 mg/m^2 daily for 3 days starting on the same day as DOX) to single-agent DOX resulted in a numerically, but not statistically, improved outcome in a randomized trial comparing DOX/prednisone with DOX/cyclophosphamide/prednisone (PFS of 5.6 months vs 8.2 months, respectively).[274] This trial was powered only to detect a three-fold difference in PFS; therefore larger trials should be undertaken to confirm any benefit. Alternatively, a less time-intense protocol with treatments every 3 weeks involves the previously mentioned rabacfosadine/DOX protocol.[230]

If clients are reticent to include IV medications, the author often recommends a protocol of either oral lomustine (CCNU; 70 mg/m^2 by mouth [PO] every 3 weeks for five treatments) and prednisone or oral cyclophosphamide (250 mg/m^2 [PO] every 2–3 weeks) with prednisone. The CCNU protocol has been associated with short median remissions (40 days) in one small case series[275]; however, in the author's experience, a subset of dogs have remained in remission for several months on this protocol when clients decline IV medication.

If financial or other client concerns preclude the use of systemic chemotherapy, prednisone alone (2 mg/kg PO, daily) will often result in short-lived remissions of approximately 1 to 2 months; however, an occasional durable remission will result. In these cases, it is important to educate clients that, should they decide to pursue more aggressive therapy at a later date, dogs receiving single-agent prednisone therapy are more likely to develop multidrug resistance (MDR) and experience shorter remission and survival durations with subsequent combination protocols.[258,276–278] This is especially true after long-term prednisone use or in dogs that have experienced a relapse while receiving prednisone. Therefore the earlier that clients opt for more aggressive therapy, the more likely a durable response will result.

A CBC should be performed before each chemotherapy treatment. Dogs should have a minimum of 1500 neutrophils/μL (some oncologists use a cut-off of 2000 neutrophils/μL) and 50,000 platelets/μL before the administration of myelosuppressive chemotherapy.[279] If the neutrophil count is lower than 1500/μL, it is recommended to wait 5 to 7 days and repeat the CBC; if the neutrophil count has increased to more than 1500 cells/μL, the drug can be safely administered. A caveat to these restrictions is that for dogs presenting before initiation of chemotherapy with low neutrophil and platelet counts due to bone marrow effacement (myelophthisis), myelosuppressive chemotherapy is instituted in the face of cytopenias to clear the bone marrow of neoplastic cells and allow hematopoiesis to normalize.

In those breeds likely to have homozygous *MDR1* gene mutations (e.g., collies; see Chapter 12), and therefore to be at risk for serious chemotherapy toxicity,[280] the author [DMV] will initiate a CHOP protocol out of sequence, beginning with non-MDR1–substrate drugs, such as cyclophosphamide. This ensures treatment of the lymphoma while allowing sufficient time for analysis of *MDR1* gene mutations before initiating MDR1 substrate drugs. No specific protocols have been scrutinized for treating dogs that are double-mutant for *MDR1*; however, if using *MDR1*-substrate drugs, the author initiates treatment using a 40% to 50% dose reduction. Subsequent dose modifications (increased or decreased dosage) can be implemented, depending on the level of adverse events observed, particularly low neutrophil counts at nadir. The author does not dose-modify for heterozygous *MDR1* gene mutations as little documented clinically significant chemosensitivity exists in these animals.

The Case for Treating T-Cell Lymphoma Differently

With some exceptions (e.g., TZL), multicentric T-cell lymphoma, compared with multicentric B-cell lymphoma, is associated with similar initial response rates, but significantly lower response durations (e.g., PFS) after chemotherapy (including CHOP-based protocols).[68,112,113,116,123,226,242,244,277,281–283] In addition, the effectiveness of a single treatment of DOX in the treatment of naïve lymphoma in one retrospective case series suggested a lower initial response rate for T-cell, compared with B-cell, immunophenotypes; however, this study performed only a single day 7 evaluation.[281] Many question whether dogs diagnosed with T-cell lymphoma should be treated with standard CHOP-based protocols or with alternative protocols. This is a valid question; however, the answer remains elusive because adequately powered randomized controlled trials do not currently exist to demonstrate if an alternate protocol is better for this immunophenotype. Several alternative protocols (MOPP, LOPP, VELCAP-TSC) have been reported and reviewed for induction therapy in dogs with multicentric T-cell lymphoma.[110,284–286] These alternative protocols tend to add or substitute alkylating agents (e.g., nitrogen mustard, lomustine, procarbazine) for DOX. Although reports have suggested improvements in remission durations in dogs with either confirmed T-cell lymphoma or lymphoma with hypercalcemia and no immunophenotypic classification, the confidence intervals of the medians all overlap with data from CHOP-based protocols, and differences in determining PFS, response evaluation, and study population (in particular, some do not adequately distinguish indolent multicentric lymphoma) in these reports preclude confident comparisons. As yet, no controlled, randomized trials have documented improvement with this approach. Ultimately, the development of better protocols for treating T-cell lymphoma awaits careful, randomized, prospective trial assessment. Until such time, the author prefers to initiate CHOP-based induction and switch to lomustine-based rescue at the first sign of progression or to enter dogs into clinical trials with novel agents. Although species differences may exist, in people with aggressive T-cell NHL, alternative protocols rich in alkylating agents have not shown superiority over CHOP-based protocols, and the National Comprehensive Cancer Network recommend human patient participation in clinical trials as the "gold standard" for aggressive nonindolent T-cell lymphomas.

Evaluation of Treatment Response

VCOG has published criteria for evaluation of treatment response (v1.0) to standardize reporting of outcome results and comparisons among protocols for peripheral nodal disease using criteria readily available in the practice setting.[253] The most important of these outcome measures and the preferred temporal outcome criterion for assessing protocol activity is now considered to be PFS, which is defined as being the time from treatment initiation to tumor progression or death from any cause. This brings veterinary outcome reporting more in line with human standards. Because the majority of dogs with lymphoma eventually experience relapse after chemotherapy-induced remissions and because methodology for differentiating complete and partial responses is analysis dependent on how responses are determined, PFS removes many sources of bias. Further, overall survival in published reports invariably includes patients who go on to receive varied rescue

protocols that bias the overall result, making it a less comparable outcome. Widespread application of these standardized criteria should permit more suitable comparisons in the future. True iCR rarely occur in dogs with lymphoma; documenting iCRs is limited to investigative trials striving to achieve them because we lack meaningful therapeutic options.

Improved methods of detecting minimal residual disease (MRD) or early recurrence have been investigated in dogs with lymphoma and include advanced imaging and detection of molecular and biologic markers of MRD. Advanced functional and anatomic imaging techniques (i.e., PET/CT) are the current standard for assessing treatment response and early relapse of lymphoma in humans and have also been investigated in dogs (see Fig. 33.10).[221,223–226] As these techniques become available to a broader veterinary population, their clinical application will surely increase. Molecular detection of MRD applies clonality and PCR techniques. Beyond diagnostic applications, these techniques have been applied to determine cytoreductive efficacy of various chemotherapeutic drugs and to document and predict early relapse in patients before more conventional methods.[123,217,246,287–293] Regarding biomarkers of MRD, preliminary investigations have suggested serum lactate dehydrogenase activity, thymidine kinase 1 activity, haptoglobin, and serum C-reactive protein may be candidates in the dog.[202–206,294]

As we become more proficient at defining MRD, the pressing clinical question becomes how we use this information. Theoretically, such information could suggest when more aggressive therapy or alternative therapy should be instituted in patients who have not achieved a "molecular remission" or who are undergoing early relapse; however, until we determine what these interventions should be based on prospective trial assessment, the clinical utility of MRD analytics remain theoretical.

Reinduction and Rescue Chemotherapy

Eventually, the vast majority of dogs that achieve a remission will relapse or experience recrudescence of lymphoma. This usually represents the emergence of tumor clones or tumor stem cells (see Chapter 2) that are inherently more resistant to chemotherapy than the original tumor, the so-called MDR clones that either were initially drug resistant or became so after exposure to selected chemotherapy agents.[295] Evidence suggests that in dogs with relapsed lymphoma, tumor cells are more likely to express genes (e.g., *MDR1*) that encode ABC-transporter protein transmembrane drug pumps often associated with MDR.[196,197,296–299] *MDR1* represents only one of the plethora of mechanisms that lead to drug-resistant disease (see Chapter 12). Other causes of relapse after chemotherapy include inadequate dosing and/or frequency of administration of chemotherapy, failure to achieve high concentrations of chemotherapeutic drugs in certain sites such as the CNS, and initial treatment with prednisone alone.

At the first recurrence of lymphoma, it is recommended that reinduction be attempted first by reintroducing the induction protocol that was initially successful, provided the recurrence occurred temporally far enough from the conclusion of the initial protocol (e.g., ≥2 months) to make reinduction likely. The cumulative dose of DOX that will result from reinduction, baseline cardiac assessment, the use of cardioprotectants, alternative drug choices, and client education should all be considered. In general, the duration of reinduction remission will be half that encountered in the initial therapy; however, a subset of animals will enjoy long-term reinductions, especially if the dog completed the initial induction treatment protocol and was currently not receiving chemotherapy for several months when relapse occurred. Reinduction rates of nearly 80% to 90% can be expected in dogs that have completed CHOP-based protocols and then relapse while not receiving therapy.[232,300] The duration of a second CHOP-based remission in one report was predicted by the duration of the interval between protocols and the duration of the first remission.[123,300]

If reinduction fails or the dog does not respond to the initial induction, the use of so-called "rescue" agents or "rescue" protocols may be attempted. These are single drugs or drug combinations that are typically not found in standard CHOP protocols and are withheld for use in the drug-resistant setting. The most common rescue protocols used in dogs include single-agent use or a combination of rabacfosadine, actinomycin D, mitoxantrone, DOX (if DOX was not part of the original induction protocol), dacarbazine (DTIC), temozolomide, lomustine (CCNU), L-asparaginase, mechlorethamine, vincristine, vinblastine, procarbazine, prednisone, and etoposide. Some rescue protocols are relatively simple and convenient single-agent treatments, whereas others are more complicated (and expensive) multiagent protocols, such as MOPP. Overall rescue response rates of 40% to 90% are reported; however, responses are usually not durable with median response durations of 1.5 to 2.5 months being typical regardless of the complexity of the protocol. A small (<20%) subset of animals will enjoy longer rescue durations. Table 33.5 provides a summary of canine rescue protocols and published results.[270,301–320] Current published data from rescue protocols do not include sufficient numbers for adequate statistical power, nor do they compare protocols in a controlled, randomized prospective fashion. Therefore comparative evaluations of efficacy among various protocols are subject to substantial bias, making direct comparisons difficult. Choice

TABLE 33.5 Summary of Response for Rescue Protocols[a]

LPP (lomustine, procarbazine, prednisone)	41	61	29	34 days	84 days	307
Temozolomide	26	32	13	15 days	NR	308

[a]Minimum of 25 cases. Few of these protocols include sufficient numbers for adequate statistical power and fewer compare treatment protocols in a randomized prospective fashion. In addition, staging, inclusion, and response criteria vary considerably between protocols presented. Therefore evaluations of efficacy between the various protocols are subject to bias making direct comparisons difficult and indeed precarious.

[b]Prednisone often used concurrently.

[c]Various temporal response end-points were used including disease-free interval, time to progression, progression-free survival, time to discontinuation, and remission duration.

TABLE 33.6 First-Line Rescue Protocol[a]

Cycle 1	
Week 1	**Baseline ALT _____ Units/L** L-Asparaginase, 400 Units/kg SC CCNU[b] 70 mg/m^2 PO Prednisone, 2 mg/kg PO, once daily
Week 2	Prednisone, 1.5 mg/kg PO, once daily
Week 3	Prednisone, 1.0 mg/kg PO, once daily
Cycle 2	
Week 1	**Optional ALT _____ Units/L** L-Asparaginase, 400 U/kg SC CCNU 70 mg/m^2 PO Prednisone, 1.0 mg/kg PO, EOD
Week 2	Prednisone, 1.0 mg/kg PO, EOD
Week 3	Prednisone, 1.0 mg/kg PO, EOD
Cycle 3–5	
Week 1	**Mandatory ALT _____ Units/L** CCNU 70 mg/m^2 PO Prednisone, 1.0 mg/kg PO, EOD
Week 2	Prednisone, 1.0 mg/kg PO, EOD
Week 3	Prednisone, 1.0 mg/kg PO, EOD

[a]Treatment discontinuation criteria: (1) After completion of protocol, two treatments beyond complete response (CR); (2) progressive disease; (3) increase in ALT activity >2× upper limit of normal (or 2× baseline if higher than baseline at initiation)—institute drug discontinuation and reinstitution/dose reduction dependent on normalization of ALT.

[b]Prophylactic liver protectants recommended (e.g., Denamarin).

ALT, Alanine aminotransferase.

of a particular rescue protocol should depend on several factors, including cost, time commitment required, efficacy, adverse event profile, and experience of the clinician with the protocols in question. As the complexity of rescue protocols does not yet appear to be associated with significant gains in rescue durability, the author (DMV) tends to choose simpler and less costly protocols (e.g., CCNU/L-asparaginase/prednisone) (Table 33.6); however, the use of multiple varied rescue protocols, switching as needed based on response, continues as long as clients are comfortable with their dog's quality of life. This sequential application of several different rescue protocols can result in several months of extended survival with acceptable quality of life.

Strategies to Enhance Effectiveness of Therapy in Lymphoma

Despite the plethora of published chemotherapeutic protocols for dogs with lymphoma, it appears we have achieved as much as we can from currently available cytotoxic chemotherapeutics in standard settings. The 12-month median survival "wall" and the 20% to 25% 2-year survival rates have not improved dramatically. Further advances in remission and survival durations await the development of new methods of delivering or targeting traditional chemotherapeutic drugs, new generations of chemotherapeutic drugs, or novel nonchemotherapeutic treatment modalities; in particular, the development of targeted immunotherapies, which is the standard of care in physician-based oncology. Mechanisms of avoiding or abrogating MDR, enhancing tumor apoptosis (programmed cell death), tumor ablation, and immune-system reconstitution, as well as novel immunomodulatory therapies for lymphoma, are all active areas of investigation in both human and veterinary medicine.

Treatment Approaches Using Immunologic or Biologic Agents

Monoclonal Antibody Approaches

Enhanced durability of first remissions in humans with B-cell NHL has been achieved primarily through the institution of monoclonal antibody (mAb)-based therapies (so-called R-CHOP protocols that are the current "standard-of-care" in people). The "R" refers to rituximab (Rituxan), a recombinant chimeric murine/human antibody directed against the CD20 antigen, a hydrophobic transmembrane protein located on normal pre-B and mature B lymphocytes. After binding, rituximab triggers a host cytotoxic immune response against CD20-positive cells. Unfortunately, rituximab does not have therapeutic activity in dogs because of a lack of external recognition of a similar antigen on canine lymphoma cells and the inherent antigenicity of human-derived antibodies in dogs.[321,322] Recently, caninized mAb designed to target either B-cell (blontuvetmab; Blontress) or T-cell (tamtuvetmab; Tactress) lymphomas were conditionally approved by the USDA for use in dogs with lymphoma; however, after being assessed in prospective clinical trials involving a large number of dogs, their target specificity was found to be inadequate to effect clinical efficacy, and they are no longer available and are not currently recommended for use. Several laboratories throughout the world are working to characterize and develop more specific and effective mAb therapies for use in canine lymphoma,[323–326] and practitioners await their development.

Antitumor Vaccine Approaches

Several antitumor vaccine approaches have been investigated in dogs with lymphoma, including tumor vaccine extract using killed lymphoma cells combined with Freund's adjuvant[327,328] and autologous killed and/or gene engineered lymphoma tumor cell vaccines[329,330]; however, no significant gains in remission times or overall survival have been documented. Exploratory vaccines targeting telomerase[331,332] (see Chapter 15, Section D), heat shock proteins,[333,334] and RNA-loaded CD40-activated B cells[335,336] in dogs with lymphoma have also been conducted. These studies involved small numbers of nonrandomized patients and lacked controlled populations for comparison. A xenogeneic DNA vaccine designed to target canine CD20 is currently undergoing clinical trials in the United States. Although preliminary activity is suggested in many of these reports and they are serving to enhance our basic understanding of immunotherapeutic methodologies, their development is still early; complete safety and efficacy trials have not been completed to date.

Adaptive Immunotherapy Approaches

Much excitement has been generated in physician-based medicine about adaptive immunotherapy approaches, in particular the application of chimeric antigen receptor T cells (CAR-T; see Chapter 14). These approaches are currently the subject of several proof-of-concept trials in dogs with NHL.[337,338]

Surgery

Most dogs with lymphoma have multicentric disease and therefore require systemic chemotherapy to effectively treat their disease.

VetBooks.ir

However, surgery has been used to treat solitary lymphoma (stage I) or solitary extranodal disease. Careful staging is necessary in such cases to rule out multicentric involvement before treating local disease. Surgery has also occasionally been applied for palliative removal of nodes that are mechanical obstructions in drug resistant settings.

The benefit of surgical removal of the spleen in dogs with massive splenomegaly remains unclear; however, for indolent lymphomas confined to the spleen, long-term survival after splenectomy is the norm.[100,102,339,340] In an older report, 16 dogs with lymphoma underwent splenectomy to remove a massively enlarged spleen and were subsequently treated with chemotherapy.[340] Within 6 weeks of splenectomy, five of the 16 dogs died of disseminated intravascular coagulation (DIC) and sepsis. The remaining 11 dogs (66%) had a CR, and seven dogs had a MST of 14 months. No staging or histologic information was provided, so the information appears of limited usefulness, although those with follow-up lived approximately 1 year. In two reports of indolent nodular lymphoma of the spleen (MZL and mantle cell lymphoma [MCL]), outcome was available on seven MZL cases, including three cases that did not receive adjuvant chemotherapy after surgery,[100,102] and only one died of lymphoma after splenectomy. In a recent report of indolent lymphomas, four splenic lymphomas (three MZL and one MCL) underwent splenectomy alone and all survived more than 1 year, with none dying of their primary disease.[101] In another report of 41 dogs undergoing splenectomy for lymphoma, those dogs with indolent forms enjoyed long-term survival.[339] Splenectomy should be considered if the lymphoma is not documented in other sites after thorough staging, if lymphoma is an indolent form, or if splenic rupture has occurred. Of note, no control population consisting of dogs that did not undergo splenectomy exists, so the natural history of indolent splenic lymphoma remains uncertain.

Radiation Therapy

Radiation therapy, although of limited routine use in the treatment of lymphoma, may be indicated in selected cases.[341–351] Potential indications are as follows:

1. Curative intent therapy for stage I LN and solitary extranodal disease (i.e., nasal, cutaneous, spinal lymphoma)
2. Palliation for local disease (e.g., mandibular lymphadenopathy, rectal lymphoma, mediastinal lymphoma where precaval syndrome is present, localized bone involvement)
3. Total body radiation combined with bone marrow or stem cell reconstitution
4. Whole or staged half-body RT after chemotherapy-induced remissions

In the latter case, staged half-body irradiation sandwiched between chemotherapy cycles or after attainment of remission by induction chemotherapy has been preliminarily investigated as a form of consolidation or maintenance.[261,344,345,349,352–354] RT is delivered to either the cranial or caudal half of the body in 4 to 8 Gy fractions and, after a 2- or 4-week rest, the other half of the body is irradiated in a similar fashion. Although these preliminary investigations were not randomized, they suggest that RT applied when dogs are in either complete or partial remission is safe and warrants further investigation to determine whether significant therapeutic gain can be realized. A pilot study of low-dose (1 Gy) single-fraction total body irradiation in seven dogs with relapsed drug-resistant lymphoma, although safely applied, resulted in only partial nondurable (1–4 week) remissions.[341]

Total body irradiation (and/or ablative chemotherapy) for complete or partial bone marrow ablation followed by reconstitution with bone marrow or stem-cell transplant in dogs, although a recognized model in comparative research settings,[355] is still in its early phases of development and application in clinical veterinary practice.[356–359] Because of the high cost, limited accessibility to relatively sophisticated equipment, and management requirements, these types of procedures are limited to preliminary investigations at a few centers. Currently, long-term results documenting significantly enhanced efficacy in sufficient numbers of treated cases have yet to be presented.

Treatment of Extranodal Lymphoma

In general, the veterinary literature contains little information on treating various extranodal forms of lymphoma in dogs, and our ability to predict outcome is thus limited. In general, it is recommended that, after extensive staging, in those cases where disease is shown to be localized to a solitary site, local therapies (e.g., surgery, local RT) can be used while withholding systemic therapies (i.e., chemotherapy) until systemic progression or recurrence is documented. In contrast, if multiple extranodal sites are involved or they are part of a more generalized process, systemic chemotherapy should be chosen.

Alimentary Lymphoma

Most dogs with alimentary lymphoma are presented with diffuse involvement of the intestinal tract, and involvement of local LNs and liver is common. Chemotherapy in dogs with diffuse intermediate- or high-grade disease has been reported to be unrewarding for the most part[61,126,360,361] with MSTs of only a few months after CHOP-based chemotherapy; however, durable remissions in a small subset of cases have been reported. A small-cell T-cell intestinal lymphoma has been reported in dogs that appears to have a more indolent course similar to small-cell T-cell intestinal lymphoma in cats.[64,125] In reports of 17 and 20 dogs, MSTs after receiving conservative treatment (prednisone and chlorambucil most commonly) were 1.5 to 2.0 years.[64,125] Solitary alimentary lymphoma is rare in the dog; however, if the tumor is localized and can be surgically removed, results (with or without follow-up chemotherapy) can be encouraging. Colorectal lymphoma, generally a high-grade B-cell phenotype, is also associated with an indolent outcome with median progression-free and overall survival times greater than 3 years after initiation of chemotherapy.[362,363]

Primary Central Nervous System Lymphoma

CNS lymphoma in dogs usually results from extension of multicentric lymphoma; however, primary CNS lymphoma has been reported.[87,133,135,136,364] If tumors are localized (rare), local RT should be considered. Few studies have reported the use of chemotherapy. In one study, cytosine arabinoside (Ara-C) at a dosage of 20 mg/m^2 was given intrathecally; this treatment was combined with systemic chemotherapy and CNS RT.[133] Overall, the response rates are low and of short duration (several weeks to months), although occasional durable responses are encountered.

Cutaneous Lymphoma

The cutaneous lymphomas represent an assorted group of clinical entities that vary considerably in presentation and outcome.[71,74,77,119,129,130,365,366] Epitheliotropic cutaneous lymphoma is most common and has been categorized into two clinically separate entities (mucocutaneous and cutaneous) based on outcome differences, with the mucocutaneous form appearing to have better overall outcomes.[129] Treatment of cutaneous and mucocutaneous

VetBooks.ir

lymphoma depends on the extent of disease. Solitary lesions have a better prognosis and may be treated with surgical excision or RT, although thorough staging for systemic disease should be undertaken before local therapy and active surveillance for subsequent development of recurrent or systemic involvement should be implemented. Fractionated RT has been associated with long-term control.[366,367] Diffuse cutaneous lymphoma is best managed with systemic therapy, although the rate and durability of response is generally less than in multicentric lymphoma. The most widely used protocols for epitheliotropic and nonepitheliotropic cutaneous T-cell lymphoma (CTCL) include CCNU (with or without L-asparaginase [see Table 33.6]) along with prednisone, pegylated L-asparaginase (very costly), and oral retinoic acid analogs (limited availability; acitretin, etretinate, isotretinoin).[269,366,368–372] Multiagent protocols (generally CHOP-based) may also be used, but have generally been instituted after single-agent therapies have failed. Although reported response rates can range from 40% to 80%, median remission durations are generally short (approximately 3–6 months); occasionally, durable remissions are encountered. Sporadic reports of other therapies for cutaneous lymphoma in small numbers of cases include the use of COAP (cyclophosphamide, vincristine [Oncovin], Ara-C, and prednisone), topical mechlorethamine (Mustargen), rabacfosadine, recombinant human interferon-alpha, and masitinib.[132,269,368,373] All these reports involved small numbers of cases and resulted in relatively short response durations. Whole-body surface RT has also been explored for the treatment of diffuse cutaneous lymphoma in preliminary trials.[348,374]

A form of cutaneous lymphocytic infiltration has been characterized as an indolent T-cell lymphoma based on clonality.[77] It is associated with slow progression and long-term survival after corticosteroid management; however, it does have the potential to progress to high-grade lymphoma.

Prognosis

The prognosis for dogs with lymphoma is highly variable and depends on a wide variety of factors that are documented or presumed to affect response to therapy. Although rarely curable (<10% of cases), CRs and a good quality of life during extended remissions and survival are typical. Factors that have been shown to influence treatment response and survival for peripheral nodal lymphoma are summarized in Tables 33.7 and 33.8.[a] The prognostic factors most consistently identified for peripheral nodal lymphoma are immunophenotype, WHO substage (see Fig. 33.11B), and an indolent subclassification (Fig. 33.12). Many reports have confirmed that dogs with nonindolent intermediate- and high-grade T-cell lymphomas have significantly shorter remissions and survival durations than dogs with intermediate or high-grade B-cell disease.[68,69,112,113,116,277,391] This holds true primarily for dogs with multicentric lymphoma because the immunophenotype of solitary or extranodal forms of lymphoma has not been thoroughly investigated with respect to prognosis. In addition, it has been shown that dogs with B-cell lymphomas that express lower than normal levels of B5 antigen (expressed in 95% of nonneoplastic lymphocytes) or low levels of class II MHC expression experience shorter remissions and survival durations.[69,391] Dogs presented with WHO substage *b* disease (i.e., clinically ill) also do poorly compared with dogs with substage *a* disease.[68,112,116,235,387] Dogs with stage I and II disease have a better prognosis than those dogs in more advanced stages (stage III, IV, and V).

[a]108, 111, 123, 139, 177–179, 207, 210, 213, 235, 237, 273, 276–278, 287, 290, 293, 294, 299, 328, 365, 375–397.

Proliferative assays such as analysis of bromodeoxyuridine (BrdU) uptake, Ki67 antibody reactivity, and AgNOR indices to measure proliferative activity of tumor cells have been shown to provide prognostic information in dogs treated with combination chemotherapy; however, different studies are contradictory and the information is rarely helpful clinically. In addition, in one report, the proportion of tumor cells undergoing apoptosis was modestly predictive of remission duration.[123,174]

The anatomic site of disease is also of considerable prognostic importance. Primary diffuse cutaneous, diffuse GI, hepatosplenic, and primary CNS lymphomas tend to be associated with a poor prognosis. Dogs with indolent cutaneous T-cell lymphocytic infiltration experience long-term survivals.[77] Sex has been shown to influence prognosis in some studies.[235,237] Neutered females tend to have a better prognosis; male dogs may have a higher incidence of the T-cell phenotype, which may account for the poorer prognosis.

Reported biomarkers of prognosis, summarized in Table 33.8, include increased circulating levels of glutathione-*S*-transferase, thymidine kinase, lactate dehydrogenase, C-reactive proteins, and VEGF. Finally, one report suggests that a history of chronic inflammatory disease of several types predicts likelihood of early relapse.[202,398] These putative prognostic indicators require further confirmation in larger trials.

Of particular interest is the capacity of gene expression analysis to predict and indeed subcategorize the lymphomas into prognostic categories.[14,20,178,179,384] Although these types of analysis are not currently widely available in the veterinary clinical setting, they are routinely used for prognostication and therapeutic decision making in people and are likely to become more readily available to veterinary clinicians in the next decade. The potential of genetic molecular profiling in veterinary oncology is illustrated by Frant et al[178]: they were able to subcategorize dogs with peripheral nodal lymphoma into three prognostic categories based on a benchtop quantitative real-time (qRT)-PCR diagnostic analysis of expression of only four genes.[178]

The Indolent Lymphomas

Histologic grade (subtype) greatly influences prognosis. Dogs with lymphoma classified as intermediate or high grade tend to respond to chemotherapy, but can relapse early. Dogs with low-grade indolent lymphomas have a poorer response to chemotherapy, yet have a survival advantage over dogs with intermediate- and high-grade lymphomas (see Fig. 33.12). Several case compilations have documented that dogs with indolent lymphoma (e.g., MZL, MCL, TZL) experience prolonged STs, often in the absence of any or aggressive chemotherapy; that is, they often enjoy prolonged survival despite intervention rather than because of intervention.[100–102] One caveat is that canine nodal marginal zone lymphoma, which is designated as an indolent disorder, is generally more aggressive with median progression-free intervals of 5 months and overall STs of only 8.5 months; this is substantially less than splenic MZL, which is associated with long-term survival or cure after splenectomy.[108] Many dogs with indolent lymphoma will live near normal life-spans and ultimately die of non–lymphoma-related disorders. Generally, with the indolent lymphomas, unless the presence of disease is having an effect on the quality of life or results in clinically significant cytopenias (myelophthisis), active surveillance in the absence of treatment is recommended. If treatment is deemed necessary, more conservative protocols (e.g., chlorambucil/prednisone or cyclophosphamide/prednisone) are initiated. The goal of therapy is to control the disease (stable disease or partial response) as CRs are unusual with the indolent lymphomas.

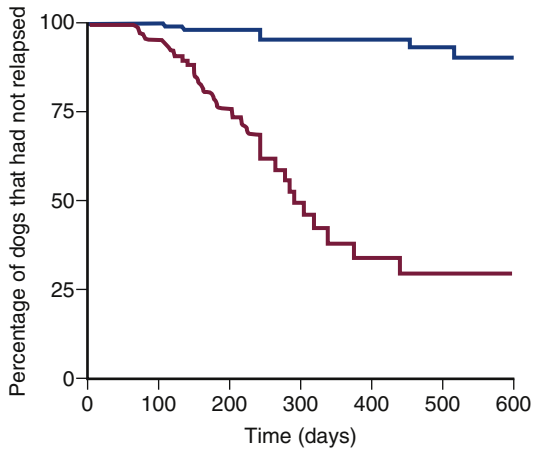
Steroid pretreatment	X		Prolonged steroid pretreatment: unfavorable	276,278
Cranial mediastinal lymphadenopathy	X		Present: unfavorable	122
Chemotherapy-induced hematologic toxicity		X	Grade III or IV chemotherapy-induced neutropenias: favorable	381,392
Geographic location		X	Mixed	383

Lymphocytic Leukemia

Lymphocytic leukemia is typically defined as proliferation of neoplastic lymphocytes in bone marrow. Neoplastic cells usually originate in the bone marrow, but occasionally in the spleen, and may or may not be circulating in the peripheral blood. Our ability to diagnose lymphocytic leukemias using morphologic, flow cytometric, immunophenotypic, and cytochemical techniques has increased significantly in the past decade. Although little information on treatment and prognosis is available for acute lymphocytic leukemias (ALL), clinically relevant information on chronic lymphocytic leukemias (CLL), their prognosis, and treatment have recently come to light. Differentiating between true leukemia and stage V lymphoma can be difficult and arbitrary, and is often based on lack of significant lymphadenopathy, degree of blood and bone marrow involvement, and immunophenotypic characteristics.



Incidence, Risk Factors, and Etiology

Lymphocytic leukemia is more common than acute myeloid leukemia and myeloproliferative disorders, but the true incidence

TABLE 33.8 Circulating (Serum/Plasma) Biomarkers as Prognostic Indices in Dogs with Lymphoma

Biomarker	Comments	References
Lactate dehydrogenase activity	Increased: unfavorable	202,210

is unknown. Overall, CLL is much more common than ALL. Smaller reports state that German shepherd dogs and golden retrievers may be overrepresented.[170,399] Based on a recent compilations of more than 400 dogs with B-cell CLL (B-CLL), small-breed dogs are much more likely to be affected.[106] Lymphocytic leukemia can occur in dogs of any age, but typically occurs in middle-aged to older dogs (mean of 7–10 years of age); CLL usually occurs in older dogs (mean of 10–11 years of age),[106,170,394,399,400] although a distinct form of B-CLL in English bulldogs occurs in younger dogs (mean, 6 years of age).[106] A significant sex predilection is not reported. As with lymphoma, the etiology of lymphocytic leukemia is for the most part unknown. Genetic factors likely play a role and have been compared between dogs and humans.[12]

Pathology and Classification

Lymphocytic leukemias can be subdivided based on cell size, maturity, genetic aberrations, microRNA expression, and immunophenotype.[12,170,180,394,399–402] The simplest classification divides leukemia into two groups: chronic (small cells with a mature cytologic phenotype) and acute (large cells with an immature cytologic phenotype). Immunophenotypic assessment using flow cytometric and molecular assays can further characterize these two major subtypes.

Of the CLLs, approximately two-thirds are T cell (T-CLL) and one-third are B-CLL. Three primary subtypes of CLL, based primarily on immunophenotyping, have been reported[106,164,170,394,400]: (1) T-CLL, which is the most common form, with cells in the majority of cases being $CD3^+/CD8^+$ granular lymphocytes; (2) B-CLL ($CD21^+$), which is the next most common subtype; and (3) atypical CLL, which represents a combination of immunophenotypes ($CD3^-$, $CD8^+$; $CD3^+$, $CD4^-$, $CD8^-$; $CD3^+$, $CD4^+$, $CD8^+$, and $CD3^+$ + $CD21^+$). This is in contrast to CLL in humans, which is primarily a disease of B cells. In CLL, lymphocytes often are indistinguishable morphologically from normal small lymphocytes (Fig. 33.13) and have a low rate of proliferation; accumulation of lymphocytes likely results from their prolonged lifespan.

ALL has also been classified as a lymphoid precursor neoplasm and can be derived from either B cells (B-ALL) or T cells (T-ALL). The majority are B-ALL ($CD21^+$, $CD3^-$, $CD4^-$, $CD8^-$), although a smaller percentage (<10%) are T-ALL ($CD3^+$, $CD4^-$, $CD8^-$, $CD21^-$).[170] In general, these cells tend to be intermediate or large cells with moderate amounts of basophilic cytoplasm. Perhaps the most distinguishing feature of the large lymphocytes is the nuclear chromatin pattern, which typically is less condensed than the chromatin in small lymphocytes but more condensed than the chromatin in myeloblasts. Large lymphocytes are larger than neutrophils, have a high nuclear-to-cytoplasmic ratio, and contain basophilic cytoplasm (see Fig. 33.13). Nucleoli, although present, are less prominent in large lymphocytes than in myeloblasts. Nevertheless, these cells cannot be distinguished easily from immature cells of other hematopoietic lineages, and identification of lineage-specific markers by immunocytochemical, flow cytometric, or molecular/genetic analysis is required to ascertain their lineage.[401,403,404] If the cells express CD34, a stem-cell marker, an acute phenotype is implied[170,394,399]; however, both myeloid and lymphoid lineages express CD34 and our ability to differentiate ALL from acute myeloid leukemia relies on detection of other markers, including T- and B-cell markers and myeloperoxidase, a myeloid marker. Furthermore, some T-ALLs do not express CD34.[404]

• **Fig. 33.13** (A) Peripheral blood from a dog with acute lymphocytic leukemia (ALL). Note the large lymphoid cells with visible nucleoli. Chromatin from disintegrated cells also is visible. (Wright's stain, ×60 objective.) (B) Peripheral blood from a dog with chronic lymphocytic leukemia (CLL). Note the small lymphocytes of normal mature morphology (smaller than the neutrophil). (Wright's stain, ×60 objective.)

History and Clinical Signs

Dogs with CLL are often asymptomatic and a diagnosis is pursued based on an incidental finding of increased circulating mature lymphocytes on routine CBCs. In more advanced disease, some owners report lethargy and decreased appetite. Mild lymphadenopathy and splenomegaly may be present, although late in the disease splenomegaly may be marked.[405] In a compilation of nearly 500 dogs with B-CLL, 50% had some degree of peripheral lymphadenopathy, 50% had splenomegaly, 30% had hepatomegaly, 23% had visceral lymphadenopathy, and 3% had a mediastinal mass.[106] The white blood cell (WBC) count is usually >30,000 cells/μL but can vary from normal to more than 100,000 cells/μL because of an increase in circulating mature lymphocytes. Lymphocytosis is persistent, and granulocytes are usually present in normal numbers. Other than lymphocytosis, hemograms of dogs with CLL tend to have few abnormalities when lymphocytes are less than 30,000/μL.[170,394,400] Mild anemia, neutropenia, and thrombocytopenia are common, but may become marked as the disease progresses and lymphocyte counts increase above 30,000/μL. In B-CLL, the median lymphocyte count was 24,600/μL and neutropenia and thrombocytopenia were uncommon (1% and 7%, respectively).[106] Despite the well-differentiated appearance of the lymphocytes in CLL, these cells may function abnormally. Paraneoplastic syndromes include monoclonal gammopathies, immune-mediated hemolytic anemia, pure red cell aplasia, and, rarely, hypercalcemia; 80% of dogs with B-CLL were reported to be hyperglobulinemic and 13% were hypercalcemic.[106,406,407] In 22 dogs with CLL, 68% had monoclonal gammopathies (usually IgM or IgA).[407] The immunophenotypes were not reported in this latter report, but a monoclonal gammopathy would be more likely to occur in B-CLL.

Dogs with ALL usually present with clinical signs of anorexia, weight loss, and lethargy. Splenomegaly is typical and other physical abnormalities may include hemorrhage, lymphadenopathy, and hepatomegaly.[408] Infiltration of bone marrow by neoplastic lymphocytes may be extensive, resulting in significant depression of normal hematopoietic elements or myelophthisis.[170,394,399,404,408,409] Anemia, neutropenia, and thrombocytopenia are typically much more severe than with CLL and may become life threatening. Infiltration of extramedullary sites, such as the CNS, bone, and GI tract, may also occur and can result in neuropathies, bone pain, and GI signs, respectively.

Diagnostics and Clinical Staging

Consideration of signalment, history, physical findings, and morphologic appearance and immunophenotype of cells is essential in making an accurate diagnosis. It is helpful to know the profile of lymphocyte subsets in the peripheral blood of normal dogs to determine whether a particular subset has expanded. Approximately 80% of circulating lymphocytes in normal dogs are T cells and about 15% are B cells. NK cells and double-negative ($CD4^-$, $CD8^-$) T cells constitute the remaining fraction. In the T-cell fraction, helper T cells ($CD4^+$) outnumber cytotoxic T cells ($CD8^+$).[407] Lymphocytic leukemia should be a consideration if atypical lymphocytes are in circulation, the immunophenotype of the lymphocytes in circulation is homogeneous as determined by flow cytometric analysis, a phenotype typically present in low frequency has increased, or if clonality is documented (e.g., by PARR analysis). Other differential diagnoses for lymphocytosis include infectious diseases, such as chronic ehrlichiosis, postvaccinal responses in young dogs, IL-2 administration, and transient physiologic or epinephrine-induced lymphocytosis. In some cases, reactive and neoplastic lymphocytoses are difficult to distinguish.

Expansion of neoplastic lymphocytes in bone marrow is the hallmark of ALL and, in most cases, CLL. Careful examination of peripheral blood and bone marrow by an experienced cytopathologist is important in establishing a diagnosis of lymphocytic leukemia; in cases of marked lymphocytosis with atypia, peripheral blood can be used for analysis of immunophenotype and clonality, and examination of bone marrow is not essential. If diagnostic bone marrow cannot be adequately obtained by aspiration, bone marrow core biopsy should be performed. In ALL, large lymphocytes predominate in the bone marrow and are also present in peripheral blood, and other lineages are decreased. In B- and T-cell CLL, lymphocytes are small mature cells that occur in excessive numbers in bone marrow (≥30% of all nucleated cells) early in the disease.[405] In T-CLL, lymphocytes may contain pink granules. Infiltration becomes more extensive as the disease slowly progresses, and eventually the neoplastic cells replace normal marrow.

A separate clinical staging system has not been developed for lymphocytic leukemias. Currently, all dogs with leukemia are classified as stage V based on the WHO Staging System for lymphoma as presented in Box 33.2.

VetBooks.ir

Treatment of Chronic Lymphocytic Leukemia

Because of the indolent and often asymptomatic nature of CLL, the decision to treat is often based on the clinical and laboratory findings in the individual dog. Most oncologists recommend active surveillance (monthly or bimonthly physical examination and CBC) over active therapy when CLL is identified incidentally, there are no accompanying clinical signs, and other significant hematologic abnormalities are not identified. If the dog is significantly anemic or thrombocytopenic or is showing evidence of significant lymphadenopathy or hepatosplenomegaly, therapy should be considered. There is no consensus on what degree of lymphocytosis is used to initiate therapy; the definition of "excessively high" varies among oncologists, and a standard has not been established in veterinary medicine. The author (DMV) prefers to base treatment decisions on the presence of significant constitutional signs and peripheral cytopenias rather than an absolute lymphocyte count. Currently, the most effective drug available for treatment of CLL, once therapy is deemed necessary, is chlorambucil.[400,405] Chlorambucil is given orally at a dose of 0.2 mg/kg or 6 mg/m^2 PO once daily for 7 to 14 days; the dose can then be reduced to 0.1 mg/kg or 3 mg/m^2 PO daily. For long-term maintenance, a dose of 2.0 mg/m^2 every other day can be used. The dose is adjusted based on clinical response and bone marrow tolerance. Pulse-dose chlorambucil (20–30 mg/m^2 q 2 weeks) has been anecdotally used for CLL in some cases; however, no compilations of cases have been reported to assess effectiveness of this protocol. Oral prednisone is used concurrently with chlorambucil at doses of 1 mg/kg daily for 1 to 2 weeks, then 0.5 mg/kg every other day thereafter. The addition of vincristine or the substitution of cyclophosphamide for chlorambucil has been advocated in animals that do not respond to chlorambucil.

Treatment of CLL, once initiated, is primarily palliative with rare complete remissions and a uniformly fatal course. Owing to the indolent nature of this disease, however, STs have been in the range of 1 to 3 years with a good quality of life.[400,405,410] The phenotype of CLL is usually stable over months to years; however, the disease may evolve into an acute phase, and some dogs will develop a form of lymphoma that is rapidly progressive and characterized by the presence of pleomorphic large lymphocytes[411,412]; in humans, this is termed *Richter's syndrome.*[413] Based on a data set of 153 cases, 2% of T-CLLs and 10% of B-CLLs progressed to a Richter-like acute disease often characterized by lymphadenopathy, coughing, vomiting, weight loss, and neurologic signs.[412] In these eight dogs, the progression to acute disease occurred 2 to 16 months after initial diagnosis of their CLL and MST after this progression was only 41 days despite aggressive (CHOP-based) chemotherapy in half of the cases.[412]

Treatment of Acute Lymphocytic Leukemia

Much of the morbidity in dogs with ALL results from effacement of bone marrow (myelophthisis) and subsequent life-threatening peripheral cytopenias. Neutropenia, thrombocytopenia, and anemia may be severe. Dogs often require supportive therapy, such as fresh whole-blood transfusions, broad-spectrum antibiotics, fluid therapy, and nutritional support. Careful monitoring for sepsis, hemorrhage, and DIC is important. Specific treatment of ALL would require aggressive chemotherapy; however, consistently efficacious protocols have not been developed in veterinary medicine, and there are few published reports. CHOP-based protocols, similar to those used for lymphoma (see Table 33.4), have been used by the author (DMV) and others for dogs with ALL; however, responses and durability of response are generally disappointing. The standard of care in humans with acute leukemia generally involves bone marrow ablative treatments with stem cell or marrow replacement, technology that is not widely available or often pursued in veterinary oncology.

Prognosis

In general, CLL is an indolent disease (with the aforementioned exception of atypical CLL), and many dogs will not require therapy for some time after diagnosis; several dogs have been reported to survive a year or more without treatment.[400,414] For those dogs that are treated, normalization of lymphocyte counts can be expected in 70% of cases. In one report of 17 dogs treated with vincristine, chlorambucil, and prednisone, MST was approximately 12 months with an expected 30% survival at 2 years.[405] In larger compilations of cases that include immunophenotypic analysis, treatment protocols were poorly documented, although most received chlorambucil and prednisone. The immunophenotype of CLL has been shown to be prognostic; in a report of 43 cases, MSTs of 930 days, 480 days, and 22 days were reported for T-CLL, B-CLL, and atypical CLL, respectively.[400] In this group of dogs, young age and anemia were also associated with a poor prognosis. In another series with limited treatment information, dogs with CLL of a CD8$^+$ immunophenotype that presented with less than 30,000 lymphocytes/μL or greater than 30,000 lymphocytes/μL had MSTs of 1098 and 131 days, respectively.[400]

Prognosis for dogs with ALL is generally very poor. In a study of 21 dogs treated with vincristine and prednisone, dogs achieving complete or partial remission (29%) had an MST of 120 days, and few dogs survived longer than 8 months.[408] In one report of 46 cases of ALL with a CD34$^+$ phenotype, dogs had a MST of 16 days (range, 3–128 days), even though the majority received a CHOP-based treatment protocol.[394] In addition, dogs with B-cell ALL (CD21$^+$) in which the lymphocytes were large cells (forward scatter lymphocyte/forward scatter neutrophil ratio of greater than 0.58 by flow cytometric analysis) had a MST of only 129 days, independent of treatment protocol.[394]

SECTION B: FELINE LYMPHOMA AND LEUKEMIA

DAVID M. VAIL AND MARIE PINKERTON

Lymphoma

Lymphoma (malignant lymphoma or lymphosarcoma) comprises a diverse group of neoplasms that have in common their origin from lymphocytes. The neoplasms usually arise in lymphoid tissues such as lymph nodes, spleen, and bone marrow; however, they may arise in almost any tissue in the body. Lymphoma is one of the most common neoplasms seen in the cat. See Box 33.4.

Incidence

Epidemiologic reports before 1990 suggested that lymphoma accounted for 50% to 90% of all hematopoietic tumors in the cat,[421,422] and because hematopoietic tumors (lymphoid and

VetBooks.ir

• BOX 33.4 Key Clinical Summary Points: Feline Lymphoma

- A varied group of lymphoid cancers discussed in three major groups based on varied presentation, diagnosis, management, and outcome (Table 33.9): Alimentary/Gastrointestinal, Peripheral Nodal, and Extranodal.
- Feline leukemia virus (FeLV) infection, a major etiologic agent of the disease, is no longer relevant in the majority of cases because of viral elimination and vaccination programs instituted in the 1980s.
- The alimentary/gastrointestinal forms predominate, and distinct subtypes exist representing both indolent (majority) and aggressive (intermediate-/high-grade) lymphomas (Table 33.10).
- Indolent (low-grade) subtypes in any anatomic site are managed with conservative chemotherapy (chlorambucil and prednisolone), with high response rates and durable survival durations (≥1.5–3 years) expected.
- Intermediate- or high-grade subtypes of any anatomic site are managed with more aggressive CHOP- or COP-based chemotherapy protocols (Tables 33.11, 33.12), with moderate response rates (50%–65%) and less durable (<1 year) survival durations expected.
- Cats with intermediate- or high-grade lymphoma that achieve a complete response with chemotherapy (approximately 35% of cases) often enjoy more durable (>1 year) survival durations.
- Solitary forms of lymphoma may be managed with local therapies (i.e., surgery, radiation therapy) provided thorough staging has ruled out systemic spread and active surveillance for identifying recurrence is instituted.

myeloid) represent approximately one-third of all feline tumors, it was estimated that lymphoid neoplasia accounted for an incidence of 200 per 100,000 cats at risk.[423] In one series of 400 cats with hematopoietic tumors, 61% had lymphoma and 39% had leukemias and myeloproliferative diseases (MPDs), of which 21% were categorized as undifferentiated leukemias, most likely myeloid in origin.[424] However, a significant change in the epidemiology and characteristics of lymphoma in cats coincided with the widespread integration of feline leukemia virus (FeLV) diagnostic assays and affected animal elimination regimens of the late 1970s and 1980s, and was further enhanced by the commercially available FeLV vaccines appearing in the late 1980s. The decline in FeLV-associated lymphoma is mirrored by a global decline in the overall prevalence per year of FeLV positivity in cats tested.[425–429] Importantly, many of these studies reveal that despite a sharp drop in FeLV-associated lymphoma, the overall prevalence of lymphoma in cats is increasing. The increased prevalence appears because of an increase in the number and relative frequency of the alimentary (and, in particular, the intestinal) and extranodal anatomic forms of lymphoma.[426,430–433] This is supported by an epidemiologic survey of several hundred cases of feline intestinal lymphoma; 534 (86%) were from the 20 years after 1985 and only 14% were from cases diagnosed in the 20 years before 1985.[432] This change in incidence has also been observed in Europe.[426,431]

The true annual incidence rate for lymphoma in cats is currently unknown. With respect to feline pediatric (<1 year of age) tumors, a study in the United Kingdom (n = 233 pathology specimens) found that 73 (31%) represented hematopoietic tumors, of which 51 (70%) were lymphoma; note that FeLV status was unavailable for this compilation of cases.[433]

The typical signalment for cats with lymphoma cannot be uniformly stated as it varies widely based on anatomic site and FeLV status, and therefore will be discussed individually under site-specific discussions. In general, based on two large compilations (n = 850) of cases in North America and Europe,[427,428] domestic shorthair (DSH) cats are most commonly affected and Siamese cats appear overrepresented in some reports. A 1.5:1 male-to-female ratio was observed in two studies, with no association with gender or neutering status observed in one.[427,428] In a large compilation of Australian cases, male cats and the Siamese/oriental breeds were overrepresented,[434] and similar breed findings have been observed in North America, although similar gender predilections have not been found. Within the Siamese/oriental breeds, there appears to be a predisposition for a mediastinal form that is not FeLV-associated and represents a younger population (median of 2 years).

Etiology

Viral Factors

FeLV was the most common cause of hematopoietic tumors in the cat in the so-called "FeLV era" of the 1960s through the 1980s, when approximately two-thirds of lymphoma cases were associated with FeLV antigenemia. Several studies have documented the potential molecular means by which FeLV can result in lymphoid neoplasia (see Chapter 1, Section C). As one would predict, along with a shift away from FeLV-associated tumors came a shift away from traditional signalment and relative frequency of anatomic sites. This is also supported outside of North America by similar signalment and anatomic frequency data observed in Australia, where FeLV infection is less common, and in Europe, where FeLV incidence has declined and signalment and anatomic site prevalence has shifted accordingly.[426,431,434,435] The median age of approximately 11 to 12 years now reported in North America and Europe is considerably higher than the median ages of 3 to 5 years reported in the FeLV era.[421,422,426–429,431] The median age of cats within various anatomic tumor groupings has not changed, and anatomic forms traditionally associated with FeLV, such as the mediastinal form, may still occur in younger, FeLV antigenemic cats. Similarly, the alimentary form and extranodal forms occur most often in older, FeLV-negative cats.[436–441] Table 33.9 presents an overview of the characteristics of the various anatomic sites of lymphoma in cats. As our ability to interrogate FeLV associations on a molecular basis has improved (e.g., PCR amplification and fluorescent in situ hybridization), several reports exist defining the role or potential role of FeLV in cats with and without FeLV antigenemia.[442–447] Collectively, these studies indicate FeLV proviral insertion exists in a proportion of feline lymphoma tissues and is more common in those of T-cell origin, particularly the thymic and peripheral lymph node anatomic forms. They also suggest that several common FeLV integration sites exist.

There is also evidence that feline immunodeficiency virus (FIV) infection can increase the incidence of lymphoma in cats.[425,448–456] In contrast to the direct role of FeLV in tumorigenesis, most evidence suggests an indirect role for FIV secondary to the immunosuppressive effects of the virus. Shelton et al determined that FIV infection alone in cats was associated with a five-fold increased risk for development of lymphoma.[454] Coinfection with FeLV further potentiates the development of lymphoproliferative disorders. Experimentally, cats infected with FIV have developed lymphoma in the kidney, alimentary tract, liver, and multicentric sites. FIV-associated lymphoma is more likely to be of B-cell immunophenotype, as opposed to the T-cell predominance associated with FeLV. It has been suggested that FIV infection may be associated more commonly with alimentary lymphoma of B-cell origin,[449,457] and this may be related to chronic dysregulation of the immune system or the activation of oncogenic pathways; however,

TABLE 33.9 General Characteristics of the Most Commonly Encountered Anatomic Forms of Lymphoma in Cats

Anatomic Form	Relative Frequency	Median Age (yr)	Immuno-Phenotype (Generally)	FeLV Antigenicity	Local versus Diffuse/ Multicentric	Biologic Behavior	General Prognosis
Alimentary/ Gastroin-testinal							
LGAL	Common	10–13	T-cell, small	Rare	Diffuse	Indolent	Good
I/HGAL	Uncommon	12	B-cell, large	Rare	Generally Diffuse	Aggressive	Poor–Fair
LGL	Uncommon	9	T-cell, large	Rare	Generally Diffuse	Aggressive	Poor
Nasal	Uncommon	9–10	B cell (75%)	Rare	Local common	More indolent	Good–Fair
Mediastinal	Uncommon	2–4	T-cell, large	More common	Local common	Indolent or aggressive forms	Fair–Poor
Peripheral nodal							
Non-Hodg-kin's	Uncommon	3–4	B-cell (75%), large	More common	Multicentric	Aggressive	Fair–Poor
Hodgkin's-like	Rare	11	T-cell rich B-cell, large	Rare	Local initially	Indolent	Good– Fair
Laryngeal/ Tracheal	Rare	9	ID	Rare	Local common	ID	Fair–Good
Renal	Uncommon	9	B-cell	Rare	Multicentric	Aggressive	Poor–Fair
CNS	Rare	4–10	ID	Rare	Multicentric	Aggressive	Poor
Cutaneous	Rare	10–13	T-cell	Rare	Local initially	Indolent to aggressive	Fair
Subcutane-ous	Rare	10–13	B-cell, large	Rare	Local initially	Aggressive	Fair
Ocular (PSOL)	Rare	10–11	B-cell	Rare	Local	Often indolent	Good–Fair

Common = >50% of clinical presentations; Moderate = 20%–50% of clinical presentations;
Uncommon = 5%–20% of clinical presentation; Rare = <5% of clinical presentations.
ID, Insufficient data; *I/HGAL*, intermediate-/high-grade alimentary lymphoma; *LGAL*, low-grade alimentary lymphoma; *LGL*, = large granular lymphoma; *PSOL*, presumed solitary ocular lymphoma.

FIV antigenemia was only rarely associated with alimentary lymphoma in other large compilations of cases.[428,458–461]

Interrogations of gammaherpesvirus 1(FcGHV1) in cats with lymphoma did not show an association; however, FcGHV1 antigenemia was associated with an overall poorer prognosis for cats with lymphoma, the causality of which is speculative.[462]

Genetic and Molecular Factors

As discussed in Section A of this chapter (canine lymphoma), recent advances in molecular cytogenetics (see also Chapter 1, Section A, and Chapter 8), including gene microarray techniques, have and are currently being applied to investigations of chromosomal aberrations and gene expression changes in veterinary species with lymphoma. Indeed, a predisposition of the oriental cat breeds to develop lymphoma suggests a genetic predisposition and indicates heritable risk.[427,435,436] Altered oncogene/tumor suppressor gene expression, epigenetic changes, signal transduction, and cell death-pathway alterations are common in lymphomas of humans and are likely also involved in the cat. Several genetic factors have already been discussed as they relate to FeLV associations. In addition, N-*ras* aberrations have been implicated, although they are rare in cats.[463] Furthermore, telomerase activity (see Chapter 2) has been documented in feline lymphoma tissues.[464,465] Alterations in cellular proliferation and in cell-cycle and death (apoptosis) pathways, in particular the cyclin-dependent kinase cell-cycle regulators and the Bcl-2 family of proapoptotic and antiapoptotic governing molecules, have also been implicated in feline lymphoma.[466–468]

Environmental Factors

Evidence for exposure to environmental tobacco smoke (ETS) as a risk factor for lymphoma in humans has prompted investigations in cats. In one report, the relative risk of developing lymphoma in cats with any exposure to ETS and with 5 or more years of exposure to ETS was 2.4 and 3.2, respectively.[469] A large European study documenting an association between proximity of waste management and cancer in dogs failed to show increased risk in cats.[470]

Immunosuppression

Immune system alterations in the cat, such as those accompanying FIV infection, has been implicated in the development of lymphoma.[450,452,454,471] As is the case in immunosuppressed human organ transplantation patients, reports of immunosuppressed feline renal transplant recipients document increased risk of lymphoma

after transplant and associated immunosuppressive therapy.[472–474] In these studies, approximately 10% of transplanted cats developed de novo malignant lymphoma and, in one report, all cats had intermediate- or high-grade multicentric B cell lymphoma.

Chronic Inflammation

Although definitive proof is lacking, there is a growing body of indirect evidence to suggest that lymphoma can be associated with the presence of chronic inflammation, which theoretically could be the case with intestinal and nasal lymphoma. In particular, an association has been suggested between intestinal lymphoma and inflammatory bowel disease[427,475]; however, others have not found support for this concept.[476] In addition, an association between gastric *Helicobacter* infection and gastric mucosa-associated lymphoid tissue (MALT) lymphoma in cats is suggested in one study, and it warrants further investigation because this is a recognized syndrome in humans.[477,478] In a case-control study investigating mucosa-invading and intravascular bacteria in feline intestinal lymphomas, statistically significant differences were found in prevalence of mucosa-invading bacteria, which were identified in 82%, 18% and 3% of large cell lymphoma, small cell lymphoma and lymphocytic-plasmacytic enteritis biopsy samples, respectively.[477] Furthermore, intravascular bacteria were only present in cases of large cell intestinal lymphoma (29% of cases). The etiologic significance of this has not been explored, but is also warranted. Finally, a suggestion that chronic inflammation from injection sites may be involved in the risk of developing subcutaneous lymphoma in cats,[431] similar to its documented association with subcutaneous soft tissue sarcomas.

Diet and Intestinal Lymphoma

Although no direct evidence exists, a link between diet and the development of intestinal lymphoma in cats has been suggested.[427] Support is offered by the relative and absolute increase in the alimentary form of lymphoma in the past 20 years and the fact that several dietary modifications in cat food have occurred in a similar timeframe in response to diseases, such as urinary tract disease. Further investigation is warranted to prove or disprove such assertions.

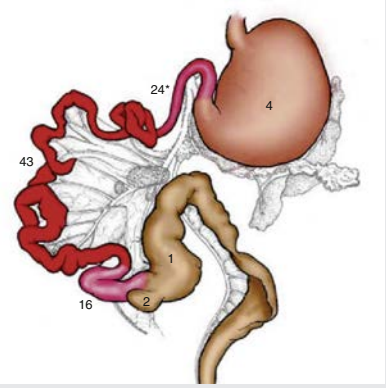
Pathology and Natural Behavior

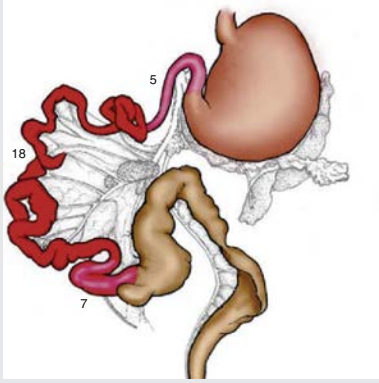
Lymphoma can be classified based on anatomic location and histologic and immunophenotypic (flow cytometric or immunohistochemical) criteria; often, the two are intimately associated because certain histologic and immunophenotypic types are commonly associated with specific anatomic locations (see Table 33.9). The interrogation of lymphoma subtypes by flow cytometric analysis, PARR clonality analysis and genetic characterization, as is the standard of practice for human lymphoma and becoming so in canine lymphoma, is less well described and applied in the feline lymphomas, partly due to the prevalence of intrabdominal anatomic forms making sampling more difficult and partly due to variable PCR primer availability and sensitivity.[479,480] The largest compilation of feline cases subjected to rigorous histologic classification was reported by Valli and others using the NCI Working Formulation.[481] The WHO has also published a histologic classification system that uses the REAL system as a basis for defining histologic categories of hematopoietic tumors in domestic animals.[482,483] This system incorporates both histologic criteria and immunohistologic criteria (e.g., B- and T-cell immunophenotype) and was discussed in length in Section A of this chapter. The updated Kiel classification system has also been used to classify feline lymphoma.[484,485] Regarding anatomic location, a profound change in presentation, signalment, FeLV antigenemia, immunophenotype, and frequency of anatomic sites has occurred in cats with lymphoma in the "post-FeLV" era (see Table 33.9). Because of this shift, characteristics of feline lymphoma discussed in this chapter will be primarily limited to reports collected from cases presenting after 1995.

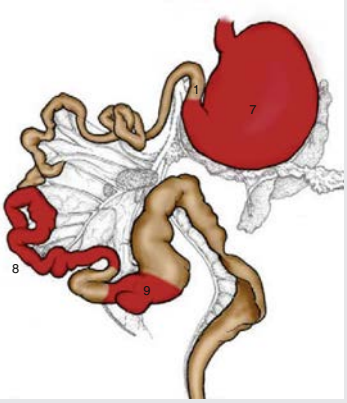
Several anatomic classifications exist for lymphoma in the cat, and some categorize the disease as mediastinal, alimentary, multicentric, nodal, leukemic, and individual extranodal forms. Others have combined various nodal and extranodal forms into categories of atypical, unclassified, and mixed, and others have combined intestinal, splenic, hepatic, and mesenteric nodal forms into one category termed *intraabdominal.* Some discrepancies in the discussion of frequency will inevitably result from the variations in classification used in the literature. The relative frequency of anatomic forms and their associated immunophenotype may also vary with geographic distribution and may be related to genetic and FeLV strain differences, as well as prevalence of FeLV vaccine use. For the purposes of this chapter, the feline lymphomas will be discussed in three separate sections: alimentary/gastrointestinal, peripheral nodal, and extranodal. Signalment, clinical presentation, diagnosis, treatment, and prognosis will be discussed individually under each of these three sections.

Alimentary/Gastrointestinal Lymphoma

Lymphoma is the most common tumor type found in the GI tract of cats, representing 55% of cases in an epidemiologic survey of 1129 intestinal tumors in the species.[432] The Siamese breed is reported at increased risk; however, the majority of cases occur in DSH cats.[427,432,436,441] Although lymphoma may occur in cats of any age, it is primarily a disease of aged cats with a mean of 10 to 13 years for T-cell alimentary lymphoma and 12 years for B-cell lymphoma.[427,432,441,486,487] Alimentary/GI lymphoma can be confined to intestinal/gastric infiltration or a combination of intestinal, mesenteric lymph node, and hepatosplenic involvement. Uncommonly, cats may be presented with extraabdominal coinvolvement. The tumors can be solitary, but more commonly are diffuse throughout the intestines. No consistent sex bias is noted. Anatomically, alimentary lymphoma is nearly four times more likely to occur in the small intestine than the large intestine.[486] In a series of colonic neoplasia in cats, lymphoma was the second most common malignancy (41%), second only to adenocarcinoma.[459] Most feline GI lymphomas can be categorized into one of three types based on histopathology and immunohistopathology: (1) low-grade alimentary lymphoma (LGAL), (2) intermediate- or high-grade alimentary lymphoma (I/HGAL), and (3) large granular lymphoma (LGL). Salient, generalizable characteristics of each are presented in Table 33.10.







Pathology and Natural Behavior

Low-Grade Alimentary Lymphoma

It is now clear that the vast majority of LGALs represent mucosal, epitheliotropic, small T-cell immunophenotypes that arise primarily from MALT.[436,441,487–492] Thus the major differential for LGAL is benign lymphocytic-plasmacytic enteritis (LPE; commonly referred to as inflammatory bowel disease [IBD]), which is also most commonly characterized by a small, T-cell, epitheliotropic infiltration. The largest compilation of LGAL (n = 120) classified GI lymphoma based on immunophenotype, then as either mucosal (infiltrate confined to mucosa and lamina propria with minimal submucosal extension) or transmural (significant extension into submucosa and muscularis propria).[487] They then compared

TABLE 33.10 Characteristics of the Three Most Common Forms of Alimentary/Gastrointestinal Lymphoma in Cats

Characteristic	Low-Grade Alimentary Lymphoma (LGAL)	Intermediate-/High-Grade Alimentary Lymphoma (I/HGAL)	Large Granular Lymphoma (LGL)
Incidence	50%–80% of cases	≈20% of cases	≈10% of cases
Clinical presentation	Nonspecific gastrointestinal signs (anorexia, weight loss, diarrhea, inappetence)	Nonspecific gastrointestinal signs; vomiting common if gastric; hematochezia more common if large bowel	Nonspecific gastrointestinal signs; vomiting more common
Clinical course	Indolent clinical progression	Acute clinical progression	Acute clinical progression
Abdominal palpation	Generally normal, modest intestinal thickening and abdominal lymphadenopathy possible	More common to palpate gastric/intestinal mass, mesenteric lymphadenopathy, organomegaly	More common to palpate gastric/intestinal mass, mesenteric lymphadenopathy
Abdominal ultrasound findings	Often unremarkable; diffuse intestinal wall thickening if present is limited to muscularis propria /submucosa; normal intestinal wall layering; mild lymphadenopathy/organomegaly possible	More commonly thickened transmural intestinal wall; loss of normal intestinal wall layering; mass effect more likely; mesenteric lymphadenopathy more likely	More commonly thickened transmural intestinal wall; loss of normal intestinal wall layering; mass effect more likely; mesenteric lymphadenopathy more likely; effusion uncommon but more likely
Topography[a]			
General diagnostics	Cytology generally not helpful; biopsy (full thickness preferred, but endoscopic helpful) with histopathology, immunophenotype, and clonality analysis often helpful to differentiate from LPE	Cytology (mass/lymph node) often diagnostic; biopsy with histopathology, immunophenotype, and clonality analysis less commonly required.	Cytology (mass/lymph node) often diagnostic; biopsy with histopathology, immunophenotype, and clonality analysis less commonly required.
Cell size	>80% small, <20% large	>90% intermediate/large	Intermediate/large
Immunophenotype	>80% T-cell ($CD3^{+}$)	≈100% B-cell ($CD79a^{+}$)	Cytotoxic T-cell ($CD3^{+}/CD8^{+}/CD79a^{-}$), or NK cell ($CD3^{-}/CD79a^{-}$); often $CD103^{+}$ and granzyme B^{+}
Clonality	>90% clonal or oligoclonal	>70% clonal or oligoclonal	>90% clonal or oligoclonal
WHO EATCL classification	90% type II (mucosal) 10% type I (transmural)	90% type I (transmural) 10% type II (mucosal)	≥90% type I (transmural)
Epitheliotropism	Common	Rare	Common
Recommended treatment	Chlorambucil/prednisolone	CHOP- or COP-based chemotherapy; surgery considered if large discreet lesion prechemo; surgery performed if obstruction/perforation	CHOP- or COP-based chemotherapy; surgery considered if large discreet lesion prechemo; surgery performed if obstruction/perforation
Chemotherapy response and outcome	>80% response; median survival 1.5–3 years	≈50%–60% response (30% CR); median survival 3–10 months; more durable if CR	≈30% response; median survival 45–90 days; occasionally more durable

[a]Numbers indicate number of cases having lymphoma at that location. Areas in red indicate most commonly affected regions of the intestine.

CR, Complete response; *LPE*, lymphocytic-plasmacytic enteritis; *WHO EATCL*, World Health Organization enteropathy-associated T-cell lymphoma.

VetBooks.ir

infiltration patterns with the WHO classification scheme[493] as well as documenting anatomic location, cell size, presence of epitheliotropism, clonality, and outcome data. This information is summarized in Table 33.10. Of the 120 cases, none tested serologically positive for FeLV and only three cats tested positive for FIV. Four cats had large B-cell lymphoma (gastric, cecal, or colonic) concurrent with small T-cell lymphoma of the small intestine. Topographically, T-cell variants are much more likely to occur in the small intestine (94%) and rarely in the stomach or large intestine. The majority of T-cell variants are mucosal (equivalent to WHO enteropathy-associated T-cell lymphoma [WHO EATCL] type II), and the majority of B-cell tumors are transmural (equivalent to WHO EATCL type I classification). Regarding cell size, nearly all mucosal T-cell tumors were composed of small lymphocytes, and slightly more than half of transmural T-cell and all B-cell variants were composed of larger cells. Epitheliotropism is common with LGAL T-cell tumors, but is rare in B-cell tumors. Other abdominal organ involvement is common, and in one report of 29 cases of low-grade T-cell intestinal lymphoma, liver and mesenteric node involvement was documented in 53% and 33% of cases, respectively.[494] Hepatic lymphoma can occur concurrently with GI lymphoma or be confined solely to the liver.[486,495] Most are T-cell and clonal or oligoclonal based on PCR analysis.

Intermediate- or High-Grade Alimentary Lymphoma

Unlike LGAL, the majority of I/HGALs are large or intermediate sized B-cell lymphomas. They arise from organized lymphoid tissues; MALT in the stomach and Peyer's patches and mucosal lymphoid nodules concentrated in the distal small intestine, cecum, and colon.[436,487,488,496,497] Therefore I/HGAL is more common in the stomach, distal small intestine, cecum, and colon (see Table 33.10). These B-cell variants can be solitary or at multiple sites that occur simultaneously within the stomach, small intestine, and ileocecocolic junction. The majority are transmural (equivalent to WHO EATCL type I classification) and epitheliotropism is rarely observed.

Large Granular Lymphoma

LGL represents a less common, distinct form of alimentary lymphoma occurring in older (median age 9–10 years) cats.[436,438,487,497–501] These granulated round cell tumors have also been termed *globule leukocyte tumors,* although they are likely variations of the same disease. LGL is characterized by lymphocytes described as 12 to 20 µm in diameter with a round, clefted, or cerebriform nucleus, variably distinct nucleoli, finely granular to lacey chromatin, and a moderate amount of basophilic granular cytoplasm that is occasionally vacuolated.[500] Prominent magenta or azurophilic granules are characteristic (Fig. 7.34, Chapter 7). They are usually granzyme B positive by immunohistochemistry.[487] This population of cells includes cytotoxic T cells and occasionally NK cells: most are $CD3^+$, $CD8^+$, and $CD20^-$ and have T-cell receptor gene rearrangements.[487,501] In one report, nearly 60% expressed CD103 (integrin alpha E).[501,502] LGL was confined to the intestines in 93% of cases in a large compilation,[438] but can occur extraabdominally (e.g., nasal).[438,498] Approximately 10% express neither B- or T-cell markers and are thus classified as NK cells. These NK tumors commonly originate in the small intestine, especially the jejunum, are transmural, often exhibit epitheliotropism, and at least two-thirds present with other organs involved; most with mesenteric lymph node involvement and many with liver, spleen, kidney, peritoneal malignant effusions, and bone marrow infiltration. Also, thoracic involvement may occur with malignant pleural effusion and a mediastinal mass present. Peripheral blood involvement was present in 10% to 15% in some reports[438,500] and as often as 86% in another report.[501] Affected cats are generally FeLV/FIV negative.

History, Clinical Signs, and Physical Examination Findings

Low-Grade Alimentary Lymphoma

LGAL is most commonly associated with nonspecific signs associated with the GI tract; most cats present with weight loss (>80%), vomiting and/or diarrhea (70%–90%), and hyporexia (70%–90%), whereas icterus is uncommon (7%).[436,486,503,504] Abdominal palpation is often unremarkable, but intestinal thickening, mesenteric lymphadenopathy, and organomegaly can occasionally be appreciated. Clinical signs are usually present for several months before diagnosis (median, 6 months).[504]

Intermediate- or High-Grade Alimentary Lymphoma

I/HGAL tends to cause similar clinical signs as LGAL; however, they tend to progress more acutely and are more likely to present with a palpable abdominal mass originating from the GI tract, enlarged mesenteric lymph nodes, or liver.[436,439,461,496,503,505] Icterus is also more common in large cell forms. Hematochezia and tenesmus may also be present if the colon is involved.[459] Rarely, cats may present with signs consistent with an acute abdomen due to intestinal obstruction or perforation and concurrent peritonitis.

Large Granular Lymphoma

Cats with intestinal LGL have typical GI clinical signs, but are also more likely to be acutely presented.[438,498,500,501] A palpable abdominal mass is present in approximately half of cases, and hepatomegaly, splenomegaly, and renomegaly are common. Abdominal and pleural effusions, and icterus are observed in nearly 10% of cases.

Diagnosis and Clinical Staging

For most cats with suspect alimentary/GI lymphoma, the diagnostic evaluation should include a baseline assessment consisting of a CBC with differential cell and platelet count, serum biochemistry profile, urinalysis, and retroviral (FeLV/FIV) screen. Anemia and neutrophilia are common findings in all forms of alimentary lymphoma; however, they tend to be more profound in I/HGAL and LGL.[436,438,488,498] Circulating neoplastic lymphocytes are rare with LGAL, but may be observed in up to 15% of I/HGAL and LGL. Serum biochemistry profiles can help establish the overall health of the animal and suggest extra-GI involvement (e.g., liver enzymes elevations/icterus may indicate hepatic infiltration; azotemia may indicate renal involvement). For cats with alimentary lymphoma, hypoproteinemia and anemia are reported to occur in up to 23% and 76% of cases, respectively.[461,486,506] Hypercalcemia is rarely seen in cats, but has been reported in cats with lymphoma at various anatomic sites. Hypoglycemia, hypoalbuminemia, hyperglobulinemia, abnormal serum folate (high or low), elevated lactate dehydrogenase (LDH), and hypocobalaminemia are often reported.[436,438,506,507]

Low-Grade Alimentary Lymphoma

LGAL must be differentiated from LPE, which have similar clinical presentations and histologic cell populations.[441,487–491,508] LGAL is more commonly associated with modest (or palpably

absent) intestinal thickening without mass effect similar if not identical in presentation to LPE. The key elements necessary for the diagnosis of LGAL (and differentiation from IBD) include procurement of tissue for histopathology, and if necessary, assessment of immunophenotype and clonality.

Abdominal ultrasound is by no means pathognomonic as both LGAL and LPE can have normal ultrasound appearance or reveal modest intestinal wall thickening with preservation of wall layering.[436,461,486,488,508–510] Changes, if present, predominantly involves the muscularis propria and submucosal layers, although mucosal thickening can also occur. Focal mural masses are uncommon. Mesenteric lymphadenopathy is also common and reported in 45% to 80% of affected cats. LGAL generally involves the small intestine and, less commonly, the stomach and large intestine. Cats with LGAL will uncommonly have ultrasonographic abnormalities in other abdominal organs such as the stomach, liver, spleen, colon, and pancreas, and occasionally, mild effusions are observed.

Cytologic evaluation of thickened bowel or associated mesenteric lymphadenopathy alone is generally not sufficient for differentiating LGAL from LPE.[486,488,502] Therefore tissue procurement is required for diagnosis (and differentiation from LPE). The debate still exists as to whether endoscopically obtained tissue is sufficient for diagnosis or if full-thickness tissue procured during laparotomy or laparoscopy is necessary in light of similarities with LPE.[436,487,491,509,511,512] Although histologic morphology and intestinal infiltrative patterns (e.g., villous nests or plaques) can be highly suggestive of lymphoma, they may not provide a definitive diagnosis. Most agree that although full thickness biopsies are preferred, less invasive endoscopic biopsies, with ancillary immunophenotypic and molecular (i.e., PARR; see Chapter 8) assessments, are sufficient in the majority of cases (see Table 33.10). If the differentiation of lymphoma and LPE is equivocal after standard histopathologic assessment, the addition of immunophenotypic and clonality analysis in a stepwise fashion, as proposed by several reports, enhances specificity and sensitivity and usually provides a definitive diagnosis.[436,441,479,480,487,489,491,513,514] As LGAL most commonly involves the jejunum and ilium, endoscopic biopsy by both gastroduodenoscopy and ileocolonoscopy may be necessary to procure representative samples.

Intermediate- or High-Grade Alimentary Lymphoma and Large Granular Lymphoma

The diagnosis of I/HGAL and LGL is generally less complicated than for LGAL.[436,438,488,498] The former are often diagnosed with physical examination, abdominal imaging (e.g., ultrasound), and cytologic or histologic assessment of needle aspirate or needle biopsy samples from intestinal masses, enlarged mesenteric lymph nodes, or liver because mass lesions and gross lymphadenopathy are more commonly present. Ultrasonographically, I/HGAL is more likely to involve the stomach and colon than LGAL. In a series of 16 cats with I/HGAL of the stomach, all had either ultrasonic evidence of wall thickening or the presence of a mass, and 20% had abdominal lymphadenopathy.[439] Less commonly, abdominal exploration is necessary if lesions are subtle or not amenable to transabdominal sampling. Further staging via thoracic imaging, peripheral lymph node aspiration, and bone marrow assessment may be performed, but rarely contributes prognostic information or alters treatment decisions because the disease is already widespread and systemic therapy is required.

Treatment and Prognosis

In general, cats tolerate chemotherapy for lymphoma quite well, most clients are happy with their choice to initiate treatment, and quality of life generally improves after commencement of therapy.[515,516]

Low-Grade Alimentary Lymphoma

LGAL is a gratifying disease to treat as durable remissions are generally achieved with well-tolerated, conservative treatment protocols (e.g., oral chlorambucil and prednisolone).[486–488,504,517,518] Chlorambucil (20 mg/m^2 PO every 2 weeks [preferred by the author] or 2 mg PO every other day) and prednisolone (initially 1–2 mg/kg PO daily, reduced to 0.5–1.0 mg/kg every other day over several weeks) results in response rates (i.e., resolution of clinical signs) of greater than 80% and MSTs of approximately 1.5 to 3.0 years.[486,488,491,504,517,518] Most clinical oncologists continue these conservative protocols for 2 years or longer; however, one report discontinued chlorambucil/prednisolone therapy at 1 year.[517] Cats that relapse while receiving this protocol often will subsequently respond to alternative alkylating agents, such as cyclophosphamide (200–250 mg/m^2, PO, q2–3 weeks) or lomustine, or to reintroduction of chlorambucil if this had been discontinued.[505,517–519] Rescue protocols have reported MSTs ranging from 9 to 29 months. Anecdotally, many will also respond to vinblastine chemotherapy if they no longer are responsive to alkylating agents. Ultimately, more aggressive CHOP- or MOPP-based protocols may be utilized when more conservative protocols are no longer effective.

Prognostic factors for cats with LGAL are not well-defined owing to the indolent nature of the disease and typical long-term survival. Only lack of response to initial induction chemotherapy is consistently observed as a negative factor, although transmural extension may also be associated with shorter STs.[487]

Intermediate- or High-Grade Alimentary Lymphoma

More aggressive multiagent combination chemotherapy is recommended for I/HGAL and LGL subtypes of lymphoma. The agents used most commonly to treat intermediate- or high-grade lymphoma in cats are similar to those used for dogs with lymphoma (see Section A in this chapter), and induction protocols currently employed in cats are modifications of CHOP protocols initially designed for humans.[428,438–440,488,496,498,515,520–528] CHOP represents combinations of cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin), vincristine (O, Oncovin) and prednisone (P). In general, CHOP-based protocols are appropriate for cats with intermediate- and high-grade lymphoma involving any anatomic site (e.g., peripheral nodal, mediastinal, and extranodal forms), but should not be first-line therapy for low-grade variants such as LGAL. As in the dog, a plethora of CHOP-based protocols have been reported for use in cats, although virtually no high-quality comparative data exist to compare outcomes. As such, the protocol used should be based on cost, ease, client/veterinarian preference, and level of comfort. One report found that cats may better tolerate CHOP protocols that substitute vinblastine for vincristine; GI adverse events were less frequent and of lesser grade in cats receiving vinblastine.[529] The current CHOP-based protocol in use by the author for cats is presented in Table 33.11. This protocol has been used in many cats with various forms of intermediate- and high-grade lymphoma and is generally well tolerated. At present, most canine lymphoma protocols involve a 12- to 25-week induction phase whereupon chemotherapy is discontinued and no

17	Doxorubicin, 25 mg/m^2, IV
19	Vincristine, 0.5–0.7 mg/m^2, IV
21	Cyclophosphamide 200 mg/m^2, PO
23	Vincristine, 0.5–0.7 mg/m^2, IV
25[c]	Doxorubicin, 25 mg/m^2, IV

CHOP, Combinations of cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin), vincristine (O, Oncovin), and prednisolone (P); *IV*, intravenous; *PO*, by mouth; *SQ*, subcutaneous.

[a]Prednisolone is continued (1 mg/kg, PO) every other day from this point on.

[b]If in complete remission at week 9, continue to week 11.

[c]If in complete remission at week 25, therapy is discontinued after this doxorubicin, and cat is rechecked monthly for recurrence.

Note: A complete blood count (CBC) should be performed before each chemotherapy. If neutrophils are <1500 cells/μL, wait 5–7 days, repeat CBC, then administer the drug if neutrophils have risen above the 1500 cell/μL cutoff.

TABLE 33.12 COP Protocol for Lymphoma in Cats

Drug	Frequency of Drug Delivery
Cyclophosphamide: 250–300 mg/m^2, PO[a]	Given every 3 weeks on the day after vincristine
Vincristine: 0.7 mg/m^2, IV	Given weekly on weeks 1, 2, 3, and 4, then given every 3 weeks thereafter on the days before cyclophosphamide. Discontinue if in remission at 1 year.
Prednisolone: 1–2 mg/kg, PO	Given daily for 1 year.

[a]Some divide the cyclophosphamide over 3 consecutive days.

Note: A complete blood count (CBC) should be performed before each chemotherapy. If neutrophils are <1500 cells/μL, wait 5–7 days, repeat CBC, then administer the drug if neutrophils have risen above the 1500 cell/μL cutoff.

maintenance chemotherapy is used. Although data exist in dogs for a maintenance-free approach, similar comparative data do not currently exist in the cat. DOX alone (25 mg/m^2 every 3 weeks for five total treatments), CCNU (lomustine; 40–50 mg/m^2 PO q 3 weeks),[440] or palliative prednisone therapy is offered if clients decline more aggressive CHOP-based therapy. [440,530,531] Cats are generally less tolerant of DOX than are dogs; therefore a lower dosage (25 mg/m^2 or 1 mg/kg IV) is used (see Chapter 12). Cardiac toxicity does not appear to be a clinically significant problem in cats, although renal toxicity is more commonly encountered,[532] and renal function should be monitored (i.e., serial blood urea nitrogen [BUN], creatinine, and urine specific gravity) closely before and during therapy. The use of COP (i.e., CHOP without the addition of DOX) is often used in cats in Europe, and one compilation reported similar results to CHOP.[533] A COP (cyclophosphamide, vincristine, and prednisolone) protocol commonly employed in cats is presented in Table 33.12; however, several studies have reported that the inclusion of DOX is important for predicting more durable responses. [488,527,534] The use of intraperitoneal-delivered COP in a small number of cats (n = 26) was reported; three-quarters achieved a CR with a MST of 1 year.[535] This study included only three GI cases and did not histologically or immunophenotypically subtype cases beyond saying all were "large cell"; therefore larger, more controlled studies would be necessary to establish/confirm efficacy of this protocol.

Response rates and durability of response for cats with I/HGAL treated with combination protocols are generally not as good as in dogs with intermediate- or high-grade peripheral nodal lymphoma. Remission rates of 50% to 65% can be expected with approximately one-third achieving CR. Remission and survival are only durable in cases achieving a CR; MSTs for cats in CR are approximately 7 to 10 months with a subset living to 1 year or longer.[439,440,488,496,520–522,529,428,515,523–528] Rescue protocols involving alternate drugs (e.g., melphalan, lomustine, mechlorethamine, actinomycin-D, cytarabine) or reinduction with CHOP generally do not result in durable subsequent remissions.[519,536,537]

Several prognostic factors have been reported for cats with I/HGAL; however, by far the most predictive is whether a CR is achieved.[439,440,487,488,491,496,520–522,529] Negative prognostic factors identified for I/HGAL include transmural extension, FeLV antigenemia, weight loss, elevated LDH, hypoalbuminemia, hypocobaliminemia, and bicavitary involvement, while stage I disease (rare) is associated with a more favorable prognosis. Factors not found to be prognostic were immunophenotype and various proliferation indices (e.g., PCNA, AgNOR, Ki67).

Large Granular Lymphoma

Cats with LGL typically have the lowest reported response rates and shortest response durations of any of the GI lymphomas. Approximately one-third of cases will experience a response and MSTs in larger reports of cases were only 21 days; cats receiving CHOP-based or CCNU-based protocols experienced MSTs of 45 to 90 days.[438,488,500] That being said, a small subset (7% in this report) enjoyed more durable (>6 month survivals) responses and, in one small study (n = 6), a MST of 9 months was reported after a variety of interventions.[498]

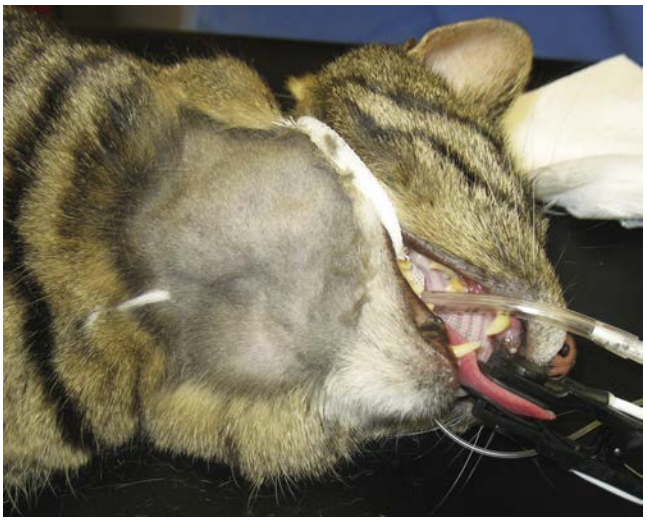
The Role of Surgery in Cats with Gastrointestinal Lymphoma

Surgery is primarily reserved for I/HGAL that have discrete lesions and in cats that are presented with intestinal perforation

VetBooks.ir

and obstructive lesions.[439,488,496] Of current debate is whether surgery should be performed on discrete lesions that are not perforated or obstructed before initiating systemic chemotherapy. This question is currently unanswered as comparative trials have not clearly established a benefit or detriment to this approach. The motivation behind performing surgery before chemotherapy often lies with concern for GI perforation resulting from robust chemotherapy response in cases with full-thickness involvement with lymphoma. Crouse reported on 23 cats with discrete I/HGAL undergoing chemotherapy without surgery. Although four cats (17%) experienced perforation, these events occurred 2 to 87 days after initiation of chemotherapy rather than in the acute postchemotherapy period, they were not associated with size or degree of hypoalbuminemia, and progressive disease was documented in three cats and only a partial response in the other cat at the time of perforation.[437] Taken together, this implies that perforations were likely due to progressive disease rather than robust response to chemotherapy. An additional motivation for surgical intervention is the theoretical advantage of immediate creation of a "minimal residual disease" state if staging does not reveal disease distant from a large GI primary tumor; chemotherapy is generally thought to result in more favorable outcomes in the minimal disease state, rather than in the macroscopic disease state. The author generally recommends surgery, albeit in the absence of convincing support in the literature, if lesions are large, discrete, and no (or minimal) involvement is documented outside the primary mass after complete staging. Multiagent chemotherapy is then initiated at suture removal owing to the high-grade nature and overall short STs associated with I/HGAL.

The Role of Radiation Therapy in Cats with Gastrointestinal Lymphoma



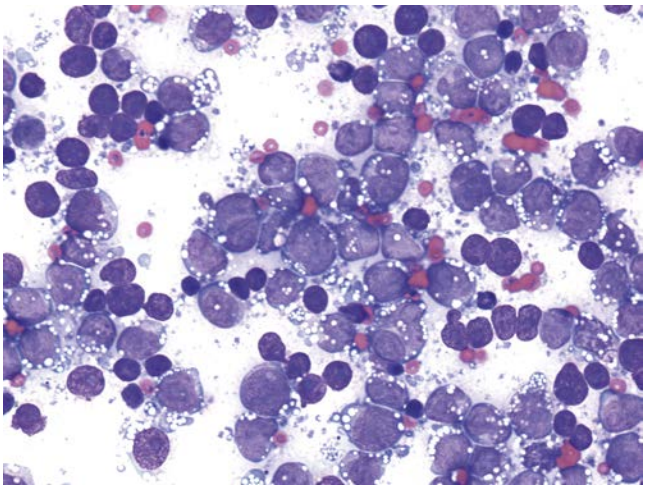
Radiation therapy (RT) for GI lymphoma in cats has not been thoroughly explored and is generally reserved for consolidation therapy (during or after chemotherapy) or as a rescue modality.[538,539] In one report, 11 cats (six small cell, four large cell, and one LGL) that progressed after chemotherapy received abdominal radiation (8 Gy in two fractions over 2 days) and experienced a MST of 7 months, although numbers were small and 40% were lost to follow-up.[538] In a second report, eight cats (seven with I/HGAL) underwent 6 weeks of CHOP-based combination chemotherapy followed 2 weeks later by whole abdomen radiation consisting of 10 daily 1.5 Gy fractions.[539,540] Although three cats died within 3 weeks of RT, five experienced durable remissions. These preliminary results warrant further investigation before RT can be recommended as standard care.

Supportive Care for Cats with Gastrointestinal Lymphoma

Intuitively, GI disease may compromise the nutritional status of affected cats. As such, careful and repeated assessments of nutritional state, caloric intake, and body weight should be undertaken. Nutritional support (see Chapter 16, Section B) should be instituted sooner rather than later in affected cats. A good plan of nutrition should help maintain or improve quality of life, immunologic status, and tolerance of chemotherapy. Cobalamin supplementation should be instituted in those cats with documented hypocobalaminemia.

Peripheral Nodal Lymphoma in Cats

Involvement limited to peripheral lymph nodes is unusual in cats with lymphoma, representing approximately 4% to 10% of cases.[427,428]



• **Fig. 33.14** A cat presented with mandibular lymphadenopathy that was confirmed to be Hodgkin's-like lymphoma after histologic assessment.

In contrast, approximately one-quarter of all other anatomic forms of lymphoma have some component of lymph node involvement. One-third of cats with nodal lymphoma are T-cell immunophenotype and FeLV antigenemic; however, complete categorizations have not occurred in the post-FeLV era and this may no longer be true.[427,428,435,492] Peripheral nodal lymphoma was the most common anatomic form of lymphoma reported in a compilation of cases in cats under the age of 1 year, representing one-third of cases in this age group.[433] As lymphoma progresses, bone marrow and hepatic infiltration may develop. Clinical staging and diagnostic approach for peripheral lymphadenopathy and peripheral nodal lymphoma is similar to the dog (see Section A of this chapter).

Cats with the nodal form of lymphoma present with variable clinical signs depending on the extent of disease; however, they are often depressed and lethargic. Peripheral lymphadenopathy, as the only physical finding, is an uncommon presentation.

An uncommon and distinct form of nodal lymphoma in cats referred to as "Hodgkin's-like" lymphoma has been reported.[541,542] This form typically involves solitary or regional lymph nodes of the head and neck (Fig. 33.14) and histologically resembles Hodgkin's lymphoma in humans. Affected cats generally present with enlargement of one or two mandibular or cervical nodes initially, and tumors are immunophenotypically classified as T-cell–rich, B-cell lymphoma. Histologically, lymph nodes can be effaced by either nodular or diffuse small to large lymphocytes with characteristic bizarre or multinucleated cells (Reed–Sternberg-like cells) (Fig. 33.15). No association with FeLV or FIV has been documented. Cats with Hodgkin's-like nodal lymphoma usually present without overt clinical signs.[541,542] Inguinal node, multicentric nodal, subcutaneous, and conjunctival involvement have been reported.[542–545] Interestingly, in both reports of subcutaneous Hodgkin's lymphoma in cats, spontaneous remissions were observed suggesting these may not have been be true lymphoid neoplasia.[543,544] The clinical course of Hodgkin's like lymphoma is generally more indolent than for peripheral nodal non-Hodgkin's lymphoma in the cat.

The treatment choice for peripheral nodal lymphoma in cats depends on whether the individual case represents a low-grade (e.g., indolent [rare]) versus an intermediate- or high-grade (e.g., intermediate/large cell) lymphoma; the latter are

• **Fig. 33.15** Fine-needle aspirate cytology of a lymph node in a cat with Hodgkin's-like lymphoma. The large lymphocytes have prominent nucleoli and smooth basophilic cytoplasm. Several binucleate lymphocytes are present.

best treated with CHOP- or COP-based protocols (discussed under I/HGAL earlier) and carry a less favorable prognosis, whereas the former generally respond to less aggressive chlorambucil/corticosteroid protocols and enjoy durable responses. Less is known regarding the treatment of Hodgkin's-like lymphoma involving solitary or regional nodes of the head and neck.[541,542] Clinical outcome after surgical extirpation of or RT to the affected node (or nodes if a reasonable number) is often associated with long-term disease control and MSTs of approximately 1 year, suggesting that it is a more indolent form of lymphoma. Eventual recurrence in distal nodes after surgical excision or RT is common, and the author currently offers clients the option of adjuvant chlorambucil/corticosteroids after surgery. This theoretically may have benefit; however, insufficient data currently exist to document a survival advantage with this approach.

Mediastinal Lymphoma

The mediastinal form can involve the thymus and mediastinal and sternal lymph nodes. Pleural effusion is common. In two large compilations, 63% of cats with thymic disease and 17% of cats with pleural effusion were documented as having lymphoma.[546,547] Hypercalcemia occurs frequently with mediastinal lymphoma in dogs, but is rare in cats. The majority of cats with mediastinal lymphoma in older reports were young (median age, 2–4 years), FeLV positive, and had T-cell immunophenotype tumor; however, many reports did not report immunophenotypic data.[427,428,433–435,548] The disease is confined to the mediastinum in most cases. A form of mediastinal lymphoma also occurs primarily in young, FeLV-negative Siamese cats that appears to be less biologically aggressive and more responsive to chemotherapy than FeLV-associated forms.[533] In a more recent report of 55 cats with mediastinal lymphoma from the United Kingdom, the majority were antigenically FeLV/FIV negative, young (median age, 3 years), male (3.2:1 male-to-female ratio), and nearly one-third were Siamese.[548] In this large cohort, immunophenotype was not reported.

The clinical signs associated with mediastinal lymphoma include dyspnea (80%), tachypnea, and a noncompressible cranial thorax with dull heart and lung sounds.[549] Rarely, a Horner's syndrome and precaval syndrome may be observed. Pleural effusion is observed in 50% of cases and characterized by serohemorrhagic to chylous effusion and, in most cases, neoplastic cells (lymphoblasts) are identified.[546,548,550] Diagnostic suspicion may begin with a noncompressible cranial thorax on physical examination and confirmation of a mediastinal mass/pleural effusion on thoracic radiographs. Fine-needle aspirate (FNA) cytology of the mass or cytologic evaluation of pleural fluid may be sufficient to establish a diagnosis. In most cats, the finding of a monotonous population of intermediate or large lymphoid cells will establish a diagnosis; however, definitive diagnosis of lymphoma in cats with a mediastinal mass and concurrent chylothorax can be challenging. CT appearance may be helpful, but generally does not contribute to a definitive diagnosis. If large lymphocytes are not identified in the pleural chylous effusion, then cholesterol and triglyceride concentrations can be measured.[551] In chylous effusions, the pleural fluid triglyceride concentration will be greater than in the serum; however, anorectic cats may have lower triglyceride levels in the pleural fluid. A major differential for mediastinal lymphoma is thymoma. The cytologic features of thymoma can be distinct from lymphoma in many cases, but the diagnosis can be challenging because of a preponderance of small lymphocytes in thymoma. Mast cells can also be seen in up to 50% of aspirations from thymomas. The addition of immunophenotypic and clonality assessment may be helpful in equivocal cases.

In the largest report, cats with mediastinal lymphoma treated with either COP- or CHOP-based protocols experienced an overall response rate of 95% with a MST of 373 days (980 days if CR was achieved).[548] In contrast, mediastinal lymphoma in young FeLV-positive cats is generally associated with a poor prognosis and MSTs of approximately 2 to 3 months are expected after treatment with CHOP- or COP-based protocols.[428,524]

Extranodal Lymphoma

Collectively, extranodal lymphoma represents the second most common site of lymphoma after GI lymphoma in cats.[431] The most common extranodal sites for lymphoma in cats include nasal (including nasopharyngeal and sinonasal), kidney, CNS, laryngeal and tracheal, cutaneous, subcutaneous, and ocular.

The clinical signs associated with feline extranodal lymphoma are variable and depend on anatomic location and extent of disease. Many, if confined to the primary site (stage I), will appear clinically healthy. However, cats with lymphoma, regardless of site, may present with nonspecific constitutional signs including anorexia, weight loss, lethargy, or depression. Secondary bone marrow infiltration, although uncommon, may lead to anemia. Signs related to paraneoplastic hypercalcemia (polyuria/polydipsia [PU/PD]) can occur in cats, however, much less commonly than in the dog. In one survey of hypercalcemia in cats, approximately 10% were diagnosed with lymphoma of various anatomic types.[552]

For most cats with suspected extranodal lymphoma, the diagnostic evaluation should include a baseline assessment consisting of a CBC with differential cell count, platelet count, serum chemistry profile, urinalysis, and retroviral (FeLV/FIV) screen. Serum biochemistry profiles can help establish the overall health of the animal, as well as, in some cases, suggest site-specific tumor involvement. For example, increased liver enzymes levels may indicate hepatic infiltration and increased BUN and creatinine may indicate renal lymphoma. Hypoglycemia was reported in approximately one-third of cats with lymphoma in one Australian

study.[506] In a series of cats with various anatomic forms of lymphoma, serum albumin concentrations were significantly lower and β-globulin concentrations (as measured by protein electrophoresis) were significantly higher than a healthy control population.[507]

The use of various imaging modalities in cats with lymphoma depends on the anatomic site and will be discussed in site-specific discussions to follow.

Cytopathologic or histopathologic evaluation of involved lymph node(s) or involved organ tissue, procured via FNA cytology (see Chapter 7) or surgical, endoscopic, or needle-core biopsy (see Chapter 9), is required for a definitive diagnosis. Cytology alone may not be sufficient in some cases, owing to difficulties encountered in distinguishing lymphoma from benign hyperplastic or reactive lymphoid conditions. In such cases, incisional or excisional biopsy is preferred as orientation and information regarding invasiveness and architectural abnormalities may be necessary for diagnosis. In addition, involved tissue, needle aspirate, and fluid samples can be further interrogated by various histochemical, immunohistochemical, flow cytometric analysis (e.g., size and immunophenotypic assessment), and molecular techniques (e.g., PARR to assess clonality) to further characterize the disease process and refine the diagnosis in equivocal cases. The reader is referred to Chapter 8 for a general discussion of flow cytometric analysis and molecular diagnostic techniques, as well as Section A of this chapter for specific applications to lymphoma. PARR in cats is approximately 80% sensitive for the diagnosis of lymphoma[553]; however, assessment of specificity has not been clearly established. Clonality assessment tools (e.g., primers) for both Ig and T-cell receptor variable region genes have been developed in cats.[479,480,554–557]

Assessment of tumor proliferation rates (e.g., Ki67, PCNA, AgNOR), telomerase activity, and serum protein electrophoresis can also be performed on involved tissues in cats; however, consistent prognostic value across the anatomic, histopathologic, and immunophenotypic variants of lymphoma in cats is not well characterized.

Thorough staging, including a bone marrow aspiration or biopsy, peripheral lymph node assessment (clinically normal or abnormal nodes), and thoracic and/or abdominal imaging, is indicated when (1) solitary site disease is suspected (stage I) and a decision between locoregional therapy (i.e., surgery and/or RT) versus systemic therapy (i.e., chemotherapy) is being considered; (2) it provides prognostic information that will help a caregiver make treatment decisions; and (3) complete staging of the extent of disease is required as part of a clinical trial. Bone marrow evaluation may be of particular interest if anemia, cellular atypia, and/or leukopenia are present. A WHO staging system exists for the cat that is similar to that used in the dog (see Box 33.2); however, because of the high incidence of visceral/extranodal involvement in cats, a separate staging system has been evaluated and is often used (Box 33.5).[558] Because lymphoma in cats is more varied with respect to anatomic locations, staging systems are generally less helpful for predicting response.

Our knowledge base for treating cats with extranodal lymphoma is not well established, and outcomes are less predictable than that in dogs, primarily due to the greater variation in histologic type and anatomic location observed in cats. This is further complicated by the plethora of papers that include very small numbers of cases representing multiple anatomic/immunophenotypic and histologic subtypes (e.g., small cell vs large cell variants) together when reporting survival analysis after chemotherapy.

BOX 33.5 Clinical Staging System for Feline Lymphoma[558]

Stage 1
- A single tumor (extranodal) or single anatomic area (nodal)
- Includes primary intrathoracic tumors

Stage 2
- A single tumor (extranodal) with regional lymph node involvement
- Two or more nodal areas on the same side of the diaphragm
- Two single (extranodal) tumors with or without regional lymph node involvement on the same side of the diaphragm
- A resectable primary gastrointestinal tract tumor, usually in the ileocecal area, with or without involvement of associated mesenteric nodes only

Stage 3
- Two single tumors (extranodal) on opposite sides of the diaphragm
- Two or more nodal areas above and below the diaphragm
- All extensive primary unresectable intraabdominal disease
- All paraspinal or epidural tumors, regardless of other tumor site or sites

Stage 4
- Stages 1–3 with liver and/or spleen involvement

Stage 5
- Stages 1–4 with initial involvement of CNS or bone marrow or both

This provides only general observations rather than specific outcome information (i.e., response rate and durability of response) that can vary significantly with respect to anatomic and histologic subtype. Most treatment decisions should be based on assessment of whether the individual case represents a low-grade (e.g., indolent) versus an intermediate- or high-grade (e.g., large cell) lymphoma and whether the disease is limited to the local extranodal site. Chemotherapy protocols for the cat have been previously discussed under sections in GI lymphoma; low-grade tumors are generally treated with chlorambucil/prednisolone protocols and intermediate- or high-grade tumors with CHOP- or COP-based protocols. Finally, much of the early work on chemotherapy protocol development for cats with lymphoma occurred during the FeLV era and care should be exercised when applying this information in the post-FeLV era.

Nasal Lymphoma

Nasal lymphoma is the most common extranodal lymphoma in cats.[559] It is usually a localized disease; however, 20% have local extension or distant metastasis at necropsy.[560] The majority of nonviral nasal/paranasal diseases in cats are neoplasia, and lymphoma represents one-third to one-half of these cases.[561–564] It occurs primarily in older (median age, 9–10 years; range, 3–17 years), FeLV/FIV antigenemic negative cats, and at least three-quarters are B-cell in origin, although T-cell and mixed B-cell/T-cell immunophenotypes are reported in 10% to 15% of cases.[428,559–561,565] An Italian report documented FeLV antigen (p27 or gp70) expression in nasal lymphoma tissues by immunohistochemistry (IHC); however, FeLV antigenemia was not reported in this cohort.[561] Siamese cats appear overrepresented and a 2:1 male-to-female ratio has also been observed.[561,565] Most are of intermediate- or high-grade histology; however, small-cell low-grade variants have been reported in up to 25% of some cohorts.[560,561,565] Epitheliotropism is common if the epithelium is present in the biopsy.

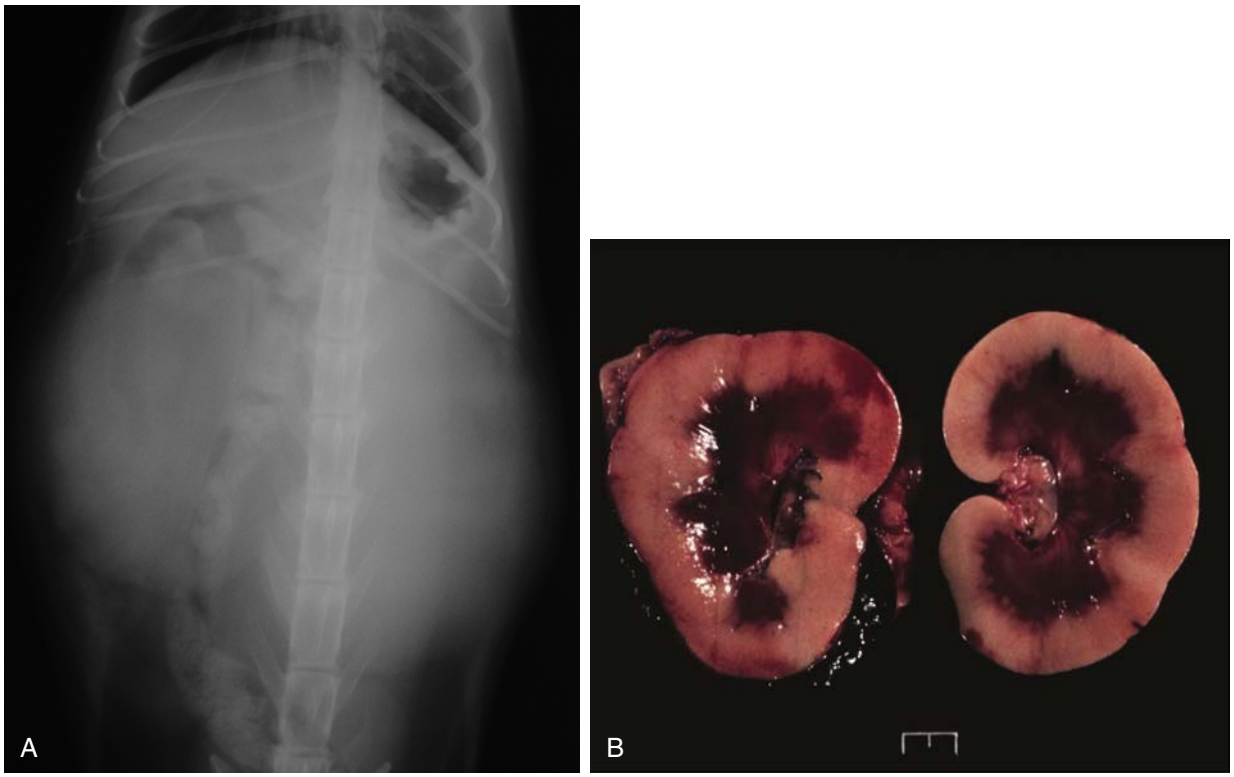
• **Fig. 33.16** Flush biopsy of nasal lymphoma. Note the large sample *(arrow)* procured by retrograde flushing of saline through on nares while occluding the contralateral nares. The sample is flushed through the pharynx and out the mouth.

Cats with nasal lymphoma present with nasal discharge (60%–85%), sneezing (20%–70%), upper respiratory noise (stridor, stertor, wheezing; 20%–60%), facial deformity (0%–20%), hyporexia (10%–60%), epiphora (10%–30%), and occasionally increased respiratory effort and coughing.[559–561,565] The nasal discharge is usually mucopurulent, although epistaxis is present in up to one-third of cases. Regional lymphadenopathy can also occur. The median duration of clinical signs before diagnosis is 2 months (range, 1–1800 days).

If nasal lymphoma is suspected, advanced imaging (CT, MRI), rhinoscopy, and biopsy are usually necessary for diagnosis (see Chapter 24, Section B). CT or MRI is useful to determine the extent of involvement and to help plan biopsy procurement and RT if that treatment option is pursued. CT characteristics include the presence of a unilateral or bilateral nasal/sinus mass or fluid, bulla effusion, and lysis of associated bony structures.[561,566–568] A biopsy can be procured either by intranasal procurement (with or without rhinoscopy) or by flushing one hemicavity with a bulb syringe and saline while occluding the contralateral cavity and collecting samples flushed out of the nasopharynx (Fig. 33.16). Thorough staging (i.e., regional node assessment, thoracic and abdominal staging, and bone marrow assessment) to ensure the disease is confined to the nasal passages is recommended if local RT without systemic chemotherapy is being considered. IHC may be necessary to differentiate nasal carcinoma from nasal lymphoma in a subset of cases; approximately 7% of samples required IHC to differentiate carcinoma from lymphoma in one large cohort of cases.[569]

In one report, 38 cats with nasal lymphoma that were not treated had MSTs of only 53 days.[561] However, in cats that are treated, durable remissions and lengthy MSTs can be expected in the majority of cases.[428,502,559,565,570–574] If disease is documented to be confined to the nasal cavity (i.e., stage I) after thorough staging, then RT is the treatment of choice. CR rates of 75% to 95% are reported with MSTs after RT of 1.5 to 3.0 years.[565,573] Cats that do not achieve a CR with RT have an MST of approximately 4.5 months. Total radiation dosage does affect STs, and a total dose greater than 32 Gy is recommended. The addition of chemotherapy to RT has not been definitively shown to enhance STs for cats with locally confined disease; combinations of RT and chemotherapy result in similar response rates and STs.[565,570,571,573,574] Chemotherapy (COP- or CHOP-based protocols) is a reasonable alternative to RT, with CR rates of approximately 75% and MSTs of approximately 2 years for cats achieving CR.[559] The author's preference is to initiate systemic chemotherapy only for cases that have confirmed disease beyond the nasal passage, cases that relapse after RT, or cases in which RT is unavailable or declined.

Renal Lymphoma



Renal lymphoma is the second most common form of extranodal lymphoma, occurring in approximately one-third of cases.[559,572] Although it can present as confined to the kidneys (<25%), it more commonly presents as concurrent with alimentary or multicentric lymphoma. The median age at presentation is 9 years, although 6% occur in cats under 1 year of age.[559,575] The majority of cases are not associated with FeLV and, although most are not associated with FIV, approximately one-half of cats reported in an Australian study were FIV positive. Little contemporary information exists on the immunohistologic classification of renal lymphoma; however, the majority are of high-grade B-cell immunophenotype.[428,435] Extension to the CNS was frequent in one report, but not similarly reported elsewhere.[575]

Cats with renal lymphoma present with signs consistent with renal insufficiency: hyporexia, weight loss, and polyuria/polydipsia.[559,575] On physical examination, marked renomegaly (bilateral, lumpy, and irregular; although a smooth variant has been observed) is palpated in the majority of cases (Fig. 33.17). Radiographic appearance is smooth-to-irregular renomegaly (Fig. 33.17A). Ultrasonographic imaging usually reveals bilateral (>80%), irregular renomegaly with hypoechoic subcapsular thickening.[156] Approximately one-third of cases will have ultrasonographic evidence of other abdominal organ involvement. The disease is usually diffuse throughout the renal cortex (Fig. 33.17B) and transabdominal FNA cytology or core biopsy is diagnostic in most cases.[576]

Treatment and outcome appears similar to other high-grade lymphomas in the cat; approximately two-thirds will experience clinical benefit with COP- or CHOP-based protocols with MSTs reported from 4 to 7 months. Owing to an inability to differentiate how much of the renal insufficiency at presentation is lymphoma-related versus due to underlying renal disease of older cats, most oncologists will start COP-based protocols and only add in DOX if renal values normalize during remission because of the potential for renal toxicity with DOX in cats.

CNS Lymphoma

CNS lymphoma can be intracranial, extracranial (i.e., spinal), or both.[157] CNS lymphoma accounted for 14% of 110 reported cases of extranodal lymphoma,[559] 15% to 31% of intracranial tumors,[158,577] and 39% of spinal cord tumors,[578] making it one of

• **Fig. 33.17** (A) Ventrodorsal projection of a cat with real lymphoma. Massive bilateral renomegaly is observed. (B) Necropsy specimen of a cat with bilateral renal lymphoma illustrating the diffuse cortical nature of the disease that is most common.

the most common malignancies encoutered in the CNS in cats.[579] Although some discordance exists in the literature, cats with CNS lymphoma are younger (median age, 4.0–10.5 years) and 17%[580] to 50% of cases are FeLV antigenemic.[577,578,581] As most reports are older, these data may no longer hold true in the current era. Approximately two-thirds of intracranial cases also have multicentric and extracranial disease; and approximately 40% of spinal lymphoma cases occur in multiple spinal cord sites with one-third also involving intracranial locations.[559,577–579,581] In a compilation of 160 cases of intracranial tumors in cats, diffuse cerebral and brainstem involvement was most common for lymphoid malignancies.[577] Spinal lesions are usually both extradural and intradural, although they can be limited to one or the other compartment.[578] Feline CNS lymphoma may be primary, but more commonly (approximately 80%) represents a multicentric process (especially with renal or bone marrow involvement).[577,581–583] A paucity of information exists on the immunophenotype of CNS lymphoma.

Cats with CNS lymphoma can present with constitutional signs (hyporexia, lethargy) and signs referring to intracranial lesions, spinal lesions, or both.[577–580,582,583] Intracranial signs may include ataxia, altered consciousness, aggression, central blindness, and vestibular abnormalities. In a study of cats with seizures, of those diagnosed with intracranial lesions, 8% were due to lymphoma.[580] Clinical signs referring to spinal cord involvement may include paresis or paraplegia (>80% with tetraparesis in 20%), ataxia, pain, constipation, and nonspecific constitutional signs (e.g., hyporexia, lethargy, weight loss).[578,582] Neurologic examination may further reveal lower or upper motor neuron bladder, tail flaccidity, and absent deep pain; approximately one-third of cats will be asymmetric and most refer to thoracolumbar involvement. The neurologic dysfunction may be insidious or progress rapidly.

In cats with suspected spinal lymphoma, survey radiographs of the spine will rarely reveal osseous lesions. CT or MRI are preferred and, in approximately 75% of the cases, an extradural or intradural mass will be detected.[577,579,580,582–584] Most lesions occur at a thoracolumbar or lumbosacral location and are often multifocal. Image-guided FNA of epidural lesions may yield a cytologic diagnosis. CT or MRI also reveals multifocal disease in the majority of cats with intracranial lymphoma.[577,580] CSF analysis may be helpful and could provide a definitive diagnosis in some cases. One of 11 cats with confirmed spinal lymphoma in one study[578] and six of 17 with confirmed intracranial lymphoma in another study[577] had evidence of neoplastic lymphocytes in the CNS, and an increased protein content was commonly found. Bone marrow and renal involvement are often present, and cytologic assessment of these or other more accessible involved organs is generally more easily attainable than from spinal sites.

Few cases report chemotherapy treatment and outcome for CNS lymphoma, and although an occasional case has experienced durable response to systemic chemotherapy, generally fewer than 50% will respond and MSTs of 1 to 4 months can be expected.[528,559,572,577,578] RT may be used and generally brisk responses would be expected owing to the inherent radiosensitivity of lymphocytes. Adjuvant chemotherapy should be considered, as many cases with CNS lymphoma have documented bone marrow or renal involvement.[582,583]

Cutaneous Lymphoma

Cutaneous lymphoma is a rarely encountered anatomic form in the cat. It is usually seen in older cats (median age, 10.0–13.5 years) with no sex or breed predominance, and is not associated with FeLV/FIV.[585,586] Cutaneous lymphoma may be solitary or

VetBooks.ir

diffuse with a varied presentation.[585,587] In decreasing order of likelihood, lesions may include erythematous patches, alopecia, scaling, dermal nodules, or ulcerative plaques. Nasal hypopigmentation, miliary dermatitis, and mucosal lesions are rarely observed. Peripheral lymphadenopathy may also be present. In most cats, the duration of signs will be prolonged, lasting several months.

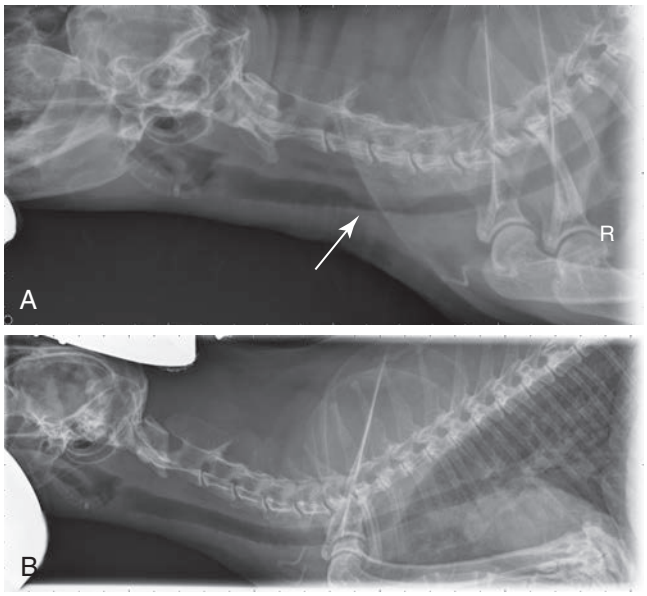
Cutaneous lymphoma often affects the head and face and is generally an indolent disease. Two forms have been distinguished histologically and immunohistochemically. Most reports in the cat are epitheliotropic and consist of T cells, although, unlike in dogs, adnexal structures are often spared. A report of nonepitheliotropic cutaneous lymphoma in cats also found 5 of 6 cases to be of T-cell derivation.[588] "Cutaneous lymphocytosis," an uncommon disease histologically resembling well-differentiated lymphoma, was characterized in 23 cats.[502] Solitary lesions were most common. All were composed primarily of T cells, with two-thirds having some B-cell aggregates. Cutaneous lymphocytosis was characterized as a slowly progressive disorder; however, a few cases went on to develop internal organ infiltration. Two case reports exist of cats with cutaneous T-cell lymphoma and circulating atypical lymphocytes.[589,590] The circulating cells were lymphocytes with large, hyperchromatic, grooved nuclei, and one case was immunophenotyped as a CD3/CD8 population. In humans, cutaneous T-cell lymphoma with circulating malignant cells is termed *Sézary syndrome*.

For cats suspected of cutaneous lymphoma, dermal punch biopsies (4–8 mm) should be taken from the most representative and infiltrative sites, while avoiding overtly infected skin lesions. Immunophenotypic and PARR analysis are often helpful in definitive diagnosis. Complete staging to rule out systemic disease is also recommended for cats with cutaneous lymphoma, as local therapy may be applied in cases of solitary disease.

Very little has been published regarding the treatment of cutaneous lymphoma in cats[585]; however, a report of a CR to lomustine exists.[591] Cats with a solitary disease could theoretically be treated with surgical excision or RT, although clinical staging is necessary to rule out possible further systemic involvement. For multiple sites, combination chemotherapy should be considered.

Subcutaneous Lymphoma

Recently several retrospective compilations of a subcutaneous form of lymphoma (SC-L) have been reported.[431,592,593] Although these have been referred to as "cutaneous" lymphoma in some reports, their clinical and histologic characteristics imply a SC localization. Most affected cats are older DSH cats, and males may be overrepresented. Overall, this appears to be an uncommon presentation, representing 0.4% of all cutaneous/SC masses submitted in a report of 97 cases.[431] Retroviral (FeLV/FIV) antigenemia is rare, although in one report of 17 cats, FeLV gp70 and/or p27 protein was expressed in the majority of tumor tissues.[593]



Cats with SC-L are presented with firm, painless SC nodules with a predilection for lateral thoracic, lateral abdominal wall, intrascapular, and tarsal locations (Fig. 33.18). Histologically, they are characterized by deep SC invasion with a monomorphic round cell population, extension into underlying tissues and overlying superficial tissue (but not epitheliotropic), and with extensive central necrosis and peripheral inflammation ("collaring"). Angiocentricity and angioinvasion are often observed. Mitotic index ranges from 3 to more than 25/10 HPF. The round cell population has been characterized as a large high-grade B cell in approximately two-thirds of cases and high-grade T cell in one-third, with an occasional NK immunophenotype reported.[431,592,593]

• **Fig. 33.18** Subcutaneous lymphoma of the tarsus in a cat. (Image courtesy Dr. Samuel Hocker.)

Most animals are otherwise healthy (substage *a*) and the disease is generally confined to the local site at presentation (stage I), although in one report the tarsal location was associated with regional popliteal lymph node involvement in nearly 20% of cases.[592] In two cases, concurrent feline injection-site sarcoma (FISS) was found at other sites. SC-L has several similarities to FISS, including clinical presentation, site of occurrence, poor demarcation, central necrosis and peripheral inflammation, although macrophages with phagocytized vaccine-like product has not been observed within the inflammatory component.[431] These similarities suggest the possibility that injection-site inflammation may play a role in the disease etiology; however, this has not been confirmed. Regardless, SC-L should remain an important differential in consideration of FISS.

The treatment of SC-L in the literature is varied and, as such, a standard of care is not currently established.[431,592,593] Although the disease is initially confined to the local primary site in most cases, recurrence after local therapy, whether surgical excision, RT, or both, occurs in nearly half of cases and eventual distant metastasis occurs in one-third of cases. Approximately 75% of affected cats go on to die of their lymphoma; therefore SC-L should be considered to have an aggressive biologic behavior. In the largest report, median progression-free and overall STs after primary site surgical removal were 101 days and 148 days respectively.[431] In the case of tarsal SC-L, even with hindlimb amputation in three cats, regional nodal or distant involvement was documented in all cases (at 56, 350, and 525 days), albeit durable disease-free intervals were observed in two cats. In a limited number of cats treated with RT, responses were brisk, but some progressed beyond the radiation field. The efficacy of chemotherapy is currently not well known; in a small number of cases receiving a variety of

• **Fig. 33.19** (A) Lateral radiographic projection of a cat with tracheal lymphoma before treatment. (B) The same cat 6 weeks after initiation of CHOP-based chemotherapy protocol.

chemotherapy protocols, although many responded or stabilized, durability was poor and MSTs were approximately 6 months.[592] Seven cases of tarsal SC-L received chemotherapy and RT with an MST of 216 days. Because the disease has a high recurrence and metastatic behavior, it is likely that a multimodality approach involving local therapy (surgery and/or RT) and systemic chemotherapy would intuitively provide the best outcomes.

Laryngeal/Pharyngeal/Tracheal Lymphoma

Laryngeal lymphoma comprised 10% of 110 cases of extranodal forms in one report and represented 11% of all laryngeal disease in the species.[559,572,594] It occurs in older cats (median age, 9 years), is not associated with FeLV, and may be a solitary lesion or occur in the presence of other multicentric sites. No information on immunophenotype is currently available. Signs associated with this location in affected cats include dyspnea, dysphonia, stridor, gagging or retching, and rarely, coughing.[559,594] Although it is generally localized to the primary site (stage I), approximately 25% had regional nodal involvement in one report. The vast majority of cats with laryngeal or tracheal lymphoma respond to either RT (if localized) or systemic chemotherapy (90% CR to COP- or CHOP-based protocols) (Fig. 33.19).[528,559] Whereas the author's experience is that most have durable responses and STs typically approach or exceed 1 year, published reported MSTs range from 5.5 to 9.0 months after achievement of a CR.[561]

Ocular Lymphoma

In a compilation of 75 cases of intraocular tumors of cats, 15 (20%) were lymphoma (seven B-cell, four T-cell and four not evaluated).[506] It was presumed, but not proved, that the majority of these were part of a systemic multicentric process. Indeed, lymphoma was the most common metastatic cancer in the feline eye. In 26 cats surveyed with systemic lymphoma, nearly half had some ocular changes with uveitis being most common, followed by exophthalmos, corneal ulceration, and chemosis.[595] In a histologic characterization of uveitis in cats, lymphoma was diagnosed in approximately one-third of cases; however, whether these were part of a systemic process or limited to the eye was unclear.[596] Nearly half of these cases were documented before 1988 and because nearly half were FeLV antigenemic cats, these data likely have little bearing on modern incidence of the disease.

Presumed solitary ocular lymphoma (PSOL) is rare in cats and was identified in 5 of 110 cases of extranodal lymphoma in one report.[559] Cats with ocular lymphoma are presented with uveitis or iridial masses, as well as signs related to systemic involvement of disease.

Only sporadic reports appear in the literature with the majority (approximately 75%) being B-cell immunophenotyped. One case of LGL PSOL is documented.[559] Intraocular, retinal, and conjunctival locations are reported.[597–600] Outcomes are poorly defined in reports; those cases that underwent enucleation often experienced long-term outcomes with STs of 6 months to 4 years reported.

General Summary of Prognosis for Cats with Lymphoma

As previously discussed, the prediction of outcome in cats with lymphoma is not generalizable because of the wide spectrum of histologic and anatomic subtypes encountered. Much has been mentioned in the previous treatment sections, and Tables 33.9 and 33.10 summarize prognostic parameters for lymphoma in cats.

Feline Leukemias, Myeloproliferative Disorders, and Myelodysplasia

For a complete discussion of leukemias and MPDs, including a general discussion of hematopoiesis, etiologies, lineage classification and descriptions, see Section C of this chapter. The classification of leukemias in cats is difficult because of the similarity of clinical and pathologic features and the transition, overlap, or mixture of cell types involved.[601–605] Most cases are from the FeLV era and generally only single case reports exist from the more contemporary post-FeLV era, which further confuses our understanding of their biology and outcome. For this reason, only a simplistic discussion, primarily relating to the lymphoid leukemias will be presented here and the interested reader is again referred to Section C of this chapter for a general discussion of nonlymphoid leukemia.

For cats with suspected leukemia, peripheral blood assessment (e.g., CBC with differential, flow cytometric analysis for size and immunophenotype, and PARR [for lymphoid leukemias]), and bone marrow aspiration or biopsy may contribute to a diagnosis. Cats with acute leukemia are likely to have malignant cellular infiltrates in organs other than bone marrow.[603] A bone marrow aspirate with greater than 30% abnormal blast cells is sufficient to make a diagnosis of an acute leukemia. In cats with suspected CLL, infiltration of the bone marrow with more than 15% mature lymphocytes helps support the diagnosis.[606] All cats with leukemia should be tested for FeLV/FIV. Determining the lineage of some leukemias can be challenging; most can be distinguished by histologic appearance, histochemical stains, or immunohistochemical or flow cytometric analysis of the leukemic cells for cellular antigens that identify their lineage (see Chapter 8 and Section C of this chapter).[601,605,607] In addition, examination of blast cells by electron microscopy may

VetBooks.ir

reveal characteristic ultrastructural features. The French–American–British (FAB) classification system is considered useful in cats with myelodysplastic syndromes and almost all reported cases have been FeLV antigenemic.[607,608]

Lymphoid Leukemia

ALL was the most commonly encountered type of leukemia in cats in the FeLV era; however, it is much less common today. ALL is characterized by poorly differentiated lymphoblasts and prolymphocytes in blood and bone marrow. Approximately 60% to 80% of cats with ALL are FeLV positive, and most malignant cells have T-cell immunophenotypes[609]; however, little information is available in the contemporary literature.

CLL is rarely reported in cats and is characterized by well-differentiated, small, mature lymphocytes in peripheral blood and bone marrow.[606,607,610,611] In the largest compilation, most cats were older, half were presented incidentally, and half with nonspecific constitutional signs (weight loss, hyporexia).[606] No specific serum biochemical abnormalities were noted; however, 50% were anemic, 10% thrombocytopenic, and all had peripheral lymphocyte counts of greater than 9000/µL (although this was the cutoff required for diagnosis). All cats tested (n = 13) were negative for FeLV/FIV. Median peripheral lymphocyte counts were 34,200/µL (range, 9 to >300,000/µL). Whereas most are of the T-cell lineage, B-cell CLL has also been reported in cats.[606,607,610,611] In one report of 18 cases of CLL in cats, most were found to be T-helper cells ($CD3^+/CD4^+/CD8^-$).[611]

Treatment of Leukemias

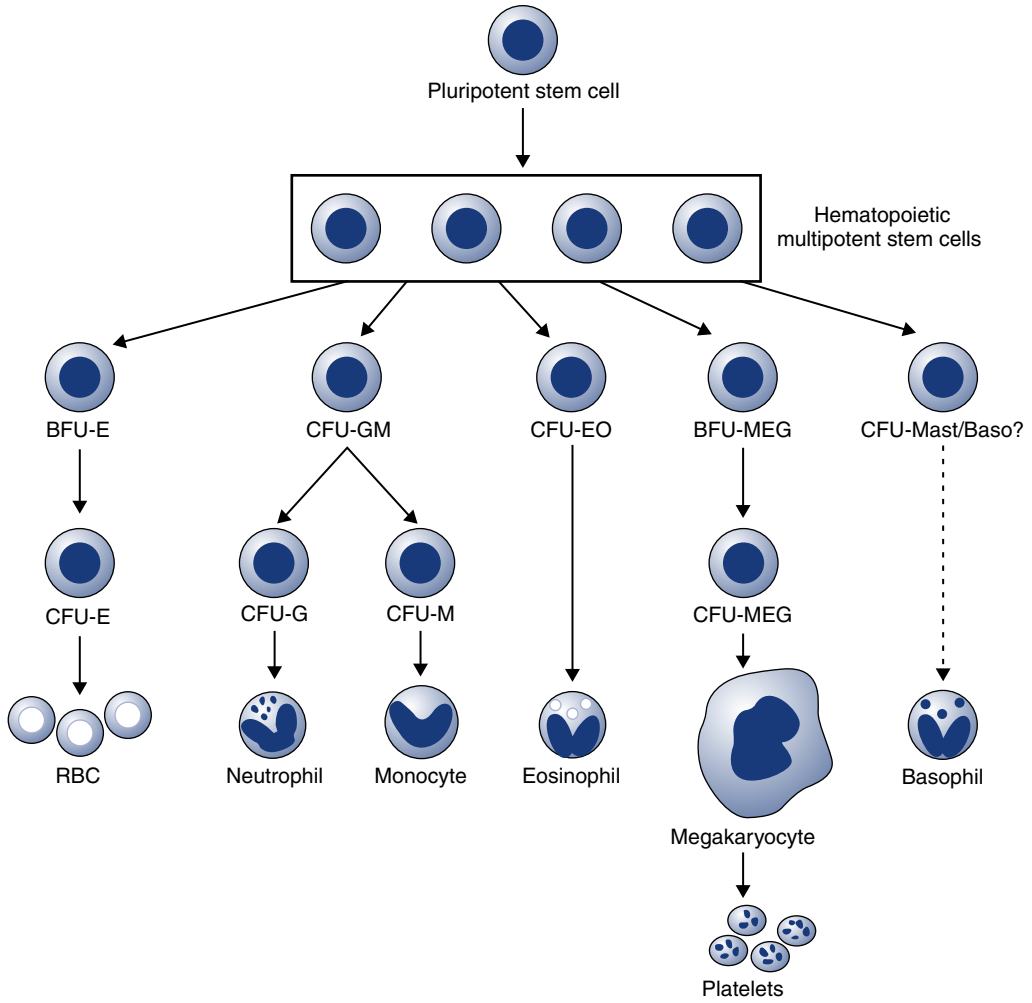
The use of chemotherapy to treat ALL has been disappointing. Using COP-based protocols, a 27% CR rate has been reported.[612]

CLL can be treated with chlorambucil (0.2 mg/kg PO or 2 mg/cat qod; alternatively, 20 mg/m^2 q2 weeks) and prednisolone (1 mg/kg PO daily). In 16 cats treated with chlorambucil and prednisolone, approximately 90% responded with a median remission duration of 6 months; however, half achieved CR with a median remission duration of 14 months.[606] Several of these cats were rescued with various protocols after recurrence, many with prolonged second remissions. As in humans and dogs, if significant clinical signs or profound cytopenias are not present, treatment can be withheld; one cat with CLL remained stable without chemotherapy for over a year.[610]

The prognoses for feline ALLs are generally very poor, although some exceptions exist in case report form in the historic literature.

SECTION C: CANINE ACUTE MYELOID LEUKEMIA, MYELOPROLIFERATIVE NEOPLASMS, AND MYELODYSPLASIA

DAVID M. VAIL AND KAREN M. YOUNG



Myeloproliferative disorders (MPDs) are a group of neoplastic diseases of bone marrow in which there are clonal disorders of hematopoietic stem cells.[613] Aberrant proliferation of cells with defective maturation and function leads to reduction of normal hematopoiesis and invasion of other tissues. These disorders have been classified based on biologic behavior, degree of cellular differentiation, and lineage of the neoplastic cells (granulocytic, monocytic, erythroid, megakaryocytic, or mixed). Newer classification systems in humans have incorporated genetics and molecular genetic analysis; these are currently areas of active investigation in the study of animal MPDs.[614] In 1991, the Animal Leukemia Study Group made recommendations for classifying nonlymphoid leukemias in dogs and cats.[615] More recently, the Oncology Committee of the American College of Veterinary Pathologists (ACVP) has been reexamining criteria for a classification system and spearheading large multiinstitutional studies to validate the criteria. Long-term objectives of these studies are to define molecular lesions, establish prognostic markers, and identify effective therapeutic approaches.[616] See Box 33.6.

• BOX 33.6 Key Clinical Summary Points: Myeloid Leukemia, Myeloproliferative Neoplasms, and Myelodysplasia

- Myeloid leukemias and myeloproliferative disorders are rare neoplastic diseases of bone marrow in which there are clonal disorders of hematopoietic stem cells (Table 33.13).
- Clonal disorders of bone marrow include *myeloaplasia* (usually referred to as *aplastic anemia*), *myelodysplasia*, and *myeloproliferation.*
- The terms *acute* and *chronic* refer to the degree of cellular differentiation of the leukemic cells, but these terms also correlate with the biologic behavior of the neoplasm.
- The *acute myeloid leukemias* (AMLs) are aggressive leukemias that progress rapidly, are poorly responsive to treatment, and are associated with short survival times (typically <2 months).
- In AML, determination of the leukemic lineage (i.e., neutrophilic, monocytic, erythroid, or megakaryocytic origin) requires advanced diagnostic testing (cytochemical staining, flow cytometric analysis, clonality testing, or genetic analysis).
- *Myeloproliferative neoplasms* (MPNs), previously termed chronic myeloproliferative disorders, are characterized by excessive production of differentiated bone marrow cells, resulting in the accumulation of erythrocytes (*polycythemia vera*), granulocytes and/or monocytes (*chronic myelogenous leukemia* and its variants), or platelets (*essential thrombocythemia*).
- Because of the degree of differentiation of cells in MPNs, these disorders must be distinguished from nonneoplastic causes of increases in these cell types.
- Compared with AMLs, MPNs and myelodysplasias have a more chronic course and may have better responses to therapy, although most will progress and ultimately result in mortality.

Incidence and Risk Factors

Myeloid neoplasms are uncommon or rare in the dog and occur 10 times less frequently than lymphoproliferative disorders.[617] Accurate information about incidence and other epidemiologic information has been generally lacking owing to a lack of a consistent use of a uniform classification system; however, several larger compilations have been published recently.[618–622] There is no consistent breed predilection; most are large-breed dogs with a median age of 7 to 8 years, although acute myeloid leukemia (AML) can occur in dogs as young as 7 months of age. AML occurred more frequently in males than females (2:1 ratio) in two large compilations.[618,621] In dogs, the etiology of spontaneously occurring leukemia is unknown. It is likely that genetic and environmental factors (including exposure to radiation, drugs, or toxic chemicals) play a role. In humans, acquired chromosomal derangements lead to clonal overgrowth with arrested development.[623] Chromosomal

• **Fig. 33.20** A simplified scheme of hematopoiesis. *BFU,* Blast-forming units; *CFU,* colony-forming units; *E,* erythroid; *EO,* eosinophil; *GM,* granulocytic-monocytic; *MEG,* megakaryocyte.

abnormalities have been reported in dogs with AML, chronic myelogenous leukemia (CML), and lymphoid leukemia.[624–627] However, because karyotyping is difficult to perform in dogs because of the large number and morphologic similarity of their chromosomes and their resistance to banding, defining genetic factors in canine myeloid neoplasms has awaited application of molecular technologies and use of the canine genome mapping.[614,626,628–630] Certain forms of leukemia in dogs have been produced experimentally after irradiation.[631–633] In contrast to MPDs in cats, no causative viral agent has been demonstrated in dogs, although retrovirus-like budding particles were observed in the neoplastic cells of a dog with granulocytic leukemia.[634]

Pathology and Natural Behavior

A review of normal hematopoiesis will aid in understanding the various manifestations of MPDs. Hematopoiesis is the process of proliferation, differentiation, and maturation of stem cells into terminally differentiated blood cells. A simplified scheme is presented in Fig. 33.20. Pluripotent stem cells differentiate into either lymphopoietic or hematopoietic multipotent stem cells.[635] Under the influence of specific regulatory and microenvironmental factors, multipotent stem cells in bone marrow differentiate into progenitor cells committed to a specific hematopoietic cell line, for example, erythroid, granulocytic-monocytic, or megakaryocytic. Maturation results in the production of terminally differentiated blood cells (erythrocytes, granulocytes, monocytes, and platelets) that are delivered to the circulation. In some cases, as in the maturation of reticulocytes to erythrocytes, final development may occur in the spleen.

The proliferation and differentiation of hematopoietic cells are controlled by a group of regulatory growth factors.[635,636] Of these, erythropoietin is the best characterized; it regulates erythroid proliferation and differentiation and is produced in the kidney, where changes in oxygen tension are detected. The myeloid compartment depends on a group of factors, collectively referred to as *colony-stimulating factors* (CSFs). These factors act at the level of the committed progenitor cells, but also influence the functional capabilities of mature cells. Some of these factors have a broad spectrum of activity; others are more restricted in their target cells and actions. CSFs are produced in vitro by a multitude of cell types, including monocytes, macrophages, lymphocytes, and endothelial cells, and these cells likely play a role in the production and regulation of these factors in vivo. The gene for thrombopoietin also has been cloned, and it appears that this hormone alone can induce differentiation of megakaryocytes and platelet production.[637] Recombinant forms of many of these growth factors are increasingly available.

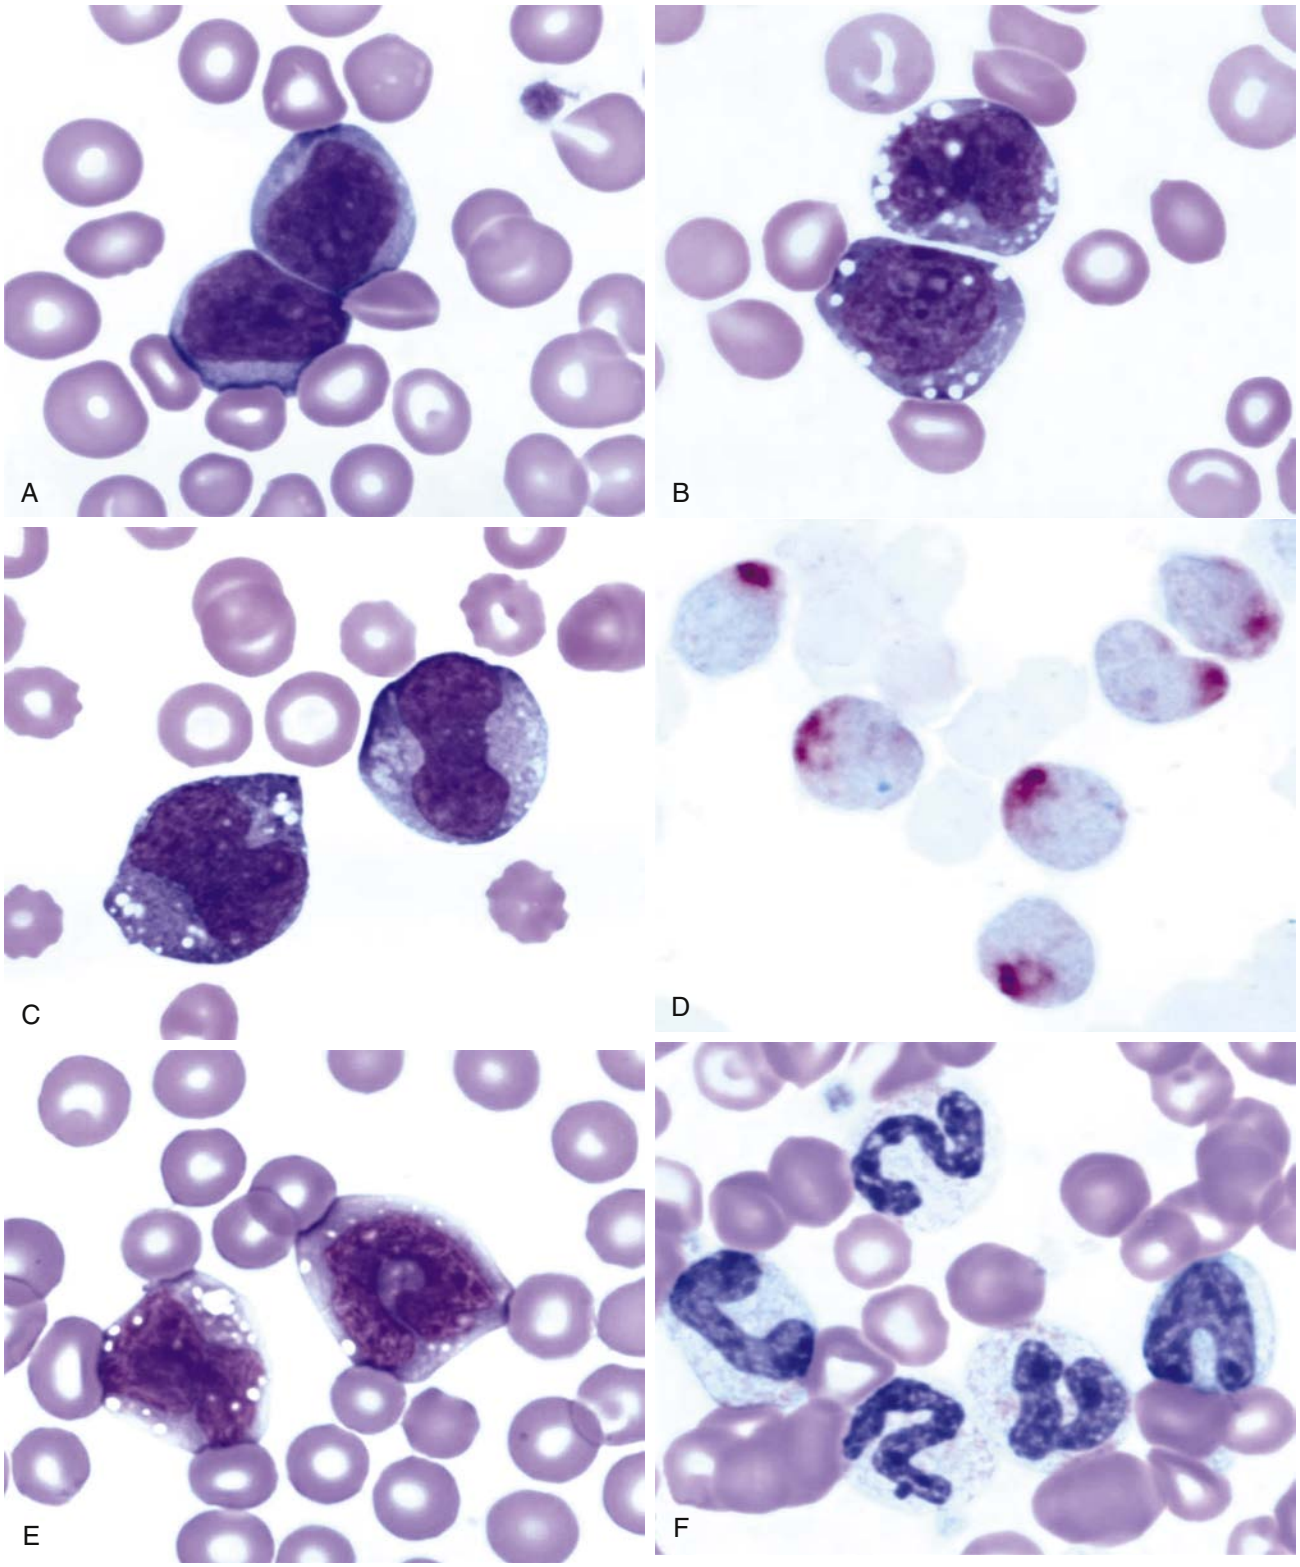
VetBooks.ir

Clonal disorders of bone marrow include myeloaplasia (usually referred to as *aplastic anemia*), myelodysplasia, and myeloproliferation. A preleukemic syndrome, characterized by peripheral pancytopenia and bone marrow hyperplasia with maturation arrest, is more correctly termed *myelodysplasia* because the syndrome does not always progress to overt leukemia. This syndrome has been described in cats, usually in association with FeLV infection, but is rarely recognized in dogs.[638–641] These clonal disorders may be manifested by abnormalities in any or all lineages because hematopoietic cells share a common stem cell. In addition, transformation from one form to another may occur.[642]

Myeloid neoplasms are classified in several ways. The terms *acute* and *chronic* refer to the degree of cellular differentiation of the leukemic cells, but these terms also correlate with the biologic behavior of the neoplasm.[643] Disorders resulting from uncontrolled proliferation or decreased apoptosis of cells incapable of maturation lead to the accumulation of poorly differentiated or "blast" cells. These disorders are included under the umbrella term of AML. Disorders resulting from unregulated proliferation of cells that exhibit progressive, albeit incomplete and defective, maturation lead to the accumulation of differentiated cells and thus are called chronic disorders. These disorders are termed *myeloproliferative neoplasms* (MPN) and include polycythemia vera, CML and its variants, essential thrombocythemia, and possibly primary myelofibrosis. Myeloid neoplasms are further classified by the lineage of the dominant cell type(s), defined by Romanowsky stains, special cytochemical stains, ultrastructural features, flow cytometric analysis, molecular genetic analysis, and immunologic cell markers, and they have been classified into subtypes.

AML has a more sudden onset and is more clinically aggressive. In both acute and chronic disorders, however, abnormalities in proliferation, maturation, and functional characteristics can occur in any hematopoietic cell line.[613] In addition, normal hematopoiesis is adversely affected. Animals with acute leukemias usually have decreased numbers of circulating normal cells. The pathogenesis of cytopenias is complex and may result in part from production of inhibitory factors. Eventually, neoplastic cells displace normal hematopoietic cells, termed *myelophthisis.* Anemia and thrombocytopenia are particularly common. Neutropenia and thrombocytopenia result in infection and hemorrhage, respectively, which may be more deleterious to the animal than the primary disease process.

Acute Myeloid Leukemia



AML is rare and is characterized by aberrant proliferation and/or decreased apoptosis of a clone of cells without maturation. This results in accumulation of immature blast cells in bone marrow and peripheral blood (Fig. 33.21). The white blood cell (WBC) count is variable and ranges from leukopenia to counts greater than 250,000/μL. Spleen, liver, and lymph nodes are frequently involved, and other tissues, including tonsils, kidney, heart, and the CNS, may be infiltrated as well.[621] The median age is approximately 7 to 8 years; however, young dogs may be affected.[618–621,644] The clinical course of these disorders tends to be rapid. Production of normal peripheral blood cells is usually diminished or absent, and anemia, neutropenia, and thrombocytopenia are common with infection and hemorrhage occurring as frequent sequelae. Occasionally, neoplastic blasts are present in bone marrow, but not in peripheral blood. This is termed *aleukemic* leukemia, whereas *subleukemic* suggests a normal or decreased WBC count with some neoplastic cells in circulation.

In 1985, the Animal Leukemia Study Group was formed under the auspices of the American Society for Veterinary Clinical Pathology to develop specific morphologic and cytochemical criteria for classifying acute nonlymphocytic leukemias. Recognition of specific subtypes of leukemia is required to compile accurate and useful information about prognosis and response to treatment, as well as to compare studies from different sites. In 1991 this group proposed a classification system following adaptation of the FAB system and criteria established by the NCI Workshop.[615] Group members examined blood and bone marrow from 49 dogs and cats with myeloid neoplasms. Romanowsky-stained specimens were examined first to identify blast cells and their percentages. Lineage specificity was then determined using cytochemical markers. The percentage of blasts and the information about lineage specificity were used in combination to classify disorders as acute undifferentiated leukemia (AUL), AML (subtypes M1–M5 and M7), and erythroleukemia with or without erythroid predominance (M6 and M6Er). A description of these subtypes is presented in Table 33.13.

Because the modified FAB system has been adopted only recently, the names given to these disorders in the literature vary considerably. In addition, in the absence of cytochemical staining, immunophenotyping, or electron microscopic evaluation, the specific subtype of leukemia has often been uncertain, making retrospective analysis of epidemiologic information, prognosis, and response to therapy confusing at best. Although defining specific subtypes may seem to be an academic exercise owing to the uniformly poor prognosis of acute leukemias, this information is critical to improving their management. Because of the low incidence of AML, national and international cooperative efforts will be required to accumulate information on the pathogenesis and response to different treatment modalities of specific subtypes. Utilization of a uniform classification system is an essential first step. Different forms of AML are demonstrated in Fig. 33.21. With the exception of acute promyelocytic leukemia or M3, all AML subtypes have been described in dogs. Combining three recent compilations of 85 dogs with AML, the relative frequency of subtypes in decreasing order were: 42% monocytic leukemia (M5a, M5b), 33% myelomonocytic leukemia (M4), 13% myeloblastic leukemia without differentiation (M1), 5% megakaryoblastic leukemia (M7), and one each of myeloblastic leukemia with some differentiation (M2) and erythroleukemia (M6).[619–621] AML of mixed lineages comprised 5% of cases. Many single case or small case series reports also exist describing various subtypes in dogs.[617,632–637,639–671] Monocytic leukemias have likely included those with and without monocytic differentiation (M5a and M5b),[672,673] but in some cases the diagnosis may have been chronic myelomonocytic or chronic monocytic leukemia. There are few reports in dogs of spontaneously occurring erythroleukemia (M6) in which the leukemic cells include myeloblasts, monoblasts, and erythroid elements.[674–676] AULs have uncertain lineages because they are negative for all cytochemical markers. These leukemias should be distinguished from lymphoid leukemias by flow cytometric analysis of the leukemic cells for cellular antigens that identify their lineage.[620,677] In addition, examination of blast cells by electron microscopy may reveal characteristic ultrastructural features.

Canine karyotyping is difficult, but with advancements in molecular cytogenetic analysis, chromosome painting, and genomic hybridization, AML in dogs can now be analyzed at the base-pair level,[626,628,629] and missense mutations in *flt3,* c-*kit,* and *ras* sequences have been identified in dogs with AML, similar to

TABLE 33.13 Subtypes of Leukemias and Dysplasias Adapting the FAB System

Subtype	Description
Acute Leukemias	
AUL	Acute undifferentiated leukemia (formerly called reticuloendotheliosis)
M1	Myeloblastic leukemia, without differentiation
M2	Myeloblastic leukemia, with some neutrophilic differentiation
M3	Promyelocytic leukemia (not recognized in animals)
M4	Myelomonocytic leukemia
M5a	Monocytic leukemia, without differentiation
M5b	Monocytic leukemia, with some monocytic differentiation
M6	Erythroleukemia
M6Er	Variant of M6 with erythroblasts comprising erythroid component
M7	Megakaryoblastic leukemia
Chronic Myeloid Leukemias	
CML	Chronic myelogenous leukemia
CMML	Chronic myelomonocytic leukemia
CMoL	Chronic monocytic leukemia
Hematopoietic Dysplasia	
MDS	Myelodysplastic syndrome
MDS-Er	Myelodysplastic syndrome with erythroid predominance

what has been found for human AML.[678] BCR–ABL translocation is also reported in dogs with acute myeloblastic leukemia.[679] Recurrent DNA copy number abnormalities (CNA) have been interrogated in 24 dogs with AML and there is potential for CNA clustering to be used in diagnostic models.[626] In addition to serving as diagnostic and prognostic markers, cytogenetic lesions may be therapeutic targets. As cytogenetic abnormalities continue to be identified, this information will need to be incorporated into classification schemes.

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (MPNs), previously termed *chronic myeloproliferative disorders,* are characterized by excessive production of differentiated bone marrow cells, resulting in the accumulation of erythrocytes (polycythemia vera), granulocytes and/or monocytes (CML and its variants), or platelets (essential thrombocythemia). Primary myelofibrosis, a clonal disorder of bone marrow stromal cells characterized by proliferation of megakaryocytes and granulocytic precursors with accumulation of collagen in bone marrow, has been recognized only rarely in animals. Phenotypic-driver mutations in the *JAK2*, *CALR*, and *MPL* genes have been identified in people with polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis.[680] Only *JAK2* mutations have been investigated in dogs with PV, and an identical mutation to that in people was found in 1 of 5 cases in dogs.[681] Myelofibrosis is considered a response to injury and may occur secondary to other neoplasms, systemic inflammation, drug exposure, or FeLV infection in cats.

Polycythemia Vera

Polycythemia vera (PV) is a clonal disorder of stem cells, although whether the defect is in the pluripotent stem cell or the hematopoietic multipotent stem cell is still not clear. The disease is rare and must be distinguished from more common causes of polycythemia. In PV, there is neoplastic proliferation of the erythroid series with terminal differentiation to RBCs. The disease has been reported in dogs that tend to be middle-aged with no breed or sex predilection[682–692] and is characterized by an increased RBC mass evidenced by an increased packed cell volume (PCV), RBC count, and hemoglobin concentration. The PCV is typically in the range of 65% to 85%. The bone marrow is hyperplastic, although the myeloid-to-erythroid (M:E) ratio tends to be normal. In contrast to the disease in humans, other cell lines do not appear to be involved and transformation to other MPNs has not been reported. The disease in dogs may be more appropriately termed *primary erythrocytosis*. In humans, progenitor cells have an increased sensitivity to insulin-like growth factor 1, which stimulates hematopoiesis.[691] It is not known whether this hypersensitivity is the primary defect or is secondary to another gene mutation. In any case, the result is overproduction of red blood cells (RBCs). Acquired *JAK2* gene mutations are identified in 90% of humans with PV, and an identical mutation in the *JAK2* gene of 1 of 5 dogs with PV was reported.[681]

Chronic Myelogenous Leukemia

In dogs, CML is more similar to chronic neutrophilic leukemia, a rare form of MPN in humans, than to CML in humans because it is a neoplastic proliferation of the neutrophil series, although concurrent eosinophilic and basophilic differentiation can occur. CML can occur in dogs of any age.[693–698] Neutrophils and neutrophilic precursors accumulate in bone marrow and peripheral blood as well as in other organs. The peripheral WBC count is usually, but not always, greater than 100,000/μL. Both immature and mature neutrophils are present (see Fig. 33.21F). Mature forms are usually more numerous, but sometimes an "uneven" left shift is present. Signs of dysplasia may be evident, including hypersegmentation, ringed nuclei, and giant forms. Eosinophils and basophils may also be increased. The bone marrow is characterized by granulocytic hyperplasia and morphologic abnormalities may not be present. Erythroid and megakaryocytic lines may be affected, resulting in anemia, thrombocytopenia, or less commonly, thrombocytosis. This disorder must be distinguished from severe or extreme neutrophilic leukocytosis ("leukemoid reactions") caused by inflammation or immune-mediated diseases. Extreme neutrophilia can also occur as a paraneoplastic syndrome. In humans with CML, characteristic cytogenetic abnormalities are present

VetBooks.ir

in all bone marrow cells, signifying a lesion at the level of an early multipotent stem cell. Typically, these individuals have a chromosomal translocation, resulting in the Philadelphia chromosome or BCR–ABL translocation between chromosomes 9 and 22.[699] The analogous chromosomes in dogs are chromosomes 9 and 26, and BCR–ABL translocation, termed the "Raleigh chromosome," has been reported in several cases of CML in dogs.[614,627,700,701] Variants of CML are chronic myelomonocytic leukemia and chronic monocytic leukemia (CMoL).[702–704] CMoL has also been associated with BCR–ABL translocation in the dog.[702] These diagnoses are made based on the percentage of monocytes in the leukemic cell population. An infrequent myeloproliferative neoplasm, atypical chronic myeloid leukemia, has been reported in a dog and had features of both myelodysplastic syndrome and chronic leukemia.[700] In this dog, BCR–ABL translocation was present in fewer than 10% of cells, considered a negative finding.

In addition to accumulating in bone marrow and peripheral blood, leukemic cells also are found in the red pulp of the spleen, the periportal and sinusoidal areas of the liver, and sometimes lymph nodes. Other organs, such as the kidney, heart, and lung, are less commonly affected. In addition, extramedullary hematopoiesis may be present in the liver and spleen. Death is usually due to complications of infection or hemorrhage secondary to neutrophil dysfunction and thrombocytopenia, respectively. In some cases, CML may terminate in "blast crisis," in which there is a transformation from a predominance of well-differentiated granulocytes to excessive numbers of poorly differentiated blast cells in peripheral blood and bone marrow. This phenomenon is well documented in the dog.[693,696,698]

Basophilic and Eosinophilic Leukemia

Basophilic leukemia, although rare, has been reported in dogs and is characterized by an increased WBC count with a high proportion of basophils in peripheral blood and bone marrow.[705–707] Hepatosplenomegaly, lymphadenopathy, and thrombocytosis may be present. All the dogs have been anemic. Basophilic leukemia should be distinguished from mast cell leukemia (mastocytosis). Whether dogs develop eosinophilic leukemia remains in question. Reported cases have had high blood eosinophil counts and eosinophilic infiltrates in organs.[708,709] One dog responded well to treatment with corticosteroids. The distinction between neoplastic proliferation of eosinophils and idiopathic hypereosinophilic syndrome remains elusive. Nonmyeloproliferative disorders associated with eosinophilia such as parasitism, skin diseases, or diseases of the respiratory and GI tracts should be considered first in an animal with eosinophilia. One distinguishing feature should be clonality, with reactive eosinophilia comprising polyclonal cells and the neoplastic condition arising from a single clone. As clonality assays become more available, this discrepancy may be resolved.

Essential Thrombocythemia

In humans, ET, or primary thrombocytosis, is characterized by platelet counts that are persistently greater than 600,000/μL. There are no blast cells in circulation and marked megakaryocytic hyperplasia of the bone marrow without myelofibrosis is present. Thrombosis and bleeding are the most common sequelae, and most patients have splenomegaly. Other MPDs, especially PV, should be ruled out, and importantly, there should be no primary disorders associated with reactive thrombocytosis,[710] including inflammation, hemolytic anemia, iron deficiency anemia, malignancies, recovery from severe hemorrhage, rebound from immune-mediated thrombocytopenia, and splenectomy. In addition, certain drugs such as vincristine can induce thrombocytosis. ET has been recognized in dogs.[642,711–714] In one dog, the platelet count exceeded 4 million/μL and bizarre giant forms with abnormal granulation were present. The bone marrow contained increased numbers of megakaryocytes and megakaryoblasts, but circulating blast cells were not seen. Other findings included splenomegaly, GI bleeding, and increased numbers of circulating basophils. Causes of secondary or reactive thrombocytosis were ruled out.[713] Basophilia was also reported in a more recent case.[711] In another dog, ET was diagnosed and then progressed to CML.[642] In some cases reported in the literature as ET, the dogs had microcytic hypochromic anemias. Because iron deficiency anemia is associated with reactive or secondary thrombocytosis, care must be taken to rule out this disorder. However, spurious microcytosis may be reported if a dog has many giant platelets that are counted by some analyzers as small RBCs.[712] Microscopic review of the blood film may be helpful in these cases.

Other Bone Marrow Disorders

Myelofibrosis

Primary myelofibrosis has been reported only rarely in dogs, and myelofibrosis is more typically a secondary, or reactive, process.[715,716] In humans, myelofibrosis is characterized by collagen deposition in bone marrow and increased numbers of megakaryocytes and granulocytic precursors, many of which exhibit morphologic abnormalities. In fact, breakdown of intramedullary megakaryocytes and subsequent release of factors that promote fibroblast proliferation or inhibit collagen breakdown may be the underlying pathogenesis of the fibrosis.[717] Focal osteosclerosis is sometimes present. Anemia, thrombocytopenia, splenomegaly, and myeloid metaplasia (production of hematopoietic cells outside the bone marrow) are consistent features.

In dogs, myelofibrosis occurs secondary to MPDs, radiation damage, and congenital hemolytic anemias.[718–721] In some cases, the inciting cause is unknown (idiopathic myelofibrosis). There may be concurrent marrow necrosis in cases of ehrlichiosis, septicemia, or drug toxicity (estrogens, cephalosporins), and there is speculation that fibroblasts proliferate in response to release of inflammatory mediators associated with the necrosis.[715] Myeloid metaplasia has been reported to occur in the liver, spleen, and lung.[721] Extramedullary hematopoiesis is ineffective in preventing or correcting the pancytopenia that eventually develops.

Myelodysplastic Syndrome

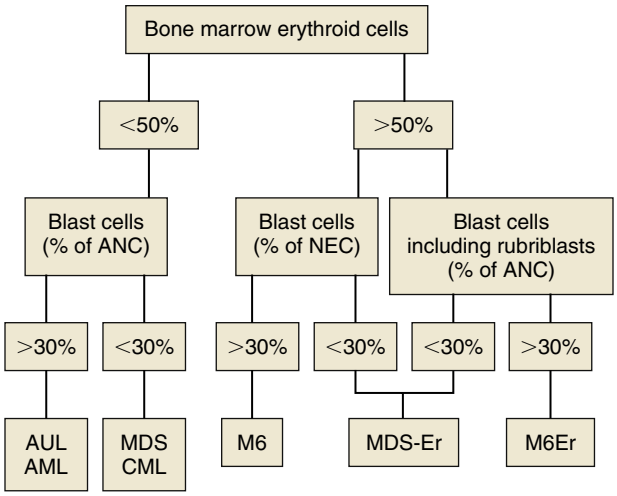
Dysfunction of the hematopoietic system can be manifested by a variety of abnormalities that constitute myelodysplastic syndrome (MDS). In dogs, in which the syndrome is rare, there usually are cytopenias in two or three lines in the peripheral blood (anemia, neutropenia, and/or thrombocytopenia). Other blood abnormalities can include macrocytic erythrocytes and metarubricytosis. The bone marrow is typically normocellular or hypercellular, and dysplastic changes are evident in several cell lines. If blast cells are

present, they make up fewer than 30% of all nucleated cells,[614] although this threshold is being changed to less than 20%.[616,722] Myelodysplasia is sometimes referred to as *preleukemia* because, in some cases, it may progress to acute leukemia.[639–641] Based on reported cases, poor prognostic factors include increased percentage of blast cells, cytopenias involving more than one lineage, and cellular atypia.[616] Primary MDSs are clonal disorders and are considered neoplastic. Complex classification schemes for human MDS, based on percentages of blasts in bone marrow, cytogenetic analysis, cytopenias, need for transfusions, and other variables, comprise at least nine subtypes; their applicability to veterinary medicine is unknown.[617] Three subtypes are proposed for dogs and cats and include MDS with excessive blasts (MDS-EB), in which blast percentages are greater than 5% and less than 20%, and progression to AML may occur; MDS with refractory cytopenia (MDS-RC) with blast percentages less than 5% and cytopenias in one or more lineages; and MDS with erythroid predominance (MDS-ER) in which the M : E ratio is less than one and prognosis is poor.[616] Larger studies are needed to determine the utility of this classification scheme and other potential prognostic factors, such as sex and age and, in cats, FeLV positivity. In addition to accumulating enough cases, another confounding factor to studying and classifying MDS is the presence of reversible MDSs that occur secondary to immune-mediated, infectious, and other diseases in both dogs and cats.

History and Clinical Signs

Dogs with myeloid neoplasms have similar presentations regardless of the specific disease entity, although animals with AML have a more acute onset of illness and a more rapid clinical course. A history of constitutional signs (e.g., lethargy, hyporexia, and weight loss) is common.[618–621] Clinical signs include emaciation, persistent fever, pallor, and petechiation. Peripheral lymphadenopathy is reported in 40% to 75% of cases and hepatosplenomegaly in approximately 40% of cases. Shifting leg lameness, ocular lesions, and recurrent infections are also seen. Vomiting, diarrhea, dyspnea, and neurologic signs are variable features. Serum biochemical analytes may be within reference intervals, but can change if significant organ infiltration occurs. Animals with MDS may be lethargic and anorectic and have pallor, fever, and hepatosplenomegaly. In PV, dogs often have erythema of mucous membranes owing to the increase in RBC mass. Some dogs are polydipsic. In addition, neurologic signs such as disorientation, ataxia, or seizures may be present and are thought to be the result of hyperviscosity or hypervolemia.[690] Hepatosplenomegaly is usually absent.

Peripheral blood abnormalities are consistently found in more than 90% of cases.[615,618–621] In addition to the presence of neoplastic cells, other abnormalities, including bi- and pancytopenia, may be present. Low numbers of nucleated RBCs are present in the blood of about half the dogs with acute nonlymphocytic leukemia. Nonregenerative anemia and thrombocytopenia are present in most cases. Anemia is usually normocytic and normochromic, although macrocytic anemia is sometimes present. Pathogenic mechanisms include effects of inhibitory factors leading to ineffective hematopoiesis, myelophthisis, immune-mediated anemia secondary to neoplasia, and hemorrhage secondary to thrombocytopenia, platelet dysfunction, or disseminated intravascular coagulation. Anemia is most severe in AML, although both anemia and thrombocytopenia may be milder in animals with the M5 subtype (acute monocytic leukemia). In myelofibrosis, anemia is characterized by anisocytosis and poikilocytosis. In addition, pancytopenia and leukoerythroblastosis, in which immature erythroid and myeloid cells are in circulation, may be present. These phenomena probably result from replacement of marrow by fibrous tissue with resultant shearing of red cells and escape of immature cells normally confined to bone marrow. In PV, the PCV is increased, usually in the range of 65% to 85%. The bone marrow is hyperplastic and the M : E ratio is usually in the normal range.



Neoplastic cells are often defective functionally. Platelet dysfunction has been reported in a dog with acute megakaryoblastic leukemia (M7)[658]; and, in CML, neutrophils have decreased phagocytic capacity and other abnormalities. One exception to this was a report of CML in a dog in which the neutrophils had enhanced phagocytic capacity and superoxide production.[723] The authors hypothesized that increased synthesis of granulocyte-macrophage (GM)-CSF resulted from a lactoferrin deficiency in the neoplastic neutrophils and mediated the enhanced function of these cells.

Diagnostic Techniques and Workup

In all cases of myeloid neoplasms, diagnosis depends on examination of peripheral blood and bone marrow. AML is diagnosed on the basis of finding blast cells with clearly visible nucleoli in blood and bone marrow. Most dogs with acute leukemia have circulating blasts. These cells may be present in low numbers in peripheral blood, and careful examination of the smear, especially at the feathered edge, should be made. Even if blasts are not detected in circulation, indications of bone marrow disease such as nonregenerative anemia or thrombocytopenia are usually present. Occasionally, neoplastic cells can be found in CSF in animals with invasion of the CNS. Smears of aspirates from tissues such as the lymph nodes, spleen, or liver may contain blasts but usually contribute little to the diagnostic workup.

Examination of blasts stained with standard Romanowsky stains may give clues as to the lineage of the cells (see Fig. 33.21A–C, and E). In myelomonocytic leukemia, the nuclei of the blasts are usually pleomorphic, with round to lobulated forms. In some cells, the cytoplasm may contain large azurophilic granules or vacuoles. Blasts in megakaryocytic leukemia may contain vacuoles and have cytoplasmic blebs. In addition, bizarre macroplatelets may be present. Although these distinguishing morphologic features may suggest a definitive diagnosis, cytochemical staining, immunophenotyping, flow cytometric analysis, clonality testing, and genetic analysis are usually required to definitively define the lineage of the blasts; the reader is referred to several large compilations for which these methodologies have been discussed and applied in dogs.[618–621,626,671,724–726] Several investigators have reported modification of diagnoses after cytochemical staining. It is especially important to distinguish AML from lymphocytic leukemia to provide accurate prognostic information to the owner and institute appropriate therapy.

The Animal Leukemia Group has recommended the following diagnostic criteria, summarized in Fig. 33.22.[615] Using well-prepared Romanowsky-stained blood and bone marrow films, a minimum of 200 cells are counted to determine the leukocyte differential in blood and the percentage of blast cells in bone marrow and/or blood. In bone marrow, blast cells are calculated both as a percentage of all nucleated cells (ANC) and nonerythroid cells, and are further characterized using cytochemical markers.[724,725,727] Neutrophil differentiation is identified by positive staining of blasts for peroxidase, Sudan Black B, and chloracetate esterase. Nonspecific esterases (α-naphthyl acetate esterase or α-naphthyl butyrate esterase), especially if they are inhibited by

• **Fig. 33.22** A scheme to classify myeloid neoplasms and myelodysplastic syndromes in dogs and cats. *AML*, Acute myeloid leukemias M1–M5 and M7; *ANC*, all nucleated cells in bone marrow, including lymphocytes, plasma cells, macrophages, and mast cells; *AUL*, acute undifferentiated leukemia; *Blast cells*, myeloblasts, monoblasts, and megakaryoblasts; *CML*, chronic myeloid leukemias, including chronic myelogenous, chronic myelomonocytic, and chronic monocytic leukemias; *M6*, erythroleukemia; *M6Er*, erythroleukemia with erythroid predominance; *MDS*, myelodysplastic syndrome; *MDS-Er*, myelodysplastic syndrome with erythroid predominance; *NEC*, nonerythroid cells in bone marrow. sodium fluoride, mark monocytes. Canine monocytes may also contain a few peroxidase-positive granules. Acetylcholinesterase is a marker for megakaryocytes in dogs and cats. In addition, positive immunostaining for von Willebrand's factor (factor VIII–related antigen) and platelet glycoproteins on the surface of blasts identifies them as megakaryocyte precursors.[648,658,659,661,665,667] Alkaline phosphatase (ALP) only rarely marks normal cells in dogs and cats, but is present in blasts cells in acute myeloblastic and myelomonocytic leukemias. However, owing to reports of ALP activity in lymphoid leukemias in dogs, its specificity as a marker for myeloid cells is not certain. A recent study indicated that ALP was a useful marker for the diagnosis of AML if neoplastic cells express only CD34.[728] Omega exonuclease is a specific marker for basophils, which are also positive for chloracetate esterase activity.[707]

Blood and bone marrow differential counts and cytochemical staining should be performed and interpreted by experienced veterinary cytopathologists. If erythroid cells are less than 50% of ANC and the blast cells are greater than 20%, a diagnosis of AML or AUL is made. If erythroid cells are greater than 50% of ANC and the blast cells are greater than 20%, a diagnosis of erythroleukemia (M6) is made. If rubriblasts are a significant proportion of the blast cells, a diagnosis of M6Er, or erythroleukemia with erythroid predominance, can be made. It should be noted that in the human AML classification system, the blast threshold has been lowered from 30% to 20%, and similar recommendations are now made for AML in dogs and cats.

In some cases, electron microscopy is required to identify the lineage of the blast cells. For example, megakaryocyte precursors are positive for platelet peroxidase activity and contain demarcation membranes and alpha granules.[648,665] Both of these features are detected at the ultrastructural level. Increasingly, cytogenetic abnormalities are being identified in animal leukemias; cytogenetic analysis may yield important diagnostic and prognostic information and become a valuable tool for identifying targeted therapeutic approaches.

Although morphologic and cytochemical analyses have formed the mainstay of cell identification, newer technologies now are routinely used to classify leukemias by using monoclonal antibodies to detect antigens associated with certain cell types. Cells can be immunophenotyped using flow cytometric analysis or immunocytochemistry.[618–621,671,677,722,729–732] Cells from both acute lymphoid leukemia and AML are positive for CD34. Many lymphocyte markers, including CD3, CD4, CD8, CD21, CD79, and IgG, are available for dogs and can be used to rule out lymphoblastic leukemia in dogs with acute leukemias. Other markers include myeloperoxidase (MPO) and CD11b for myeloid cells and CD41 for megakaryoblasts. There is some overlap in expression of these cellular antigens. For example, canine (but not human) granulocytes express CD4. It is highly recommended to use a panel of antibodies (similar to using a battery of cytochemical stains) because antigens are often expressed on multiple lineages, and lineage infidelity can occur. These tests have become more valuable with the availability of canine reagents. Currently, the ACVP Oncology Committee recommends that the following immunophenotyping panel be done on bone marrow and/or blood smears to characterize animal leukemias: for B lymphocytes, CD79a; for T lymphocytes, CD3; for myeloid cells, MPO and CD11b; for megakaryoblasts, CD41; for dendritic cells, CD1c; and for acute leukemias, CD34.[632] In 2 large reports of 60 cases of AML in dogs, most were CD45/CD18/CD34 positive and, in one report, 64% had clonal or biclonal rearrangements of either the T- or B-cell receptor.[619,621]

Because of the degree of differentiation of cells in MPN, these disorders must be distinguished from nonneoplastic causes of increases in these cell types. To make a diagnosis of PV, it must first be established that the polycythemia is absolute rather than relative. In relative polycythemias, plasma volume is decreased from hemoconcentration, dehydration, or hypovolemia, and the absolute RBC mass is not increased. Splenic contraction can also result in relative polycythemia. Absolute polycythemia, in which RBC mass is increased, is usually secondary to tissue hypoxia, causing appropriately increased production of erythropoietin. Rarely, erythropoietin may be produced inappropriately by a tumor (e.g., renal cell carcinoma) or in renal disease (pyelonephritis) or localized renal hypoxia.[733–735] These causes of polycythemia should be eliminated by appropriate laboratory work, thoracic radiographs, arterial blood gas analysis, and renal ultrasonography. In humans with PV, plasma erythropoietin (EPO) concentrations are low. EPO concentrations in dogs with PV tend to be low or low-normal, whereas in animals with secondary absolute polycythemia, the levels are high.[736,737] Samples for determination of EPO concentrations should be taken before therapeutic phlebotomy used to treat hyperviscosity and, owing to fluctuations in EPO concentrations, should be repeated if results are incongruous with other information.

There are no pathognomonic features of CML in dogs, and other common causes for marked leukocytosis with a left shift (extreme neutrophilia) and granulocytic hyperplasia of bone marrow must be eliminated. These include infections, especially pyogenic infections; immune-mediated diseases; and some neoplasms that cause neutrophilia by elaborating CSFs. In CML, maturation

sometimes appears disorderly, and there may be variation in the size and shape of neutrophils at the same level of maturation. In addition, neoplastic leukocytes may disintegrate more rapidly and appear vacuolated.[697] Because of the invasive nature of CML, biopsy of liver or spleen may also help distinguish true leukemia from a leukemoid reaction, assuming the animal can tolerate the procedure. Fluorescent in situ hybridization analysis is available to identify chromosomal rearrangements, including translocations (e.g., Raleigh chromosome), inversions, and deletions, in dogs; some of these aberrations are associated with certain forms of leukemia, and continued investigations will likely yield a larger database of cytogenetic abnormalities and their links to hematologic malignancies.[614,624–630,678,679,681,699–702]

Basophilic leukemia is diagnosed by finding excessive numbers of basophils in circulation and in bone marrow. Basophilic leukemia must be differentiated from mastocytosis based on the morphology of the cell type present. Basophils have a segmented "ribbon-like" nucleus and variably sized granules, whereas mast cells have a round-to-oval nucleus that may be partially or totally obscured by small, round, metachromatic-staining granules. This distinction is usually easy to make; however, in basophilic leukemia, changes in the morphology of the nucleus and granules make the distinction less clear.[706]

ET has been diagnosed based on finding persistent and excessive thrombocytosis (>600,000/μL) without circulating blast cells and in the absence of another MPD (e.g., PV), myelofibrosis, or disorders known to cause secondary thrombocytosis,[710] including iron deficiency anemia, chronic inflammatory diseases, recovery from severe hemorrhage, rebound from immune-mediated thrombocytopenia, and absence of a spleen. Thrombocytosis is transient in these disorders or abates with resolution of the primary disease. In ET, platelet morphology may be abnormal with bizarre giant forms and abnormal granulation.[713] In the bone marrow, megakaryocytic hyperplasia is a consistent feature and dysplastic changes may be evident in megakaryocytes.[712] Spurious hyperkalemia may be present in serum samples from dogs with thrombocytosis from any cause due to the release of potassium from platelets during clot formation.[738] Measuring potassium in plasma is recommended in these cases and usually demonstrates a potassium concentration within reference interval. Platelet aggregability has been variably reported as impaired[713] or enhanced.[712] In the one dog in which it was measured, plasma thrombopoietin (TPO) concentration was normal.[711] It is unclear whether TPO plays a role in ET or is suppressed by the high platelet mass.

In MDS, abnormalities in two or three cell lines are usually manifested in peripheral blood as neutropenia with or without a left shift, nonregenerative anemia, or thrombocytopenia. Other changes include macrocytosis and metarubricytosis. The bone marrow is typically normocellular or hypercellular with an increased M : E ratio, and blasts cells, although increased, constitute less than 20% of nucleated cells; in a report of 13 dogs with primary or secondary MDS, in all but one dog the blast cell percentage was less than 20%.[739] Dysplastic changes can be detected in any cell line. Dyserythropoiesis is characterized by asynchronous maturation of erythroid cells typified by large hemoglobinized cells with immature nuclei (megaloblastic change). If the erythroid component is dominant, the MDS is called *MDS-Er* (see Table 33.13).[615,638] In dysgranulopoiesis, giant neutrophil precursors and abnormalities in nuclear segmentation and cytoplasmic granulation can be seen. Finally, dysthrombopoiesis is characterized by giant platelets and micromegakaryocytes.

Myelofibrosis should be suspected in animals with nonregenerative anemia or pancytopenia, abnormalities in erythrocyte morphology (especially shape), and leukoerythroblastosis. Bone marrow aspiration is usually unsuccessful, resulting in a "dry tap." This necessitates a bone marrow biopsy obtained with a Jamshidi needle.[740] The specimen is processed for routine histopathologic examination and, if necessary, special stains for fibrous tissue can be used. Because myelofibrosis occurs secondary to other diseases of bone marrow, such as chronic hemolytic anemia or bone marrow necrosis, the clinician should look for a primary disease process.

The concept of clinical staging of patients with AML, MPD, and MDS is obviously much different than that of patients with solid tumors. As these hematologic tumors are "liquid," that is they involve primarily the peripheral blood and bone marrow compartments, clinical staging is generally not performed beyond these two compartments. Certainly, infiltration of peripheral nodes and other organs occurs; however, documentation of their involvement with advanced imaging or tissue aspirates does not alter treatment or prognosis in any significant way. Two studies have documented the proof-of-concept use of 3-T body MRI to distinguish diffuse versus focal bone marrow and/or parenchymal involvement of hematopoetic neoplasia; however, the clinical utility of this methodology is currently unknown.[741,742]

Treatment

Acute Myeloid Leukemia

Treatment of acute nonlymphocytic leukemias has been unrewarding to date. There is limited information on the response of specific subtypes of leukemia to uniform chemotherapeutic protocols, in part owing to the rarity of these diseases and the paucity of cases in the literature. Veterinarians are advised to contact a veterinary oncologist for discussion of new protocols and appropriate management of these cases, as novel agents are currently in development and may become available in the future.

The overriding therapeutic goal is to eradicate leukemic cells and reestablish normal hematopoiesis. Currently, this is best accomplished by cytoreductive chemotherapy and the agents most commonly utilized include combinations of anthracyclines, such as doxorubicin, cyclophosphamide, vincristine, 6-thioguanine, and prednisone.[618–620,640,644,646,707,743–746] In dogs, cytosine arabinoside (Ara-C), 100 to 200 mg/m^2, given by slow infusion (12–24 hours) daily for 3 days and repeated weekly, has been used, as well as several other variations using subcutaneous injections of Ara-C (see Chapter 12). Several variations of CHOP- or COP-based protocols (see Section A of this chapter), with or without Ara-C, have been used as well. The overall prognosis with currently available treatment is poor. Although response rates to multiagent protocols are relatively high (50%–70%), responses are not durable and MSTs, despite aggressive protocols, are generally 0.5 to 2.0 months.[618–620] Obviously, effective therapies for AML in dogs await further investigation.

Regardless of the chemotherapy protocol used, significant cytopenias either persist or are sequela to chemotherapy, and intensive supportive care will be necessary. Transfusions of whole blood or platelet-rich plasma may be required to treat anemia and thrombocytopenia, and infection should be managed with aggressive antibiotic therapy. Because of the generally poor response, many clients will choose palliative supportive care; however, the acute progression of disease does not allow for prolonged palliation in most cases and MSTs with supportive care are generally only 1 to 2 weeks.

Polycythemia Vera

In treating PV, therapy is directed at reducing RBC mass. The PCV should be reduced to 50% to 60% or by one-sixth of its starting value. Phlebotomies should be performed as needed, administering appropriate colloid and crystalloid solutions to replace lost electrolytes; 20 mL of whole blood/kg of body weight can be removed at regular intervals.[687] In humans, phlebotomy continues to be the therapeutic approach used most frequently.

The chemotherapeutic drug of choice is hydroxyurea, an inhibitor of DNA synthesis. This drug should be administered at an initial dose of 30 mg/kg for 10 days and then reduced to 15 mg/kg PO daily.[690] The major goal of treatment is to maintain the PCV as close to normal as possible. Radiophosphorus (^{32}P) has been shown to provide long-term control in people with PV and ET but has seen only limited use in veterinary medicine.[747,748] A *JAK2* inhibitor, ruxolitinib (Jakafi), has been approved for second-line use in people with PV.[680] A mutation in the *JAK2* gene that is identical to that observed in people was documented in one of five dogs with PV[681]; therefore one could speculate that oclacitinib (Apoquel), which has some *JAK2* inhibitory activity and is FDA-approved for use in dogs with atopy, could have therapeutic potential for PV in some dogs. This potential application for oclacitinib has not, as yet, been investigated.

Chronic Myelogenous Leukemia

It has now been documented that a subset of CML in dogs is associated with a BCR–ABL chromosomal abnormality ("Raleigh chromosome") similar to the "Philadelphia chromosome" translocation responsible for a large majority of CML in humans. Imatinib mesylate (Gleevec), a tyrosine kinase inhibitor, is known to be an effective therapy for CML in humans. For dogs with CML that have the Raleigh chromosomal abnormality, it is intuitive that these types of drugs may have activity, and indeed tyrosine kinase inhibitors have been investigated in dogs with BCR–ABL translocation CML.[701] One dog with chronic monocytic leukemia treated with toceranib (Palladia) and prednisone therapy achieved a clinical remission (before developing progressive disease) and a partial cytogenetic response. In addition, molecular techniques may be used to monitor cytogenetic aberrations, such as DNA copy number aberrations and BCR–ABL translocations, after treatment to gauge the cytogenetic response to therapy.[627,701] The author (DMV) and others have anecdotally used toceranib and/or imatinib in a handful of CML cases with responses that have lasted several months; the true activity and durability of response with these agents in dogs awaits further investigation.

CML has also been managed with chemotherapy to control the proliferation of the abnormal cell line and improve the quality of life. Hydroxyurea is the most effective agent for treating CML during the chronic phase.[627,696,749] The initial dosage is 20 to 25 mg/kg twice daily. Treatment with hydroxyurea should continue until the leukocyte count falls to 15,000 to 20,000 cells/μL.[694,696,705] Then the dosage of hydroxyurea can be reduced by 50% on a daily basis or to 50 mg/kg given biweekly or triweekly. In humans, the alkylating agent busulfan can be used as an alternative.[750] An effective dosage has not been established in the dog, but following human protocols, 0.1 mg/kg/day PO is given until the leukocyte count is reduced to 15,000 to 20,000 cells/μL. Vincristine and prednisone therapy resulted in a short remission in one dog with CML.[627]

Despite response to chemotherapy and control for many months, most dogs with CML will eventually enter a terminal phase of their disease. In one study of seven dogs with CML, 4 dogs underwent terminal phase blast crisis.[696] In humans, blast crisis may be lymphoid or myeloid.[751] Dogs with blast crisis have a poor prognosis, despite rescue with more aggressive multiagent chemotherapy.

Essential Thrombocythemia

Few cases have been reported, but one dog was treated successfully with a combination chemotherapy protocol that included vincristine, Ara-C, cyclophosphamide, and prednisone.[714] Treatment is controversial in humans because of the lack of evidence that asymptomatic patients benefit from chemotherapy. Patients with thrombosis or bleeding are given cytoreductive therapy. Hydroxyurea is the drug of choice for initially controlling the thrombocytosis.[710] *JAK2* small molecule inhibitors have been used in people with ET,[680] and although no studies have investigated *JAK2* mutations in dogs with ET, one could speculate on the use of oclacitinib (Apoquel) in dogs. Radiophosphorus treatment is also occasionally used in people with ET.[747]

Myelodysplastic Syndrome

There is no standard therapeutic regime for MDS. Often, humans receive no treatment if the cytopenias do not cause clinical signs. Transfusions are given when necessary, and patients with fever are evaluated aggressively to detect infections. Growth factors, such as EPO, GM-CSF, G-CSF, and IL-3, are sometimes used in patients who require frequent transfusions to increase their blood cell counts and enhance neutrophil function.[752,753] In one case report, human EPO was administered (100 U/kg SQ q48 hours) to a dog with MDS because of profound anemia. The rationale for use of EPO was to promote terminal differentiation of dysplastic erythrocytes. Human recombinant EPO should be used with caution in animals, as anti-EPO antibodies may be induced and target endogenous EPO. The PCV increased from 12% to 34% by day 19 of EPO treatment. This dog remained in remission for more than 30 months.[638] Other factors that induce differentiation of hematopoietic cells include retinoic acid analogs, 1,25 dihydroxyvitamin D3, interferon-α, and conventional chemotherapeutic agents, such as 6-thioguanine and Ara-C.[754–756] The propensity of these factors to enhance progression to leukemia is not known in many cases, but the potential risk exists.

Prognosis

In general, the prognosis for animals with MPN is better than for dogs with AML, in which it is grave. The prognosis for PV and CML is guarded, but significant remissions have been achieved with certain therapeutic regimes and careful monitoring. Animals commonly survive a year or more.[696,714]

SECTION D: MYELOMA-RELATED DISORDERS

DAVID M. VAIL

Myeloma-related disorders (MRDs) arise when a cell of the plasma cell or immunoglobulin-producing B-lymphocyte precursor lineage transforms and proliferates to form a clonal neoplastic population of similar cells. This population is believed in most instances to be monoclonal (i.e., derived from a single cell) because they typically produce homogeneous immunoglobulin, although some examples of biclonal and polyclonal MRD neoplasms exist. A wide variety of clinical syndromes are represented by MRDs, including multiple myeloma (MM), extramedullary plasmacytoma (EMP [both cutaneous and noncutaneous]), IgM

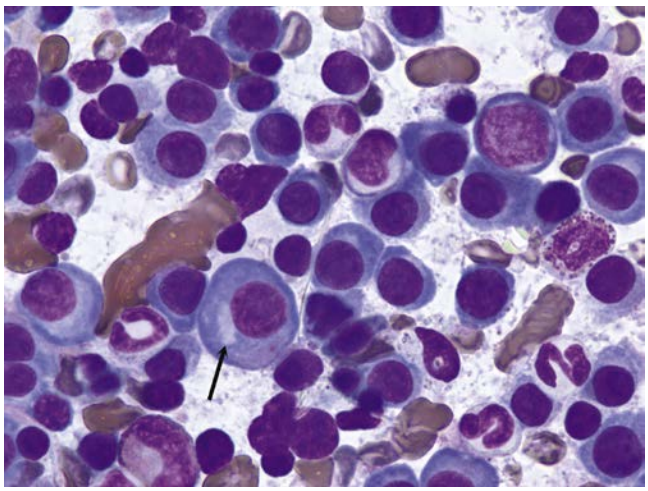
VetBooks.ir

• BOX 33.7 Key Clinical Summary Points: Myeloma-Related Disorders

- Myeloma-related disorders (MRDs) represent clonal neoplastic populations of plasma cells.
- They include multiple myeloma (MM), extramedullary plasmacytoma (EMP), (Waldenström's) macroglobulinemia, solitary osseous plasmacytoma (SOP), and plasma cell leukemia.
- Dogs and cats with MM are presented with a wide variety of clinical signs (Tables 33.14, 33.15) and clinicopathologic abnormalities (Table 33.16) resulting from high levels of circulating M component, organ or bone infiltration with neoplastic cells, or both.
- Diagnosis of MM usually follows the demonstration of bone marrow or visceral organ plasmacytosis (Fig. 33.23), the presence of osteolytic bone lesions (Figs. 33.25, 33.26), and the demonstration of serum or urine myeloma proteins (M component; Fig. 33.24).
- Most (>80%) dogs with MM respond to chemotherapy (melphalan/prednisone) and enjoy durable remissions, with median survival times of 1.5 to 2.5 years. Most (50%–80%) cats also respond to chemotherapy (cyclophosphamide/prednisolone) although the durability of response tends to be shorter, with median survival times reported from 4 to 13 months
- Cutaneous and oral solitary EMPs are usually cured after surgical excision.
- Cutaneous **plasmacytosis**, however, is associated with multiple lesions (10s to 100s), is a biologically aggressive disease, with treatment and outcomes more like those for MM.
- Noncutaneous/nonoral EMPs and SOPs can be initially confined to local sites and respond to local therapy (i.e., surgery, radiation therapy); however, frequent rechecks are necessary, because many will eventually progress systemically.

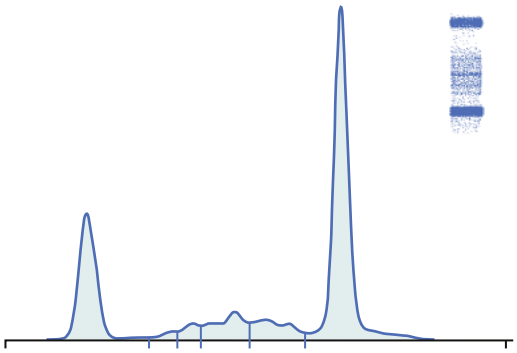
(Waldenström's) macroglobulinemia, solitary osseous plasmacytoma (SOP), and Ig-secreting lymphomas and leukemias (including plasma cell leukemia). MM is the most important MRD based on clinical incidence and severity. There appears to be some discordance and blurring of the distinction between MM and multicentric noncutaneous EMP in cats and these two MRDs will be discussed together in this species. See Box 33.7.

Multiple Myeloma



Incidence and Etiology

Although MM represents fewer than 1% of all malignant tumors in animals, it is responsible for approximately 8% of all hematopoietic tumors and 3.6% of all primary and secondary tumors affecting bone in dogs.[757,758] In a compilation of bone marrow disorders in dogs (n = 717), MM represented 4.4% and 19.8% of all abnormal samples and neoplastic processes, respectively.[759] Furthermore, in a compilation of serum protein electrophoretic samples (n = 147 dogs), MM accounted for 4.3% of abnormal and 28.5% of neoplastic processes encountered, respectively.[760] Several compilations have suggested a male predisposition,[761–763] whereas others have not observed this.[758,764] Older dogs are affected with an average age of between 9 and 10 years (range, 3–14 years).[758,761–764] In one large case series, German shepherd dogs were overrepresented based on the hospital population.[758] The true incidence of MM in the cat is unknown; however, it is a more rare diagnosis than in the dog, representing only 1 of 395 and 4 of 3248 tumors in two large compilations of feline malignancies, and 0.9% of all malignancies and 1.9% of hematologic malignancies in another report.[765–767] MM represented 1.4% and 14% of abnormal and malignant serum protein electrophoretic samples, respectively, in a compilation of 155 feline samples.[768] MM occurs in aged cats (median age 12–14 years), most commonly in domestic short hair cats, and no sex predilection has been consistently reported, although a male preponderance may exist.[764,767,769–771] MM has not been associated with coronavirus, FeLV, or FIV infections.



The etiology of MM is for the most part unknown. Genetic predispositions, molecular aberrations (e.g., c-*kit*), viral infections, chronic immune stimulation, and carcinogen exposure have all been suggested as contributing factors.[764,772–779] Suggestion of a familial association in cats follows cases reported among siblings.[770] Evidence exists that molecular mechanisms of cellular control, including overexpression of cell cycle control components like cyclin D1 (see Chapter 2), and receptor tyrosine kinase dysregulation may be involved in canine MM and plasma cell tumors.[774,776] In rodent models, chronic immune stimulation and exposure to implanted silicone gel have been associated with development of MM,[778,779] as have chronic infections and prolonged hyposensitization therapy in humans.[775] Viral Aleutian disease of mink results in monoclonal gammopathies in a small percentage of cases.[777] Exposure to the agricultural industry, petroleum products, and irradiation are known risk factors for development in humans.[780–782] In addition, progression of solitary plasma cell tumors to MM has been reported in both dogs and cats, and a single case of a B-cell lymphoma progressing to MM exists in the dog.[783–785]

Pathology and Natural Behavior

MM is a systemic proliferation of malignant plasma cells or their precursors arising as a clone of a single cell that usually involves multiple bone marrow sites in dogs. In cats, as previously stated, a blurring of the distinction of MM and multicentric noncutaneous EMP within the MRD occurs because widespread abdominal organ involvement without significant bone marrow infiltration has been described in a proportion of cases in European compilations.[771,786] Because both MM and multicentric noncutaneous EMP have a similar clinical course and widespread systemic involvement with hyperglobulinemia in cats, they will be discussed as MM in this chapter. Malignant plasma cells can have a varied appearance on histologic sections and cytologic preparations. The degree of differentiation ranges from those resembling normal plasma cells in late stages of differentiation (Fig. 33.23) to very large anaplastic round cells (often referred to as *plasmablasts*) with a high mitotic index representing early stages of differentiation.[763,764,767,786] Binucleate and multinucleate cells are often present (see Fig. 7.32, Chapter 7). In 16 cats with MM in one case series,[787] the majority (83%) of plasma cells were immature and had marked atypia, including increased size, multiple nuclei, clefted nuclei, anisocytosis, anisokaryosis, variable nuclear: cytoplasmic ratios, decreased chromatin density, and variable nucleoli; nearly one quarter had "flame cell" morphology characterized by peripheral eosinophilic cytoplasmic processes.[767] However, in a European compilation of feline multicentric noncutaneous MRD cases (n = 17), 78% had well-differentiated morphologies.[786] The authors of this latter case series developed a grading system dependent on the percentage of plasmablasts within the neoplastic cells in which well-differentiated, intermediate-grade, and poorly differentiated MMs have less than 15%, 15% to 49%, and 50% or more plasmablasts, respectively.[786] Malignant plasma cells typically produce an overabundance of a single type of or component of immunoglobulin, which is referred to as the *M component*

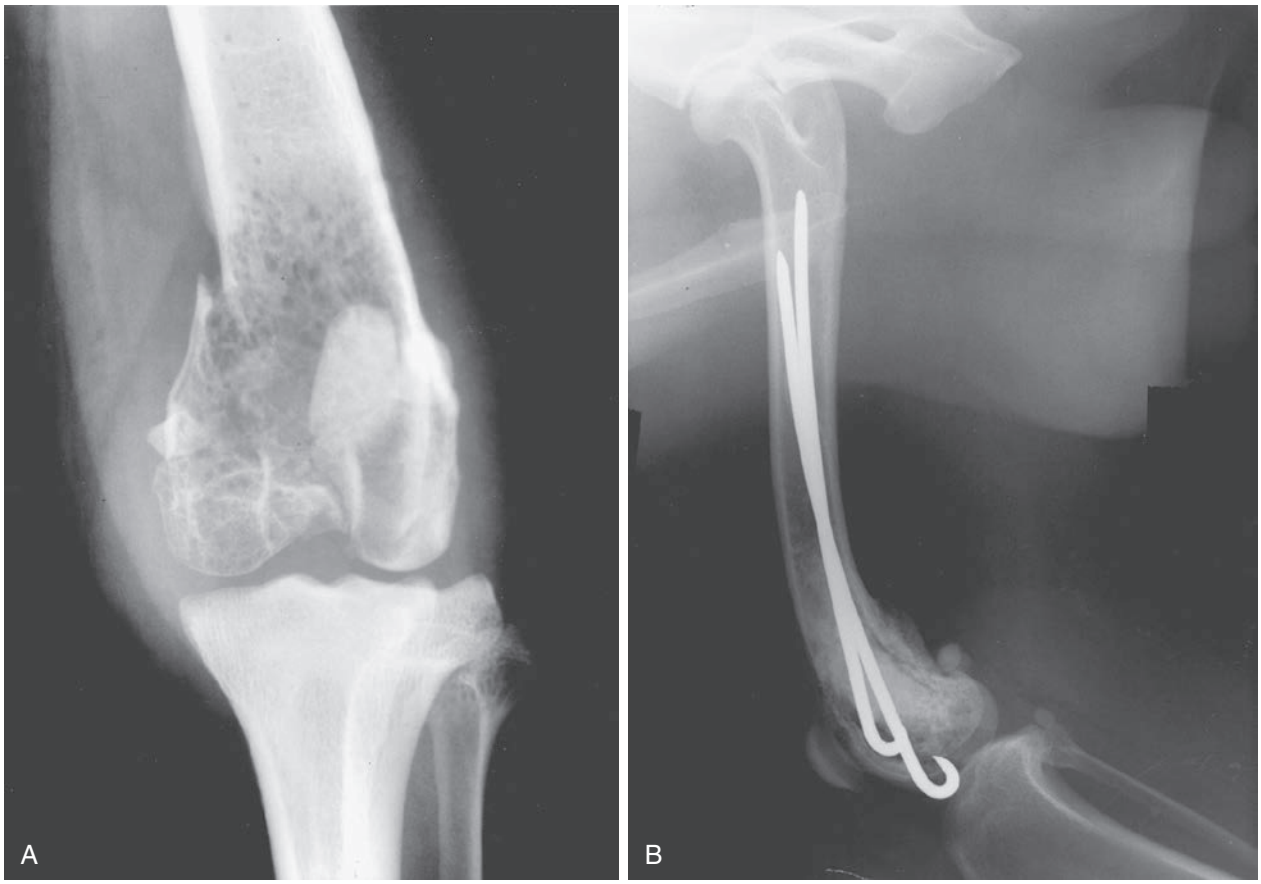
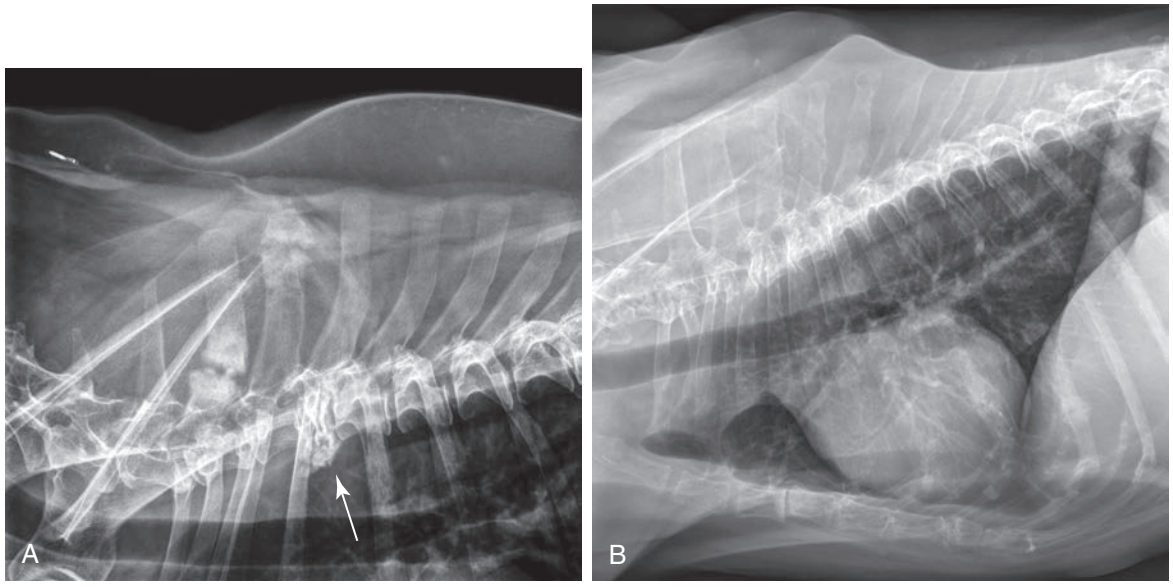
(Fig. 33.24). The M component can be represented by any class of the entire immunoglobulin or only a portion of the molecule, such as the light chain (Bence Jones protein) or heavy chain (heavy chain disease) of the molecule. In the dog, the M component is usually represented by either IgA or IgG immunoglobulin types in nearly equal incidence, whereas the ratio of IgG to IgA in cats is approximately 5:1 in some reports and approximately 1:1 in others.[757,763–767,786,788] However, in two recent compilations of dogs with MM, including 27 dogs in which the immunoglobulin was typed, the vast majority (78%) were of the IgA type.[761,762] If the M component is the IgM type, the term *macroglobulinemia* (Waldenström's) is often applied. Several cases of biclonal gammopathy in dogs and cats have been reported,[761,767,770,771,789–795] and several cases of nonsecretory MM have been reported in dogs.[762,796–798] Rarely, cryoglobulinemia occurs in dogs with MM and IgM macroglobulinemia, and this has also been reported in a cat with IgG myeloma.[764,799–801] Cryoglobulins are paraproteins that are insoluble at temperatures below 37°C and require blood collection and clotting to be performed at 37°C before serum separation. If whole blood is allowed to clot at temperatures below this, the protein precipitates in the clot and is lost. Pure light-chain M component is rare, but has been reported in both dogs and cats.[762,802,803]



The pathology associated with MM is a result of either high levels of circulating M component, organ or bone infiltration with neoplastic cells, or both. Associated pathologic conditions include bone disease, bleeding diathesis, hyperviscosity syndrome (HVS), renal disease, hypercalcemia, immunodeficiency (and subsequent susceptibility to infections), cytopenias secondary to myelophthisis, and cardiac failure.

Bone lesions can be isolated, discrete osteolytic lesions (including pathologic fractures) (Fig. 33.25A), diffuse osteopenias, or both (Fig. 33.26). Approximately one-quarter to two-thirds of dogs with MM have radiographic evidence of bony lysis or diffuse osteoporosis.[757,761,763,764] The incidence of radiographic skeletal lesions in cats varies tremendously within reports from as few as 8% in some case series to as high as 65% in others.[765,767,770,771,788] Those bones engaged in active hematopoiesis are more commonly affected and include the vertebrae, ribs, pelvis, skull, and the metaphyses of long bones. Skeletal lesions are rare with IgM (Waldenström's) macroglobulinemia, in which malignant cells often infiltrate the spleen, liver, and lymphoid tissue rather than bone.[764,804,805]



Bleeding diathesis can result from one or a combination of events. M components may interfere with coagulation by (1) inhibiting platelet aggregation and the release of platelet factor-3; (2) causing adsorption of minor clotting proteins; (3) generating abnormal fibrin polymerization; and (4) producing a functional decrease in calcium.[764,806,807] Approximately 10% to 30% of dogs and up to one-quarter of cats have clinical evidence of hemorrhage.[757,761,767,770,771] In dogs, nearly half have abnormal prothrombin (PT) and partial thromboplastin (PTT) times. Thrombocytopenia may also play a role if bone marrow infiltration is significant (i.e., myelophthisis).

HVS represents one of a constellation of clinicopathologic abnormalities resulting from greatly increased serum viscosity. The magnitude of viscosity changes is related to the type, size, shape, and concentration of the M component in the blood. HVS is more common with IgM macroglobulinemia because of the high molecular weight of this class of immunoglobulin. IgA-secreting myelomas (IgA is usually present as a dimer in the dog) may undergo polymerization resulting in increased serum viscosity.[757,764,808] IgG-associated HVS can also occur, albeit less frequently. High serum viscosity occurs in approximately 20% to 40% of dogs with MM and can result in bleeding diathesis, neurologic signs (e.g., dementia, depression, seizure activity, coma), ophthalmic abnormalities (e.g., dilated and tortuous retinal vessels, retinal hemorrhage [Fig. 33.27], retinal detachment), and increased cardiac workload with the potential for subsequent development of cardiomyopathy.[757,761,764,804,805,808–811] In a retrospective compilation of 83 dogs with retinal hemorrhage, 5% were due to MM.[812] These consequences of HVS are thought to be a result of sludging of blood in small vessels, ineffective delivery of oxygen and nutrients, and coagulation abnormalities. HVS

has been reported in cats with IgG-, IgA-, and IgM-secreting tumors.[764,765,813–818] In several of these cases, relative serum viscosity was increased above control ranges.

Renal disease is present in approximately one-quarter to one-half of dogs with MM, and azotemia is observed in 30% to 40% of cats.[757,761,763,767,769,771] The pathogenesis of renal failure is often multifactorial and can ensue as a result of Bence Jones (light-chain) proteinuria, tumor infiltration into renal tissue, hypercalcemia, amyloidosis, diminished perfusion secondary to HVS, dehydration, or ascending urinary tract infections.[757,764,806,807] Normally, heavy- and light-chain synthesis is well balanced in nonneoplastic immunoglobulin production. In the case of MM, an unbalanced excess of light-chain products may be produced. Light chains are of low molecular weight and are normally filtered by the renal glomerulus, and their presence in urine can result in protein precipitates and subsequent renal tubular injury. The presence of light chains in urine without a concomitant monoclonal spike in serum, although rare, is indicative of pure light-chain disease.[802] Tubules become obstructed by large laminated casts containing albumin, immunoglobulin, and light chains. Bence Jones proteinuria occurs in approximately 25% to 40% of dogs with MM.[757,763,764] Bence Jones proteinuria is reported to occur in approximately 40% of cats with MM/MRD.[767,768] Hypercalcemia is reported in 15% to 50% of dogs with MM and is thought to result primarily from the production of osteoclast-activating factor by neoplastic cells.[757,761,762,764,819] Other factors, including increased levels of various cytokines, TNF-α, IL-1, and IL-6, have been implicated in human MM. In two dogs with MM and hypercalcemia, serum elevations in circulating N-terminal parathyroid hormone-related peptide were noted.[820] Hypercalcemia may also be exacerbated by associated renal disease. Hypercalcemia, initially thought to be a rare event in cats with MM, occurred in 10% to 25% of recently reported cases.[767,769–771,821]

Susceptibility to infection and immunodeficiency have long been associated with MM and are often the ultimate cause of death in affected animals.[757,764,788] Infection rates in humans with MM are 15 times higher than normal and usually present as pneumonia or urinary tract infections.[822] Response to vaccination has also been shown to be suppressed in humans with MM.[822] "Normal" immunoglobulin concentrations are often severely depressed in affected animals.[764] In addition, leukopenia may be present secondary to myelophthisis. Reports of multiple concurrent infections in both dogs and cats affected with MM exist and, in one dog with several concurrent infections, a polyclonal and a monoclonal gammopathy existed pretreatment, with the former persisting after successful treatment of the myeloma.[772,773]

Variable cytopenias may be observed in association with MM. A normocytic, normochromic, nonregenerative anemia is encountered in approximately one-half to two-thirds of dogs with MM.[757,761–764] This can result from marrow infiltration (myelophthisis), blood loss from coagulation disorders, anemia of chronic disease, or increased erythrocyte destruction secondary to high serum viscosity. Rare erythrophagocytic forms of MM have also been reported in both dogs and cats and may contribute to anemia.[823–825] Similar factors lead to thrombocytopenia and leukopenia in 30% and 80% of dogs with MM, respectively; and in cats, approximately two-thirds, one-half, and one-third will be anemic, thrombocytopenic, and neutropenic, respectively.[761,762,767,769–771]

Cardiac disease, if present, is usually a result of excessive cardiac workload and myocardial hypoxia secondary to hyperviscosity. Myocardial infiltration with amyloid and anemia may be complicating factors. Nearly one-half of cats with MM in two reports presented with a cardiac murmur, the etiology of which was not established.[767,769] Three cats with HVS presented with congestive heart failure, murmurs, and echocardiographic signs consistent with hypertrophic cardiomyopathy.[813]

History and Clinical Signs

Clinical signs of MM may be present up to a year before diagnosis with a median duration of 1 month reported in dogs.[757,764] In one cat, M-component elevations were detected 9 years before clinical presentation.[767] In this latter case, the M-component elevation was consistent with monoclonal gammopathy of unknown significance (MGUS). MGUS (i.e., benign, essential, or idiopathic monoclonal gammopathy) is a benign monoclonal gammopathy that is not associated with osteolysis, bone marrow infiltration, or Bence Jones proteinuria. MGUS has also been reported in dogs.[826,827] Signs of MM can be variable based on the wide range of pathologic effects possible. Tables 33.14 and 33.15 list the relative frequencies of clinical signs observed in the dog and cat, respectively, based on a compilation of several rep orts.[757,761,762,764,767,769–771,788] Bleeding diathesis is usually represented by epistaxis and gingival bleeding. Funduscopic abnormalities may include retinal hemorrhage (see Fig. 33.27), venous dilatation with sacculation and tortuosity, retinal detachment, and blindness.[757,761,6,764,769,771,808–812] CNS signs may include dementia, seizure activity, tremors, and deficiencies in midbrain or brainstem localizing reflexes secondary to HVS or extreme hypercalcemia. Signs reflective of transverse myelopathies secondary to vertebral column infiltration, pathologic fracture, or extradural mass compression can also occur.[757,764,799,828,829] One case of ataxia and seizure activity in a dog with EMP secondary to tumor-associated hypoglycemia has been reported.[830] In addition, paraneoplastic polyneuropathy has been reported in a dog with MM.[831] A history of chronic respiratory infections and persistent fever may also be present in cats. Hepatosplenomegaly and renomegaly can occur due to organ infiltration. Bleeding diathesis due to HVS is less common in the cat; however, epistaxis, pleural and peritoneal hemorrhagic effusions, retinal hemorrhage, and central neurologic signs have been reported in both dogs and cats.[761,764,765,769,813–818] Polydipsia and polyuria can occur

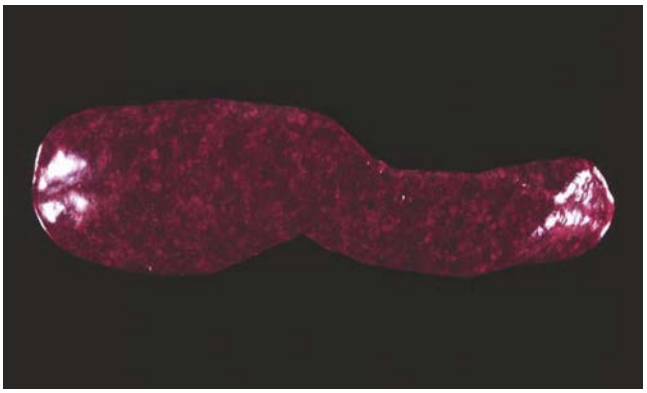
TABLE 33.15 Approximate Frequency of Clinical Signs Reported for Cats with Myeloma-Related Disorders ($n = 68$)[764,767,769–771,788]



Clinical Sign	Frequency Range Reported (%)
Lethargy and weakness	40–100
Anorexia	33–100
Pallor	30–100
Polyuria/polydipsia	13–40
Vomiting/diarrhea	10–30
Dehydration	20–33
Palpable organomegaly	20–25
Lameness	7–25
Heart murmur	0–45
Hind limb paresis/paralysis	0–45
Bleeding diathesis	0–40
CNS signs	13–30
Concurrent cutaneous plasma cell tumor	0–30
Fundic/ocular changes	13–33
Lymphadenopathy	0–10

CNS, Central nervous system.

secondary to renal disease or hypercalcemia, and dehydration may develop. Hindlimb paresis secondary to osteolysis and instability of lumbar vertebral bodies or extradural compression has been reported in cats.[770,832]

Diagnosis and Staging

The diagnosis of MM in dogs usually follows the demonstration of bone marrow plasmacytosis (see Fig. 33.23), the presence of osteolytic bone lesions (see Figs. 33.25 and 33.26), and the demonstration of serum or urine myeloma proteins (M component) (see Fig. 33.24). In the absence of osteolytic bone lesions, a diagnosis can also be made if marrow plasmacytosis is associated with a progressive increase in the M-component or if plasma cell clonality (e.g., PARR) is documented. In the cat, because the degree of bone marrow infiltration may not be as marked, it has been suggested that consideration of plasma cell morphology and visceral organ infiltration (Fig. 33.28) be given in cases with demonstrable M-component disease in the absence of marked (<20%) marrow plasmacytosis.[767,771,786]

• **Fig. 33.28** Necropsy specimen of a spleen from a cat with multiple myeloma showing diffuse plasma cell infiltration.

All animals suspected of plasma cell tumors should receive a minimal diagnostic evaluation including a CBC, platelet count, ionized calcium, serum biochemistry profile, and urinalysis. Particular attention should be paid to renal function and serum calcium levels. If clinical hemorrhage is present, a coagulation assessment (e.g., platelet count, PT, PTT) and serum viscosity measurements are indicated. All animals should undergo a careful funduscopic examination. Serum electrophoresis and immunoelectrophoresis are performed to determine the presence of a monoclonal M-component (see Fig. 33.24) and to categorize the immunoglobulin class involved. Heat precipitation and electrophoresis of urine may be performed to determine presence of Bence Jones proteinuria because commercial urine dipstick methods are not capable of this determination. Definitive diagnosis usually follows the performance of a bone marrow aspiration in the dog. A bone marrow core biopsy or multiple aspirations may be necessary because of the possibility of uneven clustering or infiltration of plasma cells in the bone marrow. Normal marrow contains less than 5% plasma cells, whereas myelomatous marrow often greatly exceeds this level. Current recommendations require more than 20% marrow plasmacytosis to be present, although a 10% cutoff in cats has been recently recommended with special attention to cellular atypia.[767] Even the 10% threshold may be problematic in cats, and cellular atypia and visceral organ involvement (assessed through needle aspiration cytology or tissue biopsy) should be considered equally important in this species.[767,771,786] Rarely, biopsy of osteolytic lesions (i.e., Jamshidi core biopsy; see Chapter 25) is necessary for diagnosis in the dog. In one case of MM in a dog, splenic aspirates were diagnostically helpful.[833] Overall frequencies of clinical diagnostic abnormalities for dogs and cats with MM are compiled from published series having at least five cases each and are listed in Table 33.16.

Immunohistochemical and Molecular Diagnostics

Histochemical and IHC analyses of cells or tissues suspected of MRD are more often applied in the case of solitary plasmacytomas

VetBooks.ir

TABLE 33.16 Approximate Frequency of Clinical Diagnostic Abnormalities for Dogs and Cats with Multiple Myeloma (*n* = 68 cats, 134 dogs)[757,761,762,764,767,769–771,788]

	FREQUENCY RANGE REPORTED (%)	
Abnormality	**Dogs**	**Cats**
Increased M component	99	94–98
Monoclonal	95	77–100
Biclonal	5%[a]	16–23
IgG	40	84
IgA	60	16
Noncutaneous extramedullary extension	NR	65–100[b]
Marrow plasmacytosis (>10%)	100	50–100
Complete blood count (CBC) abnormalities		
Anemia (nonregenerative)	61	50–80
Thrombocytopenia	39	50
Neutropenia	26	37
Circulating plasma cells (leukemia)	7	5–25
Hypoalbuminemia	62	36–60
Hypocholesterolemia	NR	68
Proteinuria	45	71–91
Bence Jones proteinuria	38	40–59
Bone lysis	64	5–45
Serum hyperviscosity	35	35–44
Azotemia	29	22–40
Hypercalcemia	27	10–25
Increased activities of liver enzymes	NR	43–50

[a]Several single case reports exist for biclonal gammopathy in dogs with MM.

NR, Not reported.

or where EMP is suspected in the absence of marrow involvement and will be discussed in subsequent sections; however, they have been occasionally useful in the diagnosis of MM. Molecular diagnostic techniques for MM have received limited use thus far in veterinary oncology; however, determining clonality of the immunoglobulin heavy chain variable region gene has been performed in feline and canine plasmacytoma and myeloma using PARR techniques (see Chapter 8),[762,834] and use of this technology in cases where diagnosis is not straightforward is expanding. The author has used PARR analysis both before treatment and after clinical remission in a small number of dogs with MM involved in clinical trials and documented its utility for (1) initial diagnosis and (2) to characterize molecular remission.[762]

Imaging

Routine thoracic and abdominal radiographs are recommended in suspected cases. Occasionally, bony lesions can be observed in skeletal areas on these standard films, and organomegaly (liver, spleen, kidney) is observed in the majority of cats.[767,769,771] Abdominal ultrasound is recommended in all cats suspected of MM because this modality reveals involvement of one or more abdominal organs in the majority of cases. These include splenomegaly with or without nodules, diffuse hyperechoic hepatomegaly with or without nodules, renomegaly, and iliac lymph node enlargement. In one case series in cats with MM, 85% of organs with ultrasonographic abnormalities were subsequently confirmed to have plasma cell infiltration.[771] Skeletal survey radiographs are recommended to determine presence and extent of osteolytic lesions, which may have diagnostic, prognostic, and therapeutic implications. Although nuclear scintigraphy (bone scan) for clinical staging of dogs with MM has been performed, because of the predominant osteolytic activity with osteoblastic inactivity present, scans seldom give positive results and are therefore not useful for routine diagnosis.[835] In physician-based oncology, bone mineral density analysis (dual-energy x-ray absorptiometry [DEXA] scan) to document osteoporosis, MRI of bone marrow, and PET/CT are commonly used for staging; however, these modalities have not been applied consistently in the veterinary literature. A clinical staging system for canine MM has been suggested[757]; however, at present, no prognostic significance has been attributed to it.

Differential Diagnosis of MM

Disease syndromes other than plasma cell tumors can be associated with monoclonal gammopathies and should be considered in any list of differentials. These include other lymphoreticular tumors (B-cell lymphoma, extramedullary plasmacytoma, and chronic and acute B-lymphocytic leukemia), chronic infections (e.g., ehrlichiosis, leishmaniasis, feline infectious peritonitis), and MGUS.[763,767,826,71,836–839]

Treatment

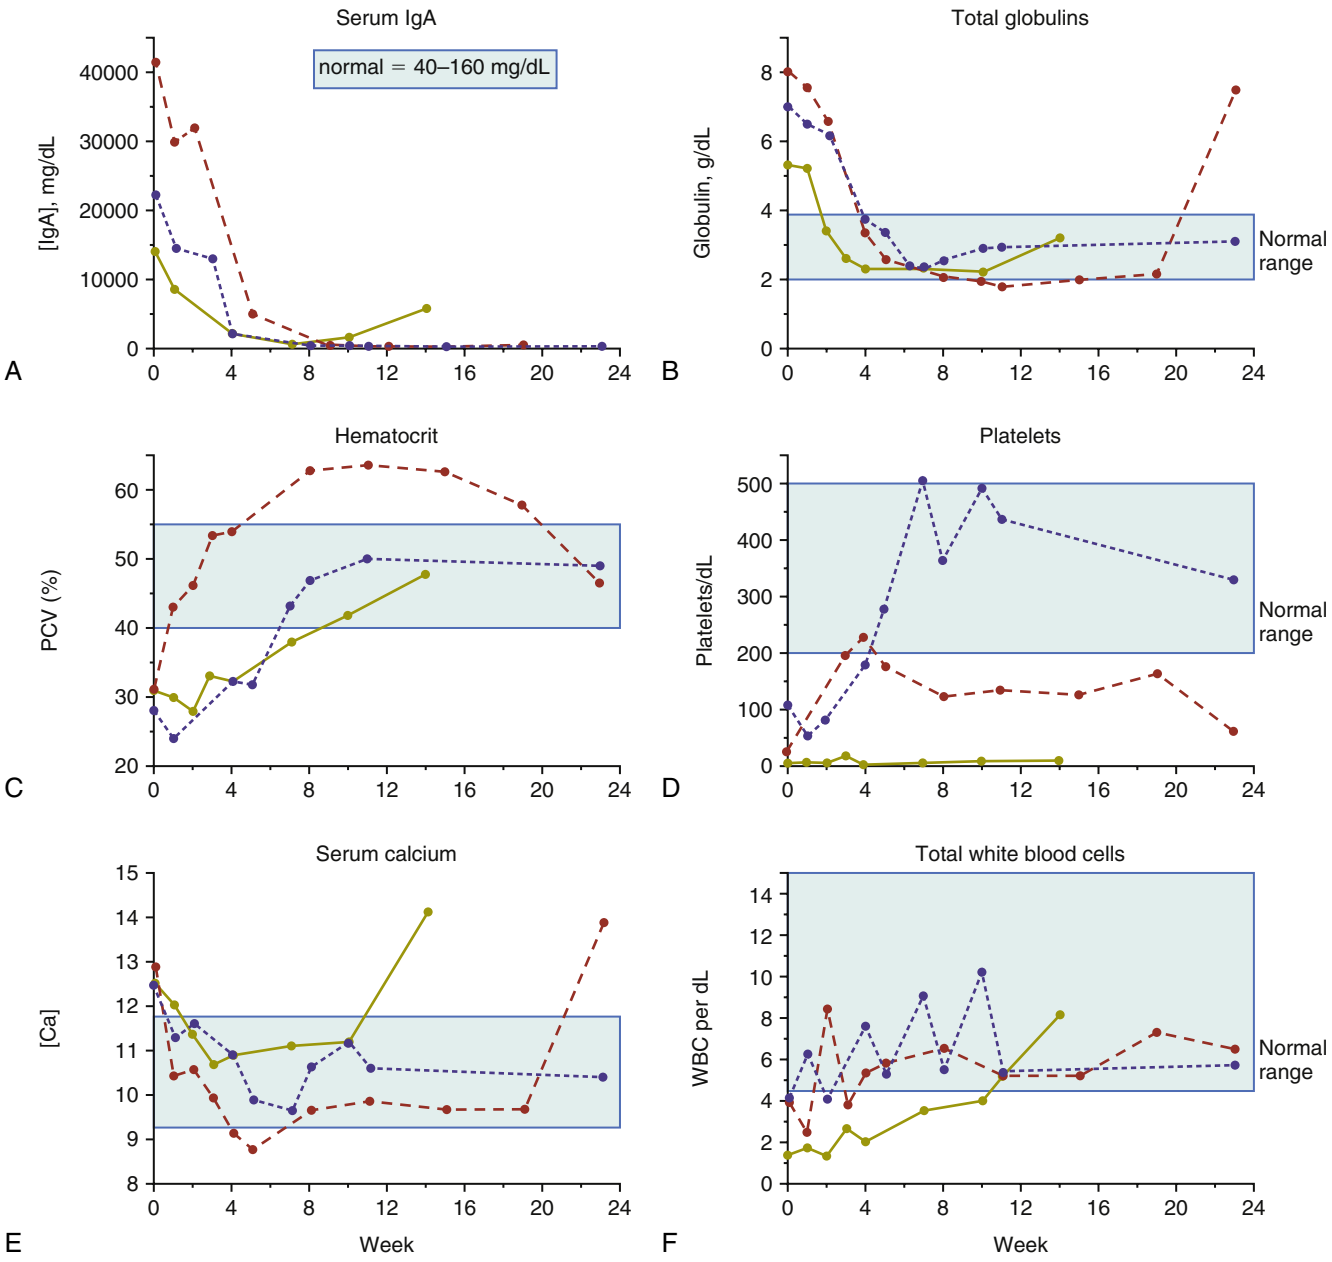
Initial Therapy of Multiple Myeloma

Therapy for MM is directed at both the tumor cell mass and the secondary systemic effects they elicit. With the exception of treating life-threatening sequelae (e.g., marked hypercalcemia, infection, renal failure), all diagnostic procedures to confirm MM should be completed before initiating primary therapy to ensure a diagnosis is confirmed and baseline values are procured for monitoring response. Chemotherapy is effective at reducing malignant cell burden, relieving bone pain, allowing for skeletal healing, and reducing levels of serum immunoglobulins in the majority of dogs with MM, and will greatly extend both the quality and quantity of most patients' lives. MM in dogs is initially a gratifying disease to treat for both the clinician and the companion animal caregiver as durable remissions are the norm, although complete elimination of neoplastic myeloma cells is rarely achieved and eventual relapse is to be expected. Although most cats with MM will also initially respond to chemotherapy, overall response rates and durability of response and overall survival times are generally not as high nor as durable as in the dog; although a more recent compilation of 15 cats had a more favorable response to chemotherapy (see Prognosis section to follow).[769]

Melphalan, an alkylating agent, is the chemotherapeutic of choice for the treatment of multiple myeloma in the dog.[757,761,764] Two different melphalan protocols can be used. A continuous daily dosing regimen has been historically used in the dog with an initial starting dose of 0.1 mg/kg PO, once daily for 10 days, which is then reduced to 0.05 mg/kg PO, once daily continuously. The author prefers a pulse-dose protocol that was recently shown to result in statistically similar (albeit numerically superior) efficacy and with a similar adverse event profile.[761] The pulse-dosing regimen uses melphalan at 7 mg/m^2 PO, daily for 5 consecutive days every 3 weeks. This protocol also has the advantage of requiring the caregiver to administer fewer treatments with less overall exposure to chemotherapy during delivery and in body fluids. This protocol has been used successfully by the author in a small number of cases in which myelosuppression was limiting more traditional continuous low-dose therapy.

The addition of prednisone or prednisolone is thought to increase the efficacy of melphalan therapy. Prednisone is initiated at a dosage of 0.5 mg/kg PO, once daily for 10 days, then reduced to 0.5 mg/kg every other day before discontinuation after 60 days of therapy, although some continue every other day prednisone continuously. Melphalan is continued indefinitely until clinical relapse occurs or myelosuppression necessitates a dose reduction or discontinuation. The vast majority of dogs on melphalan and prednisone combination therapy tolerate the regimen well. The most clinically significant toxicity of melphalan is myelosuppression, in particular a delayed thrombocytopenia which can be slow to recover and in some cases irreversible. CBCs, including platelet counts, should be performed biweekly for 2 months of therapy and monthly thereafter in dogs on continuous protocols and just before pulse-dose when using the alternate protocol. If significant myelosuppression occurs (usually thrombocytopenia or neutropenia), a drug holiday is instituted with reintroduction at a lesser dose after marrow recovery. Alternatively, a different alkylating agent (e.g., cyclophosphamide, lomustine) may be substituted.

Although melphalan and prednisolone therapy can also be used in cats with multiple myeloma, it appears this protocol is more myelosuppressive than in the dog and many clinicians prefer to use a cyclophosphamide (250 mg/m^2 PO or IV every 2–3 weeks) and prednisolone (1 mg/kg PO daily for 2 weeks and then every other day) protocol or a COP protocol (see Section B of this chapter) in this species. Alternatively, some have used cyclophosphamide at a dose of 25 mg/cat twice weekly.[769,771] If using melphalan in the cat, a dosing schedule similar to the dog has been reported; 0.1 mg/kg once daily for 10 to 14 days, then every other day until clinical improvement or leukopenia develop. Long-term continuous maintenance (0.1 mg/kg, once every 7 days) has been advocated.[770] An alternative protocol advocated in the cat uses melphalan at 2 mg/m^2, once every 4 days continuously, and appears to be well tolerated.[771]



Cyclophosphamide has been used as an alternative alkylating agent or in combination with melphalan in dogs and cats with MM.[757,764,769,771] There is no evidence to suggest that it is superior to melphalan in the dog. In the author's practice, cyclophosphamide in dogs with MM is limited to those cases presenting with severe hypercalcemia or with widespread systemic involvement in which a faster acting alkylating agent may more quickly alleviate systemic effects of the disease. Cyclophosphamide is initiated at a dosage of 200 to 250 mg/m^2 IV or PO, once, at the same time oral melphalan is started. Because cyclophosphamide is less likely to affect platelets, it may be substituted in those patients in which thrombocytopenia has developed secondary to long-term melphalan use.

Chlorambucil, another alkylating agent, has been used successfully for the treatment of IgM macroglobulinemia in dogs at a dosage of 0.2 mg/kg PO, once daily.[764,804] Little or no clinical signs of toxicity result from this dosing schedule. Chlorambucil has also been used in cats with MRD.[771]

Lomustine (CCNU), yet another alkylating agent, has been used in a limited number of cats with MM and a partial response has been reported after dosing at 50 mg/m^2 PO, every 21 days.[840]

Evaluation of Response to Therapy

Evaluation of response to systemic therapy for MM is based on improvement in clinical signs, clinicopathologic parameters, radiographic improvement of skeletal lesions, ultrasonographic improvement of organ involvement, and, in some cases, bone marrow reassessment with molecular analysis of clonality.[757,761,762,764,771] Subjective improvement in clinical signs of bone pain, lameness, lethargy, and hyporexia should be evident within 3 to 4 weeks after initiation of therapy. Objective laboratory improvement, including reduction in serum total globulin, M component and calcium, along with normalization of the hemogram, is usually noted within 3 to 6 weeks (Fig. 33.29). Radiographic improvement in osteolytic bone lesions may take months and resolution may only be partial. Ophthalmic complications (including long-standing retinal detachments) and paraneoplastic neuropathies often resolve along with tumor mass.[810,831] In cats responding to chemotherapy, clinical improvement is noted in 2 to 4 weeks and serum protein and radiographic bone abnormalities were greatly improved by 8 weeks.[770,771]

• **Fig. 33.29** Clinicopathologic data changes over time (weeks) after initiation of cytotoxic chemotherapy in three dogs with IgA multiple myeloma. *Light blue area,* Normal reference range. (A) Serum IgA (mg/dL); (B) Total globulins (g/dL). (C) Hematocrit (%). (D) Platelets/dL. (E) Serum calcium (mg/dL). (F) Total white blood cells/dL.

As previously discussed, complete resolution of MM does not generally occur and a good response is defined as a reduction in measured M-component (i.e., immunoglobulin or Bence Jones proteins) of at least 50% of pretreatment values.[764] Reduction in serum immunoglobulin levels may lag behind reductions in Bence Jones proteinuria because the half-lives are 15 to 20 days and 8 to 12 hours, respectively.[841] For routine follow-up, quantification of the increased serum globulin, immunoglobulin, or urine Bence Jones protein is performed monthly until a good response is noted and then every 2 to 3 months thereafter. Repeat bone marrow aspiration or imaging (in the case of visceral disease) for evaluation of plasma cell infiltration may be occasionally necessary. Bone marrow reevaluation is particularly prudent when cytopenias develop during chemotherapy, and drug-induced myelosuppression must be differentiated from myelophthisis due to neoplastic marrow recurrence.

Therapy Directed at Complications of Multiple Myeloma

The long-term control of complications, including hypercalcemia, HVS, bleeding diathesis, renal disease, immunosuppression with infection, ophthalmic complications, and pathologic skeletal fractures, depend on controlling the primary tumor mass. However, therapy directed more specifically at these complications may be indicated in the short term.

If hypercalcemia is marked and significant clinical signs exist, standard therapies, including fluid diuresis, with or without pharmacologic agents (e.g., zoledronate, calcitonin), may be indicated (see Chapter 5). Moderate hypercalcemia will typically begin to

VetBooks.ir

improve within 2 to 3 days after initiation of melphalan/prednisone chemotherapy without the addition of therapies directed at hypercalcemia specifically.

HVS is best treated in the short term by plasmapheresis.[764,808,813,838,844–846] Whole blood is collected from the patient and centrifuged to separate plasma from packed cells. Packed red cells are resuspended in normal saline or another crystalloid and reinfused into the patient. More advanced plasmapheresis methods have also been used in dogs with HVS.[842] Bleeding diathesis will usually resolve along with HVS; however, platelet-rich plasma transfusions may be necessary in the face of thrombocytopenia.

Renal impairment may necessitate aggressive fluid therapy in the short term and maintenance of adequate hydration in the long term. Careful attention to secondary urinary tract infections and appropriate antimicrobial therapy is indicated. Ensuring adequate water intake at home is important, and occasionally, educating owners in subcutaneous fluid administration is indicated. Continued monitoring of renal function is recommended along with follow-up directed at tumor response.

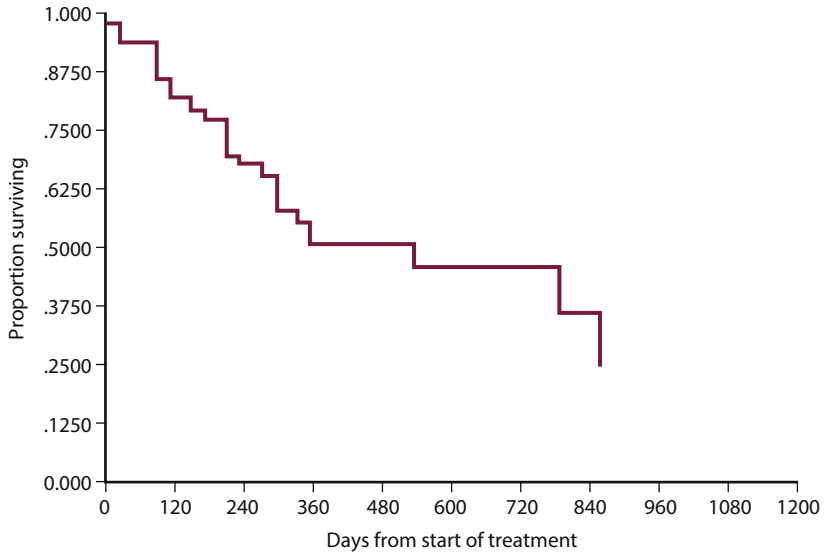
Patients with MM can be thought of as immunologically impaired. Some have recommended prophylactic antibiotic therapy in dogs with MM[764]; however, in humans, no benefit for this approach over diligent monitoring and aggressive antimicrobial management when indicated has been observed.[806] Cidal antimicrobials are preferred over static drugs, and avoidance of nephrotoxic antimicrobials is recommended.

Pathologic fractures of weight-bearing long bones and vertebrae resulting in spinal cord compression may require immediate surgical intervention in conjunction with systemic chemotherapy. Orthopedic stabilization of fractures should be undertaken and may be followed with RT (see Fig. 33.25). Inhibition of osteoclast activity by bisphosphonate drugs (in particular zoledronate), has been shown in several meta-analyses to reduce the incidence and severity of skeletal complications (e.g., bone pain, pathologic fracture) of MM in humans and to result in some prolongation of overall survival.[835,845,846] This class of drugs may hold promise for use in dogs and cats with various skeletal tumors; however, they have not been adequately evaluated for time-to-event efficacy in MRD in companion species.

Rescue Therapy

When MM eventually relapses in dogs and cats undergoing initial melphalan or alternative alkylator therapy or in the uncommon case that is initially resistant to alkylating agents, rescue therapy may be attempted. Switching to an alternate alkylating agent (e.g., cyclophosphamide, lomustine, chlorambucil) may be effective.[761,769] The author has also had limited success with VAD, which is a combination of doxorubicin (30 mg/m^2 IV, every 21 days), vincristine (0.7 mg/m^2 IV, days 8 and 15), and dexamethasone sodium phosphate (1.0 mg/kg IV, once a week on days 1, 8, and 15), given in 21-day cycles. Whereas most dogs initially respond to rescue protocols, the duration of response tends to be short, lasting only a few months. Liposomal doxorubicin has produced a long-term remission in a dog with MM previously resistant to native doxorubicin.[847]

Investigational Therapies



MM is ultimately a uniformly fatal disease in most species and thus significant effort is being placed on investigational therapies for this disease. Currently, bone marrow ablative therapy and marrow or stem cell rescue, thalidomide (and other antiangiogenic therapies), bortezomib (a proteasome inhibitor), arsenic trioxide, bisphosphonates, and several molecular targeting therapies are under investigation; however, their use in veterinary species is limited or completely absent at present. Bortezomib has been shown to have activity against canine melanoma in cell culture and mouse xenograft models.[848] A bortezomib protocol that is well-tolerated in dogs has been used successfully in the treatment of golden retriever muscular dystrophy but has not been, as yet, reported in dogs with MM.[849] One case report exists of a dog with MM that was resistant to melphalan, prednisone, and doxorubicin that subsequently achieved a partial response to tyrosine kinase inhibitor therapy (toceranib) that was maintained for 6 months.[776] Rabacfosadine (Tanovea-CA1) has been used investigationally in dogs with MM, either as induction therapy or for rescue in melphalan-resistant disease and significant efficacy, including durable molecular complete responses, was noted.[762] However, rabacfosadine is currently conditionally approved for use only in dogs with lymphoma.

Prognosis

The prognosis for dogs with MM is good for initial control of tumor and a return to good quality of life.[757,761,762] In a group of 60 dogs with MM, approximately 43% achieved complete remission (i.e., serum immunoglobulins normalized), 49% achieved a partial remission (i.e., immunoglobulins <50% pretreatment values), and only 8% did not respond to melphalan and prednisone chemotherapy.[757] Long-term survival is the norm, with a median survival time of 540 days reported (Fig. 33.30). More recently, in 38 dogs treated with melphalan/prednisone, 86% had objective responses (94% for pulse-dose protocol and 79% for continuous daily protocol) with a median progression-free and overall survival time (MST) of 601 and 930 days, respectively.[761] The 1-, 2-, and 3-year survival rates were 81%, 55%, and 30%, respectively. The presence of hypercalcemia, Bence Jones proteinuria, and extensive bony lysis were found to be negative prognostic factors in the dog in one large cohort,[757] but not in another.[761] Only the presence of renal disease and a high peripheral neutrophil:lymphocyte ratio at diagnosis were negative indices in the latter report.[761] Despite long-term durable responses in treated dogs, MM is generally a uniformly fatal disorder as drug-resistant recurrence of tumor mass and associated clinical signs is expected. Eventually, the tumor is no longer responsive to available chemotherapeutics and death follows from infection, renal failure, or euthanasia for intractable bone or spinal pain.[757,764]

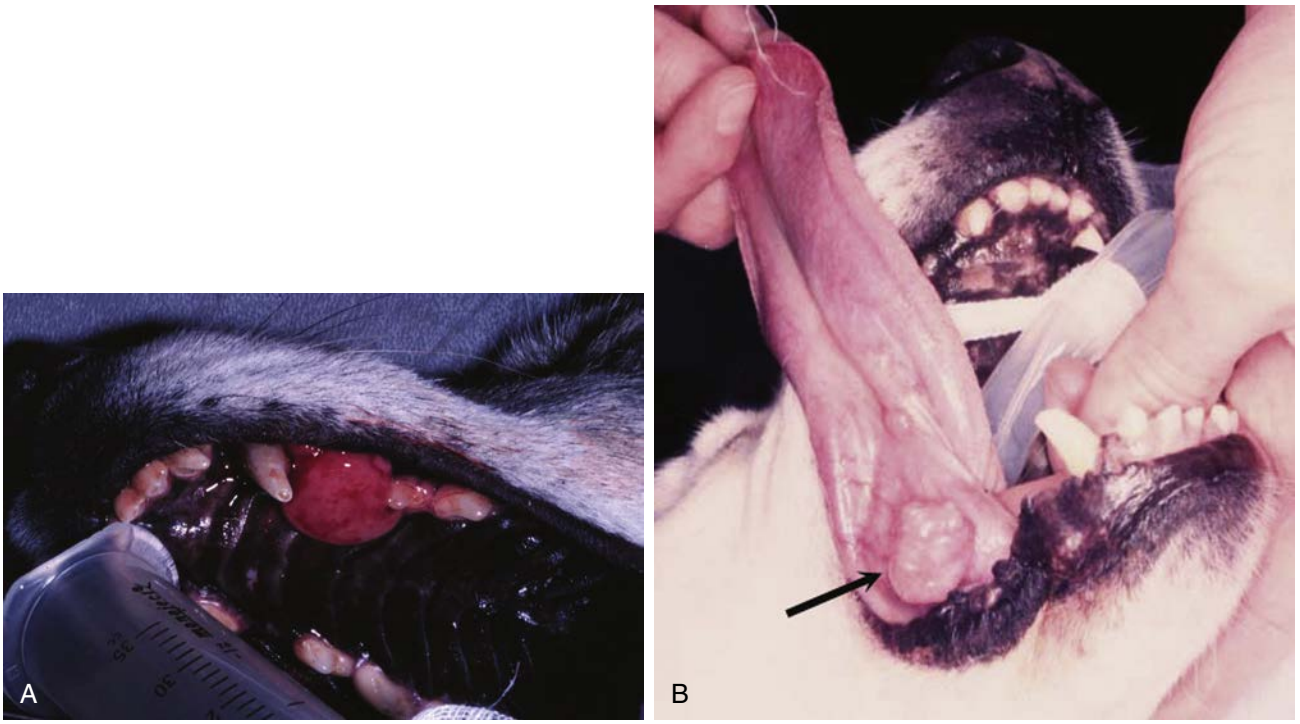
The prognosis for MM in the cat is not as favorable as it is in the dog.[764,767,769–771,788] That being said, approximately 50% to 83% of cats with MM will respond to chemotherapy and although older compilations report MSTs of approximately 4 months, several long-term responses (i.e., >1 year) have been reported and a recent compilation documented MSTs of 8 to 13 months with treatment.[764,767,769–771,788,790,821] One investigator grouped MM in cats into two prognostic categories (Table 33.17) based on criteria known to predict behavior in dogs.[770] Although no rigorous statistical analysis was performed on this small group of nine cats, the MST for cats in "aggressive" and "nonaggressive" categories was 5 days and 387 days, respectively.

Experience in dogs with IgM macroglobulinemia is limited.[764,804–805] Response to chlorambucil is to be expected, and in nine treated dogs, 77% achieved remission with an MST of 11 months.[764]

• **Fig. 33.30** Survival curve of 37 dogs with multiple myeloma treated with chemotherapy. The median survival time (MST) is 540 days. (From Matus RE, Leifer CE, MacEwen EG, et al. Prognostic factors for multiple myeloma in the dog. *J Am Vet Med Assoc*. 1986;188:1288-1292.)

TABLE 33.17 Classification of Multiple Myeloma in Cats Based on Clinical and Diagnostic Criteria Suspected of Predicting Prognosis[770]

Behavior Category	Criteria
Aggressive	Hypercalcemia, presence of bony lesions with pathologic fracture, low packed cell volume (PCV), presence of light-chain Bence Jones protein in urine, azotemia, hypercreatinemia, persistence of high serum protein level after 8 weeks of treatment, little or no clinical improvement
Less aggressive	Normal serum calcium, normal creatinine, blood urea nitrogen, PCV levels, presence of bony lesions without pathologic fractures, absence of light-chain Bence Jones protein, normalization of serum protein level after 8 weeks of treatment.



• **Fig. 33.31** A cutaneous plasmacytoma on the limb of a dog.

Solitary and Extramedullary Plasmacytic Tumors

Solitary collections of monoclonal plasmacytic tumors can originate in soft tissues or bone and are referred to as *extramedullary plasmacytoma* (EMP) and *solitary osseous plasmacytoma* (SOP), respectively. The systemic, multicentric, biologically aggressive EMP syndrome encountered in cats has been discussed in the MM section and will only receive limited discussion in this section.[771,786] A number of large case compilations of cutaneous plasmacytoma have been reported in the dog.[774,783,850–861] The most common locations for EMP in the dog are cutaneous (86%; Fig. 33.31), mucous membranes of the oral cavity and lips (9%; Fig. 33.32), and the gastrointestinal tract (4%). The skin of the limbs and head (including the ears) are the most frequently reported cutaneous sites.[783] Oral plasmacytoma represents 5% of oral tumors, 2% of lingual tumors, and approximately 20% of all EMPs.[853] Other EMP sites uncommonly encountered include spleen, genitalia, eye, uterus, liver, larynx, trachea, third eyelid, sinonasal cavity (one case reported in the cat[862]), and intracranial sites.[863–871] The American cocker spaniel, English cocker spaniel, and West Highland white terrier (and perhaps Yorkshire terriers, boxers, German shepherds, and Airedale terriers) have been reported inconsistently to be at increased risk for developing plasmacytomas and the median age of affected dogs is 9 to 10 years of age.[783,853]

VetBooks.ir

• **Fig. 33.32** Examples of oral solitary plasmacytoma in dogs; one involving the maxilla (A), the other involving the underside of the tongue (B). Both dogs were cured after surgical excision.

Pathology and Natural Behavior of Solitary and Extramedullary Plasmacytic Tumors

Cutaneous and oral EMP in dogs are typically benign tumors that are highly amenable to local therapy.[783,851,853,862,872] There exists, however, an uncommon form of multiple cutaneous plasmacytomas in the absence of MM referred to as *cutaneous plasmacytosis* in dogs that is a biologically aggressive disease with treatment and outcomes more like MM.[850,873,874] Three dogs with multiple oral plasmacytomas have been reported.[871] These were locally aggressive but did not metastasize and these dogs enjoyed long-term survival after surgical excision.

The natural behavior of noncutaneous/nonoral EMP appears to be somewhat more aggressive in the dog. Gastrointestinal EMP have been reported on a number of occasions in the veterinary literature, including the esophagus,[870] stomach,[874–877] and small[877] and large intestine.[876–880] Metastasis to associated lymph nodes is more common in these cases; however, bone marrow involvement and monoclonal gammopathies are less commonly encountered. Colorectal EMPs tend to be of low biologic aggressiveness, and most do not recur after surgical excision.[879] Conversely, the majority of SOPs eventually progress to systemic MM; however, the time course from local tumor development to systemic MM may be many months to years.[797,881] SOPs have been reported in the dog involving the appendicular skeleton, as well as the zygomatic arch, and ribs.[797]

SOPs are less common in cats, and fewer reports exist in the literature.[771,785,882–886] They occur in older cats (mean ages 9–14 years), with no significant sex predilection. The skin is the most common site; however, other sites include the oral cavity, eye, GI tract, liver, subcutaneous tissues, and brain. Reports exist of cutaneous EMP in cats that progressed to systemic MRD.[771,785,886]

History and Clinical Signs of Solitary and Extramedullary Plasmacytic Tumors

Clinical signs associated with EMPs and SOPs relate to the location of involvement, or in those rare cases with high levels of M component, HVS may occur. Most cutaneous plasmacytomas are solitary, smooth, raised pink, variably alopecic nodules from 1 to 2 cm in diameter (see Fig. 33.31), although tumors as large as 10 cm have been reported. Combining large series, greater than 95% occur as solitary masses and less than 1% occur as part of a systemic MM process.[774,98–861,873,874] Cutaneous and oral EMPs usually have a benign course with no related clinical signs.

Cutaneous plasmacytosis, however, is associated with multiple lesions, often with more than 10 and up to hundreds of lesions.[850] Some are ulcerated on presentation, but 81% were asymptomatic at presentation. Gastrointestinal EMPs typically have nonspecific signs which may suggest alimentary involvement. One dog with GI EMP was presented with intussusception.[878] Colorectal plasmacytomas often cause rectal bleeding, hematochezia, tenesmus, and rectal prolapse.[879] One case of ataxia and seizure activity in a dog with EMP secondary to tumor-associated hypoglycemia has been reported.[830] SOP is usually associated with pain and lameness if the appendicular skeleton is affected or neurologic signs if vertebral bodies are involved.

Diagnosis for Solitary and Extramedullary Plasmacytic Tumors

The diagnosis of SOP and EMP usually requires tissue biopsy or needle aspiration cytology for diagnosis. Cells making up solitary plasmacytic tumors in both cats and dogs have been histologically classified into mature, hyaline, cleaved, asynchronous,

VetBooks.ir

monomorphous blastic and polymorphous blastic cell types; however, no prognostic significance has been observed after classification, although it has been suggested that the polymorphous-blastic type may act more aggressively in the dog.[774,852,859,880] A divergent pseudoglandular histologic subtype has been reported in a small number of dogs that may be confused with epithelial neoplasia.[851] Intravascular tumor cells were observed in 16% of cutaneous plasmacytoma samples in one report, but this was not found to correlate with outcome and most were behaviorally benign.[783] A different classification was proposed for EMP in cats based on percentage of plasmablasts, and some prognostic importance has been documented.[786] In the case of poorly differentiated plasmacytic tumors, IHC studies, directed at detecting immunoglobulin, light and heavy chains, MM-1/interferon regulatory factor-4 (MUM1/IRF4), and thioflavin T, may be helpful in differentiation from other round cell tumors.[797,857,859,882,883,887–889] Of note, canine cutaneous histiocytoma (not histiocytic sarcoma) can be immunoreactive for MUM1 and therefore should be considered in any MUM1⁺ differential.[853] Immunoreactivity has been demonstrated for canine IgG $F(ab)_2$ and vimentin.[854] A variant characterized by an IgG-reactive amyloid interspersed with the neoplastic cells has also been described.[861] A panel of monoclonal antibodies (recognizing tryptase, chymase, serotonin, CD1a, CD3, CD79a, CD18, and MHC class II) in association with a histochemical stain (naphthol AS-D chloroacetate) has been advocated for use on formalin-fixed, paraffin-embedded sections of cutaneous round cell tumors to help classify poorly differentiated round cell tumors (mast cell tumors, histiocytomas, lymphomas, and plasmacytomas).[888] In addition, clonality of the immunoglobulin heavy chain variable region gene can be performed in plasmacytomas and myelomas using PCR technology, and this may have some diagnostic utility in difficult cases.[762]

It is important to thoroughly stage dogs and cats with plasmacytomas that are at higher risk for systemic spread if contemplating local or locoregional therapy without systemic therapy. This should include bone marrow aspiration cytology, serum electrophoresis, abdominal ultrasound, and skeletal survey radiographs to ensure the disease is confined to a local site before initiation of therapy. Several, albeit rare, instances of monoclonal gammopathy or plasma cell leukemia have been reported in dogs with cutaneous plasmacytoma, cutaneous plasmacytosis and gastrointestinal EMP.[850,874,890,891] Staging is likely most important in cases of cutaneous plasmacytosis, SOP, and GI EMP due to their relatively high metastatic rate, but is less important for cutaneous, oral, and colorectal plasmacytomas because of their more typical benign behavior. Cutaneous plasmacytosis was associated with lymph node or abdominal viscera involvement in approximately 30% of cases; however, no cases in a large compilation had positive bone marrow aspirates and only one dog had a monoclonal gammopathy.[850] For GI EMP (including colorectal EMP), endoscopic evaluation of the entire GI tract is recommended. A single case report of the use of PET/CT imaging for extramedullary splenic plasmacytoma in a dog exists; however, its utility remains unknown.[892]

Therapy for Solitary and Extramedullary Plasmacytic Tumors

Cutaneous and oral plasma cell tumors in the dog are almost always benign and carry an excellent prognosis after conservative surgical excision.[774,783,853,859,860,879,893] The exception is cutaneous plasmacytosis where excision is not possible due to the number of lesions and the fact that 30% of cases have documented systemic disease.[850] Systemic chemotherapy is therefore indicated for dogs with cutaneous plasmacytosis; approximately three-quarters of 14 cases experienced objective responses to either melphalan or lomustine and median progression-free and overall STs were 153 and 542 days, respectively.[850] EMPs of the trachea, liver, and uterus have also been reported in dogs, and all had a benign course after local resection.[864–866] Successful therapy with melphalan and prednisone has been rarely applied for a local recurrence or incomplete margins in dogs and cats. RT has been used infrequently for cases that are not surgical candidates, including the application of strontium-90 plesiotherapy for lingual plasmacytoma in a dog.[894] Surgery is recommended, in combination with RT, for those cases of SOP in which the lesion results in an unstable, long bone fracture (see Fig. 33.25), or the patient is nonambulatory from neurologic compromise resulting from a vertebral body SOP. In the latter case, spinal cord decompression, mass excision, and possibly spinal stabilization may be necessary.[829] RT can be used alone (i.e., without surgery) in those cases where fractures are stable, as a palliative measure for bone pain, or in the case of vertebral SOP if the patient is ambulatory and stable. Good local control is usually achieved; however, most progress to systemic MM.[797,828,881] SOP of the axial skeleton can be managed by excision or RT alone. There is controversy as to whether systemic chemotherapy should be initiated at the time of local therapy for SOP when systemic involvement is not documented. Systemic spread may not occur for many months to even years beyond primary SOP diagnosis in humans and dogs, and studies in humans reveal no benefit to initiating systemic chemotherapy before progression to systemic disease.[807,828] Two cases of SOP in cats were recently reported; one was treated with external-beam RT and one managed with melphalan chemotherapy and both enjoyed durable remissions of greater than 4 years.[895] Similarly, EMP of the GI tract in humans are treated most commonly by surgical excision and thorough staging of disease. Systemic therapy is not initiated unless systemic involvement is documented. Systemic chemotherapy has been used after gastric EMP in a cat; however, the utility of adjuvant therapy in the species is unknown.[896]

Long-term follow-up of patients with SOP is indicated to recognize both recurrence of disease and systemic spread. Careful attention is given to serum globulin levels, bone pain, and radiographic appearance of bone healing in cases of SOP. Restaging of disease, including bone marrow evaluation, is indicated if systemic spread is suspected.

Prognosis for Solitary and Extramedullary Plasmacytic Tumors

Prognosis for solitary plasma cell tumors is generally good. Cutaneous and mucocutaneous plasmacytomas are usually cured after surgical excision.[774,859,893] In large compilations of cases in dogs, the local recurrence rate was approximately 5%, and nodal or distant metastasis occurred in only 7 of 349 cases (2%).[774,783,98,855,859,860] New cutaneous plasmacytomas at sites distant from the primary developed in fewer than 2% of cases. Neither tumor cell proliferation rate (as measured by Ki67 IHC), intravascular tumor infiltration/emboli in the dog, nor histopathologic grading in dogs and cats were prognostic in large compilations of cases, although it has been suggested that the polymorphous-blastic and plasmablastic type may act more aggressively in the dog and cat.[774,783,786,859] The presence of amyloid and overexpression of cyclin D1 (prognostic in human plasmacytomas) were not shown to be of prognostic value in dogs.[774] Dogs with EMP of the alimentary tract

VetBooks.ir

and other abdominal organs (e.g., liver, uterus) treated by surgical excision alone or in combination with systemic chemotherapy (if metastasis is present) can enjoy long-term survival in the majority of cases.[797,864–866,870,875–877,880] In a compilation of nine dogs with colorectal plasmacytoma, two dogs had local recurrence at 5 and 8 months after surgery, and the overall MST was 15 months after surgery alone.[879] DNA ploidy and Myc oncoprotein expression in biopsy samples were determined to be prognostic for EMPs in dogs; however, those that were malignant were all from noncutaneous sites (i.e., lymph node, colon, spleen). Therefore location appears to be as predictive.[897] As previously discussed, the majority of cases of SOP will eventually develop systemic disease; however, long disease-free periods usually precede the event.

The prognosis in cats is less well-defined because of the paucity of reported cases. If disease is confined to a local site and/or regional nodes, surgical excision and chemotherapy can result in long-term control; however, early, widespread metastasis and progression to MM is also reported in cats.[771,785,857,882,884,885,896]

34 Miscellaneous Tumors

SECTION A: HEMANGIOSARCOMA

CHRISTINE MULLIN AND CRAIG A. CLIFFORD

Incidence and Risk Factors

Hemangiosarcoma (HSA), also known as *malignant hemangioendothelioma* or *angiosarcoma* (AS), is a malignant tumor composed of neoplastic endothelial cells. HSA occurs more frequently in dogs than in any other species[1–4] and represents about 2% of all canine tumors in general and 45% to 51% of canine splenic malignancies.[1–5] HSA is much less common in the cat, occurring in approximately 0.5% of cats examined at necropsy and accounting for 2% of all feline neoplasms in general.[6]

HSA is seen mostly in middle-aged to older animals, although there are rare reports of HSA occurring in dogs less than 3 years of age.[2,3,6,7] Any breed is potentially at risk, but German shepherds, golden retrievers, Labrador retrievers, and other large-breed dogs are overrepresented in several case series.[2,3,6,8,9] There may be a slight male predisposition in dogs.[3,6,10] In cats, older domestic shorthairs are most commonly affected,[11] although there is no clear sex predisposition.

In dogs, cutaneous HSA develops more frequently in the skin along the ventral abdomen and conjunctiva in short-haired and lightly pigmented breeds, reflecting the causal association with ultraviolet light exposure that has also been documented in research beagles.[12–14] Some reports suggest a hormonal association with canine HSA development, specifically with regard to neutering, given the findings that HSA appears more common in spayed females versus intact females and late neutered females versus intact or early neutered females.[2,15,16] The significance of these findings in the general population of client-owned dogs is unclear, because no large and well-controlled studies have been performed to assess the effect of neutering on the risk of dogs developing HSA.

Although traditionally considered to develop from malignant transformation of mature peripheral endothelial cells, recent molecular data suggest that HSA may arise from bone marrow progenitor cells that undergo dysregulated maturation and subsequently move to peripheral vascular sites to form tumors.[17–19] Furthermore, genomic profiling studies have identified distinct molecular subtypes of HSA that suggest a probable heterogeneity within this tumor type.[19–21] Mutations in tumor suppressor genes such as *p53* and *Ras* have been implicated in the pathogenesis of AS in murine and human studies[22–24]; although it appears that *p53* and *Ras* mutations are infrequent in canine HSA,[25,26] *PTEN* inactivation was demonstrated in more than 50% of evaluated canine HSA samples.[27] Key growth- and apoptosis-regulating proteins such as pRB, cyclin D1, Bcl2, and survivin are overexpressed in HSA when compared with hemangiomas or normal tissues.[26,28]

There is growing evidence that dysregulation of angiogenic pathways may be important in the pathogenesis of HSA. Several studies have demonstrated abundant expression of angiogenic markers such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), and angiopoetin-2, with concomitant expression of their corresponding cellular receptors in HSA cells and tissues.[18,29–31] An increased level of VEGF was documented in the plasma of dogs with HSA as compared with healthy controls,[32] whereas serum endothelin-1, a proangiogenic vasoactive peptide, was higher in dogs with splenic HSA as compared with healthy dogs and those with other splenic diseases.[33] These findings suggest the potential role for overstimulation of proangiogenic pathways as a promoter of tumor cell proliferation and survival.

Pathology and Natural Behavior

In the dog, the most common primary site for HSA is the spleen.[1,3,5,6,8,34] Other frequent anatomic sites include the heart, skin and subcutis, and liver.[3,12,15,35–39] Primary HSA has also been reported in the lung, kidney, retroperitoneal space, muscle, bone, oral and nasal cavities, eyelid and conjunctiva, urinary bladder, digit, and mediastinum.[7,40–48] Although HSA is the most common splenic neoplasm encountered in the dog, it is by no means the only differential for splenomegaly or splenic masses in dogs[1,5,10,34] Two large pathologic studies reported that approximately 50% of dogs with splenic tumors had malignant disease and 50% to 74% of these malignancies were HSA,[1,34] whereas other studies evaluating dogs presenting with a nontraumatic hemoabdomen found that 63% to 70% of all dogs had HSA.[49–51] It is important to note that several other splenic masses may have a similar gross and ultrasonographic appearance to HSA, and the differential diagnosis list for a dog with a splenic tumor includes other neoplasms (e.g., lymphoma, nonangiomatous/nonlymphomatous sarcomas) and nonneoplastic etiologies (e.g., nodular hyperplasia, extramedullary hematopoiesis, hematoma).[1,5,34] Interestingly, in one study larger splenic masses and heavier spleens were more likely to be benign.[52]

VetBooks.ir

The heart is the second most common primary site for canine HSA and is the most common cardiac neoplasm in dogs. HSA most commonly originates from the right atrium or auricle; however, other cardiac sites have been reported.[15,35–37] Although previously thought to be a rather frequent occurrence based on necropsy studies, one study showed the presence of concurrent splenic and cardiac HSA to be uncommon (8.7%).[53]

Although typically aggressive, the biologic behavior of HSA can vary depending on primary tumor location, as certain primary HSA sites, specifically the skin, can be associated with a less aggressive disease course.[14] The more common visceral forms are characterized by local infiltration and metastatic dissemination early in the course of disease. Metastasis occurs either hematogenously or via intracavitary implantation after tumor rupture. Metastasis can occur at any site; however, the liver, omentum, peritoneum, and lungs are the most frequent sites of dissemination.[2–4] In dogs, HSA is the most common tumor to metastasize to the brain.[54]

In the cat, cutaneous and visceral (e.g., spleen, liver, intestine) locations are the most commonly reported primary sites for HSA.[11,55–60] Other reported sites in the cat include the heart, thoracic cavity, eyelid or conjunctiva, digit, and nasal cavity.[39,55,61–63] The biologic behavior of feline HSA is not as well described as in dogs, but is likely similar. Feline cutaneous and subcutaneous HSA are associated with the same clinical problems as other soft tissue sarcomas, specifically local invasiveness and postoperative tumor recurrence.[11,56,58] As in dogs, feline visceral HSA has a high metastatic rate, with the most common metastatic sites being the liver, omentum, and lungs.[15,55,59]

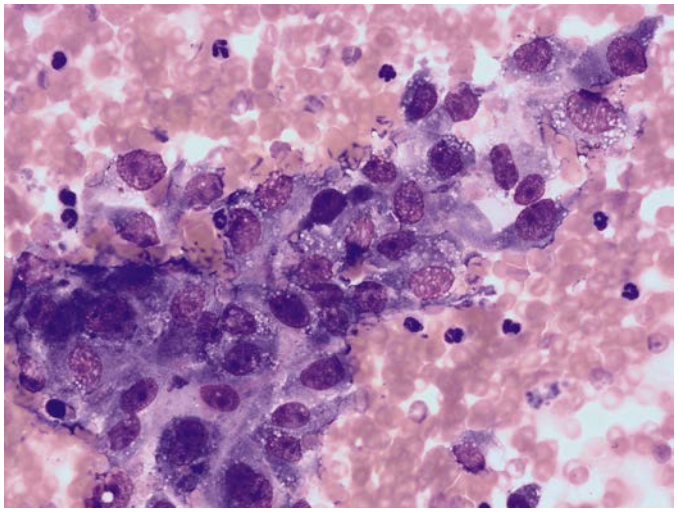
Grossly, HSA lesions may be of variable size, pale gray to dark red or purple, soft to gelatinous and friable, and typically contain blood-filled or necrotic areas that can ooze or overtly bleed (Fig. 34.1). Histologically, HSA is composed of markedly pleomorphic and mitotically active spindloid endothelial cells that form irregular anastomosing vascular spaces and channels that contain variable amounts of blood and/or thrombi.[1–,3,5,6,10,12,13,34,36,38] Immunohistochemistry for von Willebrand's factor (factor VIII–related antigen) or CD31/platelet endothelial cell-adhesion molecule can be used to demonstrate endothelial derivation and support the diagnosis of HSA and rule out other sarcomas.[10,56,64,65]

History and Clinical Signs

Historical findings are largely dictated by tumor location and may vary from vague, nonspecific signs of illness to acute collapse and death secondary to hemorrhagic shock. The majority of patients with visceral HSA will present in an emergent scenario secondary to tumor rupture and subsequent internal hemorrhage. Associated clinical signs include acute lethargy, weakness, and collapse secondary to blood loss. Other common historical findings include weight loss, hyporexia, abdominal distension, vomiting, exercise intolerance, and dyspnea.[37,49–51] Dogs with renal HSA may have a history of hematuria.[40] Possible physical examination findings in the emergency setting include tachycardia with poor pulse quality, pale mucous membranes, and palpable abdominal fluid wave or abdominal mass effect.[49–51] Patients with cardiac tamponade secondary to rupture of a right atrial HSA are typically critical on presentation and may have muffled heart sounds, pulsus paradoxus, ascites (secondary to right heart failure from tamponade), or circulatory collapse.[36,37] HSA presentations involving the skin or subcutis differ in that they are generally not seen on an emergent basis and further vary based on whether the lesion is primarily dermal, subcutaneous, or intramuscular. Tumors may range from small, discrete, blood blisterlike lesions to much larger, deeply seated, painful, bruised and/or bleeding masses.[12–14,38,66–68]

• **Fig. 34.1** Postoperative image of splenic hemangiosarcoma from a dog, illustrating the multilobulated and friable nature of this tumor. (Photo courtesy Julius Liptak, BVSc, MVetClinStud, FACVSc, DACVS, DECVS, Alta Vista Animal Hospital, Ottawa, Canada.)

In the cat, clinical signs depend on location and extent of the tumor. Cats with visceral HSA usually have a history of lethargy, anorexia, vomiting, collapse, dyspnea, or distended abdomen.[11,55,57,59,69] On physical examination, pallor, pleural or peritoneal fluid, and a palpable abdominal mass may be detected. Feline cutaneous and subcutaneous HSAs appear clinically similar to those seen in dogs.[11,55–58]



Diagnostic Techniques and Workup

Complete staging for a confirmed or suspected HSA patient typically includes hematology and serum biochemistry profile, coagulation profile, three-view thoracic radiographs, abdominal ultrasound, and in some cases, echocardiography. In both dogs and cats, regenerative and nonregenerative anemias are common and typically characterized by the presence of schistocytes, acanthocytes, and nucleated red blood cells, which are associated with microangiopathic-related damage, vasculitis, and acute hemorrhage.[70–73] Blood typing and/or cross matching may be indicated if surgery is planned in a severely anemic patient. Neutrophilic leukocytosis is common and may be secondary to a paraneoplastic syndrome or tumor necrosis. Thrombocytopenia, likely secondary to acute hemorrhage, intratumoral destruction, and coagulopathic consumption, is also quite common and observed in 75% to 97% of cases.[37,72,73] Alterations in secondary coagulation parameters (prothrombin time [PT], partial thromboplastin time [PTT], fibrin degradation product [FDP], fibrinogen, d-dimers), consistent with disseminated intravascular coagulation, are present in nearly 50% of patients with visceral HSA.[72,73] Serum biochemistry changes are typically nonspecific and may include hypoalbuminemia, azotemia, and elevations in liver enzymes.[37] In one study, more than 50% of cats with visceral HSA had increased aspartate transaminase activity.[69]

A clinical staging system for HSA is presented in Table 34.1. Because most patients present with primary visceral disease, abdominal ultrasound is frequently employed as part of the initial

TABLE 34.1 Clinical Staging System for Canine Hemangiosarcoma

Primary Tumor (T)	
T0	No evidence of tumor
T1	Tumor less than 5 cm diameter and confined to primary tissues
T2	Tumor 5 cm or greater or ruptured, invading subcutaneous tissues
T3	Tumor invading adjacent structures, including muscle
Regional Lymph Nodes (N)	
N0	No regional lymph node involvement
N1	Regional lymph node involvement
N2	Distant lymph node involvement
Distant Metastasis (M)	
M0	No evidence of distant metastasis
M1	Distant metastasis
Stages	
I	T0 or T1, N0, M0
II	T1 or T2, N0 or N1, M0
III	T2 or T3, N0, N1 or N2, M1

• **Fig. 34.2** Lung mass aspirate from an 11-year-old Catahoula leopard hound with multiple masses throughout the liver and lungs. investigation. Ultrasonographically, lesions typically have a heterogeneous appearance ranging from hypoechoic to targetoid to mixed echogenicity with areas of cavitation, often accompanied by a peritoneal effusion.[74,75] Although preliminary data suggest that the more advanced technique of contrast harmonic ultrasonography may hold promise in identifying HSA and differentiating it from benign etiologies, it is still not a widely used technique in clinical practice.[76,77] Three-view thoracic radiographs are essential as part of routine screening for pulmonary metastatic disease. The radiographic appearance of HSA varies but is often described as a nodular to interstitial coalescing miliary pattern. One study reported a sensitivity of 78% for detecting metastatic pulmonary HSA with radiography and that the false-negative rate was significantly decreased when three views (vs. one or two) were obtained.[78] In dogs with pericardial effusion secondary to cardiac HSA, radiographs will typically reveal a globoid cardiac silhouette, with or without distension of the caudal vena cava.[79]

For dogs with cardiac HSA, echocardiography is the main modality for identifying the primary tumor, and the presence of pericardial effusion tends to improve the detection of such masses.[80] Echocardiography can also be used to assess cardiac function before doxorubicin (DOX) chemotherapy in breeds at risk for dilated cardiomyopathy.[81] For dogs with cardiac HSA that has ruptured, electrocardiographic (ECG) signs consistent with pericardial effusion (decreased amplitude QRS complex and electrical alternans) may be noted during cardiac evaluation. In addition, ventricular arrhythmias are common in dogs with splenic and cardiac HSA.[35,82]

Advanced imaging modalities including computed tomography (CT) and magnetic resonance imaging (MRI) can be used for all forms of HSA, and their integration into routine metastasis screening, surgical planning, and serial restaging may improve prognostication and patient selection for therapy. Specifically, CT and MRI may aid in defining the anatomic origin and extent of disease for surgical and radiation therapy (RT) planning,[83] in discriminating between benign and malignant splenic and hepatic lesions, and in early detection of pulmonary metastasis.[84–86]

Recently, there has been interest in the assessment of biomarkers for cancer screening and diagnosis, particularly with respect to HSA. Plasma cardiac troponin I, a highly specific and sensitive marker for myocardiocyte damage, was shown to be significantly elevated in dogs with cardiac HSA versus dogs with HSA at other sites, dogs with other neoplasms, and dogs with non-HSA pericardial effusions.[87,88] In addition, plasma concentrations of VEGF and urine concentrations of bFGF were shown to be elevated in dogs with HSA versus normal controls[32,89]; however, neither was found to correlate with remission status, disease stage, or outcome. Thymidine kinase, a marker of DNA synthesis expressed only in proliferating cells, was significantly higher in the serum of dogs with HSA compared with that of healthy dogs.[90] Another biomarker, serum collagen XXVII, whose peptide components are associated with invasion and angiogenesis, was significantly higher in dogs with large HSA metastatic burdens compared with healthy dogs and interestingly, reductions in collagen XXVII peptide levels were noted after surgical resection of HSA lesions.[91] Conversely, these levels became elevated again on tumor recurrence, thus showing potential utility for this peptide as a serial biomarker for HSA.[91]

Ultimately, a definitive diagnosis of HSA usually requires histopathology. Fine-needle aspirate (FNA) cytology of suspected HSA lesions is often of low diagnostic yield due to hemodilution.[92] Similarly, cytology of HSA-associated effusions is rarely diagnostic; although tumor cells are likely present, they are heavily diluted with peripheral blood. In the infrequent scenario in which cytology is diagnostic, samples typically consist of large, pleomorphic spindle cells that display multiple criteria of malignancy (Fig. 34.2).

Treatment

Surgery

Surgery remains the primary method of treatment for almost all dogs and cats with localized, nonmetastatic HSA. For cutaneous or subcutaneous HSA, surgical considerations are similar to those for malignant skin tumors and soft-tissue sarcomas (see Chapter 22). Dermal HSA is typically discrete, and surgical margins of 1 to 2 cm and a fascial plane deep are often adequate. For some subcutaneous and almost all intramuscular HSA, the tumor will be very locally invasive and may have associated edema and bleeding. Wide margins can be difficult to achieve and amputation may be required if the tumor is located on a limb.

For splenic HSA, splenectomy is indicated and can be performed with sutures, staples, or electrothermal vessel sealant devices. At the time of splenectomy, the abdomen should be thoroughly explored and any suspicious lesions in the liver and/or omentum (Fig. 34.3) should be excised and submitted for histopathology. A recent study showed that although hepatic lesions that were multiple and/or dark red or black were more likely to be HSA, only 50% of grossly abnormal livers were confirmed to contain HSA metastasis. Furthermore, almost 60% of histologically benign lesions were obtained from grossly abnormal livers.[93] For solitary hepatic and renal HSA, liver lobectomy and nephrectomy are indicated, respectively.

Surgical tumor removal is rarely performed for primary cardiac HSA; however, right atrial appendage masses can be resected with a stapling device or hand suturing via thoracotomy or thoracoscopy.[35,94,95] A small number of case reports and series describe reconstructive procedures with pericardial patch grafts where extensive tumor resection was performed.[96,97] Aside from tumor removal, an open or thoracoscopic pericardiectomy can be performed as a palliative procedure.[98]

Chemotherapy

Given the very high metastatic rate of canine HSA, adjuvant chemotherapy is indicated in essentially all cases, with the exception of most purely dermal HSAs. The literature suggests that DOX, which has been evaluated in both the adjuvant and neoadjuvant settings, is the most active agent against HSA. Protocols reported include single-agent DOX and DOX-containing combination protocols such as DOX and cyclophosphamide (CYC) (AC); DOX and minocycline; vincristine, DOX, and CYC (VAC); vincristine, DOX, and methotrexate; dacarbazine, DOX, and vincristine (DAV); DOX and ifosfamide; DOX and dacarbazine; and DOX and deracoxib.[3,99–107] Other chemotherapy agents with apparent single agent activity against HSA include ifosfamide, liposome-encapsulated DOX (Doxil, Caelyx), which has been evaluated both as an intravenous and intraperitoneal treatment, and epirubicin, which is a noncardiotoxic stereoisomer of DOX.[108–111]

Owing to the vascular nature of the disease, therapy directed against angiogenesis is a logical avenue of exploration. There has been growing interest in the use of metronomic chemotherapy (low-dose chemotherapy with or without nonsteroidal antiinflammatory drugs and other potentially antiangiogenic agents) in HSA patients.[112] One study reported a similar outcome for dogs with stage II splenic HSA treated with a combination of splenectomy, piroxicam, and metronomic chemotherapy (alternating courses of CYC and etoposide) compared with that of dogs receiving conventional DOX-based chemotherapy.[113] Two subsequent studies assessing metronomic chemotherapy and DOX in canine HSA produced divergent results. In the first study, slightly more than half the dogs received DOX alone and the rest received DOX followed by metronomic chemotherapy with CYC and thalidomide. The median time to metastasis and median survival time (MST) were significantly longer for dogs receiving DOX plus metronomic therapy.[114] In the other study, dogs were treated with splenectomy and DOX with or without subsequent metronomic CYC and there was no significant difference in outcome noted in the group receiving metronomic therapy.[115] It is worth pointing out that in the latter study, several dogs had stage III disease and there were a number of patients with macroscopic HSA remaining after surgery, whereas dogs with measurable metastasis were not included in the first study. Furthermore, a third study documented significantly improved outcomes in dogs receiving adjuvant single-agent thalidomide postsplenectomy, suggesting that the discrepant survival benefit noted between the two previously mentioned studies may be due to the inclusion of thalidomide along with CYC.[116] Lomustine and chlorambucil have also been evaluated in the metronomic setting for dogs with HSA, but patient numbers were too small and presentations too variable to derive a meaningful interpretation of the associated outcomes.[117,118]

In cats, similar DOX-based protocols may be employed for patients considered to be at high risk of metastasis or for those with advanced disease,[11,58,59] although systematic evaluations are lacking. Metronomic chemotherapy may also be considered for cats with HSA, although agent dosing and scheduling are empiric. Some antitumor activity of carboplatin has been reported in feline HSA.[119]

Immunotherapy

Very few studies have been conducted to evaluate biologic therapy for HSA. One early study evaluating the postoperative use of a mixed killed bacterial vaccine with DOX chemotherapy and reported some improvement in survival time in dogs with splenic HSA as compared with that seen with splenectomy alone.[3] Another study evaluated the combination of an allogeneic tumor cell lysate vaccine and DOX for various forms of canine HSA and showed

VetBooks.ir

that although dogs mounted an HSA-specific immunity, there was no significant improvement in survival.[120] Dogs receiving adjuvant AC chemotherapy combined with liposome-encapsulated muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE), an immunomodulator derived from mycobacterial cell walls that increases monocyte tumoricidal activity, had a significantly better MST (9.1 months) than dogs receiving AC alone (5.7 months).[121] Although approved for the treatment of osteosarcoma in humans in the European Union, L-MTP-PE is not commercially available in the United States and thus no further formal investigations have been performed.

Radiation Therapy

RT is uncommonly used for HSA because of the predilection for this tumor in visceral sites as well as the high metastatic rate. One study evaluating hypofractionated (palliative) RT for nonsplenic HSA reported a high response rate, but no significant effect on overall survival.[122] Hypofractionated RT has been evaluated for dogs with cardiac HSA and in a pilot study appeared to reduce the frequency of cardiac tamponade, leading to an MST of 2.5 months.[123]

Targeted Therapies

Given the marginal improvement in survival achieved with conventional therapy for dogs with visceral HSA, the potential application of more targeted therapies is certainly warranted. Expression of receptor tyrosine kinase family members including PDGF receptor (PDGFR), VEGF receptor (VEGFR), and stem cell factor receptor (KIT), among others, has been documented in canine HSA.[29–31] Although in vitro assessments of targeted small molecule inhibitors such as masitinib (inhibitor of PDGF and KIT), imatinib (inhibitor of KIT and PDGFR), and dasatinib (inhibitor of KIT, PDGFR, and SRC) have demonstrated growth inhibition and induction of apoptosis in canine HSA cell lines, the drug concentrations required for this effect in vivo may be difficult to achieve without significant toxicity.[30,124] Toceranib phosphate (TOC, Palladia), which blocks signaling of KIT, PDGFR, and VEGFR family members, has demonstrated in vivo activity against multiple tumor types.[125] Although there is some interest in the use of toceranib phosphate for HSA given the high expression of VEGF and VEGFR, the administration of TOC in dogs with stage I or II HSA after splenectomy and DOX therapy resulted in no apparent improvement in median disease-free interval or MST.[126] eBAT, a bispecific epidermal growth factor (EGF)-urokinase angiotoxin, was evaluated in a small group of dogs before standard DOX chemotherapy, leading to an MST of 8.5 months and a 6-month survival rate of 70.6%, both of which were significantly improved compared with a historical control group receiving DOX only.[127]

Alternative Therapies

Yunnan Baiyao (YB), a Chinese herbal medicine that has long been used for its antiinflammatory, hemostatic, pro-wound healing, and analgesic properties in people, has also been anecdotally used to control bleeding in dogs with both nonmalignant and malignant conditions, including HSA. In a preliminary in vitro study, YB led to dose- and time-dependent cell death via caspase-mediated apoptosis in three canine HSA cell lines[128]; however, two laboratory studies demonstrated no modulation of coagulation parameters in normal dogs receiving oral YB[129,130] and a recent retrospective study evaluating a combination of YB and epsilon-aminocaproic acid in dogs with presumed cardiac HSA suggested no benefit in terms of time to recurrence of hemopericardium or overall survival time.[131] Polysaccharopeptide (PSP), the bioactive agent from the mushroom *Coriolus versicolor*, was recently evaluated in a small pilot study in dogs with splenic HSA. A modest numerical improvement in MST was noted in the high dose cohort (n = 5) in comparison to historical controls receiving DOX-based therapy, although a true positive effect of PSP on time to metastasis and overall survival was not clearly evident based on statistical analysis.[132]

Prognosis

Canine

The prognosis for canine HSA is highly dependent on tumor location, stage of disease, and therapy pursued. A summary of the results of several reports on the treatment of splenic HSA is presented in Table 34.2. Overall, the prognosis for dogs with splenic HSA treated with surgery alone is extremely poor, with MSTs ranging from 19 to 86 days, largely due to the high metastatic rate.[1–3,5] Therefore the generally accepted treatment approach for splenic HSA includes DOX-based chemotherapy after surgery. Even with the addition of chemotherapy, MSTs increase only to 5 to 7 months[99–103,107] and the 12-month survival percentage remains 10% or less. Stage plays a role in prognosis, where stage I (nonruptured, nonmetastatic) splenic HSA may have a more favorable outcome (MST 239–355 days) than stage II (ruptured) splenic HSA (MST 120–148 days) when postoperative chemotherapy is used.[107,121] One study incorporated a histologic grading scheme into survival analysis and demonstrated that dogs with low-grade tumors had a better prognosis than dogs with intermediate- or high-grade tumors.[99] Primary renal HSA may be associated with a more favorable outcome than other visceral HSA, with an MST of 9 months in one small study.[40] Conversely, retroperitoneal HSA typically carries a poorer prognosis, with a reported MST of 37.5 days.[41] For true cutaneous HSA, which includes superficial tumors involving the dermis only, surgical removal can often be curative and MSTs of 780 to 987 days have been reported for dogs treated with surgery alone.[14,38] In one study, dogs undergoing surgical removal of dermal HSA were noted to have increased overall survival (MST 1570 days), particularly dogs with ventral tumor location (MST 1085 days), and those with evidence of solar-induced changes on histopathology (MST 1549 days).[14] Conversely, dogs whose cutaneous tumors displayed subcutaneous invasion had a higher chance of developing metastasis (relative risk 2.04) and a subsequently poorer longterm survival (MST 539 days).[14] HSAs originating in the subcutaneous and intramuscular tissues are typically more aggressive than dermal HSA, with higher metastatic rates and shorter MSTs.[6,38,66,68] Therefore adjuvant chemotherapy is typically part of recommended therapy for dogs with subcutaneous and intramuscular HSA.[66,68] Two studies reported divergent results, where one study reported an MST of more than 3 years for dogs receiving adjuvant DOX after surgical removal of subcutaneous HSA, and 9 months for dogs undergoing the same treatment for intramuscular HSA.[66] The other study reported an overall MST of 8 months for dogs with nonmetastatic subcutaneous or intramuscular HSA treated similarly.[68] For dogs with apparently inoperable subcutaneous or intramuscular tumors, DOX-based chemotherapy may offer some palliation and, in one study, some

TABLE 34.2 Outcomes for Dogs Treated for Splenic Hemangiosarcoma

tumors responded sufficiently to allow for complete resection.[67] Traditionally, the prognosis for cardiac HSA is considered poor. Without treatment, most dogs succumb to the disease within 2 weeks.[37] In the rare case where surgical removal of cardiac HSA is possible, survival times generally range from 1 to 3 months.[25,94,95] In a small group of dogs receiving adjuvant chemotherapy after surgical tumor removal, an increased MST (175 days) was reported.[94] Although pericardiectomy (via thoracotomy or thoracoscopy) can be considered as a palliative measure, it does not appear to improve survival by itself, with reported MSTs of 2.7 to 4 months.[98] Chemotherapy appears to offer some benefit, as a retrospective study evaluating the use of DOX chemotherapy for dogs with presumptive cardiac HSA documented a 41% objective response rate and MST of almost 4 months.[37] There is also some evidence to suggest that systemic therapy may offer some benefit to patients with other forms of advanced and inoperable HSA. One study evaluating the combination of DOX and deracoxib reported an MST of 149 days for dogs with stage III splenic HSA, which was similar to the MST of 150 days for dogs of all stages combined.[107] Dogs with advanced stage HSA treated with a DAV protocol had a response rate of 47% and median time to progression of 101 days.[104] Similarly, dogs with stage III HSA treated with a VAC protocol had an MST (195 days) that was similar to that of dogs receiving the same treatment for stage I/II disease (MST 189 days).[133]

Feline

In cats, the prognosis for visceral HSA is poor. Most cats die from recurrence of the primary tumor or metastasis, and MSTs are generally short (77–197 days), owing to metastasis.[59,134] On the other hand, cats with cutaneous and subcutaneous HSAs that are treated with aggressive surgery have reported MSTs of approximately 9 months to 4 years.[11,58] Similar to those in dogs, feline HSAs with subcutaneous involvement are associated with higher rates of incomplete excision (50%–94%) and local recurrence (50%–80%).[11,55,56,58]

Conclusion

In summary, HSA remains one of the most aggressive cancers in dogs and cats and the longterm prognosis for most forms is generally poor. Surgery still offers the best approach to treat HSA even though it is typically only palliative; standard DOX-based chemotherapy has led to incremental improvement in prognosis. New approaches to treatment using combinations of surgery, conventional chemotherapy, metronomic and antiangiogenic therapy, immunotherapy, and targeted agents are needed to improve the outlook for this disease.

Comparative Aspects

In humans, a spectrum of endothelial tumors, including hemangioma, hemangioblastoma, Kaposi's sarcoma, hemangioendothelioma, and AS, is seen. AS is extremely rare in humans and can be a late sequela to RT in women treated for breast cancer.[135] With this exception, it has a lesion distribution and behavior similar to canine HSA. As in dogs, metastasis is frequent and adjuvant chemotherapy provides minimal benefit.

SECTION B: THYMOMA

CARLOS H. DE MELLO SOUZA

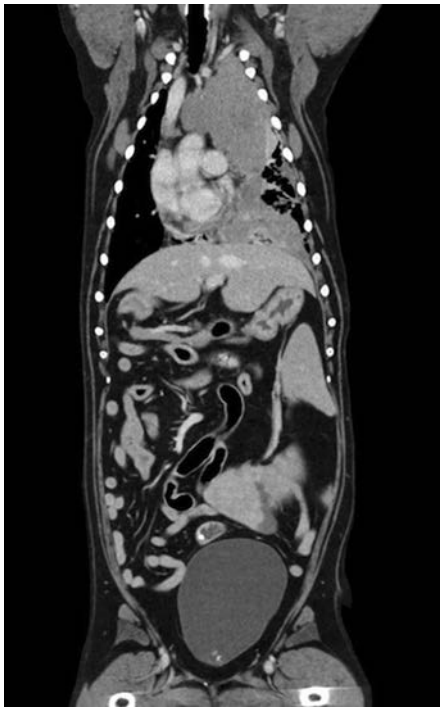
Incidence and Risk Factors

Thymoma is an uncommon cranial mediastinal tumor in dogs and cats, but is the second most common cranial mediastinal tumor in both species. Thymomas can occur at any age, but they usually affect older patients. The mean age at presentation in dogs and cats is 9 and 10 years, respectively.[136,137] A breed predisposition has not been clearly identified, but in a recent retrospective multiinstitutional study, 38% of 116 dogs with thymoma were Labrador retrievers and golden retrievers.[138] A sex predisposition has not been identified.[136–138] Risk factors predisposing animals to thymoma have not been identified.

VetBooks.ir

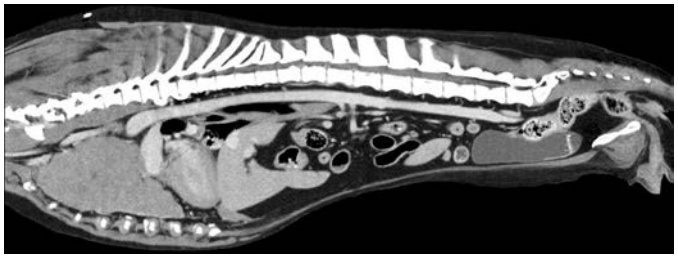
Pathology and Natural Behavior

Thymomas are neoplasms of thymic epithelial cells, but they commonly include other cell populations such as mast cells and mature lymphocytes.[136,139–141] Different histologic types of thymoma have been described, including epithelial, lymphocyte-rich, and clear cell. In cats, cystic thymomas seem to be the most common form, but squamous cell carcinomas and thymolipoma have also been reported.[136,140–144] Thymomas are carcinomas and thus should be considered malignant tumors. The terms benign or malignant thymoma are commonly used and are based on clinical evidence of invasiveness rather than on histologic features of malignancy. Metastasis is rare in both species, [141,145–147] but reported metastatic rate has been as high as 20% in cats with cystic thymomas.[142] The differential diagnoses for mediastinal masses include lymphoma, ectopic thyroid tumor, branchial cysts, and, rarely, sarcomas and metastatic neoplasms. It is important to note that tumors extending from the ribs or sternum into the cranial mediastinum may sometimes resemble a mediastinal mass.[148]



History and Clinical Signs

Clinical signs related to organ displacement due to the presence of a mediastinal mass include lethargy, regurgitation, vomiting, anorexia, weight loss, coughing, tachypnea, and dyspnea. Less commonly, cranial vena cava (CVC) syndrome (edema of the head, neck, and thoracic limbs) may occur and is caused by obstruction of CVC draining the cranial part of the body.[138–143,146–148] Paraneoplastic syndromes are common in dogs and cats and may occur in as many as 67% of dogs with thymoma.[139,140] Reported paraneoplastic syndromes include myasthenia gravis (MG), exfoliative dermatitis, erythema multiforme, hypercalcemia, T-cell lymphocytosis, anemia, myocarditis, and polymyositis. MG and megaesophagus in dogs and exfoliative dermatitis in cats are the most commonly described paraneoplastic syndromes. MG may occur in up to 40% of dogs with thymoma and has also been reported in cats.[138,139,146,147] Concurrent megaesophagus and aspiration pneumonia have been reported in as many as 40% of dogs with thymoma.[139] Paraneoplastic syndromes may occur at presentation, later in the course of the disease, or after tumor removal.[139,141,146,147,149–157] In addition to paraneoplastic syndromes, up to 27% of dogs will have a concurrent second tumor.[138]



Diagnostic Techniques and Workup

Physical examination findings may include edema of the head, cervical area, and/or thoracic limbs secondary to CVC syndrome. The jugular veins may be dilated and tortuous. Auscultation of the thoracic cavity may reveal decreased or absent lung sounds in the cranial thorax because of lung displacement by the mass or pleural effusion. Cardiac displacement may also occur and the heart sounds may be heard either more dorsally, caudally, or both. In small dogs and cats, decreased compressibility of the cranial thorax may also be detected.[138–141,145–146,157]

Complete blood count is often normal, but anemia and thrombocytopenia (secondary to immune-mediated destruction), neutrophilia, and lymphocytosis may occur.[138] Hypercalcemia has been reported in 34% of 116 dogs with thymomas, but is also relatively common finding in cats and dogs with mediastinal lymphoma.[138,141,147,158] Thus the presence of hypercalcemia in an animal with a mediastinal mass cannot be used as the sole means to differentiate thymoma from lymphoma. In both species, hypercalcemia is the result of excessive production of parathyroid hormone–related peptide (PTHrp).[158–162]

• **Fig. 34.4** Computed tomography of a dog with thymoma (dorsal view). A large cranial mediastinal mass that extends to most of the left side of the chest is depicted.

• **Fig. 34.5** Computed tomography of the same patient (sagittal view). The large cranial mediastinal mass compresses the cranial vena cava dorsally and the heart caudally.

Thoracic radiographs may reveal a cranial mediastinal mass, pleural effusion, and/or displacement of the cardiac silhouette (Figs. 34.4 and 34.5). In cats and dogs with MG, megaesophagus and an increase in alveolar or interstitial lung pattern suggestive of aspiration pneumonia may also be detected. In cases with pleural effusion, cytologic analysis of the pleural fluid usually reveals a modified transudate with numerous small mature lymphocytes or a mixed lymphocyte population.[139–141,146,159] Thoracic ultrasonography is useful in the diagnosis and workup of cats and dogs with a cranial mediastinal mass. Cranial mediastinal masses with a cystic appearance and heterogeneous echogenicity were significantly more likely to be thymomas than lymphomas in one study.[163] In addition, ultrasound can be used for guided aspirates or needle-core biopsies of cranial mediastinal masses.[164,165] Endoscopic thoracic ultrasound has been described in dogs, and the reported advantage of this modality is a decrease in artifacts caused by the lungs.[166]

VetBooks.ir

The cytologic diagnosis of thymoma is confirmed with the presence of neoplastic epithelial cells. These are often accompanied by mast cells and variable numbers of small mature lymphocytes.[141,166,167] Unfortunately, nondiagnostic samples are common because of a small percentage of neoplastic epithelial cells resulting in the presence of only small mature lymphocytes or because of the presence of cysts within the mass. In one study, neoplastic epithelial cells were cytologically evident in only 61% of cases.[3] The diagnosis is further complicated because of the fact that both lymphoma and thymoma may be composed mainly of small lymphocytes. In three studies, a presumptive diagnosis of thymoma was made in approximately 20%, 40%, and 77% of mediastinal masses after FNA cytology. A unique feature of thymoma, Hassal's corpuscles, are cytoplasmic structures present in thymocytes that can be used to aid on cytologic diagnosis. Unfortunately, these corpuscles are not usually visualized in Wright's Giemsa preparations in comparison to hematoxylin–eosin used for formalin-fixed samples.[139,146,167,168]

Flow cytometry may be used to aid in the specific diagnosis of mediastinal tumors. Using flow cytometry, thymic lymphocytes can be differentiated from peripheral lymphocytes by their simultaneous expression of CD4 and CD8. In one study, all cases of thymoma included 10% or more of lymphocytes coexpressing CD4 and CD8, whereas six of seven lymphomas contained fewer than 2% of $CD4^+CD8^+$ lymphocytes. The one case of lymphoma expressing more than 2% of $CD4^+CD8^+$ lymphocytes was readily differentiated from thymomas by flow cytometric scatterplot analysis.[169]

CT is recommended to determine the extent of disease, whether the thymoma is invasive or noninvasive, and to help the surgeon evaluate the feasibility of resection. The definition of surgical resectability will depend on the experience and ability of the surgeon. Vascular invasion, although more challenging, does not necessarily preclude surgery as a treatment option. Tumor thrombi have been successfully removed from within the CVC,[138] and the CVC has been reconstructed with a jugular vein autograft after excision of an invasive thymoma in a dog.[170] If the tumor is deemed inoperable, CT will still be crucial for planning RT. Furthermore, CT-guided biopsies can be obtained during the process. Despite these advantages, nonangiographic CT has been shown to have limitations, including significantly underestimating vascular invasion when compared with surgical exploration. These limitations can be potentially overcome by the use of CT angiography.[171–174]

Therapy

A variety of different modalities have been described for the treatment of thymomas in dogs and cats, including surgery, RT, chemotherapy, and multimodality treatments. Unfortunately, there are no available studies comparing the survival times (STs) of animals treated by these different modalities. In addition, in many studies, animals were treated with a combination of different methods.[139–142,146,150,157,173] In a retrospective study of 11 dogs and 9 cats with invasive and noninvasive thymomas treated with surgery alone, the MST was 790 days and 1825 days for dogs and cats, respectively. One- and 3-year survival rates were 64% and 42% and 89% and 74% for dogs and cats, respectively.[139] In another study, the MST for dogs treated surgically was 635 days, which was significantly better than the MST for dogs not treated surgically (76 days).[138] The successful resection of noninvasive thymomas in dogs by video-assisted thoracoscopy has also been reported.[175]

Two retrospective studies have evaluated RT for the treatment of thymomas. Seventeen dogs and seven cats with thymoma were treated with RT alone or as adjunctive therapy. Twenty cases were available for followup with a 75% response rate (11 partial responses and 4 complete responses). The MSTs for dogs and cats were 248 days and 720 days, respectively. In this study, the total radiation dose (15–54 Gy) and treatment interval (from daily to once weekly) varied markedly and may have affected the response rate and duration of responses. To additionally confound the effects of RT, only five dogs received RT alone. The remaining patients were treated with adjuvant RT after surgery, prednisone, and/or chemotherapy.[176] The second study evaluated eight dogs treated hypofractionated RT alone (48–49 Gy total dose, once weekly, for 6–7 weeks). The overall response rate was 50% and the 1-year survival rate was 75%.[177]

The role of chemotherapy in the management of thymomas has not been defined in cats and dogs. In a recent report, a cat with thymoma achieved a partial response after treatment with DOX, vincristine, and L-asparaginase.[178] Progressive disease was observed in 9 dogs treated with a variety of chemotherapy agents (carboplatin, DOX, vincristine and cyclophosphamide, etc).[138] Chemotherapy and RT can result in a reduction in the size of thymomas, but this effect may be the result of reduction in the nonneoplastic lymphocyte population in the thymus rather than a true anticancer effect.[139–141,146,178,179]

Prognosis

The prognosis is good for dogs and cats with noninvasive thymomas treated with surgery. Perioperative mortality rates range from 20% to 27% in dogs and 11% to 22% in cats,[139,179] but no independent risk factors were identified for perioperative mortality.[180] Prognostic factors in dogs include preoperative MG[139–142,147] and a low percentage of intratumoral lymphocytes. [139] The presence of MG, which was earlier thought to influence survival, did not do so in the most recent and largest retrospective study in dogs. The authors hypothesized that the lack of difference in survival despite these serious conditions likely reflects an improvement in both perioperative and postoperative care that has occurred in recent years.[138]

The prognostic effect of percentage of lymphocytes in the tumor was evaluated; results showed that a high percentage of lymphocytes was associated with longer STs. Age, invasiveness of the tumor, and mitotic index had no effect on prognosis.[139] One veterinary study evaluated the Masaoka–Koga staging system for thymomas in dogs. They showed that dogs classified as lower Masaoga–Koga stage (I or II) had significantly longer STs than dogs with stages II or higher.[138] In cats, cystic thymomas are commonly reported and they have been associated with a better prognosis, although no other possible prognostic factors, such as surgical resectability, were critically evaluated.[139,180,181]

In conclusion, long-term STs should be expected for dogs and cats with thymomas that can be completely resected. Tumor recurrence may occur after excision and a second surgery can be successfully performed. Vascular invasion may increase surgical complexity, but not necessarily deny surgery as an option.[138] RT appears to offer acceptable control rates for those tumors that are unresectable or recur.

Comparative Aspects

Thymic neoplasms constitute 30% of anterior mediastinal masses in adults and fewer than 15% in children. The majority are diagnosed

VetBooks.ir

in elderly patients (60 years or older) and a gender or race predilection has not been identified.[182,183] A clinicopathologic classification adopted by the World Health Organization (WHO) correlates well with biologic behavior of thymomas. In the WHO system, cells are classified as spindle (predominant in the medulla), oval and epithelioid (predominant in the cortex), or dendritic. The tumors are then further divided into medullary, mixed, predominantly cortical and cortical thymomas, and well-differentiated and high-grade thymic carcinoma. Medullary and mixed thymomas are considered benign tumors and, even in the face of capsular invasion, will not recur. Predominantly cortical and cortical thymomas display intermediate aggressiveness and have a low risk of relapse independent of their invasiveness. Well-differentiated and high-grade thymomas are highly invasive and associated with a high frequency of relapse and death. The staging system created by Masaoka uses both surgical and histologic signs of invasiveness to describe five different stages that correlate well with prognosis[182,183]:

Stage I: Tumor is grossly encapsulated and no capsular invasion is noted microscopically.
Stage II: Gross invasion occurs to surrounding fatty tissue or mediastinal pleura. Microscopic invasion of the capsule is noted.
Stage III: Gross invasion into neighboring organs (pericardium, great vessels, lungs)
Stage IVa: Pleural or pericardial dissemination
Stage IVb: Lymphatic or hematogenous metastasis

MG is the most common paraneoplastic syndrome associated with thymomas, occurring in 30% to 50% of patients. Red cell aplasia and hypogammaglobulinemia occur in 5% to 10% of patients.

Surgery is the standard-of-care in people with resectable tumors and complete surgical resection is the best predictor for longterm survival in people with thymomas. RT is most commonly indicated for people with extensive or recurrent disease. A variety of chemotherapy drugs have been used to treat inoperable thymomas or in cases in which gross residual disease is present after surgery. Cisplatin, ifosfamide, and prednisone are considered the most effective agents. In addition, neoadjuvant chemotherapy has been shown to influence longterm survival for thymomas in patients with Masaoka stages II and IVa.[182,184,185]

SECTION C: CANINE TRANSMISSIBLE VENEREAL TUMOR

J. PAUL WOODS

Incidence and Risk Factors

Canine transmissible venereal tumor (TVT), also known as transmissible venereal sarcoma and Sticker's sarcoma, infectious sarcoma, venereal granuloma, canine condyloma, transmissible sarcoma, and transmissible lymphosarcoma,[186,187–189] is a naturally occurring, horizontally transmitted infectious histiocytic tumor of dogs usually spread by coitus, but it may also be spread by licking, biting, and sniffing tumor-affected areas.[186,187,190–192] It has been observed occasionally in other canids, such as foxes, coyotes, and jackals.[186,190]

Although TVT has a worldwide distribution, its prevalence is highest in tropical and subtropical areas, particularly in the southern United States, Central and South America, southeast Europe, Ireland, Japan, China, the Far East, the Middle East, and parts of Africa.[186,190] In enzootic areas, where breeding is poorly controlled and there are high numbers of free-roaming sexually active dogs, TVT is the most common canine tumor.[186,190,191,193] In North America, the prevalence of TVT is correlated with increased rainfall and mean annual temperature.[193] Occasional cases occur in regions otherwise free of TVT after travel to endemic areas as a result of tourism.[194] Pets traveling abroad can be exposed to TVT and carry it back to nonendemic areas; therefore veterinarians may act as the first line of defense against the introduction of TVT as an emerging disease in nonendemic areas.

Because TVT is primarily spread by coitus, free-roaming, sexually intact mature dogs are at greatest risk.[186] Dogs of any breed, age, or sex are susceptible.[186,190,189] No heritable breed-related predisposition has been found.[186,189] In endemic areas, although dogs older than 1 year of age are at high risk, TVT is most common in dogs 2 to 5 years of age.[186] The physical exertions associated with coitus in the dog with extensive abrasions and bleeding make both sexes susceptible to injury to the genital mucosa, which facilitates the exfoliation and implantation of tumor cells.[186,189] Transmission can occur efficiently in either direction between the male dog and the bitch. The most common sites of involvement are the external genitalia, but other sites that can be affected through licking or sniffing include the nasal and oral cavities, subcutaneous tissues, and the eyes.[186–192,195–200]

TVT is a transmissible allograft spread directly from dog to dog across major histocompatibility complex (MHC) barriers, through transplantation of viable tumor cells.[201] TVT and Tasmanian devil facial tumor disease (DFTD) are the only known naturally occurring clonally transmissible cancers that behave like an infectious parasitic neoplastic tissue graft.[202,203] Similar to host–parasite interactions, the successful transmission of TVT requires a confluence of multiple tumor and host traits including environment and behavior to facilitate transfer of tumor cells between hosts, tumor tissue that promotes shedding of large number of cancer cells, tumor cell plasticity to survive transmission and grow in the new host, and permissible host tissue involving angiogenesis.[204,205]

These cancers have evolved into a unique niche by overcoming the limitations of existing within the single host that gave rise to the tumors by gaining the ability to spread between individuals and thus survive long after the original hosts have died.

Pathology and Natural Behavior

TVT was initially recognized in 1876 and was used for the first successful experimental transmission of a tumor.[188,189] A number of characteristics of TVT suggest that the tumor originated in inbred wolves or dogs about 10,000 to 15,000 years ago, around the time that the dog was domesticated. Subsequently, the tumor spread worldwide.[206] TVT has evolved into a transmissible parasite representing the oldest known colony of cloned somatic mammalian cells in continuous propagation.

Tumor growth generally appears on the external genitalia or nasal or oral mucosa within 2 to 6 months of mating and can either grow slowly and unpredictably for years or grow invasively and eventually become malignant and metastasize.[186–190] Extragenital lesions can occur both alone (in isolation) and in association with genital lesions; however, it has been suggested that in most cases neoplastic foci can be detected on the genitalia.

TVT usually remains localized, but metastasis occurs in up to 5% to 17% of cases to regional lymph nodes (LNs), subcutaneous

VetBooks.ir

tissue, skin, eyes, oral mucosa, liver, spleen, peritoneum, hypophysis, brain, and bone marrow.[186,195,207,208,209] Because TVT is also transmitted by licking, sniffing, and biting, many cases of reported metastases may instead actually be spread by mechanical extension, autotransplantation, or heterotransplantation.

TVT is commonly described as a round (or discrete) cell tumor and suggested to be of histiocytic origin.[187–189] This is supported by immunohistochemical (IHC) expression of vimentin, lysozyme, alpha-1-antitrypsin (AAT), and macrophage-specific ACM1, as well as negative IHC staining specific for other cell types.[187–189,192,210–212] TVT also expresses p53, proliferating cell nuclear antigen (PCNA), Ki67, MYC, retinoblastoma (Rb), cyclin D1, matrix metalloproteases (MMPs) -2 and -9, and variably expresses S-100.[212–214] IHC has been helpful in confirming metastatic TVT in various anatomic locations.[207,208,209] Furthermore, there have been reports describing TVT cells with intracellular *Leishmania* organisms, also suggesting a histiocytic origin.[200,215]

Cytogenetic and genetic analyses have provided robust evidence of clonality. Whereas normal canine chromosomes consist of 76 acrocentric autosomes plus submetacentric X and Y sex chromosomes, TVT cells have a vastly rearranged karyotype consisting of 57 to 59 chromosomes, including 15 to 17 submetacentric chromosomes as a result of multiple centric fusions.[187,188,192 ,207] However, the total number of chromosome arms in TVT is grossly comparable to that in the normal dog, so it appears that the karyotypic rearrangement is not associated with significant change in DNA content.[201,206] Although TVT cells are aneuploid, they exhibit remarkably stable and similar karyotypes in samples obtained from widely separate geographic regions (i.e., different continents).[201] Likewise, molecular genetic studies of globally distributed TVT tumors provide evidence of a monophyletic origin, which has diverged into subclades.[201,216,217]

In addition, TVT cells all share an insertion of a long interspersed nuclear element (LINE-1) upstream of the c-*myc* oncogene that is not found in normal dog genomes.[218–220] This insertion has the potential to disrupt transcriptional regulation of downstream genes, possibly initiating oncogenic activity, and may have been causally involved in the origin of the tumor.[221] This unique rearranged LINE-c-*myc* gene sequence has been used with polymerase chain reaction (PCR) as a diagnostic marker of TVT to confirm diagnosis.[222,223] TVT cells have also demonstrated point mutations in the tumor suppressor gene *p53,* which is responsible for protecting the integrity of the DNA.[219,224,225] Mutations of such a key regulator of the cell cycle, apoptosis, and senescence may be another factor in the oncogenesis of TVT.

TVT is an immunogenic tumor and the immunologic response of the host appears to play a critical role in determining the natural behavior of the disease. The course of disease is divided into three distinct phases of growth: a progressive phase (P) in which the tumor grows for 3 to 6 months, then a stationary phase (S) that can last for months to years, which is followed by a regressive phase (R) unless the dog is elderly, in poor general condition, or immunologically compromised, in which case metastasis may occur.[189,226–233] Spontaneous regressions have been associated with immune responses against the tumor; therefore immunosuppression from any cause may be a risk factor for the development and maintenance of TVT and may predispose to widespread dissemination. When spontaneous regression occurs, it usually starts within 3 months after implantation but rarely if the tumor is present for more than 9 months.[186]

Initially, in the P phase, the tumor downregulates MHC class I β_2-microglobulin and class II expression, which allows it to evade the host's histocompatibility barrier, particularly T-cell cytotoxicity.[234] Some cell-surface MHC class I expression remains, likely to prevent recognition and killing by natural killer (NK) cells. This immunoevasion is partly due to the high concentration of tumor-secreted transforming growth factor-beta$_1$ (TGF-β_1), which inhibits tumor MHC antigen expression and NK cell activity.[230] TVT also targets and damages dendritic cells (DCs).[234] It has been suggested that TVT has evolved under survival pressures to escape host immunosurveillance.[235]

Tumor-infiltrating lymphocytes (TILs) produce interferon-gamma (IFN-γ) but fail to promote tumor MHC expression due to inhibition of IFN-γ effects by tumor-derived TGF-β_1, which also suppresses the cytotoxicity of the NK cells that migrate to the tumor site because of low tumor-antigen expression.[227,229,230] However, late in the P phase, a marked increase in immune cell infiltration occurs and TILs produce high concentrations of the proinflammatory cytokine interleukin-6 (IL-6), which acts synergistically with host-derived IFN-γ to antagonize the immunoinhibitory activity of TGF-β_1 and results in MHC expression in up to 40% of tumor cells and restores NK cytotoxicity.[228,236,237] A critical threshold level of IL-6 secreted by TILs has to be reached to trigger TVT into R phase.[230,236] Therefore after progressive growth for 3 to 4 months, the tumor spontaneously regresses with upregulation of MHC antigen expression, possibly under epigenetic control.[235] Regression has been correlated with upregulation of genes involved with inflammation and chemotactic cytokines.[238,239]

In addition to cell-mediated immunity, TVT also elicits a humoral immune response demonstrable by antibodies against TVT antigens.[226,240,241] Dogs recovered from TVT have serum-transferable immunity to reinfection and puppies born to bitches exposed to TVT are less susceptible to the disease.[242] In addition to the host immune response, during TVT regression stromal cells and extracellular matrix (ECM) react comparably to wound repair with collapse of the tumor parenchyma and replacement by fibrous stroma.[233]

History and Clinical Signs

The archetypical TVT patient is a sexually intact young adult dog either living in or having traveled to an area endemic for TVT, with a history of contact (coitus, sniffing, licking, or biting) with dogs of similar signalment.[186,189,190] The primary lesions are usually on the external genitalia. In the male, the tumor is usually located on the caudal part of the penis, requiring caudal retraction of the penile sheath for visualization (Fig. 34.6).[186–189] Occasionally, it is on the prepuce. In the bitch, the tumor is usually in the posterior vagina or vestibule.[186–189] Tumors appear initially as small 1 to 3 mm hyperemic papules that progress by fusing together into nodular, papillary, multilobulated cauliflowerlike or pedunculated proliferations up to 10 to 15 cm in diameter. The mass is firm but friable, with an ulcerated inflamed surface. The tumor often oozes a serosanguineous or hemorrhagic fluid. Examples of extragenital sites are illustrated in Fig. 34.7.

Clinical signs vary according to the location of the lesions. Genital lesions often manifest with chronic signs of discomfort or hemorrhagic discharge from the penile sheath or vulva for weeks to months before diagnosis, which can result in anemia.[186,189] Lesions can predispose to ascending bacterial urinary tract infections but rarely interfere with micturition.[243] Extragenital lesions cause a variety of signs, depending on anatomic location, such as sneezing, epistaxis, epiphora, halitosis, tooth loss, exophthalmos, skin masses, facial deformation, and regional LN enlargement.

Diagnostic Techniques and Workup

A presumptive diagnosis of TVT can be obtained based on history (including travel), signalment, clinical signs, and physical findings in dogs with the classic presentation. Definitive diagnosis is based on cytologic examination of cells obtained by swabs, FNAs or imprints of the tumors or histologic examination of a biopsy from the mass. TVT is described as a discrete (or round) cell tumor. TVT has a characteristic morphologic appearance on cytopathology and is often diagnosed without the need for histopathology (see Fig. 7.37). Exfoliative cytology demonstrates uniform discrete round to polyhedral-shaped cells with moderately abundant pale blue cytoplasm and an eccentrically located nucleus, with occasional binucleation and mitotic figures.[187–189,192] Single or multiple nucleoli are often observed, surrounded by clumped chromatin. The most characteristic feature is the presence of numerous discrete clear cytoplasmic vacuoles, often referred to as a "string of pearls." In R phase, TVTs contain a higher number of infiltrating lymphocytes. Other round cell tumors, including lymphomas, mast cell tumors, plasma cell tumors, histiocytomas, and amelanotic melanomas, are important differential diagnoses but are generally not confused with TVT on cytopathology.

Histopathology of TVT reveals compact masses of round or polyhedral cells with slightly granular, vacuolated, eosinophilic cytoplasm.[187–189,192] The neoplastic cells are arranged in a diffuse pattern and supported by a thin trabecula of fibrovascular tissue. Regressing tumors are infiltrated by lymphocytes, plasma cells, and macrophages.[189] For atypical TVTs, if there is doubt about the diagnosis, specific molecular techniques can be used (e.g., in situ PCR of the rearranged LINE–c-*myc* gene sequence).[222,223]

The incidence of metastatic spread of TVT has been reported as less than 15%. However, in most cases of TVT, tumor staging is not performed. Therefore the actual metastatic rate might be higher. Regional LNs should always be evaluated for metastasis by palpation and cytopathology. A thorough physical examination is essential to rule out other possible sites of involvement (i.e., skin, subcutis, nasal and oral cavities, eye, orbit). Diagnostic imaging is usually not required except with invasive TVT of the nasal cavity, orbit, or unusual locations. However, abdominal ultrasound may be used to image regional LNs. Complete blood count (CBC), serum biochemistry profile, and urinalysis do not reveal specific changes. Dogs bearing a large tumor burden of TVT have been associated with a paraneoplastic erythrocytosis that may require temporary symptomatic therapy.[189]

Therapy

TVTs will respond to many forms of therapy; however, chemotherapy is the most effective. Single-agent vincristine (0.5–0.7 mg/m^2 or 0.025 mg/kg intravenously [IV], once weekly for 3–6 treatments) results in a complete and durable response in 90% to 95% of treated dogs.[186,190,196,197,200,232,238,241,244–248] Other single-agent and combination multiagent protocols employing cyclophosphamide, vinblastine, methotrexate, L-asparginase, and prednisolone have not demonstrated superiority to vincristine alone.[244,245] Resistant cases can be treated with DOX (25–30 mg/m^2 IV, every 21 days for three treatments).[190,195] Theoretically, if/when immune checkpoint inhibitors become available in veterinary medicine, they may be effective against TVT because it is an immunogenic tumor with regression correlated with immune cells and inflammation. The immune modulators might be used to treat chemotherapy resistant TVT or to reduce the dose of chemotherapy needed to achieve remission.

RT has demonstrated efficacy against TVT. In a study using orthovoltage RT at total doses of 1000 to 3000 cGy, all 18 dogs treated responded with a complete and durable response, with seven dogs requiring a single fraction of 1000 cGy and 11 dogs requiring two or three fractions.[249] Another study using megavoltage radiation (Co60) reported all 15 dogs achieving complete and durable responses with three fractions administered over 1 week, for an average total dose of 1500 cGy.[196] Therefore RT can be considered an effective treatment for TVT, particularly for lesions showing resistance to chemotherapy or located in sanctuary sites from chemotherapy (i.e., brain, testicle, eye).

Surgery can be an effective treatment for small localized TVT; however, surgery has an overall recurrence rate of 30% to 75%.[248,250,251] Marginal surgical excision is not effective, and it

VetBooks.ir

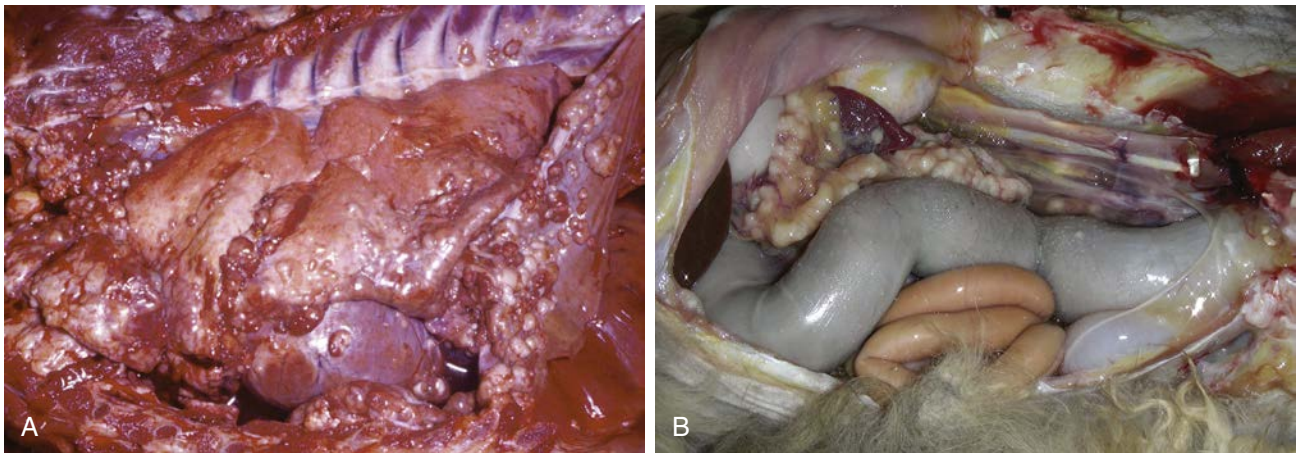
• **Fig. 34.7** Other primary tumor sites. (A) Male dog with cutaneous dissemination of transmissible venereal tumor (TVT) on the ventral abdomen. (B) Mucocutaneous TVT of the anal area in a dog. (C) Corneal involvement with TVT in a dog. (Courtesy Pr. Noeme S. Rocha.)

can be difficult to obtain wide surgical margins in the areas in which TVT typically appears. [248,250,251] In addition, tumor transplantation into the surgical wound by contamination from instruments or gloves may also cause postoperative tumor recurrence.

Other therapies described in spontaneous and experimentally induced cases include biologic-response modifiers (IL-2), piroxicam, cryosurgery, radiofrequency ablation, laser ablation, and electrochemotherapy.[252–257]

Reduction of the incidence of TVT is possible by having dog owners and breeders carefully examine all males and females before mating to avoid breeding affected animals.[186] In addition, stray dogs can act as a TVT reservoir; therefore the mingling of breeding dogs with strays should be prevented. In some areas, the control of ownerless, free-roaming dogs can drastically reduce the incidence of TVT. TVT can enter the wild canid population through physical contact, and it is not known whether TVT may pose a threat to endangered wild canids.[205]

Prognosis



In most cases, TVT remains localized and rarely becomes disseminated, with some dogs having spontaneous regression. For those dogs requiring treatment with vincristine or RT, the prognosis for complete and durable clinical remission is excellent. Therefore the overall prognosis of canine TVT is generally very good to excellent.

SECTION D: MESOTHELIOMA

LAURA D. GARRETT

Incidence and Risk Factors

Mesothelioma is a rare neoplasm of dogs and cats affecting the cells lining the coelomic cavities of the body. In 1962, Gerb et al cited reports of one case of mesothelioma in 1000 dogs and three cases in 5315 dogs.[258] In dogs, primary mesothelial tumors affecting the thoracic cavity, abdominal cavity, pericardial sac, and vaginal tunics of the scrotum have been reported.[259–264] In the cat, primary mesotheliomas have been reported in the pericardium, pleura, and peritoneum, as well as throughout the abdomen, with lung and mediastinal lymph node metastases.[265–270] Exposure to asbestos may be an important contributory factor to mesothelioma development in pet dog populations. Affected dogs often have owners who have jobs or hobbies for which exposure to asbestos is a known risk.[271] The level of asbestos in lung tissues of affected dogs has been documented to be greater than in controls.[271,272] Asbestos refers to a family of silicate minerals that crystallize into long, flexible fibers. The fibers are categorized into two groups: thin rodlike amphiboles, and long curly serpentine, the main type being chrysotile. In humans, much

• **Fig. 34.8** (A) Pleural, parietal, and pericardial surfaces of a dog at necropsy illustrating nodular lesions histologically confirmed as mesothelioma. (B) Mesothelioma involving the peritoneal surfaces of a cat at necropsy.

greater risk has been related to amphibole asbestos compared with chrysotile exposure.[273] Chrysotile now accounts for 90% of asbestos used worldwide.[273]

The underlying mechanisms of the neoplastic transformation of mesothelial cells relates to the direct and indirect interaction of asbestos with mesothelial cells and the chronic inflammatory response initiated by activated macrophages attempting to engulf the asbestos fibers. The chronic inflammatory response also creates a distinct immunosuppressive tumor microenvironment, leading to infiltration with myeloid-derived suppressor cells, tumor-associated macrophages, and regulatory T cells, which likely contributes to tumor progression.[274] Although a wide array of mutations have been identified in mesotheliomas, the most frequent mutational events involve inactivation of tumor suppressor genes, including cyclin-dependent kinase inhibitor 2A (CDKN2A), BRCA1 association protein 1 (BAP1), and neurofibromin 2 (NF2).[275,276] Numerous cytokines including platelet-derived growth factor and vascular endothelial growth factor (VEGF) produced by stimulated macrophages or mesothelial cells are likely important in the pathogenesis of mesothelioma.[277] A report of five golden retrievers that developed pericardial mesothelioma after a long (30–54 months) history of idiopathic hemorrhagic pericardial effusion supports the concept that chronic inflammation may lead to neoplastic transformation in canine mesothelial cells. [278]

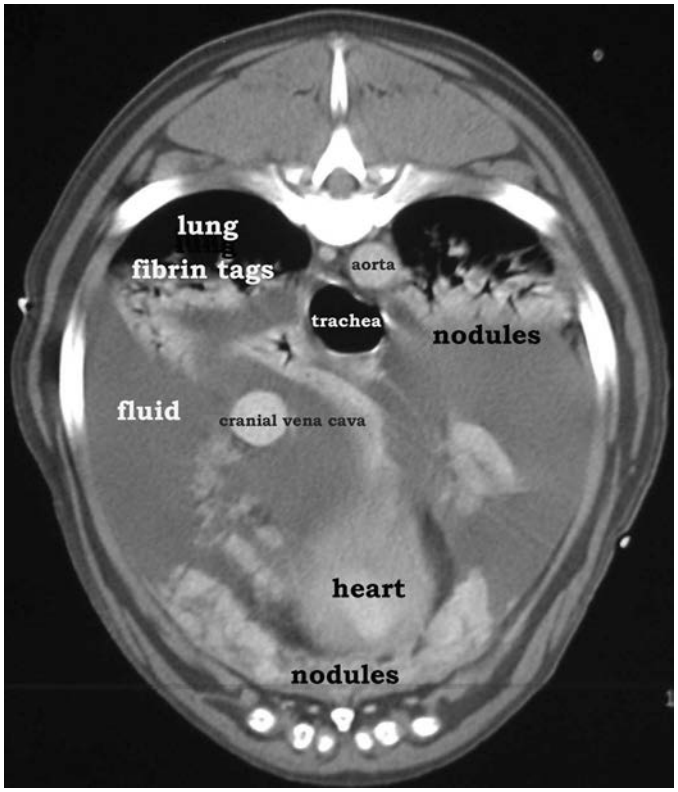
Mesothelial tumors occur most often in older animals; however, in cattle and sheep, newborn or young animals may be affected. Juvenile mesothelioma has been reported in two mixed-breed dogs under 1 year of age; no underlying etiology was identified.[279,280] A report of a 7-week-old puppy with mesothelioma suggests a congenital form may exist.[281]

Pathology and Natural Behavior

The normal mesothelium is a monolayer of flattened mesothelial cells. These cells are distinguished by the presence of microvilli, desmosomes, and phagocytic potential. Disease conditions associated with inflammation or irritation of the lining of body cavities commonly result in a marked proliferation of the mesothelial cells. Fluid accumulation in a body cavity promotes exfoliation and implantation of mesothelial cells. Mesotheliomas are considered malignant because of their ability to seed the body cavity, but distant metastasis is rare.

Mesothelial cells appear morphologically as epithelial cells; however, their derivation is from mesoderm. Mesothelioma can appear histologically as epithelial, mesenchymal, or biphasic, which is a combination of the two.[282] The epithelial form, which resembles carcinoma or adenocarcinoma, is by far the most common form in small animals. There are also several reports of a variation of the mesenchymal form, which resembles sarcoma and is referred to as *sclerosing mesothelioma*.[261,283–285] The biphasic form of mesothelioma has been reported in two dogs and a cat. [286–288] A cystic peritoneal mesothelioma has also been reported in a dog.[289] This is a rare, benign, slowly progressive form of mesothelioma in humans, which is treated with surgical excision when the disease is localized.

History and Clinical Signs



Mesotheliomas occur as a diffuse nodular mass or multifocal masses covering the surfaces of the body cavity (Fig. 34.8). Extensive effusions occur as a result of exudation from the tumor surface or from tumor-obstructed lymphatics; therefore the most common presenting sign is dyspnea from pleural effusion or a distended abdomen from peritoneal effusion. Dogs with pericardial or heart-base mesotheliomas can present with tamponade and right-sided heart failure.[290–292]

Sclerosing mesothelioma is a variation of mesothelial tumor seen primarily in male dogs, with German shepherd dogs overrepresented.[261,283,284,293] These tumors present as thick fibrous linings in the abdominal and/or pleural cavities. Restriction occurs around organs in the affected area, and in the abdomen such changes can impinge on organs and lead to vomiting and urinary tract signs.

Diagnostic Techniques and Workup

Mesothelioma should be suspected in adult dogs presenting with a history of chronic, nonspecific clinical signs and fluid accumulation in any body cavity. Routine echocardiography and abdominal ultrasound are not typically helpful because the tumor cells cling to epithelial surfaces and a mass lesion is uncommonly noted.[294]

VetBooks.ir

• **Fig. 34.9** A thoracic computed tomography image (with contrast) from a dog with histologically diagnosed mesothelioma. The effusion resolved after the first of five doxorubicin chemotherapy (30 mg/m^2, q3wk, IV) treatments.

In a study of echocardiography of dogs with pericardial effusion, a discrete cardiac mass was identified in only 5 of 15 dogs with effusion due to mesothelioma.[292] Thoracic CT may be of benefit to identify nodular lesions and to assess lung parenchyma in the presence of pleural effusion[295,296] (Fig. 34.9). Dogs with neoplastic pleural effusion are more likely to be older and on CT have thickening only of the parietal pleura compared with dogs with inflammatory effusion.[297] Although noted in only 3 of 20 dogs with malignant effusion, CT evidence of chest wall invasion was specific for neoplasia.

Cytologic evaluation of fluid can be diagnostic for other disease processes such as infection or lymphoma but will not conclusively diagnose mesothelioma. Mesothelial cells proliferate and exfoliate under any circumstance associated with fluid accumulation in a body cavity. Reactive mesothelial cells display many cytologic features of malignancy, making a definitive diagnosis of neoplasia via cytology impossible in most cases. Although one study found pericardial fluid pH analysis to be a discriminatory test to differentiate benign from malignant effusions, subsequent studies found too much overlap for the test to be of benefit.[298,299] Elevation in pleural effusion fibronectin concentrations in dogs and cats is a sensitive but nonspecific test for malignancy; mesothelioma can be ruled out if fibronectin levels are not increased.[300]

Establishing a definitive diagnosis of malignant mesothelioma may be difficult, particularly early in the disease. The diagnosis of mesothelioma requires adequate tissue sampling, preferably from an open, visually directed biopsy. Increasing availability of thoracoscopy and laparoscopy for small animals provides a less invasive way to evaluate these cases.[301] In either procedure, the clinician is encouraged to biopsy any body cavity lining and any regional lymph nodes when an obvious cause for fluid accumulation is not found. Sclerosing mesothelioma must be distinguished from chronic inflammatory diseases of the body cavity, such as chronic peritonitis, and histologic examination of biopsy material is essential to establish the diagnosis. Embolized, nonneoplastic mesothelial cells within lymph nodes is a rare finding in humans with cavity effusions and has been reported in dogs affected with idiopathic hemorrhagic pericardial effusion; care must be taken to not overinterpret these cells as indicative of metastasis.[302]

The most useful criteria in establishing a diagnosis of mesothelioma are that the tumor is primarily a neoplasm of the coelomic cavity lining and that the method of tumor spread is by transcoelomic implantation. Therefore mesothelioma should be considered when the bulk of the neoplastic tissue exists on the coelomic surface. Histologically, mesotheliomas need to be differentiated from carcinomas, adenocarcinomas, or sarcomas, depending on the morphologic type of the mesothelioma. Unfortunately, there are no cellular markers that conclusively define the mesothelial cell, and the diagnosis of mesothelioma remains a challenge in human medicine despite advances in IHC staining and molecular testing. Histologic diagnosis is based on morphologic assessment supported by clinical and imaging findings, with IHC and molecular testing adding further details.[303] Currently, the most useful mesothelial markers to support a diagnosis of malignant pleural mesothelioma in humans are calretinin, Wilms' tumor gene (WT1), cytokeratin 5/6 (CK5/6), and D2-40. However, 30% of mesotheliomas are a "null" phenotype and will be negative for these markers.[303]

Treatment and Prognosis

No satisfactory treatment exists for mesothelioma. Radical excision may benefit some animals, but usually the tumors are too advanced locally and have spread by implantation early in the course of disease. In one case report, a 2-year-old Siberian husky with a solitary sclerosing mesothelioma affecting the left thoracic diaphragmatic surface with pericardial and mediastinal adhesions was treated with aggressive surgical resection and diaphragmatic reconstruction using the transversus abdominis muscle.[304] The dog recovered well, but subcutaneous masses at the surgery site, as well as hepatic and renal masses, were noted 54 days postoperatively, leading to euthanasia. Pericardiectomy may palliate mesothelioma patients that present with cardiac tamponade; two dogs treated with surgery alone survived 4 and 9 months in one report.[305] In another report, the MST in five dogs treated with pericardiectomy was 13.6 months; three of these dogs received adjuvant IV chemotherapy (two DOX, one mitoxantrone).[306] A dog treated with pericardiectomy, intrathoracic and IV cisplatin, and IV DOX remained free of disease at 27 months.[307] In a report of eight dogs with pericardial mesothelioma, the MST was 60 days (range 15–300 days) after partial pericardiectomy. The one dog that survived 300 days was treated with DOX and intracavitary cisplatin for the 4 months preceding death.[294] Thoracoscopic partial pericardiectomy is a less invasive procedure than open thoracic surgical pericardiectomy and has been successfully performed in dogs with malignant pericardial effusions, including four dogs with mesotheliomas.[308] Although reported only in one dog, thoracoscopy portal site seeding from contamination with mesothelioma cells on instruments or cannulas or via leakage of malignant effusion is a potential complication.[309] Short-term complications and longterm outcomes of thoracoscopic pericardial window to treat pericardial effusion, idiopathic (10) or neoplastic (5), were reported in 15 dogs, one of which had mesothelioma.[310] The procedure had a complication rate of 25%, low

VetBooks.ir

mortality (7%), and short hospitalization stay (1 day). The mesothelioma case lived the longest of the neoplastic cases, at 107 days. In another study, 58 dogs with idiopathic or malignant pericardial effusion (at least 10 of which were mesotheliomas) treated with thoracoscopic pericardial window or thoracotomy and subtotal pericardectomy were evaluated. The median disease-free interval and MST for dogs with malignant effusions, although short at approximately 3 to 4 months, did not significantly differ between the two surgical techniques.[311] Thus the less invasive procedure can be considered for palliation of malignant pericardial effusions. For palliative management of pleural effusion, a permanent port can be placed that allows for both ease of effusion removal and administration of intracavitary chemotherapy.[312] The MST for animals with untreated mesotheliomas in any location is difficult to assess from reports, as the tumors are rare and animals frequently are euthanized at the time of diagnosis.

Intracavitary cisplatin has shown palliative potential in the dog; it was well tolerated and greatly decreased mesothelioma-associated thoracic fluid accumulation in three dogs in one study.[313] The treatments also appeared to arrest tumor growth for a limited time. Two doses of intracavitary carboplatin was safely administered to a cat with suspected pleural mesothelioma and resulted in transient resolution of clinical signs for a total of 54 days, at which point the owners discontinued therapy.[314] Unfortunately, local penetration of intracavitary chemotherapy occurs only to a limited depth (2–3 mm), and thus large masses will not be affected significantly, other than from ultimate exposure to the systemically absorbed intracavitary drug. In such cases, combining debulking surgery or systemic chemotherapy such as DOX or mitoxantrone with intracavitary cisplatin may be beneficial. For peritoneal mesothelioma, four doses of intracavitary cisplatin in two dogs and carboplatin in one cat, combined with piroxicam administration, resolved the effusion in all cases.[315] One of the dogs had debulking surgery first; this dog was still in remission at 2 years, whereas the other dog and the cat lived 8 and 6 months, respectively. IV chemotherapy may provide benefit in some patients; single-agent IV cisplatin administered every 3 weeks was reported to improve clinical signs in a dog with bicavitary epithelial mesothelioma, until sudden death occurred 5 months after treatment initiation.[316]

Comparative Aspects

In humans, approximately 70% to 80% of mesotheliomas are linked to occupational exposure to aerosolized asbestos fibers, with the type of employment, such as construction work, ship building, heating trades, and insulation work significantly increasing relative risk.[317] There is a long latency period from time of exposure to tumor development, ranging from 12 to 50 years. Less often, several naturally occurring minerals with elongated structures, termed naturally occurring asbestos (NOA), are associated with mesothelioma development. These cases are seen in regional populations in many sites worldwide, affect men and women equally, and have a younger age at onset compared with occupational exposure cases.[318]

In humans with mesothelioma, the median survival is approximately 1 year from symptom onset. Prognosis is associated with the histologic subtype, and multiple other factors have been assessed to refine prognosis, stratify patients for clinical trials, and guide targeted therapies.[274,319,320] Chemotherapy, specifically pemetrexed or raltitrexed, combined with cisplatin or carboplatin, is the standard of care firstline therapy.[321] There is ongoing controversy regarding the therapeutic role of surgery and/or RT, as nonrandomized observational studies have shown improved survival with multimodal treatment but randomized studies have not.[321,322] With the tremendous growth in understanding of the genetic alterations found in mesotheliomas, a wide array of other novel therapies are under investigation in randomized clinical trials in humans.[274] Overall, mesothelioma still carries a poor prognosis. Improved ability to assess an individual's tumor's markers and mutations will help guide therapy, including novel agents, and will hopefully improve survival time in the future.

SECTION E: NEOPLASIA OF THE HEART

JENNA H. BURTON AND JOSHUA A. STERN

Incidence and Risk Factors

Cardiac and pericardial neoplasms are rare in both dogs and cats. The frequency at which dogs were diagnosed with cardiac tumors in a Veterinary Medical Data Base (VMDB) search over a 14-year time frame was 0.19%, with 84% of tumors identified as primary cardiac neoplasia.[323] In two canine necropsy series, the frequency at which primary or metastatic neoplasia was detected ranged from 2.7% to 3.1% of all cases examined and represented 11.7% to 28.3% of all cancers diagnosed in these dogs at necropsy.[324,325] Reports are conflicting as to whether primary or metastatic tumors predominate in dogs as the reported frequency of secondary cardiac tumors ranges from 16% to 86%.[323–326] Cardiac metastases may be common in dogs with advanced stage cancer, but remain clinically silent and challenging to diagnosis antemortem, leading to likely underreporting of these events except when necropsy is performed.[326–328]

Cardiac tumors generally occur in middle-aged to older dogs.[323–326] Hemangiosarcoma (HSA) is the most common primary heart tumor in dogs, followed by aortic body tumors (ABTs) such as chemodectomas and paragangliomas. HSA and ABT represent 40% to 69% and 8% to 28% of all primary cardiac tumors in VMDB and necropsy studies, respectively.[323,325,326,329] Breeds potentially at increased risk for cardiac HSA include golden retrievers and German shepherds; boxers, Labrador retrievers, and cocker spaniels are commonly reported to develop cardiac HSA as well.[323,324,330–332] ABTs occur most frequently in older brachycephalic breeds, such as bulldogs, boxers, and Boston terriers, and it has been suggested that chronic hypoxia may stimulate development of these tumors in brachycephalic breeds;[323,333–335] however, nonbrachycephalic breeds such as German shepherds, Labrador retrievers, and golden retrievers also develop ABT at increased frequency and not all brachycephalic breeds develop ABT, which suggests other factors likely contribute to its pathogenesis.[323,336,337]

Cardiac tumors are even less common in cats, with an overall incidence of 0.0275% in a VMDB search.[338] Cardiac lymphoma, both primary and secondary, predominates.[326,339,340] As with other forms of lymphoma, feline leukemia virus (FeLV) infection likely plays a role in cardiac lymphomagenesis in cats.[326,339] Several case reports of ABT in cats exist and cardiac HSA is rare.[326,341–346]

Pathology and Natural Behavior

Tumors of the heart may occur at the heart base or in pericardial, intracavitary, or intramural locations. Primary tumors may

VetBooks.ir

be benign or malignant, with the latter predominating, and most occur in the right atrium and auricle in the dog.[323,329] Cardiac HSA is frequently associated with hemorrhagic pericardial effusion and cardiac tamponade and tends to have high rates of metastasis.[330,332,347] ABTs are the second most common primary neoplasm of the heart in dogs, and lymphoma and ectopic thyroid carcinoma are observed with some frequency as well.[323–326,329,348–359] Reported but rare malignant tumors include mesothelioma, myxosarcoma, chondrosarcoma, fibrosarcoma, osteosarcoma, rhabdomyosarcoma, undifferentiated sarcoma, leiomyosarcoma, thyroid carcinosarcoma, peripheral nerve sheath tumor, granular cell tumor, malignant mesenchymoma, and anaplastic carcinoma.[360–385] Histologically benign cardiac tumors have been reported and may cause lifethreatening clinical signs because of their location despite their biologically benign behavior. Reported benign cardiac tumors include myxoma, lipoma, thyroid adenoma, hamartoma, Schwannoma, leiomyoma, and fibroma.[359,386–399] In contrast to those in humans, metastatic cardiac tumors are diagnosed with less frequency than primary tumors in dogs, likely due to the high incidence of cardiac HSA in this species and absence of cardiac specific clinical signs for many secondary tumors.[323,326,328] Tumors reported to metastasize to the heart in dogs include HSA, lymphoma, mammary gland carcinoma, melanoma, pheochromocytoma, histiocytic sarcoma, gastric adenocarcinoma, liposarcoma, malignant mesenchymoma, rhabdomyosarcoma, extraskeletal osteosarcoma, fibrosarcoma, and pulmonary carcinoma.[326,328,400–412]

Cardiac tumors in cats tend to be malignant although benign intrapericardial cysts have been reported.[413,414] In addition to lymphoma, ABT, and HSA, single case reports of primary cardiac ganglioneuroma, rhabdomyosarcoma, and myxoma exist.[415–417] Metastatic lesions have been reported to arise from squamous cell carcinoma, mammary gland carcinoma, and pulmonary carcinoma.[326,418]

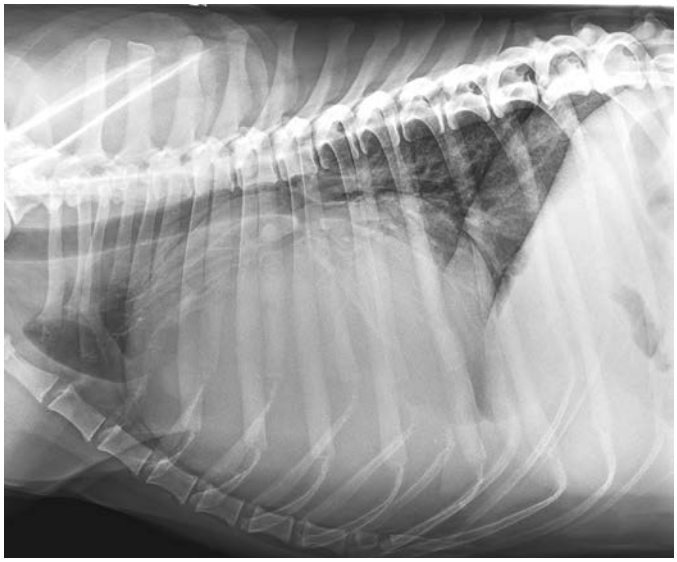
History and Clinical Signs

Tumors of the heart generally cause clinical signs secondary to alterations of cardiac function and may result from a mass obstructing blood flow to and from the heart, external cardiac compression that impedes filling such as pericardial effusion, and/or arrhythmias or decreased contractility resulting from myocardial infiltration or ischemia of the myocardium. Clinical signs are influenced more by the tumor location, tumor size, and presence of pericardial effusion than the specific histology of the tumor. Sudden death may occur secondary to cardiac arrhythmias or tumor rupture and subsequent blood loss, with or without cardiac tamponade. Tumors, particularly cardiac HSA, arising in the right side of the heart often cause signs of right-sided congestive heart failure due to inflow obstruction or the presence of cardiac tamponade secondary to pericardial effusion. Signs of right heart failure often result from the presence of bi- or tricavitary effusion and may present as abdominal distention, dyspnea, exercise intolerance, and/or acute collapse. Clinical signs commonly reported for dogs with confirmed or suspected HSA of the heart are often nonspecific in nature and are described in Table 34.3.

Clinical signs associated with ABT may include abdominal distension, weight loss, dyspnea, anorexia or inappetence, signs of gastrointestinal tract disease, lethargy, cough, and collapse. Although many dogs with ABT may have clinical signs that persist for weeks to months before diagnosis, some will present acutely as well.[336,419,420] Clinical signs for cats with cardiac neoplasia most frequently include tachypnea, dyspnea, hyporexia, weight loss, and lethargy; acute collapse appears to occur less frequently than in dogs.[339,345,421]

Diagnostic Techniques and Workup

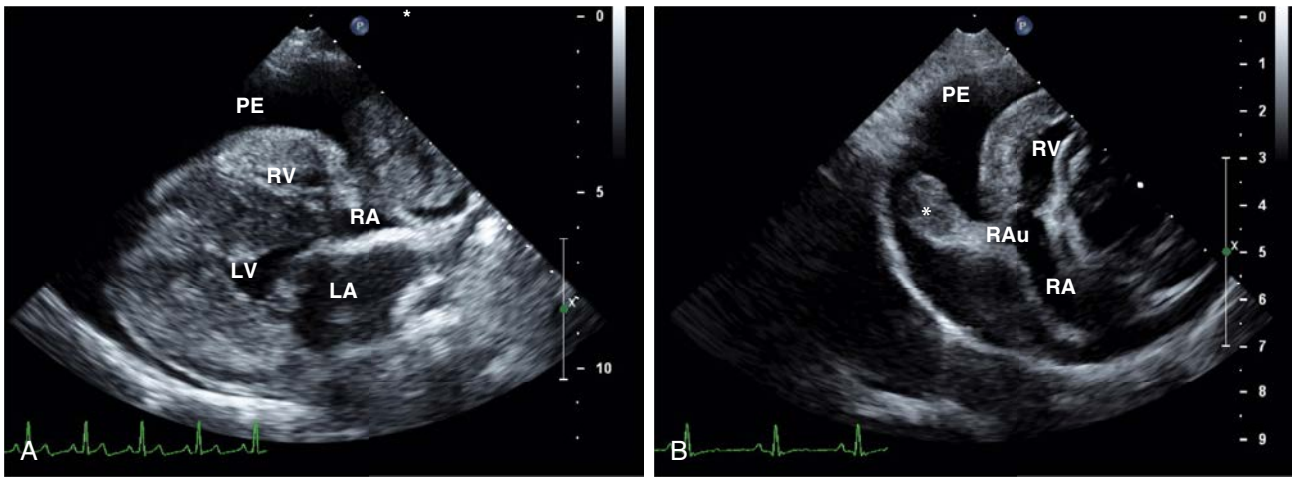
Differential diagnosis of a cardiac tumor is often made based on clinical history, physical examination, and radiographic findings. Diagnosis requires imaging, which is routinely achieved by echocardiography and sometimes through additional advanced modalities such as CT or MRI. Incidental diagnosis of subclinical cardiac tumors may be encountered at necropsy. In the majority of cases, antemortem cytologic or histologic confirmation of neoplasia is not obtained; however, in cases where technically feasible and with acceptable clinical risk, FNA or biopsy may provide importance guidance on therapeutic options.[422]



Much like clinical signs, physical exam findings vary widely depending on location and hemodynamic consequences of the cardiac tumor. Patients with incidentally identified cardiac tumors may have apparently normal physical examinations. Auscultatory abnormalities are common secondary to pericardial effusion and include muffled heart sounds, pericardial friction rubs, or tumor plops (intermittent diastolic sounds secondary to tumor motion). In addition, arrhythmias may be auscultated, particularly in patients with myocardial involvement. Pulmonary auscultation may reveal abnormalities consistent with left-sided congestive heart failure, such as increased bronchovesicular sounds and/or soft crackles. Pulse quality derangements are common in patients in low-output states, such as cardiac tamponade. Jugular venous distention and pulsation may also be observed secondary to elevated right heart pressure with pericardial effusion or obstructive lesions.

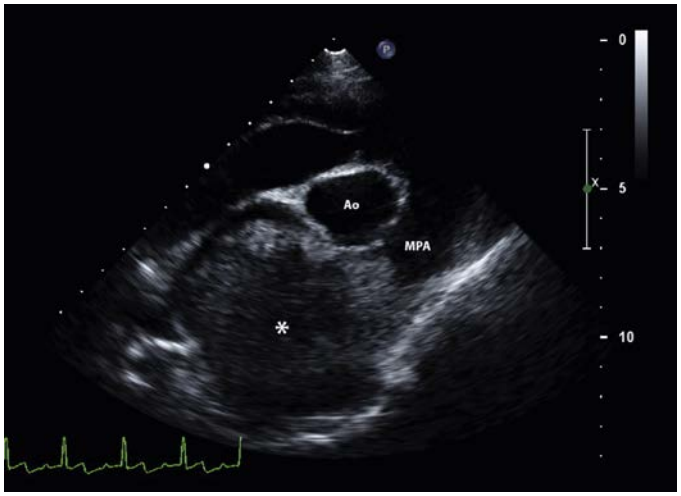
Many components of the diagnostic evaluation are related to the common concomitant condition of pericardial effusion. An electrocardiogram may be normal in patients with cardiac tumors or may show a wide variety of cardiac arrhythmias, which are frequently related to the site of the cardiac tumor and infiltration of the myocardium.[423] Conduction disturbances, such as atrioventricular blocks or bundle branch blocks, may be observed with myocardial infiltration and may be as severe as complete atrioventricular block as previously reported with cardiac lymphoma.[349] Supraventricular or ventricular arrhythmias may be observed in cases of cardiac tumors with or without pericardial effusion. ST segment changes may be observed secondary to myocardial ischemia with or without pericardial effusion.[424] Sinus tachycardia is common with cardiac tamponade or in cases with heart failure acquired secondary to obstructive cardiac tumors.

TABLE 34.3 Frequency of Commonly Reported Clinical Signs for Dogs with Suspected or Confirmed Cardiac Hemangiosarcoma



Clinical Sign	Reported Frequency (%)[331,332,458,459,462]
Lethargy	35–93
Anorexia or inappetence	19–46
Acute collapse	13–54
Coughing/respiratory difficulty	13–42
Vomiting	11–38
Weakness	0–56

Radiographs are insensitive in the diagnosis of cardiac tumors, with a reported sensitivity of only 47% for cardiac HSA.[425] Many radiographic findings are associated with the presence of pericardial effusions. Animals with a large-volume pericardial effusion may have a globoid cardiac silhouette with crisp margins owing to reduced cardiac motion (Fig. 34.10). Smaller fluid accumulations may allow visualization of chamber contours and atrial/tumor shadows.[338] In the setting of cardiac tamponade, animals may have diminutive pulmonary arteries and veins with distention of the caudal vena cava. In cardiac tamponade or in the setting of obstructive mass lesions, fluid accumulations such as pleural effusion, ascites, or pulmonary edema may be observed.[423] Mass lesions, if seen, are most common in the areas of the right atrium and heart base and may elevate the intrathoracic trachea.[338] Lung metastases may also be observed.



• **Fig. 34.10** A right lateral thoracic radiograph of a dog with pericardial effusion and cardiac tamponade secondary to cardiac hemangiosarcoma. The globoid cardiomegaly with crisp margins and diminutive pulmonary vasculature are characteristic of pericardial effusion. There is small volume pleural effusion and reduced abdominal detail, which were secondary to concomitant right heart failure.

Echocardiography is the most widely used imaging tool for identifying tumors of the heart in cats and dogs.[426—428] In a study of 107 dogs with pericardial effusion, the sensitivity and specificity of echocardiography were 82% and 100%, respectively, for detection of a cardiac mass; with detection of right atrial/auricular masses being slightly higher (82% sensitivity and 99% specificity) than that of heart base tumors (74% sensitivity and 98% specificity).[429] The positive and negative predictive values of echocardiography were 100% and 75%, respectively, for detection of a cardiac mass.[429] In a small study of histologically-confirmed HSA of the right atrium and/or auricle, echocardiography had a positive predictive value of 92% (11/12) and a negative predictive value of 64% (9/14) in dogs.[428] Tumor location (extrapericardial, noncavitary pericardial, and small auricular masses) and size appeared to be the most important factors leading to false -negative results via echocardiography.[428] This finding was supported by a larger recent study of 51 dogs with histologically confirmed HSA of the right atrium (Fig. 34.11a) or right auricle (Fig. 34.11b), where right atrial tumors were more readily diagnosed (95% detection rate) than right auricular tumors (60% detection rate).[331] Additionally, tumor location is shown to be only moderately predictive for correctly identifying underlying tumor type (i.e., HSA vs. chemodectoma, etc.).[430] Pericardial effusions are commonly associated with cardiac tumors in both cats and dogs,[385,428,429,431] being present in 42% (10 of 24) of patients with echocardiographically diagnosed cardiac tumors in a recent study.[430] Pericardial effusion is more commonly identified in patients with cardiac HSA, occurring in 82% of cases in a recent study.[331] Echocardiographic diagnosis of mesothelioma is challenging, as many small lesions are below the resolution echocardiography and a single, larger mass lesion is uncommon in this tumor type. Echocardiography is particularly useful to evaluate for acquired pulmonary or aortic stenosis (Fig. 34.12) and may aid in identifying the extent of the tumor and possible myocardial or vascular invasion. Additional advanced imaging modalities, including CT, MRI, positron emission

• **Fig. 34.11** (A) A two-dimensional, right parasternal, long-axis, echocardiographic image from a dog with a suspected cardiac hemangiosarcoma (HSA). The top of the image shows the right side of the heart and a large right atrial, heterogenous mass lesion *(asterisk)* consistent with cardiac HSA is observed along with pericardial effusion *(PE)*. The collapsed right atrium *(RA)*, right ventricle *(RV)*, left atrium *(LA)*, and left ventricle *(LV)* are labeled. (B) A cranial, left apical, echocardiographic image from a dog with PE is shown allowing visualization of the collapsed RA and right auricle (*RAu*). A small heterogeneous lesion *(asterisk)* consistent with cardiac HSA is seen at the tip of the right auricle.

• **Fig. 34.12** A right parasternal, short-axis, basilar view, echocardiographic image from a dog with a suspected aortic body tumor. A large mass lesion *(asterisk)* consistent with an aortic body tumor is seen adjacent to the cross-sectional aorta (*Ao*) and compressing the region of the main pulmonary artery branches. The right branch of the main pulmonary artery has extraluminal compression secondary to the heart base tumor, which is creating a pressure overload on the right ventricle and subsequent right-sided congestive heart failure in this patient.

tomography (PET), and PET/CT, may be useful for selected cases, particularly in preparation for possible surgical or radiation-based therapies.[432–436]

Other clinical diagnostic methods for the evaluation of cardiac or pericardial masses include pneumopericardiography, selective and nonselective angiography, gated radionuclide imaging, and endomyocardial biopsy.[338,401,437] These techniques are infrequently used in favor of accessible imaging by echocardiography, cardiac MRI, and CT/angiography. Cytologic evaluation of pericardial fluid and pericardial fluid pH has been shown in multiple studies to be of limited utility in discriminating between neoplastic and nonneoplastic causes of pericardial effusion[438–440]; however, in the setting of a patient with pericardial effusion and no obvious cardiac tumor by echocardiography, pericardial fluid cytology may offer a diagnosis in approximately 8% of cases.[441] Improved diagnostic yield (20%) of pericardial fluid cytology was identified in cases where the pericardial effusion had a hematocrit of less than 10%.[441]

Cardiac troponin I (cTnI) appears to be useful for diagnosing cardiac HSA in dogs.[442,443] cTnI is a sensitive and specific marker for myocardial ischemia and necrosis. Dogs with cardiac HSA had significantly higher concentrations of cTnI than did dogs with idiopathic pericardial effusion.[442] In another study, the median plasma cTnI concentration was higher in dogs with cardiac HSA compared with dogs with HSA at other sites, dogs with other neoplasms, and dogs with pericardial effusion not caused by HSA. Furthermore, dogs with cTnI concentrations higher than 0.25 ng/mL were likely to have cardiac HSA, and a plasma cTnI higher than 2.45 ng/mL indicated that cardiac involvement is likely in dogs with confirmed HSA.[443] In practice, the measurement of cTnI may aid in reducing the number of false-negative results by echocardiogram. The authors routinely measure cTnI in patients with pericardial effusion and no obvious tumor on echocardiogram, using the published cutoff value of greater than 0.25 ng/mL as a likely indication of cardiac HSA.[443]

For dogs and cats with a cardiac mass and suspected neoplasia, every effort should be made to determine the extent of disease and the existence of primary or metastatic sites elsewhere in the patient. In addition to echocardiography and/or other advanced imaging modalities, a minimum database is recommended, including a CBC, serum biochemical profile, urinalysis, coagulation profile, thoracic radiographs, and abdominal ultrasound. Concurrent splenic masses have been reported in 9 of 31 (29%) dogs with suspected primary cardiac HSA with 42% of dogs having metastases to other sites such as the liver, mesentery, omentum, and lungs.[444] Conversely, this same retrospective study identified concurrent right atrial lesion in 2 of 23 (8.7%) dogs with primary splenic HSA whereas a previous necropsy study reported that 6 of 25 (24%) dogs with splenic HSA had a concurrent right atrial lesion.[444,445]

In a minority of cases, a diagnosis may be obtained by FNA cytology, endomyocardial biopsy, or open surgical or thoracoscopic biopsy. A recent small case series of 6 dogs reported 100% success of obtaining a diagnostic cytology sample by FNA. This technique resulted in minor complication in two of six dogs and required general anesthesia for four of six aspiration attempts.[446] Despite this recent publication, the majority of cases remain treated based on anatomic location of the mass (e.g., right auricle assumed to be HSA) owing to the risks of obtaining a definitive diagnosis in the setting of limited therapeutic options.

Therapy

Initial treatment for patients with cardiac tumors consists of therapies directed at the secondary complications to improve cardiac output and hemodynamic function; however, interventions to manage complications such as arrhythmias and congestive heart failure will have limited efficacy unless management of the primary tumor is initiated. The use of endovascular stents as palliation has been described in two dogs with cardiac masses obstructing venous return to the right atrium.[447] Surgical resection of primary cardiac masses may be considered, but is generally limited to tumors arising from the right auricle (see Fig. 34.11b).[330,332,448–452] Successful resection of intracardiac masses has been reported, but requires specialized anesthetic intervention and surgical equipment not readily available in many veterinary hospitals, and preferably subspecialty training in cardiovascular surgery.[351,352,365,451,453]

Subtotal pericardiectomy for dogs with heart base masses has been shown to improve survival in dogs with ABTs and mesothelioma, regardless of whether pericardial effusion is present at the time of diagnosis.[336,337] However, pericardiectomy alone does not improve outcomes for dogs with cardiac HSA.[454] As dogs with pericardial effusion treated with thoracoscopic pericardial window are more likely to have recurrence of pericardial effusion than dogs treated with open thoracotomy and subtotal pericardiectomy, the latter is preferable for dogs expected to have prolonged survival (i.e., ABT or mesothelioma).[455] Thoracoscopic approaches for subtotal pericardiectomy and resection of cardiac masses are being performed more frequently as surgeons become more experienced in minimally invasive surgical techniques.[452,456,457] Resection of right atrial or auricular masses suspected to be HSA should be considered palliative owing to the high metastatic rate and adjuvant chemotherapy is recommended to prolong survival.[332]

DOX-based chemotherapy protocols are commonly used for the treatment of dogs with cardiac HSA, either as primary therapy or after surgery. Protocols described for cardiac HSA include DOX

VetBooks.ir

alone or in combination with cyclophosphamide (CYC), vincristine (VCR), VCR/CYC, metronomic chemotherapy, ifosfamide, dacarbazine, or toceranib phosphate (TOC).[458–461] The use of Yunnan Baiyao and epsilon-aminocaproic acid has been evaluated for dogs with right atrial masses and pericardial effusion; however, patient outcomes were similar to pericardiocentesis alone.[462] Preliminary evidence exists that TOC may mitigate clinical signs for dogs with heart base tumors, and further investigation into this treatment option is warranted.[463] The role of TOC in the management of heart base tumors in cats is unknown at this time.[341,342] Chemotherapy protocols for cats with cardiac or pericardial lymphoma have not been well described, but multiagent protocols such as CHOP (combinations of cyclophosphamide [C], doxorubicin [H, hydroxydaunorubicin], vincristine [O, Oncovin], and prednisone [P]) or COP (CHOP without the addition of doxorubicin) should be considered.[339,412]

The role of RT in the management of cardiac tumors has not yet been well studied. Administration of a single 12 Gy fraction to dogs with right atrial masses and concurrent pericardial effusion appears to be safe and decreased the frequency of palliative pericardiocentesis.[436] Full-course fractionated RT appears feasible and may be beneficial for dogs with heart base masses alone or postoperatively; however, reports are limited to a few cases at this time.[420,464,465]

Prognosis

The prognosis for cardiac HSA is poor. MSTs for dogs with cardiac HSA treated with surgical resection alone range from 16 days to 4 months.[330,332,448,454,457] The addition of DOX-based chemotherapy after surgical resection significantly improves survival for dogs with cardiac HSA, with an MST of 175 days when treated with surgery and adjuvant chemotherapy compared with 42 days when treated with surgery alone.[332] Dogs with presumptive cardiac HSA treated with DOX-based protocols have a response rate of 41%, progression-free survival time of 66 days, and MST of 116 to 140 days.[458,459] Although surgical resection is often not feasible for dogs with ABT, the prognosis for dogs with ABT is improved when pericardiectomy is performed with MSTs ranging from 661 to 730 days.[336,337] Dogs with ABT that do not undergo pericardiectomy have significantly worse outcomes, with reported MSTs ranging from 42 to 129 days.[336,337] Outcomes for other primary cardiac tumors in dogs have not been well studied; however, a number of case reports suggest primary resection of the mass can result in prolonged survival times.[351,354,364,365]

The prognosis for cats with primary cardiac tumors is generally poor. One study evaluating pericardial lymphoma in cats reported an MST of only 9 days; however, one cat treated with a CHOP-based chemotherapy protocol had a survival time of more than 750 days.[339]

Comparative Aspects

Primary tumors of the heart and pericardium are rare in humans; the majority of cardiac neoplasms are metastatic lesions. Reported incidence of primary cardiac tumors in people range from 0.02% to 0.056%.[466,467] About 75% of cardiac tumors in humans are benign with myxomas comprising about half of benign tumors in adults; lipoma, papillary fibroelastoma, and hemangioma occur less commonly.[468] Cardiac myxomas are generally solitary, arise from the left ventricle, and surgical resection is the treatment of choice.[469] Rhabdomyoma is the most frequent primary cardiac tumor in infants and children.[468] Familial cardiac rhabdomyomas frequently occur in association with tuberous sclerosis complex, an autosomal dominant disorder caused by mutations in predominantly the *TSC2* gene and less frequently the *TSC1* gene.[470] Infants with cardiac rhabdomyoma often have multifocal lesions that arise predominantly in the ventricles; surgical intervention is rarely required as the majority of these lesions will partially or completely regress with time.[470,471]

Sarcomas are the most common malignant cardiac tumor, with approximately one-third of malignant tumors diagnosed as angiosarcoma, one-fifth as rhabdomyosarcoma, and with lymphoma being infrequent.[468] More recent reports based on Surveillance, Epidemiology, and End Results registry data suggest that angiosarcomas and non-Hodgkin lymphoma (NHL) currently have a similar incidence rate of 0.108 and 0.107 per 10^6 person-years, respectively, with the incidence of NHL steadily increasing over the study time period (2000–2014).[472] Similar to those in dogs, most sarcomas arise from the atria, with the right atrium being more commonly affected than the left.[468,473] Surgical resection is commonly performed; however, the prognosis for primary cardiac sarcomas treated with surgery alone is poor, with in-hospital postoperative mortality of 22% and MSTs ranging from 9.6 to 20 months.[473,474] The benefit of chemotherapy and RT is not well defined; however, a small study demonstrated that neoadjuvant DOX/ifosfamide may improve survival of patients with right-sided sarcoma.[475,476]

Secondary cardiac tumors predominate in humans, with incidence rates ranging from 2.3% to 18.3% in autopsy studies.[477] Pericardial metastases are most common, followed by epicardial and myocardial metastases. Tumors with the highest rate of cardiac metastasis include mesothelioma, melanoma, pulmonary adenocarcinoma, undifferentiated carcinoma, and pulmonary squamous cell carcinoma, and breast carcinoma.[477] Tumors that have preferential cardiac metastasis compared with other sites include melanoma, bronchoalveolar carcinoma, and renal carcinoma.[477]

SECTION F: HISTIOCYTIC DISEASES

CRAIG A. CLIFFORD, KATHERINE A. SKORUPSKI AND PETER F. MOORE

Background

Several well-defined histiocytic proliferative diseases have been recognized in dogs and cats (Table 34.4).[478] The clinical presentation, behavior, and responsiveness to therapy vary tremendously between the syndromes observed. The challenge in some instances is to differentiate them from granulomatous or reactive inflammatory diseases, or from lymphoma, through examination of regular paraffin sections. Fortunately, there has been considerable progress in identifying markers that can be used to further characterize cell lineages in complex leukocytic infiltrates.

Histiocytic Differentiation

The development of canine specific markers for differentiation molecules of macrophages and dendritic cells (DCs) has enabled the identification of the cell lineages involved in canine histiocytic diseases.[479–483] The majority of canine histiocytic diseases involve proliferations of cells of various DC lineages. The term histiocyte has been used to generically describe cells of DC or macrophage

VetBooks.ir

TABLE 34.4 Recognized Histiocytic Proliferative Diseases in Dogs and Cats

Disease	Species	Cell of Origin	Key Morphologic Features	Immunophenotype
Histiocytoma	Dog	LC	Lesions have an epidermal focus ("top-heavy") and intraepidermal foci are common. Histiocytes have diverse nuclear morphology (round, ovoid, indented, or complex nuclear contours. Multinucleated cells and cytologic atypia are rare.	CD1a, CD11c/CD18, E-cadherin, Iba-1, CD204 (neg.)
Cutaneous Langerhans cell histiocytosis	Dog	LC	Multiple cutaneous lesions are observed. Metastasis to lymph nodes and internal sites is possible. Lesions are otherwise identical to histiocytoma, but may have a higher frequency of multinucleated cells and cytologic atypia.	Identical to histiocytoma
Pulmonary Langerhans cell histiocytosis	Cat	LC	There is multinodular to diffuse involvement of all lung lobes. Lesions consist of cohesive histiocytic infiltrates, which obliterate terminal airways and extend to pleural surfaces. Birbeck's granules observed by TEM.	CD1a#, CD11c*/CD18, E-cadherin, Iba-1*, CD204*
Cutaneous histiocytosis	Dog	iDC– activated	Vasocentric lesions are focused on mid-dermis to subcutis ("bottom heavy"). Lesions are pleocellular but are dominated by histiocytes and lymphocytes. Lympho-histiocytic vasculitis is commonly observed. Histiocytes lack cytologic atypia, and multinucleated giant cells are rare. Skin draining lymph nodes may be infiltrated.	CD1a, CD4, CD11c/CD18, CD90, Iba-1, CD204*
Systemic histiocytosis	Dog	iDC– activated	Lesions are identical to cutaneous histiocytosis in skin. Lesions extend to lymph nodes, ocular and nasal mucosa, and internal organs.	CD1a, CD4, CD11c/CD18, CD90, Iba-1*, CD204*
Histiocytic sarcoma	Dog, Cat	iDC	Mass lesions are observed in spleen, lung, lymph node, periarticular and other primary tissue sites. Histiocytes are pleomorphic, mononuclear and multinucleated giant cells with marked cytologic atypia.	CD1a, CD11c/CD18, Iba-1, CD204 (variable)
Histiocytic sarcoma—hemophagocytic	Dogs Cat	Macrophage	Mass lesions are lacking. Diffuse splenomegaly and insidious infiltration of liver lung and bone marrow are consistently observed. Splenic red pulp is expanded by erythrophagocytic histiocytes. Mononuclear and multinucleated giant cells, with cytologic atypia are common. Alternatively, histiocytes may have little cytologic atypia.	CD1a (low), CD11d/CD18 (dog), iba-1, CD204
Feline progressive histiocytosis	Cat	iDC	Skin nodules and plaques are observed. Lesions occupy the dermis with an epidermal focus. Intra-epidermal foci (40%) occur. In early lesions, histiocytes have minimal cytologic atypia. In later lesions, histiocytes manifest cytologic atypia as described for histiocytic sarcoma.	CD1a, CD11c*/CD18, CD5 (50%), Iba-1, CD204 (variable)
Dendritic cell leukemia	Dog	iDC	Predominant blood and bone marrow involvement is observed. There is diffuse infiltration of spleen, lung, and liver. Histiocytes manifest moderate cytologic atypia in blood and tissues.	CD1a, CD11c/CD18, Iba-1*, CD204*

CD1a* expected, not assessed to date.

CD11c* expected but not currently assessable in cats.

CD204* not reported.

Iba-1* not reported.

iDC, Interstitial dendritic cell; *LC*, Langerhans cell; *TEM*, transmission electron microscopy.

lineage. Histiocytes differentiate from $CD34^+$ stem cell precursors into macrophages and several DC lineages. Intraepithelial DCs are also known as Langerhans cells (LCs). Interstitial DCs occur in perivascular locations in many organs except the brain, although they do occur in the meninges. Perhaps the most studied interstitial DCs are the dermal DCs of skin. Dendritic cells that occur in T cell domains in peripheral lymphoid organs (lymph node [LN] and spleen) are known as interdigitating DCs. Interdigitating DCs in LNs are composed of resident DCs and migratory DCs. The migratory DCs arrive in lymphatics from tissues and consist of LCs and

VetBooks.ir

interstitial DCs.[484] Cytokines and growth factors that influence DC development include FLT3 ligand, granulocyte-macrophage colony stimulating factor (GM-CSF), tumor necrosis factor-alpha (TNF-α), interleukin-4 (IL-4), and transforming growth factor-beta (TGF-β).[484,485] Macrophage development from CD34+ precursors is influenced by GM-CSF and macrophage colony stimulating factor (M-CSF). Blood monocytes can differentiate into either macrophages under the influence of M-CSF, or into DCs under the influence of GM-CSF and IL-4.[484,486,487]

Dendritic cells are the most potent antigen presenting cells (APC) for induction of immune responses in naïve T cells. The development of canine specific monoclonal antibodies for functionally important molecules of DCs and macrophages has enabled their identification in canine tissues, especially skin.[481,488] Dendritic cells occur in two major locations: within the epidermis (LCs), and within the dermis, especially adjacent to postcapillary venules (dermal interstitial DCs).[489] Canine DCs abundantly express CD1a molecules which, together with MHC class I and MHC class II molecules, are responsible for presentation of peptides, lipids, and glycolipids to T cells.[481,482,490] Hence, DCs are best defined by their abundant expression of molecules essential to their function as APC. Of these, the family of CD1 proteins is largely restricted in expression to DCs in skin, whereas MHC class I and II are more broadly expressed.

The beta-2 integrins (CD11/CD18) are critically important adhesion molecules, which are differentially expressed by all leukocytes. CD11/CD18 expression is highly regulated in normal canine macrophages and DCs. CD11c is expressed by LCs and interstitial DCs, whereas macrophages predominately express CD11b (or CD11d in the splenic red pulp and bone marrow). A subset of dermal interstitial DCs also express CD11b.[491–493] In diseased tissues, these beta-2 integrin expression patterns may be broadened. Langerhans cells and dermal interstitial DCs are also distinguishable by their differential expression of E-cadherin (LCs+) and Thy-1 (CD90) (dermal interstitial DCs+). Langerhans cells localize within epithelial tissue via E-cadherin homotypic adhesion with E-cadherin expressed by epithelial cells.[485]

Migration of DCs (as veiled cells) beyond the skin to the paracortex of LNs, where they join forces with interdigitating DCs, occurs after contact with antigen. Successful interaction of DCs and T cells in response to antigenic challenge also involves the orderly appearance of costimulatory molecules (B7 family—CD80 and CD86) on DCs and their ligands (CD28 and CTLA-4) on T cells.[494–496] In situ DCs have low expression of MHC class II and costimulatory molecules and are more receptive to antigen uptake. Migratory DCs upregulate MHC class II and B7 family members and become more adept at antigen presentation to T cells.[495,496]

Aspects of the developmental and migratory program of DCs are recapitulated in canine histiocytic diseases. Defective interaction of DCs and T cells appears to contribute to the development of reactive histiocytoses (cutaneous histiocytosis [CH] and systemic histiocytosis [SH]), which are related interstitial DC disorders arising out of disordered immune regulation. The distant migratory potential of DCs is of immense clinical significance in the adverse prognosis of histiocytic sarcomas (HSs), which largely originate in interstitial DCs and rapidly disseminate.

Immunophenotyping

To classify hematopoietic neoplasia according to the WHO system as applied to the dog, it is important to have access to markers for IHC analysis.[497,498] Determination of lineages of histiocytes (macrophages, interstitial type DCs, and Langerhans cells) is best performed in unfixed cytologic smears or snap frozen tissues, or by flow cytometry. Important markers for the dissection of the histiocytic lineage that are only detectable in fresh smears or snap frozen tissues include CD1a, CD11b, CD11c, CD80, and CD86. It is possible to presumptively identify histiocytes in formalin fixed paraffin embedded (FFPE) tissues by using combinations of lymphoid markers coupled with CD18 and CD11d staining (Table 34.4) in an appropriate morphological context. Additional useful markers of histiocytic lineage in FFPE tissues include Iba-1 (ionized calcium binding molecule-1), the macrophage class A scavenger receptors (CD163 and CD204), and E-cadherin. Iba-1 identifies macrophages and DCs, whereas the class A scavenger receptors are largely expressed by macrophages in normal tissues.[499] However, the scavenger receptors, CD163 and CD204, are also expressed by DC subsets in some species.[500,501] The potential exists for coexpression of class A scavenger receptors on DCs in diseased tissue. Alternatively, there is some evidence for mixed lineages in HS, particularly in the central nervous system of dogs.[502]

Cutaneous Histiocytoma

Cutaneous histiocytoma is a benign tumor of Langerhans cells that often occurs as a single lesion in young dogs (<3 years of age), although histiocytomas do occur in dogs of all ages. In a retrospective review from the United Kingdom of histopathologic diagnoses of neoplasia in dogs less than 1 year, CH was the most common diagnosis, representing 89% of 20,280 submissions.[503] These tumors typically present as a solitary raised pink skin mass, often in the cranial portion of the body. The growth of the lesion can be quite rapid (1–4 weeks), but tumors usually spontaneously regress within 1 to 2 months of presentation.[503–509] IHC is rarely necessary to diagnose histiocytomas; however, expression of E-cadherin is unique to histiocytomas and can help differentiate histiocytomas from reactive histiocytosis (CH, SH).[479,482,510,511] When necessary, this differentiation can be made based on IHC or flow cytometry. The factors that determine the onset of regression in canine histiocytomas are unknown. Regression may be rapid or delayed for many months. Regression is mediated by CD8+ αβT lymphocytes.[478,482] Migration of tumor histiocytes and/or tumor infiltrating reactive interstitial DC to draining LNs likely activates CD4+ T cells, which would assist in CD8+ cytotoxic T-cell recruitment. Because massive CD8+ T-cell infiltration is observed with histiocytoma regression, immunosuppression should be avoided once a definitive diagnosis of histiocytoma has been reached to avoid interference with cytotoxic T-cell function. E-cadherin expression has been found to be associated with lymphoid infiltrate and stage of regression of histiocytomas.[512] Cases of multiple or metastatic histiocytomas are rare and may require IHC to differentiate from lymphoma or other round cell tumors if cells are poorly differentiated. These cases are usually classified as cutaneous Langerhans cell histiocytosis (LCH).[478]

Cutaneous Langerhans Cell Histiocytosis

Cutaneous LCH is a disease comprising multiple or diffuse cutaneous tumors of LC origin with or without metastasis to LNs or internal organs.[478,513,514] Lesions are identical morphologically and immunohistochemically to histiocytomas, but may have more cytologic atypia. Cutaneous LCH limited to skin appears to be more common in Shar Pei dogs, but can occur in any breed. Delayed regression of cutaneous LCH can occur, even in cases with widespread disease, and may be delayed for up to 10 months before onset of regression. In the authors' experience, lesions do

not regress in about half of cases and dogs are euthanized due to complications related to extensive ulcerated skin lesions. Attempts to treat diffuse cutaneous LCH are rarely reported, but there is one report of a complete but temporary response to lomustine (CCNU) in a dog with diffuse cutaneous LCH.[515] In addition, there is one report of a complete response to griseofulvin treatment in an 8-month-old puppy with diffuse cutaneous LCH.[516] Dogs with solitary lesions, but with metastasis to an LN, may have a better prognosis. A study reported on eight dogs with a solitary cutaneous histiocytoma and LN metastasis treated with surgery alone. Outcomes were excellent, with most alive 1 to 4 years after diagnosis.[517] Cases of diffuse LCH with rapid progression to LN and internal organ involvement appear to have a poorer prognosis in the authors' experience.

Reactive Histiocytosis

The reactive histiocytosis can be separated into CH and SH. Cutaneous histiocytosis represents a benign, diffuse aggregation of histiocytes that grows rapidly into infiltrating nodules, plaques, and crusts within the skin and subcutaneous tissue.[478,479,481,509,518,519] This disease tends to occur in younger dogs; however, one study noted a range of 2 to 11 years. A breed predisposition has yet to be identified; however, in one study, golden retrievers, great Danes, and Bouvier des Flanders were more common.[519] One study suggested a male predilection; however, in a second larger study, no sex predilection was identified.[479,519] Forty-four percent of dogs in one study had a previous history of dermatologic disease, with allergic dermatitis being most common. The median duration of time from appearance of lesions to diagnosis via biopsy in this study was 1.75 months (range 0–30 months).[519]

CH is limited to the skin and subcutis, but can be multifocal. The head, pinnae, limbs, and scrotum are the commonly reported sites.[479,518,519] Lesions may also be found on the nasal planum and within nasal mucosa, the gross appearance of which has been described as a "clown nose." In one study, 10 of 32 dogs had nasal planum/nares involvement, which presented as swelling, erythema, depigmentation, and stertorous respiration.[519] Histologically, lesions contain a pleocellular histiocytic infiltrate, often perivascular within the dermis and subcutaneous tissue. Lymphoid infiltrates and some neutrophils are common and vascular invasion may be present. These histiocytic cells express CD1a, CD1b, CD1c, CD11c, MHC class II molecules, Thy-1 and CD4 but are negative for E-cadherin.[478,479,481] The expression of Thy-1 and CD4 aids in identification of cell of origin, which appears to be the activated interstitial DC.

CH usually follows a benign course and responds to immunosuppressive therapy, although spontaneous regressions have also been reported. Local therapies are not often successful, as lesions typically recur in other locations. Systemic corticosteroids are usually the firstline therapy and partial responses are seen in the majority of dogs.[479,509,518,519] Many dogs require continuous therapy to prevent recurrence. In one study of 32 dogs, all had complete resolution of lesions within a median of 45 days (range, 10–162 days) from initial therapy.[518] In this study, initial therapy included prednisone alone or in combination with antibiotics (n = 12), prednisone with tetracycline/doxycycline and niacinamide (n = 4), prednisone and azathioprine (n = 3), and tetracycline/niacinamide either alone or in combination with vitamin E and essential fatty acids (n = 6). Of the 19 dogs receiving prednisone, daily dosages ranged from 0.5 mg/kg to 2 mg/kg. [518]

Longterm maintenance therapies may be warranted to prevent recurrence; however, affected dogs may have a prolonged survival time. In 32 dogs with complete resolution of their lesions, 17 were maintained on a variety of medications including 12 with tetracycline/niacinamide either alone (n = 7) or in various combinations with safflower oil, essential fatty, or vitamin E.[518] Other maintenance therapies included cyclosporine/ketoconazole, azathioprine alone, prednisone and azathioprine, or prednisone alone. Immunosuppressive agents such as leflunomide and cyclosporine A/ketoconazole and azathioprine may demonstrate efficacy in steroid refractory cases.

SH is similar to cutaneous histiocytosis in its IHC staining pattern and cell of origin, the activated interstitial DC. The distinguishing feature is involvement of nonskin organs. The Bernese mountain dog (BMD), Rottweiler, golden retriever, and Irish wolfhound are overrepresented and the disease appears to be familial in the BMD.[479,509,520–524] Dermal lesions manifest in the skin with similar site predilection as CHS; however, other sites including the subcutis, eyes, nasal epithelium, LNs, bone marrow, spleen, liver, lung, or mucous membranes are also affected. Clinical signs vary depending on the affected tissue and severity of disease; however, depression, anorexia, weight loss, conjunctivitis, and harsh respiration are common. Clinicopathologic features of SH are varied; however, anemia, monocytosis, and lymphopenia are consistently reported, and hypercalcemia is occasionally reported.[479,509,520–524]

Lesions may have a waxing and waning presentation, but generally do not spontaneously resolve. Corticosteroids alone appear ineffective in controlling this disease in the long term.[479,508,516] The use of azathioprine, cyclosporine A, or leflunomide has yielded longterm control in some cases. Some have suggested a significant role of T cells in this disease via inappropriate DC and T-cell interactions due to abnormal regulation of accessory ligands on both cell types.[479,481] The clinical course of this disease is often prolonged but rarely results in death. Generally, there are episodes of response to therapy followed by recrudescence, and many dogs are euthanized as a result of repeated relapses or failure to respond to therapy.[479,509,520–524]

Histiocytic Sarcoma

Genetics and Biologic Behavior

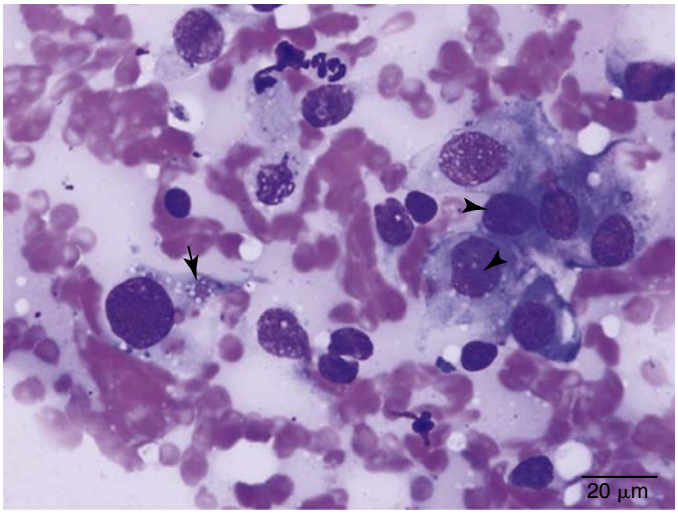
HS was first reported in the dog in the late 1970s and a predisposition in BMDs was discovered in 1986.[525,526] HS has since been identified in many breeds, and flat-coated retrievers (FCR), Rottweilers, and miniature schnauzers also appear to be overrepresented.[525–527] In Japan, the Pembroke Welsh Corgi also appears to be overrepresented.[528] Dogs are commonly middle aged or older, but HS has been reported in dogs as young as 3 years of age.

Genetic and epidemiologic studies in the BMD have revealed clues about the etiology of HS. A Swiss inheritance study found the genetic predisposition for HS in BMD to be so widespread within the breed that selective breeding was deemed impossible.[529] One genetic study evaluating copy number aberrations in the BMD and FCR found deletions of the tumor suppressor genes CDKN2A/B, RB1, and PTEN.[530] In a genome-wide association study, a haplotype spanning MTAP and part of CDKN2A was found in 96% of BMD with HS.[531] A gain-of-function mutation in PTPN11 was recently identified in canine HS, and 37% of BMDs with HS studied had the mutation compared with 9% of HS in other dog breeds.[532] Two studies have also found a correlation between prior joint disease and risk of periarticular HS (PAHS) in the BMD.[533,534]

VetBooks.ir

Breed differences have also been studied. Two studies have found that FCR are more likely to have HS of the limbs and BMD have more diffuse visceral disease.[530,535] Localized HS is seven times more frequent in the FCR than in the BMD and disseminated HS is two times more frequent in the BMD than the FCR. FCR with HS were also older at diagnosis than BMDs with HS in one study (mean 8.6 vs 7.7 years).[530] Differences in histopathology between these breeds have also been described.[536]

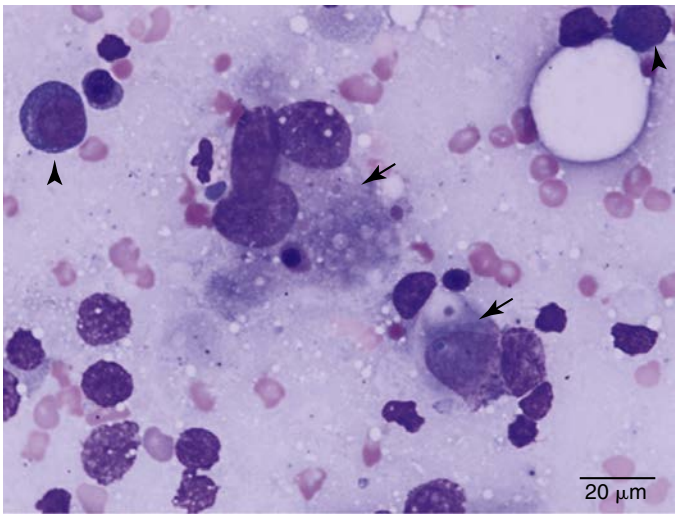
HS may present with either localized or loco-regional organ involvement or with a disseminated/multiorgan involvement. HS is the preferred term identifying malignant tumors of histiocytic origin, and the older term "malignant histiocytosis" refers specifically to the disseminated form of the disease. Reported anatomic sites include lung, LN, liver, spleen, stomach, pancreas, mediastinum, skin, skeletal muscle, central nervous system, bone, bone marrow, nasal cavity, and eyes[537–546] (Fig. 34.13). It was reported that 5% of primary brain tumors were HS, as were 4.5% of secondary brain tumors in a necropsy population.[547,548] In a series of 26 dogs with ocular HS, ocular involvement was usually found in association with disseminated disease.[543] HS is the most common periarticular tumor in dogs, and IHC staining is required to differentiate them from "true" synovial cell sarcoma.[538] In periarticular tumors, IHC for CD18, cytokeratin, and smooth muscle actin can aid in differentiation of PAHS and synovial cell sarcoma.[538]



Hemophagocytic HS (HHS) is a subtype of HS that arises from macrophages rather than DC and is described in more detail later in this section.[483] The HHS variant can be definitively differentiated only through confirmation of an IHC staining pattern consistent with macrophages, though clinical factors such as visceral location or hematologic and biochemical abnormalities may raise suspicion.[483] Clinically, this form behaves more aggressively due, at least in part, to its cellular ability to phagocytose material including host blood cells.

• **Fig. 34.13** Canine histiocytic sarcoma (HS) in the spleen. **Top.** Discrete mass formation is characteristic of HS of interstitial dendritic cell origin. **Bottom.** Diffuse splenomegaly with ill-defined mass formation is characteristic of hemophagocytic HS of macrophage origin. (Image courtesy PF Moore.)

History and Clinical Signs



Presenting complaints and clinical signs vary widely depending on site(s) of tumor involvement, but nonspecific symptoms such as lethargy, inappetence, and weight loss are common in dogs with disseminated HS. Other common signs include a visible mass, lameness, cough, vomiting, and lymphadenomegaly.[528] Lymphadenomegaly is sometimes the only clinical sign and can appear at a site distant to other tumor lesions. Patients may also present with clinical signs related to severe anemia or thrombocytopenia, especially in dogs with the HHS variant.[483,540–542]

• **Fig. 34.14** Cytology of histiocytic sarcoma in the liver of a dog. Note individualized and loosely cohesive moderately pleomorphic spindle cells with prominent nucleoli *(arrowheads)*. Some demonstrate phagocytic activity *(arrow)*. (Wright-Giemsa, 100× objective.) (Courtesy Elizabeth Little, VMD, DACVP, IDEXX Laboratories, Langhorne, PA.)

Diagnosis and Staging

A diagnosis of HS can be obtained via cytologic or histologic examination of tumor tissue; however, definitive diagnosis can be challenging in pleomorphic tumors that have morphologic characteristics similar to carcinomas or round cell tumors. HS cells are large, discrete, mononuclear cells that often display marked anisocytosis and anisokaryosis. Nuclei are round, oval, or reniform with prominent nucleoli and cytoplasm is moderate to abundant, lightly basophilic, and vacuolated. Mitotic figures are common and some tumor cells may display erythrophagocytosis and/or multinucleated giant cells (Figs. 34.14 and 34.15).[478,480,547] Evidence to support a diagnosis of HS may be acquired through immunocytochemistry or IHC on formalin fixed tissues using antibodies to CD18.[480] The class A macrophage scavenger receptor CD204 also serves as a useful marker of canine HS and has been used to evaluate both formalin-fixed, paraffin-embedded samples and air-dried cytology.[499,548] The pan-macrophage marker ionized calcium-binding adapter molecule 1 (Iba1) also appears to have utility as a marker of cells of monocyte and macrophage lineage, though it cannot differentiate the various histiocytic disorders.[549] If fresh or frozen tissue is available, further confirmation and subclassification of the cell of origin can be performed using antibody staining for CD1 or the CD11 α subunits.[478,480] Recently, the CADET[f] histiocytic malignancy assay has become commercially available. Using this assay, tumor biopsy or cytology samples are evaluated for copy number aberrations consistent with those found in cases of confirmed HS. The sensitivity and specificity of the assay have been estimated to be 78% and 95%, respectively.[530,550]

• **Fig. 34.15** Cytology of histiocytic sarcoma in the bone marrow of a dog. Neoplastic cells *(arrows)* and erythroid progenitors *(arrowheads)* are visible. Note phagocytic activity of neoplastic cells. (Wright-Giemsa, 100× objective.) (Courtesy Elizabeth Little, VMD, DACVP, IDEXX Laboratories, Langhorne, PA.)

Because HS is multifocal or disseminated in most dogs, complete staging is recommended. Complete blood count and biochemical screens may be abnormal in dogs with disseminated or HHS.[480,483,542] Anemia is common and usually regenerative when caused by erythrophagocytosis by neoplastic cells. Leukocytosis, thrombocytopenia, increased liver enzymes, hypoalbuminemia, and hypocholesterolemia are frequent findings, and hypercalcemia occurs occasionally.[542] HS was the second most common cause of pancytopenia in dogs in a retrospective study of 51 dogs at a veterinary teaching hospital.[551] Hyperferritinemia has also been documented in dogs with HS and is theorized to be result of ferritin production by tumor cells.[552,553] Eighty-nine percent of dogs with HS had hyperferritinemia in one study, although IMHA, liver disease, and lymphoma were also associated with high rates of hyperferritinemia.[553] A recent study attempting to screen healthy BMDs for early HS found that serum ferritin may serve as a potential marker of the disease. High ferritin levels were common in dogs with clinical HS, but only 2 of 5 dogs with early HS had high ferritin levels, suggesting that further study is necessary to explore the utility of ferritin as a screening test for BMDs.[554]

Thoracic radiography and abdominal ultrasonography commonly reveal abnormalities.[542] Pulmonary involvement may appear as a diffuse interstitial infiltrate, patchy consolidated areas, or focal or multifocal mass lesions. The right middle lung lobe is the most common pulmonary location for HS and internal air bronchograms are commonly seen.[555,556] Radiographic evidence of sternal, cranial mediastinal, and/or tracheobronchial lymphadenopathy may also be noted. Hepatosplenomegaly, splenic or hepatic mottling, or discrete nodules or masses in these organs are the most common abdominal ultrasonographic abnormalities.[557]

Bone marrow aspiration cytology may reveal tumor infiltrate, especially in patients with cytopenias. In addition, flow cytometry has been used to differentiate etiology of hemophagocytosis in bone marrow samples containing more than 5% macrophages and cytologic evidence of hemophagocytosis.[558] Results suggested that cellular distribution in scatter plots and number of histiocytes may help differentiate neoplastic from nonneoplastic causes of hemophagocytosis.

Treatment and Prognosis

The clinical course of disseminated HS, if left untreated, is rapid and usually fatal, whereas the localized form may be more slowly progressive.[480] Few reports documenting survival duration after surgical excision of localized HS exist. However, in a series of 18 PAHS confirmed with CD18 staining, the MST for dogs undergoing amputation was 6 months and the metastatic rate was 91%.[538] Interestingly, the periarticular form of HS may be associated with a better prognosis than that at other locations. In one study, dogs with PAHS lived significantly longer than did dogs with non-PAHS, with overall MSTs of 391 and 128 days, respectively,[559] despite the presence of suspected metastasis at diagnosis in 13 of 19 dogs with PAHS. Still, dogs with PAHS with no evidence of metastasis at diagnosis (MST 980 days) lived significantly longer than those with evidence of metastasis (MST 253 days).[559] Prolonged survival has also been reported in dogs with localized HS in other anatomic sites treated with local and systemic therapy, however.[560] Thus it is not clear whether PAHS has a better prognosis owing to its more localized nature or due to an inherent difference in clinical behavior.

CCNU appears to be the most effective chemotherapy agent against HS in dogs. One study reported a 46% response rate to CCNU in 56 dogs with gross measurable disease with a median remission duration of 85 days. The MST of responders was 172 days compared with 60 days in nonresponders.[542] In this study, anemia, thrombocytopenia, hypoalbuminemia, and splenic involvement, all factors associated with the hemophagocytic subtype of HS, were associated with a grave prognosis. Corticosteroids did not improve response to therapy in this study. In a prospective study of 21 dogs with HS treated with 90 mg/m^2 of CCNU, the response rate was lower at 29%, though 67% of dogs received only one dose of CCNU.[561] The median response duration was 96 days. CCNU therapy used as an adjuvant to surgery and/or RT RT may result in lengthy survival times in dogs with localized HS. One retrospective study documented an MST of 19 months in 16 dogs with localized HS treated with aggressive combination therapy.[560]

CCNU has also been studied in combination with DOX to treat HS, and when administered in an alternating fashion every 2 weeks, the response rate was 58% with a median time to progression of 185 days.[562] Dacarbazine has been studied in the rescue setting for HS and was associated with a response rate of 18%, with an event-free survival time in responders of 70 days.[563] The efficacy of epirubicin against HS has also been studied and was associated with a response rate of 29%.[564]

Individual reports of responses to liposomal DOX and paclitaxel chemotherapy also exist.[565,566] In addition, a case report of a dog with cutaneous disseminated HS described temporary remissions resulting from multiple treatments including cyclophosphamide, vincristine, prednisone, mitoxantrone, dacarbazine, and etoposide.[567] Studies of metronomic chemotherapy targeting angiogenesis and the immune environment have also included dogs with HS. Responses to metronomic lomustine and chlorambucil have both been reported.[568,569] The bisphosphonate clodronate has been studied in histiocytic cell lines and in five dogs with HS.[570] Two of the five dogs treated with a liposomal formulation of clodronate experienced tumor regression and further study is warranted.

The efficacy of RT against HS has not been fully studied; however, preliminary evidence suggests that HS is radioresponsive. In a report of 37 FCR with mostly PAHS, dogs undergoing RT lived

longer than those not having RT with an MST of 182 days.[571] Dogs treated with a set combined protocol of a palliative RT and CCNU had an MST of 208 days. Further study into the optimal RT protocol for HS is necessary.

Hemophagocytic Histiocytic Sarcoma

Hemophagocytic HS is a variant of HS that originates from the tissue macrophage, not the DC.[483] This more aggressive form of HS invariably involves the spleen, but dogs may also have liver, bone marrow, LN, and/or lung involvement. Splenic involvement is usually diffuse, resulting in gross enlargement with diffuse nodular infiltrates. In one study, common hematologic findings in dogs with HHS included a regenerative anemia (94%), thrombocytopenia (88%), hypoalbuminemia (94%), and hypocholesterolemia (69%).[483] A presumptive diagnosis of HHS may be obtained through splenic cytology, which shows infiltration with atypical to highly pleomorphic macrophages displaying phagocytosis of red blood cells, splenic origin red cell precursors, and white blood cells. However, definitive diagnosis and differentiation from nonhemophagocytic HS requires immunophenotyping. To date, effective treatment of HHS has not been described. Reported survival times are extremely short, ranging from days to 1 to 2 months, regardless of therapy.[483,542]

Feline Histiocytic Diseases

Histiocytic neoplasms are much rarer in cats than dogs, but three distinct forms have been documented to date. These include HS, with features similar to those of the canine disease; feline progressive histiocytosis (FPH), a cutaneous form of histiocytic neoplasia with indolent, but progressive behavior; and LCH, with disease localized primarily to the lungs.

Feline Histiocytic Sarcoma

HS of DC origin and hemophagocytic HS of macrophage origin have both been documented in cats.[572–580] With both variants, cats usually present with multifocal or disseminated disease. Spleen, liver, and bone marrow involvement are most common, but LN, lung, trachea, mediastinum, kidney, bladder, and CNS involvement is also reported. Bone marrow involvement appears commonly in cats.[573] Severe anemia and thrombocytopenia are also common findings and may indicate bone marrow involvement and/or hemophagocytic HS, which can be confirmed though immunophenotyping of tumor tissue samples.[571–573] The localized form of HS is rare in cats, but has been reported in the tarsus of three cats, on the nasal bridge or planum in three cats, and in the stomach of one cat.[580,581] An aggressive clinical course is typical of HS in cats, particularly in those with anemia and suspected hemophagocytic HS. Effective treatment options for feline HS have not been well studied, though reports of responses to CCNU, masinitib, and RT exist.[574,581]

Feline Progressive Histiocytosis

FPH is a neoplasm of DC that occurs initially on the skin and progresses over time to involve multiple organs.[581,582] Lesions appear on the skin as multiple firm, haired or hairless, dermal papules or nodules with a predilection for the head, feet, and legs. The lesions may enlarge gradually and coalesce into plaques, and can become ulcerated and painful over time. An example of a cat with advanced lesions in shown in Fig. 34.16. The disease is usually progressive over months or years (median 13.4 months) with late spread to LNs, lungs, and abdominal visceral organs. Females appear to be overrepresented.

• **Fig. 34.16** A cat with advanced feline progressive histiocytosis. The lesions consist of multiple coalescing hairless dermal nodules on the head, some of which have become ulcerated. (Courtesy Emily Rothstein, DVM, DACVD, Animal Allergy and Dermatology Service of Connecticut, Plantsville, CT.)

A diagnosis of FPH is made through biopsy and histopathologic evaluation of skin lesions. Lesions appear histologically as poorly circumscribed multinodular aggregates or masses of round cells with or without epitheliotropism in the dermis and, occasionally, invading subcutis. Cells have mild to moderate anisocytosis and anisokaryosis, and mitotic figures are rare. IHC may be necessary to confirm the diagnosis and rule out other round cell tumors.[582] Staging test results are usually negative for internal organ involvement early in the course of disease, but tumor may be found in LNs, lung, and/or abdominal viscera as the disease progresses. Surgical excision may control solitary, superficial skin lesions early in the course of disease, but development of additional skin lesions is expected. Skin lesions do not appear to respond to corticosteroid therapy, and effective medical treatment of diffuse skin or visceral lesions has not yet been described.[581] In a recent study, one cat with FPH experienced a spontaneous regression, another achieved a complete response to masitinib therapy, and yet another had a partial response to CCNU.[582]

Pulmonary Langerhans Cell Histiocytosis

A single case series exists describing an aggressive neoplasm arising from Langerhans cells in three cats.[583] All three cats presented for respiratory compromise or distress with symptom duration ranging from 5 days to 7 months. Thoracic radiographs showed a diffuse, severe bronchointerstitial lung pattern with diffuse military to nodular opacities in all lung fields. Symptomatic therapy was unsuccessful in all cats and the diagnosis of LCH was made on necropsy through the use of extensive immunostaining and electron microscopy confirming the presence of Birbeck's granules. At necropsy, metastasis to pancreas, kidneys, liver, and/or visceral LNs was noted in all three cats.

Comparative Aspects

Histiocytic neoplasia is extremely rare in people, and many purported cases were reclassified as lymphomas with the advent of IHC and advanced molecular testing.[584] More recently, the disease has been better described and classified into HS, Langerhans cell sarcoma, LCH, follicular dendritic cell sarcoma, interdigitating cell sarcoma, and indeterminate dendritic cell sarcoma.[585] HS in humans presents in the LN in one-third of patients, in the skin in one-third of patients, and in extranodal sites in the remaining patients. The intestinal tract is the most common extranodal site and hepatosplenomegaly is common. Some patients may also present with multiple anatomic sites of involvement and 70% of patients present with advanced stage (III or IV) disease.[584] HS in humans is an aggressive neoplasm that is often refractory to therapy and results in death in most patients. Similar to that in dogs, hypoalbuminemia is associated with a poorer prognosis in people with histiocytic neoplasia.[585] Braf and MEK mutations have been found in some cases of HS and other histiocytic neoplasia types.[585,586]

The results of a recent study using genome-wide array comparative genomic hybridization to evaluate copy number alternations suggest that canine HS may offer a valuable model for the human counterpart.[530] Extrapolation of data derived from canine histiocytic disorders to human histiocytic proliferation may help further our understanding of the disease to promote the development of new and effective therapeutic modalities for both species. Because many of the recurrent genetic changes are evolutionarily conserved with those reported in human histiocytic proliferations, this further points to a shared conserved pathogenesis.
