Integrative Oncology

NARDA G. ROBINSON

What *Is* "Integrative Oncology"?

Integrative oncology constitutes a diverse approach to the treatment of patients with cancer that encompasses both conventional and unconventional approaches. The term "integrative" medicine has largely replaced the longer designation, "complementary and alternative medicine" (CAM). Several National Cancer Institute (NCI)-designated comprehensive cancer centers have formally established integrative medicine centers within their hospitals, offering integrative approaches such as acupuncture, oncology massage, music therapy, meditation consultations, physical therapy, nutrition counseling, health psychology, and more. Patients and families who consult these centers are typically seeking to improve survival, manage side effects of conventional care, and take a proactive approach to treatment. Although many of these methods, such as acupuncture and massage, translate readily to veterinary care, others (e.g., botanical medicine and dietary supplements) require more caution because of physiologic differences in xenobiotic metabolism. That said, more research focusing on integrative oncologic approaches is necessary in veterinary oncology, as limited data exist at present for the target species. Consequently, the topics and techniques presented in the text that follows rely heavily on human and laboratory animal findings.

Looking for an "All Natural" Cure for Cancer

One of the most frequently asked questions clients raise is whether any "natural" approach exists that can replace more conventional cancer therapies such as surgery, chemotherapy, or radiation therapy (RT). Unfortunately, there is no reliable nonconventional cancer "cure." However, as research sheds light on the ability of botanical products to halt tumor progression in certain tumors, the incorporation of integrative approaches may become more important in the overall care of cancer patients. Furthermore, pursuing integrative medicine during and after chemotherapy and/or radiation may boost host defenses, reduce conventional treatment side effects, accelerate healing, and promote resumption of normal daily living. Clients want and need factual, science-based guidance on which therapies offer the most help and the least harm, and veterinarians that scientifically assess the benefits and risks of integrative medicine will occupy a central role and responsibility in providing vital education for those that depend on them.

Integrative Medicine Inroads into Oncology

Nearly 40% of adults and 12% of children in the United States access integrative medicine, and more than 50% of human cancer patients include some form of integrative medicine in their treatment.[1,2] They do so to improve quality of life and treatment outcomes and to fill gaps left by conventional medicine, especially in the areas of physical and emotional pain. Integrative medicine may cushion the effect of treatments that can be otherwise frightening and painful, allowing patients to relax and, at least for humans, maintain hope.

A survey of clients at the Colorado State University Flint Animal Cancer Center found that 76% accessed integrative approaches. Most did so to support the well-being of their animal. Others were seeking pain control, reduction in treatment toxicity, and appetite support.[3] The study also found that most clients had not discussed these treatments with their primary care veterinarian. What would have happened if they had done so? Would their veterinarian have challenged them and attempt to talk them out of pursuing additional options? Or, would their veterinarian have been able to provide clear and appropriate guidance on the pros and cons of various integrative medicine approaches? Until more veterinary schools offer science-based education to students in integrative therapeutics, most veterinarians will graduate and enter practice lacking a full understanding of the pharmacologic basis of botanical medicine, the neuromodulatory benefits of acupuncture and massage, the restorative effect of photobiomodulation, and the risks not only of folkloric approaches but also scientifically scrutinized care. The goal of this chapter is to elucidate the pros and cons and also the promises and pitfalls of integrative medicine for cancer patients.

Where to Begin?

No "one size fits all" approach exists. As conventional care strategies become increasingly tailored to the individual (so called *personalized medicine*), so should integrative care strategies.

Identify Treatment Goals

Before embarking on an integrative approach, clearly defining goals will help develop the initial plan. Discussions should include methods (e.g., metrics) to monitor comfort, mobility, pain control, appetite, and the activities of daily living along with strategies to achieve those goals. Revisiting and revising preliminary goals as treatment proceeds will keep the integrative approach focused and tailored to current needs and challenges.

VetBooks.ir

See the Big Picture

By definition, integrative oncology includes both conventional and complementary medical treatment methods; this may translate into multiple health care providers participating in the patient's treatment care. Communication becomes vital to avoid unnecessary, duplicative, or counterproductive approaches. Sometimes, excessive treatment can be taxing on both the patient and client, and a frank discussion about what is working and what is not may streamline care and place fewer burdens on both. Exploring the pros and cons in this broader context with the client may help alleviate family members' feelings of guilt and the fear of "not doing enough," when in reality they might be doing more than indicated or warranted.

Recognize Patient Comorbidities

The advanced age of patients with cancer raises the likelihood that those individuals will be harboring medical and/or physical problems in addition to neoplasia. Attending to the "whole patient" embodies a cornerstone of integrative oncology care. Introducing acupuncture and massage to alleviate pain and stress carries the side benefit of homeostatic regulation and stronger host defenses (i.e., robust immunologic protection and the ability to recover after injury). Evidence suggests that patients who feel better overall will more likely complete their planned course of chemotherapy and/or RT and have more positive results.[4,5]

Fully evaluating a patient with myofascial palpation[6] before chemotherapy and/or RT with respect to general well-being may provide practitioners insight into ways to address preexisting pain and dysfunction even before conventional treatment commences.

Common Approaches in Integrative Oncology

Acupuncture

Nearly two-thirds of human cancer patients experience pain.[7,8] Negative side effects from opioid analgesics or other concerns regarding conventional pain medications often prompt clients to request drug-free alternatives. Acupuncture, which uses the insertion of thin, sterile needles into certain sites (called "acupuncture points") on the body is one such alternative.

Acupuncture points correspond to influential neurovascular or myofascial zones that, when activated, promote analgesia, recovery of normal circulation and immune function, physiologic restoration, and homeostasis.[9,10] In addition to needling, other forms of somatic afferent stimulation include acupressure, laser acupuncture, and electroacupuncture, wherein one clips electrode wires to the needles to augment the stimulation and neurologic response. Research supports that patients who receive acupuncture require less medication to control pain.[11,12]

Specifically, nerve fiber stimulation begins at the needle–tissue interface, where local alterations in cytokines and inflammatory mediators lead to modulation (i.e., normalization) of circulation and immune function in the immediate area surrounding the site around the needle.[13,14] From there, agitation of the connective tissue and subsequent tugging of the collagen fibers, fibroblasts, and myofascia in the region produce activation of sensory somatic and autonomic nerve fibers. When excited, afferent pathways ferry action potentials along large nerve axons that underlie and often define the trajectory of acupuncture channels. A cascade of responses follows in the central nervous system (CNS) and autonomic nervous system (ANS), generating somatosomatic, somatoautonomic, and somatovisceral reflexes in spinal cord segments related to the excited nerve(s). In addition to propriospinal signaling, acupuncture induces changes in the neuronal firing patterns in the limbic system, cerebellum, cortex, and brainstem. Functional brain imaging research shows, by reflecting alterations in neuronal metabolism, which centers process pain, regulate autonomic function, and affect moods in response to acupuncture.[15] This aids in the ever-deepening awareness of the neurophysiologic underpinnings of acupuncture.

How Might Acupuncture Benefit a Veterinary Patient with Cancer?

Although acupuncture provides repeatable and measurable benefits for patients with advanced cancer, the treatment is underutilized.[16–22] Human integrative oncology clinics have found acupuncture to be a safe, inexpensive, and effective intervention for problems that cancer patients often encounter, including leukopenia, gastrointestinal upset, and systemic reactions.[23,24] Acupuncture may reduce the emetic effects of chemotherapy and opioids.[25,26] For pain management, many studies on acupuncture show improvement, though more rigorous studies are needed.[27] Acupuncture has also been used to treat fatigue, hot flashes, immune system support, neuropathy, anxiety, depression, xerostomia,[28-30] and sleep disturbances in humans.[31] Even for human patients with advanced, incurable cancer, acupuncture has been shown to alleviate a wide range of symptoms with no significant or unexpected adverse effects.[32]

Risks of Acupuncture

Studies indicate that acupuncture performed by a medical professional for patients with cancer poses little risk of injury.[33–35] That said, one should obviously avoid penetrating the tumor or seeding local tissues with cancer cells. Owing to the complexity of treatment and patient considerations for animals with cancer, any acupuncturist treating animals should have a thorough understanding of animal health and disease, and acupuncture anatomy and physiology, to minimize risk of injury.

Botanical Medicine

Considering their diverse and documented anticancer benefits, plant-based medicines offer some of the greatest hope for an actual cure for cancer. After all, nearly half of cancer drugs used over the past two decades arose directly as derivatives from plants or indirectly, as chemically altered derivatives.[36] Classes of plant-associated chemotherapeutics include the vinca alkaloids (vinblastine, vincristine, and vindesine), the taxanes (paclitaxel and docetaxel), camptothecin derivatives (irinotecan and camptothecin), and the epipodophyllotoxins (etoposide and teniposide).[37] The search for new and better drugs continues; to date, the NCI has screened tens of thousands of plant species for anticancer value. Of these, nearly 9% have demonstrated reproducible activity against cancer.[37]

Many natural products from both Eastern (most notably, Asian) and Western herbs have demonstrated anticancer benefits through in vitro analysis of their effects on human cancer cell lines.[38] For example, extracts and pure compounds derived from the Chinese herb *Euphorbia fischeriana* Steud exhibit antitumor, antimicrobial, antiviral, immune stimulating, and analgesic activities.[39] Research on mice has shown *E. fischeriana* extracts

VetBooks.ir

to be effective against malignant melanoma, ascitic hepatoma, and Lewis lung carcinoma. Other research on mice has demonstrated the ability of a mixture of botanical extracts made from fermented soybeans, grape seed, green tea, and more to enhance the effectiveness of chemotherapy while limiting adverse effects.[40]

Botanical products frequently encountered in veterinary integrative oncology include Asian mushrooms (immune-enhancing), curcumin from the spice turmeric, *Boswellia* from the frankincense tree (antitumor and antiinflammatory), and bloodroot (escharotic), though the latter has fallen out of favor in recent years because of its potential for causing injury and pain, as described in the text that follows. Veterinarians who decide to introduce botanical agents into a patient's care should do so with the same degree of caution and critical evaluation as one would employ with any chemotherapy drug. The tendency to overlook the potential for intrinsic toxicity or risk of herb–drug interactions could lead to unforeseen problems such as a heightened bleeding risk or alterations in serum concentrations of prescribed drugs. Furthermore, little research exists on veterinary botanical products and their pharmacokinetics and pharmacodynamics remain mostly a mystery, as do safe and effective dosing levels.

Supplement Questions and Quality Control Issues

In contrast to the more tightly regulated pharmaceutical industry, products comprising dietary supplements and herbal products raise far-reaching concerns about manufacturing quality, purity, and reliability. Contamination with microbes, heavy metals, and dirt from manufacturing, combined with undisclosed adulteration with pharmaceuticals complicate the picture and can obscure the actual risk or benefit from the listed ingredients. Chinese mixtures raise even more red flags, ranging from US Food and Drug Administration (FDA) import bans[41] on the importation of veterinary Chinese herbal products to the potential inclusion of endangered plant and animal species. Plant substitution, misidentification, and proprietary (secret) ingredients leave additional gaps in health care providers' trust in Chinese remedies.

Risk of Treatment Interactions

Scrutinizing a patient's entire integrative oncology treatment plan should help diminish the client's reliance on redundant, superfluous, and/or counterproductive concurrent approaches. In particular, the risk/benefit ratio of adding or omitting a botanical product should take into account the potential for herb-drug interactions. Pharmacologic interplay between medications and supplements could change circulating drug concentrations and render a chemotherapy, analgesic, or anesthetic compound ineffective or toxic. Herbs that have anticancer effects but contain phytoestrogens such as *Angelica sinensis* may adversely affect patients with hormone-sensitive cancer.[42]

Herb-drug interactions in oncology occur through a number of pharmacodynamic and pharmacokinetic pathways, and much more remains to be learned about specific herbs, drugs, and clinical significance through research in veterinary target species. Often ignored among herbalists and oncologists alike, herb-drug interactions pose a clinically relevant problem in oncology, due to the narrow therapeutic index of most cytotoxic drugs.[43] In fact, induction of drug-metabolizing enzymes and transporters may lower plasma levels of anticancer drugs and result in subsequent treatment failure. Inhibition of these detoxification pathways could also contribute to enhanced chemotherapy drug toxicity. Several popular herbal products have been identified as likely to contribute to herb-drug interactions under certain conditions.[44] These include, but are not limited to, St. John's wort,[45] kava-kava, ginseng, garlic, milk thistle (silybin), evening primrose oil, green tea, Echinacea,[46] vitamin E, beta-carotene, and quercetin[47] supplements.

Some plant mixtures both induce and inhibit drug-metabolizing enzymes because of the complexity of their biochemically active constituents. Many plant-based substances act as antioxidants. The antioxidant activity of some phytotherapeutics such as green tea is potent enough that clinicians should consider the risk of abrogating the benefits of chemotherapy if the two are coadministered.

Another concern involves the potential for immune system stimulation by plant products that promote lymphocyte proliferation. Although immune-enhancing herbs may help a patient fight some immunogenic cancers, adding these products (e.g., burdock root, astragalus, medicinal mushrooms, Echinacea) could prove counterproductive for conditions such as lymphoma.

Finally, several botanical ingredients can increase the risk of hemorrhage through inhibition of platelet activity and aggregation.[48] This could negatively affect patients with hemangiosarcoma, those undergoing biopsies or surgery, and individuals receiving concurrent anticoagulant or antiplatelet medications. Cancer patients may already have thrombocytopenia from chemotherapy or bone marrow infiltration (myelopthisis) that could compromise their capacity to clot.

A study of a standardized extract of Maitake mushroom in dogs with lymphoma reported no objective value, although two dogs did develop hyphema and one developed petechiae.[49] These agents can inhibit platelet function; whether the bleeding noted in this study related to the Maitake mushroom or the lymphoma was unclear.

The "4 G's" mnemonic (i.e., ginkgo, ginseng, ginger, and garlic) helps one remember which herbs most notably inhibit coagulation.[50] Many Chinese herbal formulations contain one or more of these ingredients. That said, proprietary mixtures that fail to disclose the amounts of their ingredients to keep the mixture a "trade secret" make it impossible for practitioners to ascertain the level of risk that that supplement poses.

For more information on specific plant compounds and their interaction risk, the reader is referred to Memorial Sloan-Kettering Cancer Center's website or their free app entitled "About Herbs."[51]

Additional Issues with Chinese Herbs

Recommending traditional Chinese herbal medicine (TCHM) based on rigorously derived discoveries in botanical research allows practitioners to discard untestable, abstract mechanisms of action such as claiming that they "resolve stagnation, invigorate Qi, and remove phlegm/damp accumulation."[52] Computerized databases may assist oncologists by enabling determination of relevant, potential interactions between anticancer drugs and Chinese herbs.[53] Even oncologists in China are encouraging their colleagues to maintain a watchful eye for surprise sequelae. For example, one paper warned: "[P]rofessional complacency about TCM [Traditional Chinese Medicine] use is becoming less acceptable as the knowledge base of TCM-induced toxicities and interactions expands. Being rich sources of bioactive xenobiotics, TCMs are frequent causes of puzzling complications, including hepatotoxicity, nephrotoxicity, and hematologic disorders."[54]

Some TCHMs are chemosensitizing or radiosensitizing and thus may cause conventional treatment to have more robust activity, whereas others directly antagonize medication through one or

VetBooks.ir

more mechanisms. Toxicity from Chinese herbs coadministered with chemotherapy may lead to diagnostic dilemmas when clinicians misattribute problems to the drug rather than the TCHM product, thereby delaying discontinuation of the appropriate compound. In fact, Chinese herbalists in Taiwan who work directly with herbs in the raw form are at increased risk of liver and bladder cancer, possibly owing to heavy metal contamination of TCHMs and/or the intrinsic toxicity of some ingredients.[55] This heightened risk for urologic cancers, chronic and unspecified nephritis, renal failure, and renal sclerosis "highlights the urgent need for safety assessments of Chinese herbs."[56]

Public perception holds that TCHMs may protect cancer patients' health and well-being during chemotherapy. A double-blind, randomized, placebo-controlled study questioned this assumption, showing that TCHMs did not significantly reduce hematologic toxicities (leukopenia, neutropenia, and thrombocytopenia) associated with adjuvant chemotherapy for breast and colon cancer.[57] Three licensed, experienced TCHM practitioners from China prescribed herbal formulas to patients on an individualized basis, as many believe this approach yields superior benefits. Even the myth that individualizing TCHMs produces more significant improvement could be more folklore than fact. According to some critics, "[A]lmost all individualized herbal medicine is practiced without the support of any rigorous evidence about effectiveness whatsoever."[58] They continue,

> *The lack of standardisation and use of multiple herbs in a single prescription also greatly multiply the safety risks. There are additional risks associated with variability in the diagnostics skills of the practitioner, their awareness or lack of awareness of potential interactions, and their ability or inability to identify red flag symptoms indicating serious diseases requiring immediate mainstream medical treatment. Given the risks and lack of supporting evidence, the use of individualised herbal medicine cannot be recommended in any indication.*

Examples of Herbs Suggested for Patients with Cancer

The botanical agents covered in the text that follows appear because of their popularity, not as a means of advocacy for their inclusion in veterinary oncologic care. The responsibility of prescribing or recommending herbal products lies with the practitioner handling each case and should be approached with the same critical mindset and scientific rationale as any chemotherapeutic drug or other conventional intervention.

Asian/Medicinal Mushrooms

Medicinal mushrooms and fungi display more than a hundred medicinal functions potentially relevant to the treatment of cancer.[59] These activities include antitumor, immunomodulatory, antioxidant, radical scavenging, and hepatoprotective effects that enhance humoral and cell-mediated immune responses. A variety of medicinal mushrooms and extracts have proved beneficial, improving immune parameters such as natural killer (NK) cell activity and cytokine expression, without significant toxicity.

Mushroom mixtures and mushroom-derived polysaccharide preparations modify tumor response and improve immune function in patients with solid tumors.[60] The active agents in Asian mushrooms, polysaccharides, also possess antitumor effects through inhibition of cellular proliferation and tumor growth, invasion, and angiogenesis.[61]

Enthusiasm for the use of medical mushrooms in dogs with cancer followed the publication of a 2012 study in the journal *Evidence-Based Complementary and Alternative Medicine*.[62] This research investigated the ability of an extract of turkey tail mushroom (*Coriolus versicolor*) containing standardized amounts of the bioactive agent polysaccharopeptide (PSP), to affect the survival and quality of life of a small number (n = 15) of dogs with hemangiosarcoma. Results suggested that the median time to developing abdominal metastases or finding progression was lengthened in five dogs taking 100 mg/kg/day of the commercially available preparation called "I'm-Yunity" compared with lower doses of I'm-Yunity. No differences were noted in survival times, however. Of note, the survival time of nearly 200 days for five dogs in the highest dose treatment group was numerically longer than that reported for dogs on doxorubicin-based chemotherapeutic treatment protocols, which typically falls between 141 and 179 days. These findings raise important questions. Could this product demonstrate survival effects similar to or beyond that provided by standard of care chemotherapy in larger scale studies? Could research such as this lead to changes in standard of care from cytotoxic drugs to botanical medicine? The answers to these questions are yet unanswered. No direct statistical comparison was made between this very small (n = 5) group of dogs and dogs receiving standard of care chemotherapy. The "randomization" in this trial was between I'm-Yunity dosing groups, not between I'm-Yunity and standard of care. Although these results suggest activity, a randomized trial with sufficient statistical power would be necessary to confirm activity either equivalent or superior to standard of care chemotherapy.

Human trials have found benefit with turkey tail mushroom as well. A proprietary, protein-bound polysaccharide extract of *Coriolis versicolor* reduced serum levels of immunosuppressive acidic protein in stage II and III colorectal cancer patients, increased 5-year disease-free survival, and decreased relative risk of regional metastases.[63] A meta-analysis of three trials involving more than a thousand subjects with colorectal cancer confirmed these results.[64] Moreover, a systematic review and meta-analysis of the efficacy of *Coriolus versicolor* on survival in cancer patients revealed that this mushroom confers survival benefit for patients with breast, stomach, and colorectal carcinoma.[65]

Bloodroot

Bloodroot extract acts as an escharotic when topically applied in a salve or destructive agent when injected directly into tumors.[66,67] The "black salve" version of bloodroot (*Sanguinaria canadensis*) may come admixed with mineral agents such as zinc chloride, chromium chloride, or arsenic trisulfide and possibly other herbs. Bloodroot pastes became popular in the midtwentieth century and have persisted despite risks of serious injury. It causes strong and rapid apoptotic responses through several modes of cell death, including an early and severe glutathione-depleting effect.

Sanguinarine, the active ingredient in bloodroot, supposedly targets only cancer cells, according to its enthusiastic supporters. Sanguinarine does appear to selectively target cancer cells over normal cells in vitro, and it may sensitize these cells to chemotherapy-mediated growth inhibition and apoptosis.[68] Sanguinarine has also been reported to exert dose-dependent differential antiproliferative and apoptotic effects on cancer and normal cells.[69] How tissue levels in vivo would compare with those tested in vitro is unknown, although high concentrations of sanguinarine can cause normal keratinocytes to necrose.

Websites selling black salves for veterinary cancer patients have, over the years, posted pictures showing tumor elimination for patients that were purportedly deemed untreatable by conventional practitioners. Even Dr. Andrew Weil, the author of

VetBooks.ir

the bestseller *Spontaneous Healing* and director of the Program in Integrative Medicine (PIM) at the University of Arizona in Tucson, reportedly claimed that black salve cured a tumor on his dog, though his own post is no longer available on this topic.[70] Instead, he now cautions on www.DrWeil.com that the use of bloodroot can cause excruciating pain and tissue degradation. It may also leave residual tumor.[71] Over time, the toxicity of bloodroot in dogs with cancer has come into focus and their use in cancer patients is now discouraged.[67]

Boswellia

Boswellic acids exhibit potent antiinflammatory properties in vitro and in vivo. Triterpenes in boswellic acid reduce the synthesis of leukotrienes in intact neutrophils by inhibiting 5-lipoxygenase, the key enzyme involved in the biosynthesis of leukotrienes, which mediate inflammation.[72,73] *Boswellia* extracts exert immunomodulatory effects by simultaneously inhibiting T-helper 1 (Th1) and promoting Th2 cytokine production.[74] They regulate vascular responses to inflammation and stabilize mast cells.[75] In cases of intestinal inflammation, boswellic acids may modulate the adhesive interactions between leukocytes and endothelial cells by countering the activation of leukocytes and/or downregulating the expression of endothelial cell-adhesion molecules.[76,77]

Side effects of boswellic acids may include abdominal discomfort, nausea, epigastric pain, and diarrhea.[78]

The presence of food in the stomach, and the type of food eaten, dramatically alters the bioavailability of boswellic acids, and bile acids significantly affect their absorption. When human subjects ingest boswellic acids along with a high-fat meal, the area under the plasma concentration—time curves and peak concentrations were several times greater than when the herbal preparations are taken in the fasting condition. A human study showed that the elimination half-life for boswellic acid was approximately 6 hours, suggesting that oral administration would require dosing every 6 to 8 hours.[79]

Frankincense extracts, and boswellic acids themselves, display moderate-to-potent inhibition of human drug-metabolizing CYP450 enzymes, but the potential to cause clinically relevant drug—herb interactions is unclear.[80]

Curcumin

Cancer cells have various methods to evade host defenses. Intuitively, this implies that a drug or herb would work best against cancer when it has more than one mechanism of action against the disease. Curcumin, a bioactive component of the spice turmeric, has been shown to have several mechanisms of action.[81,82] It induces phase II detoxification enzymes, suppresses tumor cell proliferation in several cancer cell lines, and downregulates transcription factors (nuclear factor κB [NFκB], activator protein 1 [AP-1], and early growth response 1 [EGR-1]).[83,84] Curcumin also downregulates enzymes such as cyclooxygenase-2 (COX-2), lipoxygenase (LOX), nitric oxide synthase (NOS), matrix metalloproteinase 9 (MMP9), and urokinase-type plasminogen activator; it also limits production of tumor necrosis factor, chemokines, cell surface adhesion molecules, and growth factor receptors (e.g., epidermal growth factor receptor [EGFR], human EGFR 2 [HER2]).[85] Curcumin may have antiangiogenic effects[86] and may alter the cytotoxicity of certain chemotherapy drugs.[87,88]

Curcumin causes cell death in several human cancer cell lines, including breast, lung, prostate, colon, melanoma, kidney, hepatocellular, ovarian, and leukemia.[89] Curcumin produces cell death through both apoptotic mechanisms and alternative means. When resistance develops to apoptosis-inducing factors, curcumin can overcome this impediment through alternative cell-signaling pathways, such as mitotic catastrophe.[84] Curcumin may also counteract the induction of prosurvival factors in cells generated by RT and chemotherapy.

Human clinical trials demonstrate no dose-limiting toxicity for pure curcumin when given at up to 10 g daily, whether orally (in human studies) or by means of intraperitoneal or intravenous administration in rodent-based experimental animal research.[84] The amount of curcumin contained in turmeric averages only about 3% by weight; concentrated curcumin supplements therefore supposedly provide higher levels of the active constituent, provided that the label and actual contents agree. The hurdles of maintaining adequate blood levels of curcumin pertain to its low bioavailability, although absorption varies between species. One way to overcome delivery challenges could include coupling it with compounds that focus curcumin's activity toward specific target cells.

Curcumin could hypothetically negate some of the effects of chemotherapy because it affects so many pathways. Research suggests that curcumin can inhibit chemotherapy-induced apoptosis in breast cancer cells, specifically in combination with camptothecin, mechlorethamine, or doxorubicin.[90] The potential benefits of certain herbs should be considered and compared against the risks. For example, a synthetic analog of curcumin helped reduce doxorubicin-induced cardiotoxicity through an anticancer–antioxidant dual function in vitro.[91] In addition, curcumin and catechin (from green tea) may work synergistically against cancer through cytotoxicity, nuclear fragmentation, and antiproliferative and proapoptotic effects.[92]

Yunnan Baiyao

Yunnan Baiyao (also known as Yunnan Paiyao) is a Chinese herbal mixture consisting primarily of notoginseng that has become a popular product among veterinary clients, particularly those caring for animals with hemangiosarcoma. This popularity is the result of claims that Yunnan Baiyao regulates bleeding. Therefore patients with a high risk of hemorrhage might be less likely to bleed if Yunnan Baiyao was indeed effective.

Westerners first learned of the Chinese herbal mixture "Yunnan Baiyao," meaning "the white medicine of Yunnan," during the Vietnam War. Members of the US military discovered that prisoners from North Vietnam often carried with them a tiny bottle of this product to take in the event that they were injured and bleeding, either internally or externally.[93] Over the ensuing decades, Yunnan Baiyao has grown in popularity among complementary medical practitioners and even in some conventional medicine practices for its hemostatic and thrombolytic properties.[94]

The Chinese doctor Qu Huangzhang developed Yunnan Baiyao in the Yunnan province of China in the early 1900s. The Yunnan province is known as "the Kingdom of Fauna and Flora" for its vast supply of plants and animals used in Chinese medicinals. Although the capsule's contents were kept secret until relatively recently, suspicion grew that its main active ingredient consisted of pseudoginseng root, now called *Panax notoginseng*, notoginseng, "tien chi," or "san qi." Notoginseng is a type of ginseng that offers the highest concentration of hemostatic constituents among all seven major ginseng types.[95] Notoginseng from the Yunnan outperforms that grown elsewhere in terms of crop yield and quality.[96] Other substances in Yunnan Baiyao formulations vary between manufacturers and may include myrrh, ox bile, Chinese yam, sweet geranium, lesser galangal root, and possibly other antiseptics or astringent substances in a starch base. Some preparations of Yunnan Baiyao

VetBooks.ir

contain a different colored "hit pill" among the regular pills; however, the contents of this pill do not specifically appear on the label, although some suspect that it may contain either a concentrated dose of notoginseng or the more troublesome herb, aconite, which has both cardiotoxic and neurotoxic effects.

That there is no formal "recipe" for Yunnan Baiyao and the fact that some manufacturers still refuse to disclose their ingredients means that many unknowns persist with currently available products and caution is warranted.

Despite the many questions regarding the contents and manufacturing quality of Yunnan Baiyao, some research has emerged that may validate its hemostatic potential.[97] For example, a prospective, randomized, double-blind, placebo-controlled study on Yunnan Baiyao for human patients undergoing bimaxillary orthognathic surgery found significant reduction in intraoperative blood loss when Yunnan Baiyao was administered preoperatively for 3 days.[98] No thrombolic events or other side effects were noted during this short-term administration. A prospective study of the effects of oral Yunnan Baiyao on thromboelastographic parameters in apparently healthy dogs showed that the product was well tolerated and increased the strength of blood clotting.[99]

On the other hand, a 2017 report of the effects of Yunnan Baiyao on blood coagulation in beagle dogs found no clinically significant effects on the coagulation parameters under study.[100]

Additional indications in the future may arise for cancer treatment because of the cytotoxic effects of notoginseng,[101] which also exhibits the capacity to specifically sensitize tumor cells to ionizing radiation. An in vitro analysis of Yunnan Baiyao on canine hemangiosarcoma (HSA) cell lines revealed a dose- and time-dependent HAS cell death by means of caspase-mediated apoptosis.[101a] That said, high doses of notoginseng could also be toxic to bone marrow stem cells.[102] Furthermore, a retrospective case-controlled study of Yunnan Baiyao administration in dogs with right atrial masses and pericardial effusion did not show a significantly delayed recurrence of clinical signs or improved survival.[103]

In summary, although Yunnan Baiyao may reduce the risk of bleeding, one must weigh the strength of its anecdotal acclaim against the unknowns regarding dosage, purity, and long-term benefits or risks.

Homeopathy

Homeopathy constitutes an alternative type of health care based on an irrational premise that the more dilute a remedy is, the more potent it is. Homeopathic remedies are produced with low to extremely low concentrations of the substance from which it was derived. This means that the amount of active pharmacologic ingredients in the solution may range from a weak extract of plant, animal, or mineral contents to barely undetectable amounts. That said, even small amounts of toxic substances, especially when ingested over long periods of time, can still induce injury or death.

Homeopathic practitioners claim that they prescribe their remedies to stimulate an individual's natural healing response. According to homeopathic principles and the "like cures like" doctrine, a natural substance that causes symptoms of illness in a healthy person can, when prepared correctly, cure that same set of symptoms in an unhealthy person. Thus when selecting a remedy for a patient, the homeopath determines which substance would most closely cause an identical "symptom picture" if given in larger quantities. She or he then recommends the homeopathic dilution to alleviate those issues based on the aforementioned "like cures like" principle.

Contrary to conventional medical pharmacotherapeutic methodology, homeopathic lore asserts that remedies are more powerful as they become more dilute. As difficult as homeopathic theory is to believe, the remedies are as easy to administer as sugar pills because, for many remedies, the pills are just that: lactose tablets impregnated on the outer surface with a diluted homeopathic mixture. Most remedies are available over the counter. Although most states consider the practice of homeopathy on animals as part of veterinary medicine, clients can and do self-prescribe and self-administer the medication to their animals. Several do-it-yourself books on veterinary homeopathy are available.

How Does Homeopathy Work?

First, there is the question of whether homeopathy does, in fact, work. Most systematic reviews and meta-analyses find that the effects of homeopathy resemble the strength of placebos. The benefits seen in humans receiving homeopathy may be due to the lengthy interviewing process itself rather than the homeopathic remedies per se.[104] Currently, there is no repeatable, rigorous evidence that homeopathy works for veterinary patients. Similarly, there is no rational mechanism of action.

In human homeopathy, evidence for the incorporation of homeopathy for symptom control in cancer patients is weak and burdened with methodological flaws, uncontrolled trials, and/or small subject numbers. Positive benefits shown in smaller studies frequently disappear when the study is repeated with larger numbers and controls.

The most reliable benefit from homeopathy may be its placebo effects on the client (i.e., bolstering a feeling that they are doing something safe and supportive for their animal with cancer). This false sense of assurance could work against the animal's best interests if it delays meaningful diagnosis and effective care, as illustrated in a human study on the effect of antecedent use of CAM in delaying medical advice sought for breast cancer.[105]

Can Homeopathy Cause Direct Harm?

Scrutiny of homeopathic claims is growing in both human and veterinary medicine. Serious adverse events and deaths in children consuming homeopathic teething pills finally came to light as a US FDA investigation became public into homeopathic products that had a 10-year track record of serious adverse effects.[106] As it turned out, dilutions assumed to be safe were not. Similarly, concerns are mounting in the veterinary community about the dangers of homeopathy for animals, whether due to intrinsic toxicity of improperly produced remedies or the ethical infractions of treating animals with substances indistinguishable from placebo.[107] Owing to its unlikelihood of helping and risk of harm, homeopathy has no place in cancer care for animals.

Massage

Massage incorporates several methods of hands-on, low-force techniques that target restrictions and pain, mostly in the soft tissues of the body. The benefits that massage may hold for cancer patients encompass quality of life, control of postoperative or postprocedural pain and stress, and support of improved mobility and functional recovery after amputation.

Cancer and its standard control measures can make people and animals physically uncomfortable. A 2011 study of patients with metastatic bone cancer, reported in the journal *Pain*, found that "[T]he reduction in pain with massage was both statistically and clinically significant, and the massage-related effects on relaxation

VetBooks.ir

were sustained for at least 16–18 hours postintervention."[108] Massage also showed benefit in terms of mood, muscle relaxation, and sleep quality.

A 2017 systematic review of controlled clinical trials on massage for children with cancer found that patients experienced less pain, nausea, stress, anxiety, and immune suppression.[109] These findings comport with assessments of the effects of massage in adults both with and without cancer.

How Does Massage Work?

Based on the rapidly expanding paradigm of autonomic neuromodulation and the desire by medical massage therapists to explain how their treatments work, a unifying theory is beginning to emerge that helps explain the effects of massage on diverse bodily activities, such as digestion, emotional states, sleep, weight regulation, pain control, and immune function.[110] Ordinarily, animals suffering from acute and chronic illness exhibit heightened sympathetic tone that can cause maladaptive changes. The complementary, dualistic reciprocity encoded within the ANS dictates that as parasympathetic tone increases, sympathetic (fight-or-flight) activity diminishes. Consequently, reducing sympathetic hyperactivity by means of massage can benefit patients by countering peripheral vasoconstriction, inflammation, muscle tension, spinal cord windup, and pain. For older veterinary patients suffering from cancer and those recovering from surgery and experiencing postoperative ileus, regulation of digestive function through massage may provide much-needed parasympathetic support.

The relaxing benefits of medical massage assist veterinary oncology patients in counteracting stress during minimally invasive procedures, although it should never be relied on to replace conventional anesthesia and analgesia for more painful events. Facial massage calms patients at least in part by activating trigeminal-vagal reflexes.[111] Veterinary technicians can include certain techniques while assisting with gentle restraint; slow, up-and-down moderate pressure massage along the midline between the nose and forehead can sometimes induce a quasihypnotic state.

What Are the Risks of Massage for Cancer Patients?

Patients with osteosarcoma, skeletal metastasis, spinal instability, low platelet count, or osteopenia should avoid deep massage. Light or moderate pressure, delivered through skilled hands after informed palpation, would not be contraindicated, except over painful regions or areas that have undergone recent surgery, demonstrate instability, or harbor infection. Massage should be avoided over implantations to deliver chemotherapy or other drugs. Massage to sites containing stents or prostheses may cause displacement. Tissues subjected to prior surgery or RT may be fragile, and massage to these areas should either be avoided or be done gently. Hypercoagulable patients may experience emboli subsequent to deep pressure over a thrombus; patients who are prone to bleeding may develop hematomas secondary to pressures that in normal patients would not cause problems. Deep abdominal massage has caused internal bleeding even in the absence of bleeding disorders. Although no evidence exists to indicate that massage promotes the likelihood of tumor metastasis, one should avoid massage directly over known tumors or predictable metastasis sites.

Photobiomodulation (Laser Therapy)

Photobiomodulation (PBM), formerly known as low-level laser therapy (LLLT) or simply laser therapy (LT), involves exposing tissues to photons from laser units or light-emitting diodes (LEDs) in a manner that stimulates cellular function and produces clinical benefits. It contrasts with laser surgery, which destroys tissue.

In contrast to acupuncture, in which input begins with the microtraumatic mechanical effects of the needle on local tissue, LT relies on the absorption and scattering of light within tissue. LT imparts a monochromatic, narrow-band, coherent light source. Photons from the laser support endogenous processes that involve cell division and proliferation; this is one of the main reasons why cancer has been considered a relative contraindication for PBM.

Physiologic responses from LT's PBM include increased phagocytosis; vasodilation; increased rate of regeneration of lymphatic and blood vessels; stimulation of enzyme activity at the wound edges; fibroblast stimulation; keratinocyte and fibroblast proliferation; scar and keloid reduction; increased adenosine triphosphate (ATP) and DNA synthesis; and stimulation of muscle, tendon, and nerve regeneration.[112] Clinically, PBM provides safe and cost-effective treatment for wound healing, neurologic recovery, pain reduction, and lymphedema control.[113]

With respect to oncologic care, a growing body of evidence suggests that LT may help alleviate oral mucositis. A 2007 Phase III, randomized, double-blind, placebo-controlled clinical trial that evaluated the efficacy of LLLT for the prevention of oral mucositis (OM) indicated that laser with a 650-nm wavelength reduced the severity of OM and pain scores.[114] No adverse effects were noted in this study. In 2011 a systematic review of studies on this topic concluded that although sample sizes were low, overall data were consistently in favor of LLLT both preventing and diminishing the severity of OM in patients receiving chemotherapy or RT.[115] PBM for the prevention of oral mucositis not only lowers morbidity; it also may save thousands of dollars per case prevented.[116]

Human patients with advanced head and neck cancer experience many complications after receiving RT or chemoradiotherapy. These interventions may cause loss of function and negatively affect quality of life. In the acute phase, complications include OM, pain, dysphagia, dysgeusia, dermatitis, changes in salivary function, and infection. Over time, patients may develop neuropathies, tooth demineralization and caries, periodontitis, soft tissue and/or bone necrosis, mucocutaneous and muscular fibrosis, trismus, lymphedema, and voice or speech changes.[116] Biologically, PBM has the potential to control pain, improve tissue health, maintain organ function and prevent or mitigate these complications. PBM has demonstrated the ability to enhance wound repair and tissue regeneration as it proceeds from the inflammatory, to the proliferative, and finally to the remodeling phases of injury resolution, resulting in significantly less inflammation and fibrosis.[117]

How Might Laser Therapy Harm Cancer Patients?

Little in vivo research is currently available pertaining to the risk of LT stimulating cancer growth. However, prudent practice warrants avoiding LT in cancer patients or at least, tumor sites. Questions remain about the safe distance from a tumor at which one can deliver light therapy and appropriate and nonproliferative wavelengths and doses of light. Until more is known about the specific effects of PBM on tumors and circulating lymphocytes, LT may be considered contraindicated for patients with lymphoma.

Conclusion

Cancer patients face a multiplicity of challenges, as both the treatment and the disease can make them miserable. Fortunately, medical research is revealing ways in which integrative options can lessen cancer patients' suffering and even improve survivorship.[118]

Considering the growing popularity of integrative medicine, oncology clients are eager to learn about nondrug, noninvasive options. With the appropriate, science-based education, veterinarians can guide clients toward legitimate, effective, and rational approaches that will make a positive difference and yield better outcomes.

Clinical Trials and Developmental Therapeutics

AMY K. LEBLANC, DOUGLAS H. THAMM, AND DAVID M. VAIL

Clinical research is essential to improving patient outcome and quality of life (QOL). Clinical trials in veterinary oncology have gained interest and focus over the past decade, with a growing number of consortia and cooperative groups that support multiinstitutional efforts, advocating for veterinary clinical trials and emphasizing the synergy between basic science and clinical progress. Clients who are motivated to seek advanced care for their pets and to enroll them in investigational trials that offer new therapies are key to ongoing advancement of clinical research in veterinary oncology.

Oncology clinical trials attempt to find better ways to prevent, diagnose, and treat cancer. Their model is different from trials involving infectious or nonneoplastic chronic diseases because the risks of morbidity and mortality can be greater, but the rewards, particularly for aggressive cancers lacking in highly efficacious standards of care, can be high. The culture of oncology care, whether physician-based or veterinary-based, should be on continued improvement in survival and QOL, and thus the option of entry into a clinical trial should be available. For example, the majority of children with aggressive childhood cancers are offered and entered into clinical trials that provide investigational therapies in addition to standard of care treatments; and the National Comprehensive Cancer Network recommends human patient participation in clinical trials as the "gold standard" for aggressive nonindolent T-cell lymphomas. In veterinary oncology, a similar trial-centric culture should be applied to patients with aggressive cancers (e.g., hemangiosarcoma, osteosarcoma, nonindolent T-cell lymphoma, feline squamous cell carcinoma, etc.) where cures are rare and outcomes are still generally poor with current standards of care.

During the years since the late 1970s, in investigations of standard cytotoxic chemotherapy agents in clinical trial settings, a "traditional" drug development approach using fairly rigid phases (I, II, III) and adherence to "rule-based" methods was advocated and employed. Since approximately 2008, however, a major shift in cancer drug development, both in human and veterinary medicine, has concerned a move from traditional cytotoxic agents to molecular targeted agents (MTAs). With many and varied MTAs entering the development pipeline, clinical trial methodologies employed for cytotoxic agents may not be ideal or appropriate. Although a clear dose–response relationship exists for most cytotoxic agents, this may not be the case for many MTAs. Thus a paradigm shift in clinical trial methodology, referred to as "model-based" methods, has been proposed.

This chapter considers clinical trial design and implementation, and not statistical analysis of generated data or in-depth biostatistical considerations in trial design. For the reader seeking more thorough reviews on trial design and statistical methods, recent references are listed throughout the chapter. It cannot be stressed enough that knowledgeable biostatisticians should be consulted to ensure statistical design and power are appropriate before study implementation.

Traditional Drug Development Phases

Traditional first-in-species drug development follows a strict, stepwise paradigm that begins with a phase I dose-finding trial, followed by a phase II efficacy/activity trial, and concludes with a phase III "pivotal" trial that pits a novel agent against or with the current standard of care (Table 18.1).[1,2] Veterinary oncology trials sometimes combine these concepts. Clinical trial designs, pertinent endpoints and analyses, the process for drug approval, and clinical trial ethics are explored in the sections that follow.

Phase I Trials (Dose Finding)

Phase I trials are the first step in the evaluation of a new agent or biologic.[3–5] The primary goal is to determine a tolerable dose to be used in future studies by evaluating adverse event (AE) profile, tolerability, and dose-limiting toxicities (DLTs). Typically, safety is determined in dosing cohorts that escalate toward the goal of a maximum tolerated dose (MTD) or, for targeted therapies, a biologically effective dose (BED). Activity/efficacy is not a primary goal. In fact, response rates in phase I trials for classic cytotoxic agents are seldom more than 10%. Secondary goals of phase I trials may include exploration of various drug administration schedules, response rates, pharmacokinetic (PK) information (absorption, distribution, metabolism, and elimination [ADME]), biomarker development, and effects on molecular targets or pathways (pharmacodynamics [PD]). These biologic endpoints are increasingly important components of phase I trials as dose determinants are inherently linked to drug exposure and effect, especially as we move away from more indiscriminant cytotoxic agents and toward study of MTAs. These biologic questions

TABLE 18.1 Goals of Phase I–III Clinical Trials

Characteristic	PHASE OF CLINICAL TRIAL		
	Phase I (Dose Finding)	Phase II (Activity/Efficacy)	Phase III (Pivotal)
Primary Goals	• Determine MTD or BED • Define DLT • Characterize type and severity of adverse events	• Determine activity/efficacy in defined populations • Inform the decision to move to a phase III trial	• Compare a new drug or combination with therapy currently regarded as standard of care
Secondary Goals	• PK/PD issues • Scheduling issues • Target modulation effects • Preliminary efficacy data • Investigate surrogate biomarkers of response	• Estimate therapeutic index • Expand adverse event data • Evaluate additional dosing groups • Expand target modulation and biomarker data • QOL measures • Explore predictors of outcome	• QOL comparisons • Comparative costs

BED, Biologically effective dose; *DLT*, dose-limiting toxicity; *MTD*, maximum tolerated dose; *PK/PD*, pharmacokinetic/pharmacodynamics; *QOL*, quality of life.

are also the basis of comparative oncology modeling of drug development and are emphasized in their design.[6–8] In the growing field of cancer immunotherapy, the same guiding principles apply for phase I trials, but with the added nuance of determining relationships between biologic agent exposure and the host immune response. This is yet another example of how clinical trials carried out in immune-competent tumor-bearing companion dogs offer a distinct advantage over xenograft models in early development of novel immunotherapeutic agents.

Human oncology phase I trials are typically small, open-label, single-arm trials that include patients who have failed standard therapies. As such, subjects are generally heavily pretreated with advanced disease. In veterinary medicine, the phase I patient may have failed standard of care or have a condition for which no effective standard of care exists, the standard of care is beyond the client's financial means, or the client is interested in investigational therapy. In addition, because failure of the standard of care is not a necessary prerequisite, phase I veterinary trials can proceed in patients with naïve disease. Many veterinary oncology trials provide financial support and/or include the provision of funds for traditional therapies if investigational agents fail. Incentivization enhances accrual.

Phase I starting dose selection is typically based on preclinical PK/PD/AE data in nontarget species exist to inform starting dose.[1,3–5,9] Different options include starting with one-third of the "no observable adverse event level" (NOAEL), or one-tenth of the severe toxicity dose in the most sensitive species, or if normal dog data are available, one-half of the MTD in laboratory dogs as they seem to be less sensitive to AEs than are tumor-bearing companion dogs owing to differences in age, comorbidity, or monitoring/observation practices.

As with starting dose, escalation strategies greatly affect the number of patients treated at a potentially ineffective dose, the length of the trial, the use of resources, and the risk of AEs.[9] The traditional method of escalation, outlined in Table 18.2, uses a "3 × 3" cohort design wherein dose escalations are made with three patients per dose level and the MTD is set based on the number of patients experiencing a DLT. A DLT is defined as grade III or greater toxicity in any category (except hematologic) according to predefined AE categories, such as those in the Veterinary Cooperative Oncology Group—Common Terminology Criteria for Adverse Events (VCOG-CTCAE version 1.1).[10] Grade IV is often the preferred cutoff for myelosuppression-related DLTs because these events are usually considered manageable with supportive care, generally transient, and often clinically silent. Additional DLTs are defined on an agent-by-agent basis because of expected toxicities. These can include or exclude some grade III

TABLE 18.2 Standard Phase I Dose Escalation Scheme

Number of Patients with DLT at a Given Dose Level	Escalation Decision Rule
0 out of 3	Enter three patients at the next dose level.
≥2	Dose escalation will be stopped. This dose level will be declared the maximally administered dose (highest dose administered). Three additional patients will be entered at the next lowest dose level if only three patients were treated previously at that dose.
1 out of 3	Enter at least three more patients at this dose level. • If none of these three patients experiences DLT, proceed to the next dose level. • If one or more of this group suffer DLT, then dose escalation is stopped, and this dose is declared the maximally administered dose. Three additional patients will be entered at the next lowest dose level if only three patients were treated previously at that dose.
≤1 out of 6 at highest dose level below the maximally administered dose	This is generally the recommended phase II dose (MTD). At least six patients must be entered at the recommended phase II dose.

DLT, dose-limiting toxicity; *MTD*, maximum tolerated dose.

VetBooks.ir

events from being DLTs, again if transient and clinically silent in nature and are prospectively defined in the study protocol. The MTD is defined as the highest dose level in which no more than one of six dogs develops a DLT. Traditionally, a fixed-dose modified Fibonacci method of dose escalation is used wherein the dose is escalated 100%, 67%, 50%, 40%, and then 33% of the previous dose as the dosing cohorts increase.[9] If the escalation increments are too conservative, more patients receive a suboptimal dose; conversely, if the escalations are too rapid, more patients are at risk for significant toxicity and the accuracy of the MTD is compromised. Interdosing cohorts can be added during the study period if more refined escalation or deescalation is found to be necessary.

Alternative, "accelerated titration" dose-escalation strategies have been suggested.[3–5,9,11,12] These include (1) two-stage designs in which initially single-patient cohorts are used and the dose is increased by a factor of two until a grade II toxicity occurs; then the second stage involves more traditional three-patient cohorts and acceleration strategies; (2) within-patient escalation in which the same patient receives a higher dose on subsequent treatments until a DLT is observed; however, this may mask cumulative toxicity; (3) escalations based on PK parameters, e.g., to achieve a target level of drug exposure; (4) escalations based on target modulation (if known); and (5) continual reassessment strategies using Bayesian methods.[11–14] In the end, it is always a trade-off of risk versus benefit; however, accelerated titration designs are generally associated with both a reduction in total patient number and a reduction in the number of patients receiving a suboptimal dose.

Although the phase I MTD approach works well for traditional cytotoxic drugs, phase I trials designed to determine the BED may be more relevant for MTAs.[15–19] Trials evaluating the BED require validated assays that measure an effect on the target in serial tumor samples and/or a surrogate tissue or fluid that documents activity at the molecular level. Examples of early incorporation of PD markers in tumor and surrogate tissue (peripheral blood) include canine phase I trials of the KIT kinase inhibitor toceranib,[20] the Btk inhibitor ibrutinib,[21] the histone deacetylase inhibitor sodium valproate,[22] and the putative autophagy modulator hydroxychloroquine.[23] Such PD modulation studies are increasingly important endpoints of phase I and II designs and are now commonly required as proof of mechanism for drug approval.

Phase II Trials (Activity/Efficacy Trials)

Several good reviews have outlined phase II trial designs.[4,24–27] The primary goal of phase II trials is, using the MTD or BED established in phase I, to identify the clinical or biologic activity in defined patient populations (e.g., tumors with a particular histology or particular molecular target) and inform the decision to embark on a larger pivotal phase III trial. The traditional phase II design (phase IIA) is a single-arm, open-label activity assessment of a novel drug or therapeutic modality that lacks a control group or uses historical controls, which are prone to bias (selection, population drift, and stage migration bias). The number of patients to be enrolled is variable depending on the "minimal useful response rate" and the rate of spontaneous regression (usually <5%). Multiple references discuss the statistical underpinnings of these power calculations, and there are several online resources for performing them. Often, "two-stage min-max" designs are employed where enrollment is halted if the response rate falls below a predetermined minimum level in an initial, small group of patients.[28] If the response rate is higher, a second stage of enrollment continues to establish an approximate response rate. For example, at least 9 to 14 patients with the same histology or molecular target are treated to test the null hypothesis of insufficient efficacy. If no responses are observed in this group, the study ends. If a response is noted in one of the cases, the accrual is increased to 31 patients to establish a more accurate response rate. If a less robust response rate is expected (e.g., 20%), then the initial accrual number must be increased. Sample-size effect on study power calculations will be outlined in a subsequent section. Some have opined that the leading cause of drug failure in later phase development is our overdependence on these unpredictable single-arm, uncontrolled phase II trials and that, as such, they should be avoided to ensure phase III trial resources are not wasted because of the results of poorly designed phase II trials.[27] It used to be considered that the consequence of type I error (false positive) was less deleterious than that of type II error (false negative) because false-positive trials are likely to be repeated, whereas false-negative trials would result in the abandonment of a potentially active treatment.[29] The goals of comparative oncology modeling can help minimize type II error by mechanistically defining activity of novel agents through more detailed PK–PD studies. In today's environment, however, with an abundance of novel drugs to be evaluated, false-positive results are just as serious because they tie up patient and financial resources. With this in mind, the ideal phase II design would be randomized across several potential investigational drugs, blinded, and controlled; modifications of this type applied to standard phase II design are discussed subsequently (controlled phase II or phase IIB trials).[30]

Endpoints of Activity/Efficacy

As the primary goal of phase II trials is assessment of activity/efficacy, endpoints used to evaluate response are critical to the design. Median survival time is the ultimate "gold standard" primary endpoint that may be objectively measured to determine whether a drug is beneficial; however, this endpoint requires too great a length of time for early phase trials to be meaningful and can be affected in veterinary patients by decisions to euthanize or seek alternative or rescue therapies. Therefore most early phase trials utilize interim or secondary endpoints that are reasonably likely to predict clinical benefit. These surrogate endpoints may allow for shorter, less expensive, and technically simpler trials, which allow for early termination if an interim outcome reaches a prespecified positive or negative level. It is important that the validity of the surrogate outcome actually correlates with lower mortality (or improved QOL)—this is often validated in larger later phase trials. With traditional cytotoxic chemotherapeutics, response is assessed based on criteria that describe changes in size or volume according to several published methodologies (e.g., Response Evaluation Criteria in Solid Tumors [RECIST], World Health Organization [WHO]).[31–33] Veterinary consensus modifications of RECIST have been published.[34] It is readily evident that such criteria may not be appropriate for MTAs that are more likely to be cytostatic rather than cytotoxic, thus resulting in disease stabilization rather than measurable regression.[35,36] In such cases, it is critical that a designation of "stable disease" persist for a clinically relevant period of time, generally not less than 6 to 8 weeks, to avoid reflection of slow progression rather than a true treatment effect. Alternatively, temporal measures such as progression-free survival (PFS) or time to progression (TTP) may be appropriate endpoints; however, these often take too long to mature for timely phase II trials.[37] Alternatively, an adequate compromise could be

progression-free rate (PFR) at predetermined time points. Again, comparative oncology models may more expediently define TTP or PFR because of compressed progression times in veterinary patients. These measures can also more accurately define efficacy in the minimal residual disease (MRD) setting such as trials interrogating novel adjuvant therapies for canine osteosarcoma (OSA) in the postamputation setting. For gauging response to immunotherapeutics, expanded response criteria have been published that help define methods of capturing unique response patterns observed in patients receiving these agents, which can be used in conjunction with RECIST or WHO methods.[38,39]

Secondary endpoints that may be evaluated in phase II trials include QOL assessments, comparative cost of therapy, days of hospitalization, validated surrogate biomarkers or measures of a molecular effect such as dephosphorylation of a growth factor receptor,[20,21] changes in microvessel density or regulatory T-cell number,[40] or target modulation that is linked to clinical outcome.[25] Importantly, phase II trials serve to expand knowledge of cumulative or long-term toxicities associated with new agents that may not be observed in short-term phase I trials designed to elucidate acute toxicity. An example of this in the veterinary literature involved a combined phase I/II trial simultaneously investigating the safety of liposome-encapsulated doxorubicin (LED) while comparing its activity with native doxorubicin in cats with vaccine-associated sarcomas.[41] Unexpectedly, the MTD established for LED in the acute phase I component of the trial was found to result in delayed and dose-limiting nephrotoxicity after long-term follow-up in the phase II component of the trial. Such discoveries are key to defining an agent's therapeutic window with repeated administrations.

New clinical trial concepts have entered into use in great part because of a recent initiative of the US Food and Drug Administration (FDA) to allow for "preclinical studies to provide evidence necessary to support the safety of administering new compounds to humans."[42] These are known as phase 0 trials, and they precede the traditional trials defined previously.[43,44] The role of phase 0 trials in cancer drug development is for biomarker and assay development/validation and evaluation of target modulation. Phase 0 trials allow for the systematic deprioritization of investigational agents that exhibit excessive toxicity or fail to show expected biologic effects and are used to direct dose selection for future studies. They represent first-in-species trials, usually of a small number of patients, and utilize lower and likely subtherapeutic drug doses. Comparative oncology trials allow the unique opportunity to answer the preclinical questions necessary to advance an agent. Phase 0 trials are "proof of concept" studies, wherein PK parameters are measured along with PD effects within target tissues, such as the tumor itself. These trials can also define surrogate markers of target effect, therapeutic response, or metabolites in surrogate tissues or fluids, such as blood or urine. Assessment of PK/PD relationships allow for a much broader understanding of new drug mechanism, therefore informing phase I/II trial design.

Controlled Phase II Trials

Sometimes referred to as phase IIB trials, these tend to be controlled, blinded, and randomized investigations of two or more novel regimens that identify promising agents to send to phase III trials for additional evaluation. Randomized phase II trials can be as simple as randomizing standard-of-care plus or minus the addition of a new drug. Another approach is to randomize subjects into multiple treatment arms or schedules with only enough power to make inferences as to which is the best drug to take forward into phase III trials; so called "pick-the-winner" trials.[26] Although often not sufficiently powered for direct comparisons, they may use a less rigorous statistical assessment, such as setting the *p*-value at 10% and using 1-tailed analyses.

Phase III Trials (Pivotal/Confirming Trials)

It has been suggested that if phase II trials are "learning" trials, phase III trials are "confirming" trials.[45] These larger, randomized, blinded, and controlled trials have the goal of comparing a new drug or combination with standard-of-care therapies. They are often performed by large cooperative groups, which ensures greater case accrual, and FDA pivotal trials require multiinstitutional involvement. An example of a multicenter phase III trial would be the randomized comparison of liposome-encapsulated cisplatin (SPI-77) versus standard-of-care carboplatin in dogs with appendicular OSA.[46] No difference was observed between treatment groups, despite SPI-77 allowing five times the MTD of native cisplatin to be delivered in a liposome-encapsulated form. True phase III trials are not common in veterinary oncology because of their size and expense, with the exception of multicenter "registration" trials that have formed the basis for New Animal Drug Applications with the FDA Center for Veterinary Medicine (FDA-CVM).[47–49] Pivotal trials have included the registration of the first approved veterinary oncology agents, two tyrosine kinase inhibitors (TKIs; Palladia, Zoetis; Kinavet, AB Sciences) for the treatment of mast cell tumors.[47,48] TKIs showed improvement in PFS over placebo controls, and these trials define the process for expanding future efforts in veterinary oncology drug approval.

Sample Size and Power

The overriding function of clinical research is to provide a definitive answer to a clinical question. However, it is possible that, once complete, clinical trial conclusions may be incorrect based on chance or design error. Chance error results when an erroneous inference is drawn from a study sample group that is not actually representative of an entire patient population. Accounting for this potential error is essential in prospective clinical trial design, and its first critical step is to articulate the study hypothesis.[50] Type I or α error (false positive) occurs if an investigator rejects the null hypothesis when it is actually true.[45,50] This is also referred to as the study's level of significance. Type II or β error (false negative) occurs when one fails to reject the null hypothesis when it is actually incorrect. Type I and II errors are due to chance and cannot be avoided completely, although steps can be taken to reduce their potential effect by increasing sample size and augmenting study design or measurements.

Power is the ultimate measure of a clinical trial's results and also must be prospectively controlled. Power is defined as $1 - \beta$, the probability of correctly rejecting the null in the sample if the actual effect in the population is equal to (or greater than) the effect size.[45,50] Power is governed by sample size, with the goal being to enroll enough patients to accurately allow for a difference to be seen between groups. Power is irrelevant if the results are statistically significant, but if not, it is important to ensure the study had adequate numbers to detect a difference between groups. If a study to detect the difference between two cancer treatments is designed with an α of 0.05, then the principal investigator (PI) has set 5% as the maximum chance of incorrectly rejecting the null hypothesis if it is true. This is the level of doubt the PI is willing to accept when statistical tests are used to compare the two treatments. If β is set at 0.10, the PI is willing to accept a 10% chance

VetBooks.ir

of missing an association of a given effect if it exists. This represents a power of 0.90 (1 – β), or a 90% chance of finding an association of that size or greater. The α and β levels are determined before trial initiation, and their set points are based on the importance of avoiding either a false-positive or a false-negative result.

Randomization

Bias is introduced error in clinical research. One of the main ways to minimize bias is through the use of randomization, wherein research participants are assigned to a group within a clinical trial by chance instead of choice.[1] Groups include either the investigational group, those to receive the study drug, or the control group, those to receive a placebo (or comparator drug). Each participant enrolling in a trial has an equal chance of receiving the study drug, and the goal is to balance the groups based on participant characteristics (e.g., age, stage of disease, previous treatments) that may influence a response to therapy. At the end of the study, if bias is reduced by randomization, then the result (positive or negative) is more likely to be true. Unfortunately, in veterinary medicine, historical rather than active controls have been used for comparison of new therapies all too often. It is common in oncology trials to also blind participants so that patients or, in our case, clients do not know which treatment group their pet is in. Blinded or true active comparator trials are becoming more frequent as regulatory registration trials ultimately require them.

Reducing bias in clinical trials is an integral concept within trial design. Stratification is a concept used often in human oncology trials and is gaining headway in veterinary oncology trial design as well.[45,51] This allows for grouping of patients based on known prognostic factors. For example, this might include the stratification of dogs with lymphoma by clinical stage or immunophenotype with the goal of creating equal numbers of each within a treatment group. One of the main benefits of stratification is that it can prevent potential bias from *known* prognostic factors. For example, a treatment cohort may be doing comparatively poorly because the majority of dogs in that cohort had T-cell lymphoma. However, a difficulty with stratification is that the more prognostic factors are controlled, the less power the study has, and thus the need to increase sample size. Randomization to treatment groups should be performed after stratification.

Phase IV Trials (Postregistration Trials)

Once a drug has been granted a license or registered for a specific label use by the appropriate regulatory body (e.g., the FDA), postregistration phase IV trials may be performed to gain more information on AEs, long-term risks, off-label benefits, and the economic effect of the agent in the marketplace.[52] Phase IV trials may also involve treatment of special populations (e.g., the elderly, pediatric patients, or individuals with renal or hepatic dysfunction). The body of data on PK generated from postregistration trials is used to inform decisions on dose in special populations. Alternatively, phase IV trials may assess the benefit of the new drug for activity against diseases not included in the current approved regulatory label.

Good Manufacturing Practice/Good Clinical Practice Criteria

Provisions that create uniformity and consistency are key in clinical research implementation. Their primary intent is to ensure the safety of trial materials and participants and the integrity of clinical data. Such provisions determine good manufacturing practice (GMP) and good clinical practice (GCP). GMP principles ensure the safe manufacture and testing of pharmaceutical drugs, biologics, and medical devices by outlining aspects of production that can affect the quality of a product. GCP guidelines were devised by the International Conference on Harmonization (ICH) to protect the rights and safety of human patients in clinical trials.[53]

GCP includes standards on how clinical trials should be designed and conducted, defines the roles and responsibilities of trial sponsors and clinical research investigators, and monitors the reporting of trial data.[53] It requires the use of a standardized clinical protocol and strict documentation of procedures and adherence to that protocol. GCP also establishes guidelines for oversight by external bodies, such as the Institutional Review Board (IRB) and the Data Safety and Monitoring Board (DSMB). The IRB serves as an independent ethics committee that has the power to approve, disapprove, or ask for modifications to planned study protocols. IRBs must include at least one nonscientist and a noninstitutional member known as a *community member.* If a clinical trial includes a vulnerable population, then the IRB must include an expert in the needs and specialties of this group. The IRB reviews protocol ethics, informed consent, and possible conflicts of interest, and provides scientific review of study protocol and results.

The DSMB (sometimes called a Data Monitoring Committee) is a third-party panel of experts consisting of at least one statistician, and is populated by clinicians who are experts in the field of research or drug of study.[54] In long-term and high-impact studies, an ethicist and/or a patient advocate representative may also serve on the DSMB. The purpose of the DSMB is to ensure the safety of participants through oversight and management of serious AEs (SAE). This group also ensures validity of data, and appropriate termination of studies for which significant benefits or risks have been uncovered or if it appears that the trial cannot be concluded successfully. However, the DSMB also reviews interim study results to determine whether an overwhelming benefit is evident in either the study or the control arm or if it is unlikely the study will answer the proposed study aim and thus should be terminated prematurely. It is important for all safety monitoring to be contemporaneous, including disclosure to the FDA of SAEs in real time. GCP compliance is necessary for FDA registration trials in both veterinary and human oncology drug development. Oversight of GMP and GCP provisions are provided by the FDA (http://www.fda.gov) and, in the European Union, oversight is provided by the European Medicines Agency (EMA; http://www.ema.europa.eu).

Effectiveness versus Efficacy Definitions

A key distinction in phase III trials is that data may be obtained within the context of randomized clinical trials (RCTs) or from effectiveness studies in the "real world." Because RCTs are designed to assess safety and efficacy of pharmaceuticals with an emphasis on study validity over generalizability, the applicability of data collected from them may be limited. The data may not be valid in more heterogeneous patients encountered in actual clinical practice and may be inaccurate because of strict protocol requirements or inclusion/exclusion criteria. Effectiveness studies, in which treatments are studied under real-world conditions, remedy some of these limitations. An efficacy study asks the question, "Does the drug work?" Whereas an effectiveness study asks the question "Does the drug help the targeted general population?" Some refer to this efficacy research as type I research (bench to

VetBooks.ir

bedside) and effectiveness research as type II (bedside to curbside) research. Generally, an RCT that determines efficacy occurs under ideal conditions whereas long-term effectiveness studies, which can be prospective or, on occasion, either meta-analyses or retrospective, define the overall effect of a drug. Also important to consider are the pharmacoeconomics of a drug, wherein a cost/benefit analysis weighs factors such as actual cost of medication, number or lives saved, minimization or exacerbation of hospital stays or doctor visits, and QOL measures, and computes their individual and societal expense. Once these outcome measures are studied and calculated, then comparisons between agents, new and old, can be made.[55–57]

Regulatory Oversight

The FDA is the regulatory body of the US government that oversees the activities of the drug and pharmaceutical industry. The FDA provides oversight for drug development primarily through written guidance, which describes rules and requirements for quality control and conduct. FDA guidance include oversight of drug standards, including chemistry, manufacturing, and control (CMC); preclinical animal toxicology; documentary requirements for investigational new drug (INDs) and new drug applications (NDAs); and ethics of clinical trials. In 1997 the FDA moved beyond its traditional approval paradigm by creating the FDA Modernization Act.[58] It necessitates PK bridging studies for new populations (e.g., pediatric PK studies) and allows for one adequate and well-controlled clinical investigation by "confirmatory evidence" comprising PK or PK/PD data to lead to drug approval. This emphasizes the importance of exposure and mechanism studies to more accurately determine the safety and effectiveness of novel drugs, especially targeted agents or ones evaluated in special populations.[59]

FDA drug development is a multistep process that defines interaction between the FDA, the drug sponsor, and their discovery and clinical teams with a shared goal of FDA approval. It involves a preclinical testing phase (IND requirements for CMC, animal testing, design of phase I clinical studies), IND evaluation, and NDA review, and marketing. FDA is attempting to improve and expedite the process of drug development through a number of initiatives. The most innovative are the Critical Path Initiative (2004), end-of-phase 2a (EOP2a) meeting (2004), and model-based drug development (2005) (physiologically based PK [PBPK], 2009).[60] In January 2017, the FDA formed the Oncology Center of Excellence (OCE), which leverages the combined skills of regulatory scientists and reviewers with expertise in drugs, biologics, and devices. This initiative will help expedite the development of oncology and hematology medical products and support an integrated approach in the clinical evaluation of such agents for treatment of cancer. In addition, the FDA is working to implement provisions of the Cancer Moonshot initiative and 21st Century Cures Act through the formation of the OCE, and has recently published a perspective on oncology drug development that explores concepts geared toward an approach that could provide earlier access to highly effective therapeutic drugs, thus complementing existing expedited programs such as breakthrough designation and accelerated approval.[61] The OCE also supports the use of common control trials, which share a common control arm, involve multiple different drugs for the same indication, and may involve different companies and/or sponsors. The Morris Animal Foundation's Osteosarcoma Project trials, currently underway through the National Cancer Institute (NCI) Comparative Oncology Trials Consortium (COTC), are emblematic of this approach, and are focused on providing advances for both humans and dogs to combat metastatic progression in the MRD setting.

Veterinary Registration Trials

Veterinary drug development follows the same critical regulatory steps described earlier but oversight is provided by the FDA–CVM and, in the case of biologics, by the US Department of Agriculture (USDA). Before 2007 with the conditional approval of ONCEPT (Canine Melanoma Vaccine, DNA, Boehringer-Ingelheim), all cancer drugs used in veterinary medicine were originally developed for humans and not approved for use in animals. Cancer chemotherapeutics are used in an "extralabel" manner as allowed by the Animal Medicinal Drug Use Clarification Act of 1994. Significant gains have occurred recently in veterinary oncology product development with full approval of toceranib phosphate (Palladia, Zoetis), masitinib (Masivet, AB Science), and ONCEPT (Boehringer-Ingelheim). Palladia and Masivet are both receptor TKIs and are approved for treatment of recurrent or inoperable grade II or III mast cell tumors with or without regional lymph node involvement.[20,47,48,62] Palladia was developed by SUGEN as SU11654, a sister compound to SU11248 later approved for human patients as Sutent.[63] ONCEPT is a xenogeneic tyrosinase DNA vaccine indicated for dogs with stage II or stage III oral canine melanoma.[64,65] Registration trials for these agents involved safety and efficacy assessments in multicenter clinical trials under GCP conditions.

Consortia

One of the most exciting achievements in veterinary oncology since 2008 has been the development of successful and collaborative consortia that are purposed to perform multicenter clinical trials and prospective tumor biospecimen repository collections. Consortium infrastructures allow larger scale clinical trials and provide the voice for collective advocacy in veterinary and comparative oncology.

Comparative Oncology Trials Consortium

The COTC is an active network of 24 academic comparative oncology centers (https://ccrod.cancer.gov/confluence/display/CCRCOPWeb/Comparative+Oncology+Trials+Consortium), centrally managed by the National Institutes of Health–NCI's Comparative Oncology Program that functions to design and execute clinical trials in dogs with cancer to assess novel therapies.[66,67] The goal of this effort is to answer biologic questions geared to inform the development path of these agents for use in human cancer patients. COTC trials are pharmacokinetically and pharmacodynamically rich, with the product of this work directly integrated into the design of current human early and late phase clinical trials. They are focused to answer mechanistic questions and define dose–toxicity and dose–response relationships. They can be designed to compare varying schedules and routes of drug administration, validate target biology, model clinical standard operating procedures (SOPs), and assess biomarkers. In addition, within this effort, the COTC PD Core was created. The COTC PD Core is a virtual laboratory of assays and services, including pathology, immunohistochemistry, immunocytochemistry, flow cytometry, genomics, proteomics, cell culture, PK, and cell biology designed to support COTC clinical trial biologic endpoints.[68] As of 2018, the COTC has completed 13 clinical trials and has been successful in promoting the utility of comparative oncology modeling within the drug development community.

VetBooks.ir

Veterinary Contract Research Organizations

Contract research organizations (CROs) are generally privately organized and run specialty networks of veterinary hospitals that design, conduct, and report clinical studies for the animal health industry. Examples include Animal Clinical Investigation (ACI; www.animalci.com), The One Health Company (www.theonehealthcompany.com), and VetPharm (www.vetpharm.com). Although oncology drug development is within their portfolios, other medical conditions, including inflammatory and metabolic disease, cardiovascular disease, and arthritis, are also managed. CROs provide multisite, pivotal, or nonpivotal studies and commercialization support to help define effective novel veterinary therapeutics.

Current Challenges and Opportunities in Oncology Drug Development

Oncology drug development is a difficult and costly process. It is estimated that only 5% to 10% of drugs entering phase I oncology clinical trials ultimately are approved by the FDA, with a cost of between 0.8 and 1.7 billion dollars per drug accrued through the development process.[55,69] The most prevalent cause of cancer drug failure is toxicity or inactivity. For every 1000 oncology agents in development, only 40% transition from preclinical studies to phase I, 75% from phase I to phase II, 60% from phase II to phase III, and 55% from phase III to approval. This means that for every 1000 preclinical candidates, only 99 new drugs will reach the clinic.

Model-Based (Adaptive) Drug Development

Adaptive Trial Designs and Stopping Rules

Adaptive trial designs[70–74] allow investigators to modify trials while they are ongoing based on newly acquired data and, in some cases, taking into account data generated in other trials or past trials. In adaptive trial designs, interim data from a trial is used to modify and improve the study design, in a preplanned manner and without undermining its validity or integrity. In the exploratory setting, an adaptive trial can assign a larger proportion of the enrolled subjects to the treatment arms that are performing well, drop arms that are performing poorly, and investigate a wider range of doses so as to more effectively select doses that are most likely to succeed in the confirmatory phase. In the confirmatory phase, adaptive design can facilitate the early identification of efficacious treatments, decisions to drop poorly performing trial arms, determining whether the trial should be terminated for futility, and making sample-size adjustments at interim time points to ensure that the trial is adequately powered. In some cases, it might even be possible to enrich the patient population by altering the eligibility criteria at an interim time point. These also include biomarker-based adaptive designs which enable adaptations based on the response of biomarkers, biomarker/target screening designs (e.g., enrichment designs such as "basket" or "umbrella" trials).[73]

Potential benefits of adaptive designs include[72] (1) they allow the investigator to correct wrong assumptions made at the beginning of the trial; (2) they help the investigator select the most promising option early; (3) they make use of information that emerges outside of the trial; (4) they enable the investigator to react earlier to surprises (either positive or negative); and (5) they may shorten the development time and consequently speed up the development process. However, adaptive designs may undermine validity and integrity of the trial if not managed appropriately. That being said, adaptations based on blinded analyses at interim, if the blinding is strictly maintained, can largely reduce or completely avoid bias.

Stopping Rules

Stopping rules, which are rules that terminate a clinical trial earlier than originally projected or within a predetermined adaptive trial design, can be applied to randomized phase II or phase III trials. Several methods and variations have been extensively reviewed.[75–77] Stopping rules are designed to protect treatment subjects from unsafe drugs, to hasten the general availability of superior drugs as soon as sufficient evidence has been collected, and to help ensure the transfer of resources and patients to alternative trials. Trials are stopped for three reasons: the investigational treatment is clearly better than the control, the investigational treatment is clearly worse than the control (less activity or more toxicity), or the investigational therapy is not likely to be better (so-called "stopping for futility" or "futility analysis"). The methods by which stopping rules are applied usually involve some type of interim analysis that evaluates the data (by a blinded individual or DSMB) generated to date and makes a determination based on predetermined rules. The interim data are often analyzed for conditional power, which is the probability of the final study result demonstrating statistical significance in the primary efficacy endpoint, conditional on the current data observed, and a specific assumption about the pattern of the data to be observed in the remainder of the study. If a study is designed a priori to involve conditional power calculations of interim data, the rules for early termination are sometimes referred to as *stochastic curtailing*.

Bayesian (Continuous Learning) Adaptive Designs

Adaptive trial designs can also be used to change the randomization weight to better performing treatment arms, add new treatment arms, drop poorly performing arms, or extend accrual beyond the original target when more information is needed. With the availability of advanced computational techniques, a new statistical methodology, the Bayesian approach, was developed that makes statistical inferences that focus on the probability that a hypothesis is true given the available evidence.

In contrast, Bayesian trials differ from the *frequentist* approach to statistics by using available patient outcome information, including biomarkers that accumulate data related to outcome (if available and validated), and even historic information or results from other relevant trials to adapt the current trial design continually based on newly informed probabilities.[78–80] An example that illustrates the utility of the Bayesian approach involves interim analysis applied to a randomized phase II trial of neoadjuvant trastuzumab, paclitaxel, and epirubicin in epidermal growth factor receptor 2 (HER2/neu)–positive breast cancer.[81] In this trial initially designed to enter 164 patients (based on the frequentist approach to power), a Bayesian approach was used to perform an interim analysis after 34 patients were enrolled; 67% of patients in the investigational treatment arm experienced complete responses compared with 25% in the standard treatment arm. The Bayesian predictive probability of statistical significance if 164 patients were accrued, based on the data available from these 34 patients, was calculated to be 95%, and the trial was stopped and the drug moved to phase III early because of these promising results. The very first Bayesian response adaptive trial involving companion animals was recently published.[82] In this trial comparing toceranib versus vinblastine therapy for canine mast cell tumors, patients were randomized based on the "play-the-winner" rule;

as more information regarding efficacy and KIT localization and c-*kit* mutation status became available, newly accrued dogs were randomized proportional to the predicted response probability.

Randomized Discontinuation Trials

This phase II design was proposed for evaluating the efficacy of newer targeted agents that are thought to have disease-stabilizing activity (cytostatic) in contrast to disease-regressing activity of more traditional cytotoxic chemotherapeutics. Several reviews of this trial design are recommended.[83–85] Trials that evaluate growth-inhibiting agents in tumors with a variable natural history seem ideally suited for randomized discontinuation trials (RDTs) because the "no treatment effect" is hard to control in these cases. In essence, these trials serve to enrich and homogenize the static agent for those patients likely to benefit from it. RDTs involve a two-stage trial design, wherein the first stage involves a "run-in" phase in which all patients receive the cytostatic agent under investigation. At the end of the run-in phase, assessment of disease response is made. If a response is noted, the subject continues on the investigational drug, whereas if progression (or excess toxicity) is noted, the subject is removed from trial and allowed to receive alternative treatment. Those patients who meet stable disease criteria enter the second stage of the RDT and are randomized to continue on the investigational drug or placebo (the discontinuation arm). Then, at predetermined times, follow-up determinations are made. Endpoints in stage II of the trial at these follow-up intervals are "stable or better" versus "progression." Time-to-event measures may be applied as well (e.g., PFS, TTP), although this takes more time to complete. If a subject progresses in the second stage, the code can be broken, and if that subject is in the placebo group, the investigational drug can be reinstituted. Therefore there are two ways for RDTs to be stopped: there are a substantial number of objective responses noted in the run-in phase making a second stage unnecessary, or the number of subjects progressing in the second stage differs statistically between the treatment and placebo groups. It becomes intuitive that the length of the run-in phase is critical to RDTs: if it is too long, some initially responding patients progress during the late stage of the run-in and are missed (therefore increasing subject numbers); if it is too short, insufficient enrichment occurs (not enough time for non-responders to progress) and the randomization might as well have been done at the outset. The two major advantages of RDTs are that all subjects receive the drug up front so that every patient is given a chance to respond to the drug (something that is popular with patients [or companion animal owners]) and enrichment of likely responders may increase power and decrease subject numbers. Potential disadvantages of RDTs include the ethics of discontinuation (but the design can allow reinstitution), the potential for a carryover effect of the drug after discontinuation (unlikely for most targeted agents), and failure to detect short duration activity (but this would likely be a clinically irrelevant duration anyway). RDTs can be improved by combining other modifications of clinical trials, such as interim analysis and Bayesian analysis, and by using active controls. For purposes of illustration, an RDT in veterinary medicine that the authors have considered would be the investigation of a cytostatic agent in dogs with pulmonary metastatic OSA. All dogs would enter the run-in phase, receive the cytostatic drug for 4 weeks, and then be evaluated for response. From what we already know about the natural history of OSA in dogs, most (probably 80%) of dogs that did not receive treatment would progress in that period. Those that were stable at 4 weeks, however, would be randomized to drug continuation or discontinuation (placebo) and followed with monthly reevaluations. This would ensure all dogs had a chance to respond to the drug and enrich the population likely to respond, and a positive result would be clinical response noted in the run-in phase or a statistical difference in PFR between groups in the second stage.

Personalized Medicine

Advancements in genomic, proteomic, and epigenetic profiling have created new opportunities to tailor cancer treatments to individual patient and tumor molecular characteristics; this field is known as personalized or molecular-based medicine. The goals of personalized medicine approaches include improving outcomes by revealing disease drivers, toxicity, susceptibilities, and resistance profiles unique to the individual patient. Molecular profiling approaches have been employed to stratify and prescribe therapies for human oncology patients. The most successful examples to date have been in the identification of HER2 overexpression in breast cancer and the oncogenic *bcr–abl* translocation in chronic myelogenous leukemia and the prescription of monoclonal antibodies (trastuzumab, Herceptin) and TKIs (imatinib, Gleevec) against these key pathways (also the basis for Bayesian approaches previously mentioned).[86–88] Veterinary oncology has also benefited from molecular-based approaches, most notably in the targeting of c-*kit* mutations in canine mast cell tumors.[48,89] TKIs (toceranib and masitinib) have shown clinical utility against macroscopic disease and have been approved by the FDA for use in this setting. Although both agents are nonselective inhibitors that also have activity against other key pathways (e.g., vascular endothelial growth factor receptor 2 [VEGFR2] for toceranib), their approval marks an important step forward in veterinary tumor biology-based therapeutics and sets the stage for future directed research in other tumor types.

The field of personalized medicine expands beyond patient prescription to also include the study of patient pharmacogenomics and pharmacometabolics, the genetic variation of response and metabolism of novel agents or medications. These include the study of individual patient single nucleotide polymorphisms (SNPs) in key metabolic pathways (cytochrome p450) and the measurement of metabolites in blood and urine. An example of this in veterinary oncology is the use of multidrug resistance gene 1 (*MDR1*) mutation analysis in certain herding breeds (e.g., collies and shelties) before initiating *MDR1* substrate chemotherapeutic agents (e.g., doxorubicin and vincristine).

Newer personalized medicine approaches based on complex mathematical algorithms have been created that include a broader base of tumor characteristics to define potential treatments. The use of pretreatment biopsies to create prospective molecular profiles has been modeled by the COTC in veterinary patients and found to be achievable in a practical clinical window.[90] More recently, so called "liquid biopsy" techniques have been developed whereby tumor DNA in blood is used to detect, track, and develop personalized treatment protocols in cancer patients.[91] The publication of the canine genome and the advent of high-throughput technologies have enabled the field of veterinary oncology to describe canine cancer biology and characterize potential therapeutic targets more globally.[92] This creates the opportunity for personalized medicine investigations in the dog to inform novel therapy development for both veterinary and human oncology patients using these algorithmic approaches. In addition, strong cancer breed predilections support "breed-based"

genetic approaches that may uncover oncogenic pathways and targets more easily and inform discovery and application of personalized medicine strategies.

Clinical Trial Ethics

There are key ethical standards employed in clinical trial design, and the goal of all clinicians is to ensure standards are met when offering a trial to a client or enrolling a patient within a clinical trial. Many clinical trials provide partially or fully funded care for eligible pets with cancer. This is important because traditional veterinary oncology treatments, surgery, chemotherapy, and radiation therapy, are expensive and costs are prohibitive for some clients. Clinical trial enrollment may present an opportunity to help some clients who may not have the financial means to pursue treatment or receive care for their pet, or provide treatment to those pets that have progressed in the face of traditional therapies. When all medical options are described to clients as far as care for their pet's disease, some may choose clinical trials to make an impact for future pets or people with cancer. This altruism (by proxy) drives the decision-making process for many caregivers.

Informed consent defines a trial's purpose and the requirements for the client to return with their pet for future follow-up procedures/appointments, and is required for all patients to enroll in a clinical trial. This consent is a written acknowledgment, created by a trial's PIs and signed by a client, of the possible positive and conversely AEs (known or unknown) of an investigational agent. Goals for clinical trials must be clearly outlined so true informed consent can be obtained. Although AEs outside of those described are always possible, informed consent ensures that clients understand that in many trials the outcome/side effects are as yet unknown. Ethical considerations also require rigorous informed consent of study procedures, especially in biologically intensive trials, because repeated invasive procedures or even serial imaging may result in the false perception of a stronger therapeutic intent.[93]

As the treatment of companion animals with cancer is purely a client-driven choice, there are no true "standards of care" in veterinary oncology. Although there are proven active regimes for the care of common cancers in dogs (i.e., *c*yclophosphamide, *h*ydroxydaunorubicin (doxorubicin), vincristine [*O*ncovin], and *p*rednisone [CHOP]-based chemotherapy in lymphoma, platinum or anthracyclines in OSA), these therapies are not required. Therefore veterinary and comparative oncology trials can offer investigational therapies in naïve disease. Clinical trials can randomize patients to placebo arms if there is an interest in comparing a novel therapy to no therapy. Although, as in human trials, informed consent must clearly state the inclusion of a placebo arm, the protocol design may include an allowance for crossover to study drug or traditional therapies either at a defined interval or in documented progressive disease. Requirements for early stopping rules can also alleviate some of these ethical concerns when overt drug inactivity or activity is evident.[94] Box 18.1 defines the suggested elements that should be included in any clinical trial informed consent document.[1]

Many regulatory safeguards have been put in place to promote the welfare and interests of animals used in biomedical and clinical research. Protocols to use animal subjects in clinical research must be approved by Institutional Animal Care and Use Committees (IACUCs), and these bodies are also involved in oversight of research study conduct to ensure ethical standards are maintained.

• BOX 18.1 Suggested "Elements of Consent" to Include in Informed Client Consent Documents

1. Purpose of research
2. Expected duration of participation
3. Description of procedures
4. Possible discomforts and risks
5. Possible benefits
6. Alternative treatment (or alternative to participation)
7. Extent of confidentiality of records
8. Compensation or therapy for injuries or adverse events
9. Contact person for the study
10. Voluntary participation and right to withdraw
11. Termination of participation by the principal investigator
12. Unforeseen risks
13. Financial obligations
14. Hospital review committee contact person

Modified with permission from Morris Animal Foundation: www.morrisanimalfoundation.org.

Some veterinary hospitals also have Clinical Review Boards that function similarly to human IRBs as described previously. In some cases, pet dogs are receiving "first in dog" drugs and AEs are expected, with grade V events (fatality) possible. Although this would be predicted to reflect what is seen in an aged and ill cancer population, it is an important element to be detailed in informed consent. The grading and reporting of AEs in clinical trials include uniform common toxicity criteria for AEs (e.g., VCOG-CTCAE version 1.1) and ethical care includes treatment for any such events.[10] Clients also have the option to withdraw their pets from a clinical trial at any time without penalty. All of these provisions are designed to ensure safety for trial participants and the ethical conduct of clinical research.

Trial Reporting

The transparent reporting of clinical trials has received considerable attention in the past several years. For randomized trials, the current "gold standard" guidelines for reporting of data is the Consolidated Standards of Reporting Trials (CONSORT; www.consort-statement.org). In these guidelines, logical and stepwise guides to the reporting of patient enrollment, patient allocation (between and within treatment groups), patient follow-up, and data analysis are clearly spelled out. Anyone devising, performing, and indeed critically appraising clinical trials should be well versed in these guidelines.

Conclusions

Clinical trials are an important research discipline to improve care and outcome for cancer patients in both human and veterinary oncology. Steps should be made to ensure study aims are achievable within a crafted study design and protocol. Rules governing design are prospective and involve questions of dose and schedule selection, toxicity, activity, and comparison to known effective therapies. Statistical expertise is also necessary to ensure appropriate clinical trial design. Regulatory oversight of veterinary oncology trials is increasing, and new approval of veterinary oncology agents will emphasize these processes over the next decade. Comparative oncology trials also are key to the inclusion of pet animals in the evaluation of novel anticancer therapeutics, imaging strategies, and medical devices. Consortia groups will continue to

advocate and advance the use and utility of veterinary oncology clinical trials. The field of veterinary oncology will continue to grow through the proper use and design of both traditional and novel clinical trial designs.

19 Tumors of the Skin and Subcutaneous Tissues

MARLENE L. HAUCK AND MICHELLE L. OBLAK

Incidence

The overall incidence of tumors of the skin and subcutaneous tissues of dogs and cats is difficult to determine because of inconsistency of reporting, particularly with tumors of the subcutaneous tissues. If tumors determined to be of "skin" origin are considered, the percentage of biopsy specimens has been reported to be 26% to 43%.[1–6] Of these, between 20% and 40% are malignant.[3,4] In a survey of neoplasms in Alameda and Contra Costa counties performed from 1963 to 1966, the estimated incidence of skin and connective tissue tumors in dogs was 150.4/100,000; this decreased to 90.4/100,000 when melanocytic skin tumors were excluded.[5] The incidence of skin and connective tissue tumors in cats was 51.7/100,000.[5] In one report, skin tumors represented 10% of all feline biopsy or necropsy accessions, but skin tumors accounted for 30% of all cancer cases.[6] Other studies report a similar percentage of tumors arising from the skin, ranging from 19%[2] to 21%.[7] Disregarding basal cell tumors (BCTs), the percentage of malignant skin tumors is higher in cats than dogs, ranging from 70%[2] to 82%.[6]

The relative prevalence of the most common tumor types in dogs and cats can be determined from prevalence studies. In dogs, the numbers are based on a large number of surveys of skin tumor types from across the globe, totaling almost 9000 skin tumor submissions to various pathology services.[1,3,7–14] The data for the prevalence of the most common tumors of dogs are presented in Table 19.1. The overall prevalence of lipomas and sebaceous adenomas is likely higher than reported because of the bias present in samples submitted for histopathologic evaluation. The data on the prevalence of feline tumors is compiled from four studies with a total of 1225 skin tumors and is presented in Table 19.2.[2,6,9,15] In cats, the top four tumor types of the skin and subcutaneous tissues are consistently BCTs, mast cell tumors (MCTs), squamous cell carcinoma (SCC), and fibrosarcoma; these account for approximately 70% of all feline skin tumors.

The remainder of this chapter focuses on SCC, BCTs, glandular skin tumors, and additional assorted primary tumors of the skin, ears, and digits. Other tumor types are discussed in specific chapters: melanomas (Chapter 20), MCTs (Chapter 21), soft tissue sarcomas (Chapter 22), cutaneous lymphoma (Chapter 33, Sections A and B), and hemangiosarcoma (Chapter 34, Section A).

Etiology

Physical Factors

Ionizing radiation and thermal injury are reported to increase the risk of skin cancer in many species; however, a recent epidemiologic study on the incidence of cancer in human burn victims demonstrated no increased risk of the development of skin cancer compared with the general population.[16] Ultraviolet (UV) radiation has long been known to cause neoplastic transformation in the skin and is a major contributor to rising rates of skin cancer of all subtypes in people.[17] Evidence for the role of UV irradiation in the development of skin tumors in cats and dogs is primarily epidemiologic[18–20] and supported by case reports on dogs diagnosed with a spectrum of sunlight-induced lesions.[21,22]

The association of SCC development with solar exposure of skin in light-colored cats has been established epidemiologically. White cats in California had a 13.4-fold increased risk of developing SCC, and 143 of the 149 cases of nonoral SCC occurred on the head or neck.[18] Similar results were found in a case series of nasal planum or pinnal SCC in cats; 58 of the 61 cats were white or partially white in color, and all but three cats spent time outdoors.[23]

Viral Factors

The ability to induce neoplastic transformation in mucosal infections of papillomaviruses (PPVs) of people is well-established. PPVs are only able to replicate in terminally differentiated cells, therefore infection of the keratinocyte can stimulate increased proliferation and terminal differentiation.[24] Neoplastic transformation arises from the viral effects on cell proliferation, integration into the genome, and interaction of papilloma viral proteins with cellular proteins, particularly the destabilization of p53 by viral protein E6 and the inhibition of pRB by viral protein E7.[25] This disruption in p53 can result in increased levels of p16 protein, which is detectable with immunohistochemistry (IHC).[26] The association of PPV infection with cutaneous SCC in people is primarily epidemiologic: organ transplant recipients and immunosuppressed individuals have an increased rate of cutaneous PPV infection and an increased risk of SCC development.[27,28]

Hemangioma	21	1.71
Melanoma	21	1.71
Malignant fibrous histiocytoma	9	0.73
Miscellaneous	124	10.12
Total	1225	100

[a]Relative incidence of the most common skin tumors in cats collated from four studies.[2,6,7,15]

The association of canine oral PPV with the development of oral papillomas has been studied since the 1950s.[29,30] The association of viral infection with the development of SCC has evolved from a combination of evidence, including the detection of canine PPV in oral and cutaneous SCCs and the induction of cutaneous SCC in 10 beagles out of 4500 vaccinated with a live oral PPV vaccine.[31–33] Canine oral PPV has also been detected in multiple cases of cutaneous SCC.[32] A novel PPV with malignant potential was cloned from a dog with footpad papillomas.[34] Dogs persistently infected with this novel virus developed invasive and metastatic SCC.[35] Several additional novel canine PPVs were detected in SCC from a variety of locations, including four dogs with cutaneous tumors.[36]

Case reports support the correlation between PPV infection and the development of invasive SCC, including lesions of mixed histology.[33,37,38] Similar to the epidemiologic studies in immunosuppressed people, a case report of a patient on ongoing chemotherapy developing cutaneous PPV infection and multiple papillomas supports the concept of immunosuppression allowing persistent infection of PPV.[39] Susceptibility to infection may also be breed dependent.[40,41] Recently a dog with multiple viral plaques developed more than 20 invasive cutaneous SCCs over a 3-year period, with no evidence of underlying immunosuppression.[42] A novel PPV was sequenced from these lesions.

In cats, PPVs are associated with viral plaques and feline fibropapillomas (also known as *feline sarcoids*).[43,44] PPV can be detected with IHC in most feline viral plaques; as these plaques progress to SCC, the ability to detect PPV antigens decreases.[45] However, when polymerase chain reaction (PCR) is used to amplify PPV DNA, up to 76% of "UV-protected" SCCs are positive, compared with 42% of SCC in regions exposed to UV irradiation.[26] In people, it has been suggested that UV exposure and PPV infection may act as cofactors in the development of SCC.[46] In a large retrospective study that tested for the presence of PPV in SCCs, SCCs in situ, or Bowen's in situ carcinomas (BISCs) in 84 cats, no correlation was found with PPV infection and UV exposure.[47] A novel feline PPV has been sequenced from three feline BISC lesions.[48] Twenty-five percent of the 73 cutaneous lesions were positive for PPV by PCR. Human PPVs 5, 21, and 38 were identified in approximately half of the virus-positive cats.

A second study evaluated the levels of p16 in 60 cats; tissues tested included 14 viral plaques, 14 BISCs, 18 invasive SCCs, and 14 trichoblastomas (controls).[26] Eleven of the invasive SCCs were solar induced, and seven were classified as non–solar-induced tumors. P16 protein levels were compared with the trichoblastomas and solar-induced SCCs and were found to be elevated in all viral plaques, BISCs, and nonsolar invasive SCCs, consistent with the presence of PPV infection.[26] Most recently, the presence of E6 and E7 RNA was demonstrated in preneoplastic and neoplastic feline cells in a pattern similar to that seen with PPV-induced SCC in people.[49] Taken together, this data supports the possibility of a role for PPV in the development of SCC in cats.

Immune Status

Immunosuppressed people have a greatly increased risk of skin cancer; organ transplant recipients have up to a 100-fold increased risk for development of SCC.[50] Although this may reflect susceptibility to persistent PPV infection in some instances, it is also thought to reflect loss of normal immune surveillance, with resulting lack of an immune response against early neoplasia. A case report of the development of multiple cutaneous hamartomas and SCCs in

VetBooks.ir

situ in a dog receiving long-term immunosuppressive therapy with prednisone and cyclosporine also demonstrated positive staining for PPV antigens.[51] Interestingly, the lesions persisted and new lesions developed even after discontinuation of the drug therapy. The successful use of immune stimulants for early cancer lesions, such as imiquimod for carcinoma in situ, supports the role of the immune system in controlling skin cancer. The ability of the immune system of dogs to cause regression of histiocytomas and papillomas also illustrates the role of immune surveillance in veterinary patients.[52]

Genetic Abnormalities in Skin Cancer

Cancer is a genetic disease (see Chapter 1, Section A). The accumulation of multiple alterations in critical genes is usually necessary for full neoplastic transformation. An understanding of these genetic abnormalities, which can include both genetic and epigenetic modifications in a particular cancer type, allows for the formulation of therapeutics to circumvent these critical mutations and their pathways. The accumulation of such genetic data is only beginning in veterinary oncology. The discovery of activating mutations in the stem cell factor receptor, c-*kit* in canine MCTs, and the subsequent successful targeting of this mutation with tyrosine kinase inhibitors, is the first step in applying this approach in veterinary oncology. The current understanding of mutations in the most common forms of skin cancer and their role in either tumorigenesis or prognosis/response to treatment are presented according to tumor type.

Basal Cell Carcinomas

In people, basal cell carcinomas (BCCs) are thought to arise from critical mutations in the hedgehog signaling pathway.[53] Limited genetic evaluation of BCTs has been performed in veterinary medicine. One study demonstrated a reciprocal translocation in a canine BCT of t(10:35).[54] In the dog, chromosome 10 contains the gene *GLI1,* which is the effector transcription factor of the hedgehog signaling cascade. Two aberrant karyotypes were found in feline BCTs: trisomy E3 and monosomy E3, although the significance of these findings is unknown.[55,56] IHC for p53 in five feline BCTs were negative.[57] Likewise, IHC evaluation for the presence of the apoptotic regulatory proteins Bcl-2 and Bax showed 23 of 24 tumors expressed Bcl-2, but only seven of the BCTs expressed Bax.[58] Interestingly, Bcl-2 staining is considered fairly specific for human BCC.[59]

Squamous Cell Carcinoma

The genetic abnormalities responsible for the development of cutaneous SCC are incompletely understood in human oncology. One common finding is mutations in p53. A pathway of sequentially necessary mutations has been proposed.[60] In addition, several genetic changes in cutaneous SCC have been suggested to be of prognostic value in people with this disease.

A number of studies have evaluated p53 in canine and feline cutaneous SCC. When p53 is present in the wild-type form, its short half-life prevents detection of the protein with IHC. The presence of a detectable form of the p53 protein correlates with mutations within the coding sequence. Three IHC studies of p53 in canine cutaneous SCC revealed that 30% were positive for p53 overexpression.[32,57,61] Interestingly, two of six cutaneous papillomas were also positive for p53 expression by IHC.[32] Detectable expression is even more prevalent in feline cutaneous SCCs, with 19 of 40 cutaneous SCCs (48%) positive for p53 expression in three studies.[56,57,62] In addition, feline actinic keratosis was found to be highly positive for p53 expression (79%), whereas BISC lesions were less commonly positive (18%).[63] These studies have raised questions about the relative roles of PPV infection and UV irradiation in the development of different subtypes of feline SCC, because both mechanisms of tumorigenesis can result in increased identification of p53.

Several studies have used IHC to evaluate changes in selected protein expression. For example, IHC staining of p27, a protein thought important in maintaining cells in G0, showed SCC to have much lower levels than benign cutaneous neoplasms.[64] β-Catenin is a protein that is responsible for normal skin homeostasis. When dysregulated, β-catenin can be oncogenic. A study of β-catenin expression in normal skin and in benign and malignant tumors demonstrated nuclear presence of this protein, representing pathway activation, in 100% of trichoepitheliomas and pilomatricomas; no nuclear expression was found in any of the other malignant tumors or normal skin.[65] This finding led the authors to suggest a role for aberrantly activated β-catenin in the formation of tumors of the hair follicle. Evaluation for the presence of cyclin D1 and cyclin A, proteins important in the regulation of the cell cycle, demonstrated that cyclin A was present in 90% of feline SCCs and 44% of canine SCCs.[57] Cyclin D1 was rarely expressed in skin tumors of any type.[57] Staining for these proteins in normal skin and benign tumors showed rare or weak staining. The investigators suggested a role for cyclin A in the regulation of proliferation and neoplastic transformation in cutaneous SCC.

The syndrome of renal cystadenocarcinoma and nodular dermatofibrosis deserves mention, because this disease often presents to the veterinarian as the result of manifestation of multiple firm, cutaneous nodules. The disorder was first described as a genetic disease in the mid-1980s, and it was not until 2003 that the causative mutation in the Birt-Hogg-Dubé *(BHD)* gene was described.[66,67] The *BHD* gene codes for the tumor suppressor protein folliculin and mutations in this gene are thought to lead to loss of function.[68] This disease is primarily seen in German shepherd dogs.[66,69]

Identification of the driver mutations underlying neoplastic transformation in the skin will be the key to optimizing the use of drugs that target these pathways and of avoiding unwanted cutaneous side effects. The use of pathway-specific drugs may have unanticipated effects in the skin. Sorafenib, a tyrosine kinase inhibitor of Raf and VEGF/PDGFR, has been associated with the rapid development of actinic keratosis and invasive SCC in people.[70,71] As understanding of these pathways and their role in normal skin homeostasis develops, preventing these types of unintended consequences may become possible.

Pathologic Classification of Skin Tumors

Skin tumors arise from the epidermis and associated structures. For ease of use, these tumors are categorized based on their differentiation into specific subelements of the skin.[72] Some histologies are divided into benign and malignant forms based on known clinical and histologic predictors of behavior. In other tumor types, such clear-cut division may not be possible.

The World Health Organization's classification system of tumor-node-metastasis (TNM) can be applied to skin tumors in the clinical setting.[73] Location is also prognostic for particular tumor types; for example, digit and oral melanomas are highly malignant tumors, whereas cutaneous melanomas are often benign. Therefore this information should be included in the clinical description of the tumor at presentation.

VetBooks.ir

History and Clinical Signs

Tumors of the skin are often noticed by pet owners and brought to their veterinarian's attention. The biologic history of these masses can be quite variable. Self-trauma or secondary infection may cause a patient to be presented for evaluation. Ultimately, however, it is critical to remember that physical examination cannot definitively determine whether a lesion is benign or malignant – cytology or histopathology is necessary to diagnose any skin tumor.

Diagnostic Techniques and Workup

The evaluation of a skin tumor is generally similar to the evaluation for any solid tumor. A complete history can be very informative. Careful elucidation of the duration, rate of growth, and clinical signs associated with the tumor may be helpful in differentiating benign from malignant masses. The clinical evaluation of any patient with a mass involves two steps: diagnosis and staging. Many cutaneous and subcutaneous masses can be diagnosed with fine-needle aspiration and cytology or direct impression cytology of a lesion. Cytology is an inexpensive and relatively noninvasive means of diagnosing many common benign skin tumors, such as lipomas or sebaceous adenomas. For lesions that appear malignant or are nondiagnostic on cytology, histopathology may be necessary. In addition to confirming a diagnosis, histopathology yields useful information on the histologic grade of some tumors, such as MCTs, or the malignant behavior of a tumor, such as vascular and lymphatic invasion. Other characteristics, such as degree of differentiation, nuclear morphology, and percentage of necrosis, may be helpful with certain tumor types.

The type of biopsy performed usually is dictated by the location of the mass. Where wide surgical excision is feasible without undue morbidity, the biopsy can be combined with a therapeutic procedure (e.g., excisional biopsy), provided this approach does not affect definitive surgical excision if a malignant process is identified. However, in most instances the biopsy is a diagnostic test. The authors' preference for a biopsy of a skin or subcutaneous mass is multiple punch biopsies or an incisional biopsy. (See Chapter 9 for a more detailed discussion of biopsy techniques.) These techniques allow the procurement of a sufficiently large piece of tissue for an accurate diagnosis and, where applicable, grading of the tumor. In addition, the use of advanced histopathologic techniques, such as IHC for evaluation of prognostic markers, can be performed. Some molecular tests, such as PCR, can be carried out on formalin-fixed tissues.

Staging involves determination of the extent of disease locally, regionally, and distantly. Assessment of the primary tumor's size by measuring the longest diameter is the first step in the staging process. For large, infiltrative or fixed masses, local assessment may require advanced imaging, such as a computed tomography (CT) or magnetic resonance imaging (MRI), to accurately determine the tumor's size and extent. One study demonstrated that the use of advanced local imaging techniques increased the stage of the primary tumor in 69% of patients.[74] Regional staging involves the assessment of the draining lymph node(s) (LN). Determination of the draining node can be difficult for some locations, so evaluation of all LNs in the region may be necessary. Radiographic or CT lymphography may be helpful for determining the sentinel LN when drainage patterns are unclear (see Chapter 9).[75,76] LN palpation is a poor predictor of metastasis because metastatic LNs may be normal in size and consistency.[77,78] Conversely, large, firm LNs may be reactive in response to an infection or inflammatory process. Aspiration and cytologic examination by an experienced clinical pathologist is critical for the assessment of regional LNs for evidence of metastasis. IHC may also be more accurate for identifying metastasis, but these techniques are still being developed in veterinary medicine.[79] Despite careful evaluation of a cytology sample, it is possible to underestimate metastatic disease. Because of the unreliable nature of LN cytology and the potential effect of LN metastasis on the prognosis and adjunctive therapy, histopathology should be considered in cases with a high risk of malignancy.[78,80]

Evaluation of the patient for distant metastatic disease before histopathologic confirmation of a neoplastic process is based on the degree of suspicion that the mass is malignant, in addition to the desires and financial limitations of the owner. After confirmation of a malignant process, additional staging for detection of distant metastatic disease and evaluation of overall suitability for proposed treatments are indicated. Such staging may include three-view thoracic radiographs, thoracic CT, abdominal ultrasound, and/or additional tests as indicated by the tumor type and clinical findings.

Treatment and Prognosis for Specific Tumor Types

Given the external location of most skin and subcutaneous tumors, the primary treatment option for achieving local control is surgery. For benign masses, marginal excision may be adequate to achieve long-term control. For malignant tumors, adequate surgical excision requires a margin of normal tissue around the neoplasm. For a pathologist to determine whether excision is complete, all surgical margins must be identified with surgical ink or sutures to ensure correct reporting of margins (see Chapter 10).[81] The surgeon must properly prepare the sample to allow the pathologist to report all critical information, including margin evaluation (see Chapter 3).[81]

Likewise, to report the tumor grade accurately in tumors for which a grading scheme has been validated, a pathologist needs a reasonably sized piece of tissue to evaluate. Needle-core or Tru-Cut biopsies often yield limited amounts of tissue and should be limited to tumors for which they are the only option.

The most common cutaneous and subcutaneous tumors, melanomas, MCTs, and soft tissue sarcomas (STSs) are discussed separately in Chapters 20, 21, and 22, respectively. The remainder of this chapter covers the additional skin tumors, focusing on those with malignant behavior.

Epithelial Tumors

Tumors of the Primitive Follicular Epithelium

The term *basal cell tumor* was used for many years to include BCCs, basal cell epithelioma, trichoblastoma, and solid-cystic ductular sweat gland adenomas and adenocarcinomas. Because of progress in the ability of pathologists to differentiate these tumors on the basis of keratin and other membrane markers, trichoblastomas and solid-cystic ductular sweat gland tumors are no longer considered BCTs. Consequently, older studies that reported high rates of BCT, particularly in cats, may not reflect diagnostic patterns today.[82] These related tumor types are believed to arise from stem cells in the outer follicular root sheath displaying variable differentiation, although the origin for all tumors in this category cannot be absolutely identified.

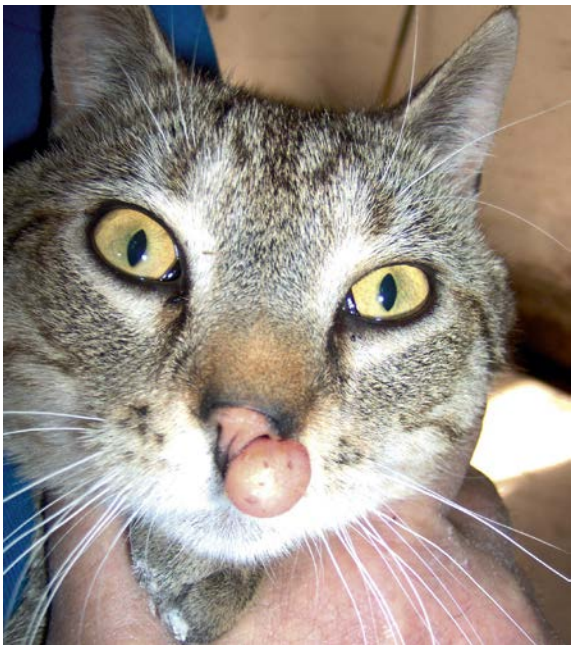
Basosquamous cell carcinoma is a tumor with characteristics of both BCC and SCC. Immunohistochemically basosquamous cell carcinomas are more closely related to BCCs and so are discussed in this section. Trichoepitheliomas are a more differentiated form of the trichoblastoma. The most appropriate nomenclature and classification schema for this group of tumors remains controversial. Tumor types are presented as categorized in the Armed Forces

VetBooks.ir

Institute of Pathology publication on the histologic classification of skin tumors.[72]

Basal Cell Carcinoma

The true incidence of BCC in both dogs and cats is unknown. The different tumors previously categorized as BCTs are difficult to distinguish histologically and cytologically, both in determining the category of tumor and in differentiating benign lesions from malignant. On cytology BCTs can contain inflammatory cells, squamous cells, sebaceous epithelial cells, melanin, and melanophages, and these cells can express the criteria of malignancy. Well-differentiated fibroblasts, reactive fibroblasts, and mast cells may also be present on cytologic examination.[83] The inability to distinguish the subtypes on cytology has led to the suggestion that these tumors be called "cutaneous basilar epithelial neoplasms" when they are evaluated by cytology alone.[84]



In histopathologic evaluation, tumors sometimes can be grossly differentiated based on growth pattern.[85] The epithelial membrane glycoprotein BerEP4 is highly specific for BCC versus SCC or cystic-solid ductular tumors for the diagnosis of BCC in people.[59] Cytokeratin 8 (CAM5.2) is used in human tumors to identify tumors with sweat gland epithelial differentiation; it also has been used to differentiate a BCC from a solid-cystic ductular tumor in a dog.[84] However, validation of these IHC markers in a larger veterinary population remains to be performed.

BCC is rare in dogs. In two studies reporting BCC or basal cell epithelioma (benign variant), the incidence ranged from 6% to 8% of all skin tumors; however, it is unclear whether trichoblastomas were included in these studies.[10,11] Breeds reported to be at increased risk for BCC included cocker spaniel and poodle in one study, and spaniels were overrepresented in another study; however, no breed predispositions were identified in other studies.[9,10] Clinically, these tumors present as plaques or nodules, often darkly pigmented. The overlying skin may be alopecic and intact or ulcerated. In dogs the median age is 9 years; however, dogs of all ages may be affected.[10,11] The three recognized histologic subtypes are solid, keratinizing, and clear cell.[85]

In dogs BCC is considered a low-grade malignancy. Although local recurrence of this tumor after surgical excision has been reported, there are no reports of metastasis. Morphometric analysis of cell nuclei has been reported to be useful in differentiating BCC with the potential for local recurrence from BCC that is unlikely to recur.[86]

In cats BCCs are now thought to be rare, and many feline BCTs are being reclassified as either solid-cystic apocrine ductular adenomas (approximately 60%) or trichoblastomas (approximately 40%).[87] However, given the preponderance of the literature referring to BCTs in cats, this group of tumors is discussed here with the realization that the population is actually not homogenous. These tumors comprise some of the most common solid tumors in cats, second only to mammary tumors in one large study.[2] They represent 10% to 26% of feline skin tumors.[2,6,9,88] They are reported in middle-aged cats with a mean age of 9.6 to 10.8 years.[2,6,88] One study reported a predisposition to BCT in Siamese cats,[2] and a second study showed an increased number of these tumors in long-haired cats (Himalayans, domestic long-hair, and Persian cats)[88]; however, a third study did not find a breed predisposition.[6] BCC can appear anywhere on the body but may have a predilection for the head and neck.[6,88] BCC can appear pigmented and may clinically resemble melanoma.

Clinically most tumors classified as BCTs appear benign in behavior. Malignant BCTs have been described in 10 of 97 cats in one series based on the presence of stromal invasion, vascular invasion, necrosis, a high mitotic index, and LN metastasis.[2]

• **Fig. 19.1** Fibropapilloma (sarcoid) on the face of a cat. (From Miller WH Jr., Griffin CE, Campbell KL: *Muller & Kirk's small animal dermatology,* ed 7, St Louis, 2013, Saunders.)

Pulmonary metastasis has been documented in one cat with a BCC.[89] Nucleomorphometric analysis was able to predict local tumor recurrence in one study of 24 cats with BCC.[90] Overall, the likelihood of metastasis with BCC in cats appears low.

Treatment for BCC is wide surgical excision, which often results in long-term control. In people with masses less than 2 cm, surgical margins of 4 mm result in a high cure rate. However, surgical margins of 5 to 10 mm are recommended in cats and dogs, when possible, because intraoperative margin assessment cannot be performed.[91] The data is limited, but adjuvant radiation therapy (RT) and doxorubicin have been used to treat BCCs in two cats; although their contribution to tumor control and survival are unknown.[89]

Basosquamous Cell Carcinoma

Histologically basosquamous cell carcinoma has characteristics of both SCC and BCC. Clinically it is indistinguishable from both BCC and SCC. The true incidence and clinical behavior of this tumor in dogs and cats are unknown.

Papillomas

Papillomas are benign epidermal proliferative lesions that often are associated with PPV infection.[34] They are considered rare in the cat and dog.[92] Papillomas typically have an exophytic growth pattern. Another benign variant is the inverted papilloma, which grows into the subcutaneous tissue rather than externally. Cutaneous papillomas are typically found in younger dogs with an average age of 3.2 years.[38] Surgical excision is usually curative, but some of these lesions spontaneously regress.[93] In patients with multiple lesions, azithromycin has been shown to be effective.[94]

In cats a particular type of papilloma, the fibropapilloma, is seen. These tumors demonstrate a proliferation of mesenchymal cells covered by hyperplastic epithelium.[44] Evaluation for PPV demonstrated a nonproductive infection of the mesenchymal cells.[95] Feline fibropapillomas may be more similar to equine sarcoids than papillomas (Fig. 19.1).

VetBooks.ir

Squamous Cell Carcinoma in Situ

SCC in situ is defined as a carcinoma that has not penetrated the basement membrane of the epithelium. In some cases it is thought to be caused by *Felis catus* papillomavirus infection.[30] When it appears in multiple sites, it is also known as *Bowen's carcinoma*, BISC, or multicentric PPV–induced SCC. This disease is seen primarily in cats, with only a few reports in dogs.[6,51,96–98] Actinic keratosis is the name typically used for SCC in situ that arises as a consequence of UV exposure.[85] Differentiation of actinic keratosis from BISC is based on location and histopathologic appearance.

Clinically SCC in situ can present as erosions of the epidermis, proliferations, or crusted plaques. They may be painful on palpation. BISC lesions can occur anywhere on the body, on both haired and unhaired skin, and in areas with and without sun exposure (Fig. 19.2). Solitary lesions are unusual.[6,97] Actinic keratosis, on the other hand, occurs in lightly haired skin with UV exposure, and these lesions are often solitary. Actinic keratosis typically is accompanied by solar elastosis and fibrosis of the skin, consistent with the effects of chronic UV exposure.[85] By definition, carcinoma in situ is not yet invasive and so metastasis has not occurred. However, left untreated, carcinoma in situ can progress to invasive carcinoma and put the patient at risk for metastasis. Patients with BISC typically continue to develop new lesions over time, but metastasis is uncommon.[6,51,96–98]

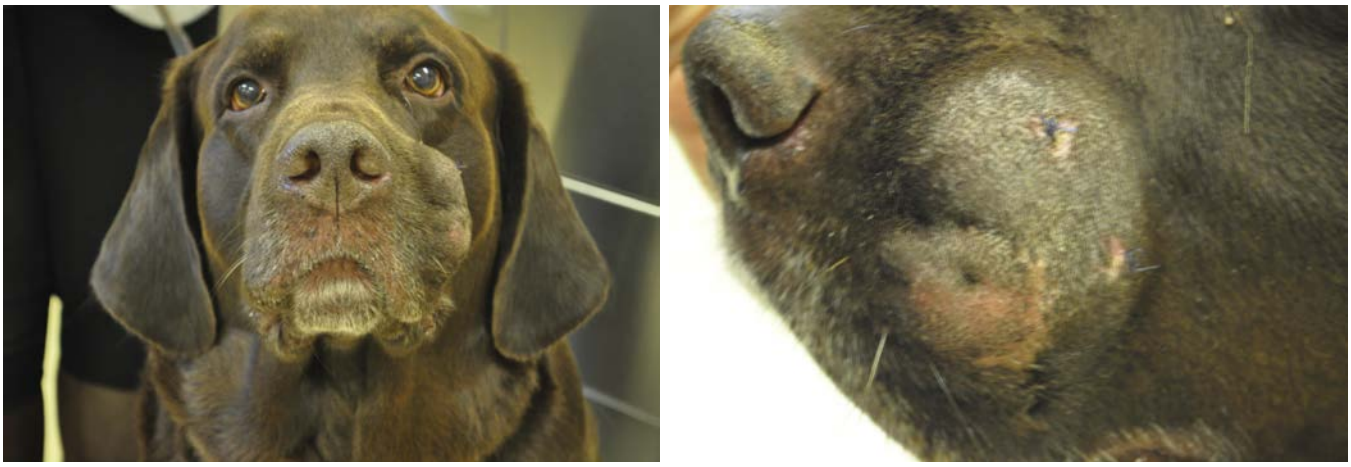
Many treatment approaches are effective for solitary SCC in situ. Surgical excision is the treatment of choice for most lesions. The median disease-free interval (DFI) and survival time (MST) in 39 cats treated with surgical excision for single nasal and pinna lesions were 594 days and 675 days, respectively.[23] Strontium-90 plesiotherapy in 14 cats with SCC in situ of the nasal planum resulted in 14 complete responses (CRs) with no recurrences and an overall survival time of >3000 days.[99] As expected, metastasis appears rare in cats with SCC in situ/actinic keratosis; in 61 cats with SCC of the nasal planum and pinnae, only one cat eventually developed metastasis to the regional LN.[23]

BISC lesions are often multifocal. As a result, marginal surgical resection is primarily indicated to improve comfort and local control when other therapies are no longer effective. Imiquimod cream (5%) has been reported to be effective in treating BISC in 12 cats, with five cats having at least one lesion undergo a complete response (CR).[97] Most cats were treated with daily application, although some were treated three times per week. One study on the use of 13-cis-retinoic acid for SCC in situ did not demonstrate clinical efficacy in cats with BISCs or SCCs.[100] Etretinate showed some promise for the treatment of SCC in situ and for invasive SCC, but this drug is no longer available.[101] Photodynamic therapy (PDT) is also effective in the treatment of BISC in people and cats, with reported response rates up to 100%.[102–104] With PDT, the clinical stage of the tumor was prognostic for survival. One author (MH) has treated a cat with BISC with palliative RT, and partial response/ stable disease was achieved for 8 months.

Squamous Cell Carcinoma

SCC is a malignant tumor of the epidermis in which the cells demonstrate differentiation to squamous cells (keratinocytes).[105]

• **Fig. 19.2** Plaquelike lesion of Bowen's in situ carcinoma on the head of a cat. Multiple such lesions may be present on the patient. (Courtesy Dr. Rodney Rosychuk.)



These tumors typically occur in cats older than 10 years of age and at a median age of 10 to 11 years in dogs.[6,38,105] Cats have a predilection for developing these tumors on their heads, particularly in lightly haired areas of white cats.[6] This predilection reflects the role of UV light in the induction of many of these tumors. A decreased risk has been reported in Siamese, Himalayan, and Persian breeds.[6,92] Labrador and golden retrievers may have a predisposition for the development of nasal planum SCC.[106] Bloodhounds, basset hounds, and standard poodles may be predisposed to develop cutaneous SCC.[105]

The clinical presentation of cutaneous SCC can be highly variable. Cutaneous SCC can appear plaquelike to papillary and from crateriform to fungiform.[85] These lesions may be erythemic, ulcerated, or crusted.[92] Paraneoplastic hypercalcemia has been reported in three cats with cutaneous SCC, two with ear canal tumors, and one with multiple cutaneous tumors.[107,108] Metastasis at the time of death was present in 6 of 15 cats with invasive SCC of the nasal planum, with the most common metastatic sites being regional LNs and the lungs.[109] Metastasis in dogs with cutaneous SCC appears rare, with only four dogs described in the literature.[35,110] Four of 17 dogs with SCC of the nasal planum had regional metastasis to the mandibular LNs.[106] Metastasis to distant sites was not reported.

Treatment for cutaneous SCC is primarily surgical when feasible. Wide surgical excision results in long-term control in both dogs and cats. In a series of 61 cats treated with surgery, RT, and cryosurgery, surgery resulted in the longest median DFI at 594 days, although many of these cats may not have had invasive disease.[23] Complete surgical excision of nasal planum SCC in dogs resulted in long-term control in four of six dogs; two dogs with incomplete excision developed local recurrence (see Chapter 24, Section A, for further discussion of nasal planum tumors).[111]

Little data is available on the use of chemotherapy to treat cutaneous SCC in dogs and cats. Carboplatin compounded with sterile sesame oil injected into nasal planum SCCs in cats resulted in a CR rate of 73% and a 55% progression-free

VetBooks.ir

• **Fig. 19.3** Large trichoblastoma on the muzzle of a dog. Local surgical excision was curative.

survival (PFS) rate at 1 year.[112] Electrochemotherapy with intravenous bleomycin has shown an 82% CR rate for 2 months to 3 years in cats with cutaneous SCC; it may be a good option for the treatment of lesions for which surgical resection may be challenging.[113] Two dogs with metastatic SCC were treated with cisplatin.[114] One dog with cutaneous SCC metastatic to the axillary LN and lungs had a marked reduction in the number and size of lung nodules, in addition to a partial response (PR) of the axillary LN after cisplatin chemotherapy; however, the response duration was only 4.5 months. The other dog had a complete and durable response of multiple lesions (>22 months). Bleomycin has demonstrated short-lived clinical activity in the treatment of both dogs and cats with SCC.[115] Two dogs with SCC were treated with actinomycin-D; one dog had stable disease after a single dose, and the second dog had a PR after treatment with a total of six doses.[116] Mitoxantrone resulted in a response in four of nine dogs with SCC in one study, but only 4 of 32 cats with SCC.[117,118]

Tumors with Adnexal Differentiation

A number of tumors arise from the hair follicle, and most of them are benign. Treatment for these benign tumors is surgical excision. Characteristics unique to these tumors are discussed individually.

Infundibular Keratinizing Acanthoma

Infundibular keratinizing acanthoma (IKA) is a benign tumor. It is common in dogs but has not been reported in cats. Previous names for this tumor include intracutaneous cornifying epithelioma (ICE), intracutaneous keratinizing epithelioma, keratoacanthoma, and squamous papilloma.[92] Peak incidence is from 4 to 9 years of age, but IKAs can occur in younger dogs.[119] Nordic breeds (particularly Norwegian elkhounds), Belgian sheepdogs, Lhasa apso, German shepherd dogs, terriers, and other breeds appear to be at increased risk for the development of these tumors.[119–122] They occur most commonly on the back, neck, trunk, tail, and upper limbs, and they may appear as solitary or multiple lesions.[119–122] They may have a central pore that communicates with the surface. Rupture of these masses can allow keratinized tissue into the adjacent dermis and incite a marked inflammatory response. When surgical excision is not feasible, treatment with isotretinoin (1.7–3.7 mg/kg/day) proved effective in three of seven dogs, with one CR and two PRs.[121]

Tricholemmoma

Tricholemmomas are rare, benign tumors in dogs.[123,124] They are well-encapsulated cutaneous or subcutaneous masses that may cause hair loss in the overlying skin. The most common location appears to be the head.[119] Surgical excision is the treatment of choice.

Trichoblastoma

Trichoblastoma is the new designation for what previously was called BCT in the dog and spindle cell variant of BCT in the cat.[92] Histologically this tumor shows differentiation to the hair germ of the developing hair follicle. Breeds at increased risk of developing trichoblastomas include poodles and setters.[119] Trichoblastomas are common in both dogs and cats. In a review of follicular tumors and tumorlike lesions, trichoblastomas comprised 26% of 308 canine follicular lesions and approximately 2% of all skin biopsies, and 26% of 50 feline follicular lesions (<2% of all skin biopsies).[119] The mean age at diagnosis was approximately 7 years for dogs and 10 years for cats.[119] The most common sites for trichoblastomas are the head and neck in dogs and the head, neck, limbs, and trunk in cats (Fig. 19.3). Although at least six subtypes have been described (ribbon, medusoid, trabecular, spindle, granular cell, and clear cell), trichoblastomas are benign and the subtype does not affect the prognosis. Surgical excision is the treatment of choice.[92,125]

Trichoepithelioma

Trichoepithelioma is an uncommon benign tumor in cats and dogs comprising approximately 4% of follicular tumors and tumorlike lesions.[119] These tumors demonstrate differentiation into all segments of the hair follicle[72]; they are dermal in origin but can extend into the subcutis. Their surface can be ulcerated or alopecic. Predisposed breeds include the basset hound, bullmastiff, standard poodle, soft-coated wheaten terrier, English springer spaniel, golden retriever, schnauzer, and setters.[92,119,126] Persian cats may or may not be predisposed.[92,126]

VetBooks.ir

Common locations include the limbs, neck, and back, and multiple trichoepitheliomas have been reported in basset hounds and English springer spaniels. Surgical excision is the preferred treatment, except in cases with a multicentric presentation.[126]

Malignant Trichoepithelioma

Malignant trichoepithelioma is differentiated from its benign variant on the basis of invasion into the surrounding tissues and lymphatic involvement. It is also known as *matrical carcinoma,* and it may be difficult to differentiate from a malignant pilomatrixoma.[127] The mitotic index is usually higher in malignant trichoepithelioma compared with the benign counterpart.[72] The few described cases in the literature were highly metastatic to the regional LNs and lungs.[126] The locally invasive nature of some trichoepitheliomas may also represent a lower grade variant of malignant trichoepithelioma.[127] Wide surgical excision is recommended.[126] No information is available on response to adjuvant therapies.

Pilomatricoma

Pilomatricoma is a benign follicular tumor demonstrating only matrical differentiation.[72] Alternative names for this tumor include the necrotizing and calcifying epithelioma of Malherbe and pilomatrixoma. These tumors are uncommon, representing 13% of the follicular lesions in one study and approximately 1% of all skin biopsies.[119] They are rare in the cat, with only one case described in 1225 skin biopsies.[2,6,7,15] Breed predispositions include the Kerry blue terrier, soft-coated wheaten terrier, Bouvier des Flandres, standard poodle, old English sheepdog, bichon frise, and Airedale terrier, among others.[92,128] The mean age at presentation is 6.5 years.[128] The most common locations are the neck, back, and trunk. These tumors are typically well circumscribed and may be very firm as a result of ossification.[127,128] Surgical excision is the recommended treatment.

Malignant Pilomatricoma

Malignant pilomatricoma is thought to be a rare tumor, although a recent study suggests it may be more common than previously reported, with four malignant variants described from a total of 13 pilomatricomas.[129] Malignant pilomatricoma has not been reported in cats. Differentiating benign and malignant pilomatricomas can be difficult histologically.[130] Invasion into underlying tissues, particularly bone, may be an indicator of potential malignant behavior in the absence of a malignant histologic appearance.[129–131] A recent review of several published cases demonstrated a high metastatic potential with metastasis to the lungs, bone, LN, mammary gland, or skin in 11 of 12 dogs.[129] There is one report of a dog with recurrent malignant pilomatricoma being treated with surgery and RT; this dog was diagnosed with pulmonary metastasis 14 months after local treatment.[130] The efficacy of chemotherapy for the treatment of dogs with malignant pilomatricoma is unknown.

Tumors of Glandular Origin

Sebaceous Hyperplasia, Sebaceous Adenoma, Sebaceous Ductal Adenoma, and Sebaceous Epithelioma

Tumors of glandular origin are very common in the dog but rare in the cat, and divisions between these tumors may be arbitrary.[92] A review of 172 sebaceous gland tumors in dogs revealed a female predisposition for sebaceous hyperplasia and an overrepresentation of miniature schnauzers, beagles, poodles, and cocker spaniels.[132,133] Coonhounds, Nordic breeds, and some terriers may also be predisposed to benign sebaceous tumors.[134] The limbs, trunk, and eyelids were the most common locations for these benign sebaceous tumors. Although these can occur even in young dogs, the peak occurrence is 7 to 13 years of age.[132–134]

Sebaceous epitheliomas may recur locally, and LN metastasis has been reported anecdotally.[135] Because lymphatic invasion occasionally may be found at the margin of sebaceous epitheliomas, these tumors sometimes are considered a low-grade malignancy rather than a benign tumor.[72] A recent report of distant metastasis in a dog with a recurrent sebaceous epithelioma confirms their malignant potential.[135] In general, adequate surgical excision is the preferred treatment.

Sebaceous Gland Carcinoma

Sebaceous gland carcinomas are uncommon in the dog and cat.[92] They are more common in intact male dogs, and the Cavalier King Charles spaniel, cocker spaniel, and terrier breeds are predisposed.[134] The tumors typically are found on the head and neck in dogs and on the head, thorax, and perineum in cats. Sebaceous carcinomas tend to be low-grade malignancies, with distant metastasis reported in one dog.[136,137] The most common finding of malignancy is local infiltration. Wide surgical excision is the recommended treatment.

Apocrine Gland Adenoma and Solid-Cystic Apocrine Ductal Adenoma

Apocrine gland adenomas are relatively common in dogs but uncommon in cats. The solid-cystic apocrine ductal adenoma previously was designated a BCT. Apocrine ductal adenomas are firm or fluid filled on palpation. Feline apocrine adenomas have a high predilection for the head.[138] Surgical excision is the recommended treatment.

Apocrine Gland Carcinoma

Apocrine sweat gland tumors are relatively uncommon in dogs (1% of all skin tumors) and cats (3% of all skin tumors) (see Tables 19.1 and 19.2). In a series of apocrine gland tumors, 40 of 44 dogs and 8 of 10 cats had malignant apocrine gland carcinomas.[139] In dogs the median age at diagnosis is 9 years, with most tumors occurring between 6 and 11 years of age.[140] Golden retrievers and the Treeing Walker coonhound may be predisposed.[138,139] The thoracic limbs are the most common site in dogs. Apocrine gland carcinomas were diagnosed in cats ranging from 6 to 17 years of age, and no breed or sex predilections were identified.[138,139] The most common locations for this tumor in cats include the head, limbs, and abdomen.[138] In both species most lesions are solitary. In addition to the nodular tumors, apocrine gland carcinomas may present as erosive and inflammatory skin disease, termed "inflammatory carcinoma."[138]

Local invasion is common, with 66% of tumors demonstrating invasion of the capsule and/or stroma, and 11% invading the vasculature.[140] In another series 23% had lymphatic invasion.[139] Grossly no features differentiated benign from malignant tumors. Despite the high incidence of local invasion, cure rates are high with surgery alone; only two dogs developed local recurrence (4%) and one dog developed distant metastasis (2%) in two case series.[139,140] Surgery is the recommended treatment.

Eccrine Adenoma and Carcinoma

Eccrine adenoma and carcinoma are benign and malignant tumors, respectively, of the sweat glands of the footpads. They are

VetBooks.ir

rare in dogs and cats, with only one report of a dog with involvement of multiple pads on one foot.[143] Wide surgical excision is the recommended treatment.[92]

Neuroendocrine Carcinoma

Neuroendocrine carcinoma is also known as *Merkel cell carcinoma*. Merkel cells are thought to be part of the mechanoreceptor in the skin. Recent studies have demonstrated a role for the Merkel cell polyomavirus in the development of human Merkel cell tumors.[144] Merkel cell tumors are highly malignant in humans; however, most case reports in cats and dogs suggest a more benign clinical course,[141,145] although distant metastasis has been reported in both species.[142,146,147] A recent evaluation of two canine neuroendocrine carcinomas demonstrated expression of β-catenin or E-cadherin, proteins whose loss predicts a more malignant behavior in humans.[148] There was also expression of chromogranin-A, neurone-specific enolase, S-100, and c-*kit* (which is also expressed in human neuroendocrine carcinomas). Current treatment recommendations reflect the generally benign behavior of these tumors and consist of wide surgical excision. The efficacy of chemotherapy for treatment of metastatic neuroendocrine carcinomas is unknown, as is the effect of c-*kit* targeted tyrosine kinase inhibition.

Renal Cystadenocarcinoma and Nodular Dermatofibrosis

Nodular dermatofibrosis is a pathognomonic cutaneous syndrome associated with renal cystadenocarcinomas, primarily described in German shepherd dogs.[66,69] These dogs have multiple firm, haired masses all over their bodies. On histopathologic examination these nodules are composed of dense, irregular collagen. They do not typically cause clinical problems unless they cause lameness or otherwise disrupt normal function. Surgical removal is indicated in these instances. Most of these dogs die as a result of renal failure or progressive renal cystadenocarcinoma (see Chapter 30), on average 3 years after initial detection of the dermatofibrosis.[149] There are no known effective treatments for the renal cysts or bilateral renal adenocarcinoma. A recent case report of nodular dermatofibrosis in an Australian cattle dog without any evidence of renal cysts or adenocarcinoma at necropsy suggests the possibility of a nonlethal version of this syndrome.[150]

Tumors of the Ear Canal

Ceruminous glands are modified apocrine glands found in the external ear canal. Benign and malignant tumors arising from these glands are the most common tumor types in the ear canal of dogs and cats. Additional tumor types that have been reported include SCC, undifferentiated carcinoma, BCC, hemangiosarcoma (HSA), MCT, melanoma, and benign fibroma, papilloma, sebaceous gland tumors, ceruminous gland cysts, and histiocytomas.[151–154] Inflammatory polyps also are found in dogs and more commonly in cats.

Most tumors of the ear canal are diagnosed as a result of the mass effect, which may cause clinical signs such as chronic otitis or partial deafness. Occasionally patients may present for pain on opening of the mouth or neurologic signs. This is more common with malignant tumors.[154] The role of chronic otitis in the development of these tumors is an area of ongoing discussion.

Ceruminous Gland Adenoma and Cyst

Ceruminous gland adenomas are benign tumors of the ceruminous gland. On gross appearance they are typically exophytic and pedunculated, although they can also be ulcerated.[155] Cats with ceruminous gland adenomas are slightly younger than those presenting with malignant tumors; in dogs both lesions present around 9 years of age.[154,155] Cocker spaniels and poodles are predisposed. Surgery is the treatment of choice.

• **Fig. 19.4** Typical appearance of a ceruminous gland cyst in the ear of a cat.

• **Fig. 19.5** Aural ceruminous gland carcinoma confined to the vertical ear canal in a cocker spaniel. (Courtesy Michelle Oblak.)

Ceruminous gland cysts are found in cats. These are darkly pigmented, sessile masses that are usually <5 mm in diameter and can occur as multiple lesions (Fig. 19.4).[153] If necessary, these can be surgically excised.

Ceruminous Gland Adenocarcinoma

Ceruminous gland adenocarcinoma is the most common malignant tumor of the ear canal in both dogs and cats (Fig. 19.5). In dogs, cocker spaniels and German shepherd dogs are at increased risk .[155] Malignant ceruminous gland tumors are more common than benign tumors in cats; however, there is conflicting information on whether malignant or benign tumors are more common in the dog.[155,156]

Ceruminous gland adenocarcinomas have metastatic potential, and full staging is recommended before treatment. Local

VetBooks.ir

invasion, including through the cartilage of the ear canal, can occur. Advanced imaging (CT or MRI) is indicated to better delineate the extent of local disease before surgery. Skull radiographs revealed lysis of the bulla in 13 of 27 dogs with malignant tumors of the ear canal, and sclerosis of the bulla was evident in eight dogs.[154] LN and distant metastasis are uncommon, with LN metastasis diagnosed cytologically in 1 of 30 dogs and pulmonary metastasis in 3 of 35 dogs, in addition to one dog with a lytic bone lesion.[154] In cats with malignant ceruminous gland adenocarcinomas, 5 of 27 cats had lysis of the bulla on skull radiographs, and five cats had sclerosis of the bulla.[154] Five of 56 cats had cytologic evidence of regional LN metastasis, but none of 32 cats evaluated had evidence of distant metastasis.[154] A staging scheme adopted from the human ear canal tumors has been proposed for primary tumors of the ear canal in cats and dogs (Table 19.3).[157]

Surgery is recommended for excision of noninvasive ear canal tumors; total ear canal ablation and lateral bulla osteotomy (TECA-LBO) is most commonly indicated.[158,159] Local tumor recurrence was significantly decreased in both dogs and cats treated with TECA-LBO compared with those treated with a lateral ear canal resection.[158,159] The MST for cats and dogs with malignant ear canal tumors treated with TECA-LBO was 42 to 50.3 months and not reached at 36 months, respectively.[158–160] RT also appears effective for the treatment of ceruminous gland adenocarcinoma[157]; six cats and five dogs treated with orthovoltage RT (12 4-Gy fractions for a total dose of 48 Gy) had an estimated mean PFS of 39.5 months and a 1-year PFS rate of 56%.

TABLE 19.3 Proposed Staging Scheme for Primary Tumors of the Ear Canal[165]

T_1	Tumor confined to the external or horizontal ear canal
T_2	Tumor extending beyond the tympanic membrane
T_3	Tumor extending beyond the middle ear/bone destruction

Several prognostic factors have been identified for ceruminous gland adenocarcinomas (Table 19.4). In cats a proposed grading scheme was not prognostic for survival, but a mitotic index ≤2 predicted improved survival.[160] A correlation between mitotic index and tumor grade was also noted in a series of cats and dogs treated with RT, although the small sample size precluded further evaluation for prognostic significance.[157] The overriding conclusion from the series of studies regarding treatment for ceruminous gland adenocarcinoma is that, with appropriate local therapy, long-term survival is possible.

Tumors of the Digit

The most common malignant digit tumors of dogs include SCC (47%), melanoma (24%), STS (13%), MCT (8%), osteosarcoma (OSA, 3%), round cell sarcoma, adenocarcinoma, malignant adnexal tumor, HSA, lymphoma, chondrosarcoma, giant cell tumor of bone, and synovial cell sarcoma. Benign and nonneoplastic diseases of the canine digits include pyogranulomatous inflammation, epithelial inclusion cysts, IKA, benign adnexal tumors, histiocytoma, hemangioma, BCT, intraosseous epidermoid cyst, infiltrating lipoma, fibroma, papilloma, hamartoma, trichoblastoma, keratoma, and plasmacytoma.[161,162] The median age at diagnosis is 10 years.[161,163] Approximately 3% of dogs with digital SCC have involvement of multiple digits. These dogs are typically large breed dogs with a black hair coat.[164,165] Predisposed breeds for multiple digit SCCs include standard poodles, black Labrador retrievers, giant schnauzers, Gordon setters, rottweilers, Beaucerons, and Briards.[165] Additional breeds that may be predisposed to digital SCC include dachshunds and flat-coated retrievers.[162] The thoracic limbs are more commonly affected than the pelvic limbs.[165] Scottish terriers were overrepresented in dogs with digital malignant melanomas.[162]

The definitive diagnosis of a digital mass can be difficult in both cats and dogs. A review of pathologists demonstrated a 20% rate of disagreement in the diagnosis of digital tumors, with 75% of the changes in diagnosis being clinically significant.[166] The differentiation between SCC and IKA was most difficult.

The most common digital tumors in cats include SCC (25%), fibrosarcoma (23%), adenocarcinoma (22%), OSA (8%), HSA

TABLE 19.4 Prognostic Factors for Primary Tumors of the Ear Canal

Prognostic Factor		Species	Median Survival (Months)	Reference
Mitoses per high power field	≤2 ≥3	Feline	≈180 ≈24	160
Extension beyond the ear canal	No Yes	Canine	30 5.9	154
Presence of neurologic signs	No Yes	Feline	15.5 1.5	154

Extension beyond the ear canal	No Yes	Feline	21.7 4	154

VetBooks.ir

(8%), MCT (7%), giant cell tumor of bone, malignant fibrous histiocytoma, sarcoma, and melanoma; nonneoplastic masses included inflammatory masses, hemangioma, and BCT.[167,168] Thoracic limb digits may be more commonly affected than pelvic limb digits. Multiple digit involvement has been reported in cats with fibrosarcoma, adenocarcinoma, and SCC.[167,169] Acrometastasis, or lung-digit syndrome, is common in cats with primary pulmonary carcinomas. In a series of 64 cats with digital carcinomas, 88% of cats had acrometastasis from primary lung tumors, whereas only 13% of cats had primary SCC of the digit.[169] Primary digital SCC and metastatic pulmonary carcinoma were differentiated based on histopathologic staining characteristics and cell morphology. In this series the MSTs of cats with acrometastasis and primary digital SCC were 4.9 weeks and 29.5 weeks, respectively.[169]

The most common clinical signs in dogs and cats with digital tumors are the presence of a mass and/or lameness. Digital tumors can metastasize, so appropriate clinical staging is recommended before definitive therapy, including regional LN evaluation and three-view thoracic radiographs or thoracic CT.[161–163,170] Regional radiographs are recommended to assess for bone involvement because this may have prognostic significance, especially for dogs with digital melanoma.[176] Bone lysis was noted in 80% of dogs with digital SCC and in 5% to 100% of dogs with digital melanoma.[161,163,171] In dogs with digital SCC, 6% to 13% had evidence of metastasis at the time of presentation, and an additional 9% to 17% subsequently developed metastasis.[161,163] A subungual location may carry a better prognosis than other sites in the digit with digital SCC.[161] In dogs with digital malignant melanoma, 32% to 40% had either regional LN or distant metastasis at the time of diagnosis, and an additional 10% to 26% developed metastatic disease after definitive treatment.[161,163] Little information is available on cats with primary digital tumors. For cats with digital SCC, three of six cats had evidence of bone invasion, one of eight had regional LN metastasis, and none of three had pulmonary metastasis.[169] Among cats with digital malignant melanoma, four of five developed metastasis to the regional LN, lung, bone, and/or vertebrae.[168]

The recommended treatment for most cats and dogs with digital tumors is digital or partial foot amputation (Fig. 19.6).[163] Limb function is very good to excellent in most dogs after either procedure, regardless of the digit(s) amputated.[172] The roles of RT and chemotherapy remain to be elucidated for the treatment of malignant digital tumors in the dog and cat. The high metastatic rate of digital malignant melanoma in dogs clearly suggests that adjuvant treatment should be considered.

For SCC of the digit treated with surgery alone, 1- and 2-year survival rates range from 50% to 83% and 18% to 62%, respectively.[161–163] When the tumors are categorized by the site of origin, dogs with SCC arising from the subungual epithelium had a significantly improved survival compared with dogs with SCC from other sites on the digit. Dogs with a subungual SCC had 1- and 2-year survival rates of 95% and 74%, respectively, whereas dogs with SCC at other digital sites had 60% and 40% 1- and 2-year survival rates, respectively.[161] MSTs for cats with digital SCC ranged from 73 days to 29.5 weeks.[167,169]

Dogs with digital malignant melanoma have 1- and 2-year survival of 42% to 57% and 13% to 36%, respectively, after treatment with surgery alone.[161–163,170,171] A more recent retrospective study that evaluated the effect of carboplatin chemotherapy on the survival of dogs with digital melanomas treated with surgery found no difference with the inclusion of chemotherapy; these dogs had 1- and 2-year survival rates of 89% and 67%, respectively, and an MST of 1350 days.[173] In a study of 58 dogs treated with an adjuvant xenogenic (murine) tyrosinase vaccine,[174] 57 dogs were treated with digital amputation, two dogs were treated with RT, and three dogs had received adjuvant chemotherapy. Sixteen dogs (28%) had either regional LN or distant metastasis at the time of presentation. The overall MST from the time of digital amputation was 476 days, with 1- and 2-year survival rates of 63% and 32%, respectively. Metastatic disease was identified as a negative prognostic factor, and distant metastatic disease was associated with a worse prognosis than metastasis to the regional LNs. For five cats diagnosed with digital malignant melanoma, survival times ranged from 0 to >577 days, with four cats developing metastatic disease.[168]

• **Fig. 19.6** Digital melanoma on a dog before digit amputation.

Melanoma

PHILIP J. BERGMAN, LAURA E. SELMIC, AND MICHAEL S. KENT

Melanoma is a relatively common cancer of dogs, especially those with significant amounts of skin pigmentation. Melanomas are relatively rare in cats. The most common location for canine melanoma is the haired skin, where they grossly appear to be small brown to black masses, but they can also appear as large, flat, and/or wrinkled masses.[1,2] Primary melanomas can also occur in the oral cavity, nailbed, footpad, eye, gastrointestinal tract, nasal cavity, anal sac, or mucocutaneous junction.[3–6] Metastatic sites are numerous including lymph nodes (LNs), lungs, liver, meninges, and adrenal glands.[3]

Melanoma arises from melanocytes, which are the cells that generate pigment through the melanosome by a number of melanosomal glycoproteins. In humans, cutaneous melanoma can arise as a result of mutations induced by repeated, intense exposure to ultraviolet light (for example, frequent tanning or working outdoors). Melanoma is currently the most rapidly increasing incident human cancer.[7,8] Significant recent research into the etiology of human melanoma suggests multiple causes independent of the aforementioned UV-associated mutagenesis.[9,10] Because most breeds of dogs have a significant hair coat that likely affords them protection from sunlight, UV-associated melanoma is less likely to be a primary causative agent in the dog. However, risk factors for canine melanoma are not well established.

The most common oral malignancy in the dog is melanoma.[2,3,11,12] Oral melanoma is most commonly diagnosed in Scottish terriers, golden retrievers, Chow Chows, poodles, and dachshunds.[2,13–16] Oral melanoma is more commonly seen in heavily pigmented breeds and is primarily a disease of older dogs without gender predilection, but may also be seen in younger dogs.[13,17,18] Differential diagnoses for oral tumors include squamous cell carcinoma, fibrosarcoma, osteosarcoma, acanthomatous ameloblastoma, and peripheral odontogenic fibroma.[2,3,12,19–21] Canine oral melanomas are found in the following locations by order of decreasing frequency: gingiva, lips, tongue, and hard palate.[2,3,11,13,16] Feline melanoma is relatively rare, but appears to be malignant in most cases.[3,22–29]

Melanomas in dogs have extremely diverse biologic behaviors depending on a large variety of factors. A greater understanding of these factors helps the clinician to determine the appropriate staging, treatment options, and prognosis. The primary factors that determine the biologic behavior of an oral melanoma in a dog are site, size, stage, and histologic parameters.[13,17,18,30,31] Unfortunately, even with a comprehensive understanding of all of these factors, there are melanomas that have an unreliable biologic behavior, hence the need for additional research into this relatively common, heterogeneous, but frequently aggressive tumor.

Pathology and Molecular Biology

Melanomas can be difficult to diagnose pathologically in some situations, especially anaplastic amelanotic melanomas, which can masquerade as soft tissue sarcomas.[32–34] Numerous investigators have attempted to increase the precision of identifying melanomas, predominantly through immunohistochemical (IHC) means.[16,33,35–37] This has been accomplished through the use of multiple IHC assays or use of an IHC cocktail of antibodies. The use of PNL2 and tyrosinase beyond the typical use of Melan A and S-100 appears to hold particular promise.[38–40]

The molecular characterization of canine and feline melanomas is significantly limited compared with the more comprehensive evaluation of human melanomas.[41] BRAF is a member of the MAPK signaling pathway that is commonly mutated in human cutaneous melanoma, but not in human oral melanoma.[42] Interestingly, BRAF mutations are also uncommon in canine oral malignant melanomas (MMs).[43] However, downstream constitutive activation of ERK has been identified in both human and canine MMs,[44] supporting the idea that certain canine and feline malignancies can have molecular signatures similar to those of human malignancies in addition to their already well known clinical similarities in the context of resistance to chemotherapy and/or radiation therapy (RT) and similar atypical sites of metastasis. A number of other investigators have reported a variety of molecular abnormalities and/or associations in canine and feline melanoma.[44-85]

Transcriptome analysis has recently uncovered a variety of possible new therapeutic targets in canine melanoma.[86] The melanoma-associated genes clustered in the areas of focal adhesion and PI3K-Akt (phosphoinositide 3-kinase/protein kinase B) signaling pathways, extracellular matrix–receptor interactions, and protein digestion and absorption. A small subset of dogs with malignant melanoma have exon 11 c-*kit* gene mutations,[62,87] and therefore the more routine use of c-*kit* mutation analysis by polymerase chain reaction (PCR) of canine MMs, and subsequent use of KIT small molecule inhibitors (particularly in dogs with advanced stage disease and/or lack of response to Oncept), should be considered. Furthermore, with somatic mutations in NRAS and PTEN being found in canine MM,[88] similar to human melanoma hotspot sites, these may represent logical therapeutic targets in the future.

Biologic Behavior and Prognostic Factors

The biologic behavior of canine oral melanoma is extremely variable and best characterized based on anatomic site, size, stage,

VetBooks.ir

and histologic parameters. On divergent ends of the malignancy spectrum, a low-grade 0.5-cm haired-skin melanocytoma is highly likely to be cured with simple surgical excision whereas a 5.0-cm high-grade oral MM has a poor to grave prognosis regardless of treatment options. Similar to the development of a rational staging, prognostic, and therapeutic plan for any tumor, two primary questions must be answered: what is the local invasiveness of the tumor and what is the metastatic potential? These will determine the prognosis and appropriate therapies.

The anatomic site of melanoma is highly, although not completely, predictive of local invasiveness and metastatic propensity. Melanomas involving the haired skin, which are not in proximity to mucosal margins, often behave in a benign manner.[1,3] Surgical excision is often curative, but histopathologic examination is imperative for delineation of margins as well as a description of cytologic features. The use of Ki67 IHC has been reported previously to more reliably predict potential malignant behavior than classical histology for cutaneous melanoma.[89]

Oral and mucosal melanoma has been routinely considered an extremely malignant tumor with a high degree of local invasiveness and high metastatic potential.[2,13,17,18,30,90] This biologic behavior is similar to that of human oral and mucosal melanoma.[3,91] Two recent studies have called this dogma into question and suggest benign oral melanomas can occur more frequently than previously thought.[92,93] Extreme caution is necessary when one receives a histopathology report suggesting a benign course with an oral melanoma, as this author (PJB) has seen approximately 30 dogs over the past 12 years presenting with florid systemic metastases despite an original histopathology report suggesting benign disease. Similar to cutaneous melanoma, Ki67 appears to hold prognostic importance in canine oral melanoma as well.[94]

The anatomic sites that split the opposite ends of the prognostic spectrum of generally benign acting, haired skin versus often malignant and metastatic oral/mucosal melanomas in dogs include melanomas of the digit and foot pad. Dogs with melanoma of the digits without LN or distant metastasis treated with digit amputation have reported median survival times (MSTs) of approximately 12 months with 1- and 2-year survival rates of 42% to 57% and 11% to 13%, respectively.[95,96] Metastasis at presentation is reported in approximately 30% to 40% of dogs,[95,97] and the majority of dogs with digit melanoma will develop regional or distant metastatic disease.[95–97] The prognosis for dogs with melanoma of the foot pad has not been previously reported; the first author (PJB) has found this anatomic site to be anecdotally similar in metastatic potential and prognosis to digit melanoma. Interestingly, human acral lentiginous melanoma (plantar surface of the foot, palms of the hand, and digit) also has an increased potential for metastasis.[98]

The most exhaustive review of prognostic factors in canine melanocytic neoplasms took a regimented, systematic approach to analyze the studies published to date in order to identify factors that appear to be repeatable, statistical, and therefore likely real, while also identifying areas where additional work is necessary because of incomplete data.[99] For veterinary clinicians and/or researchers interested in canine melanoma, this publication is strongly recommended. A flurry of recent investigations has given us a much greater understanding of feline ocular melanoma and iridiociliary cysts that are grossly similar to melanoma.[6,100–103] The use of all this information by clinicians and pathologists will allow for the best determination of prognosis for a specific patient that then allows for identification of the most logical treatment plans.

Size and Stage

For dogs with oral melanoma, primary tumor size has been found to be extremely prognostic. The World Health Organization staging scheme for dogs with oral melanoma is based on local tumor size and regional and distant metastasis, with stage I being a nonmetastatic tumor less than 2 cm in diameter, stage II being a nonmetastatic tumor 2 cm to 4 cm in diameter tumor, stage III being a tumor greater than 4 cm in diameter and/or LN metastasis, and stage IV being a melanoma with distant metastasis (Fig. 20.1).[104] The MSTs for dogs with oral melanoma treated with surgery are 511 to 874 days, 160 to 818 days, and 168 to 207 days with stage I, II, and III disease, respectively.[17,105] More recent reports suggest dogs with stage I oral melanoma treated with standardized therapies, including surgery, RT, and/or chemotherapy, have an MST of approximately 12 to 14 months, with most dogs dying of distant metastatic disease and not local recurrence.[106,107] Other investigators have found dogs with stage I oral melanoma have a median progression-free survival (PFS) time of 19 months.[108]

Diagnostic Workup and Clinical Staging

The diagnosis and clinical staging of dogs with melanoma is relatively straightforward. A minimum database should include a thorough history and physical examination, complete blood count, biochemical profile, and urinalysis.

Gross characteristics of melanomas, such as pigmentation of mass, should raise the suspicion for a diagnosis of melanoma. Pigmented melanomas can be easily confirmed via fine-needle aspiration (FNA) and cytology. In dogs, small (<2 cm), mobile, well-circumscribed, slow-growing cutaneous melanomas tend to be benign and easily excisable, whereas large, poorly defined,

T:	Primary Tumor	
	T1	Tumor ≤ 2 cm in diameter
	T2	Tumor 2–4 cm in diameter
	T3	Tumor >4 cm in diameter
N:	Regional Lymph Nodes	
	N0	No evidence of regional node involvement
	N1	Histologic/Cytologic evidence of regional node involvement
	N2	Fixed nodes
M:	Distant Metastasis	
	M0	No evidence of distant metastasis
	M1	Evidence of distant metastasis

Stage I = T1 N0 M0

Stage II = T2 N0 M0

Stage III = T2 N1 M0 or T3 N0 M0

Stage IV = Any T, Any N and M1

• **Fig. 20.1** Traditional World Health Organization TNM-based staging scheme for dogs with oral melanoma. (From Owen LN. *TNM Classification of Tumors in Domestic Animals.* 1st ed. Geneva, Switzerland; 1980.)

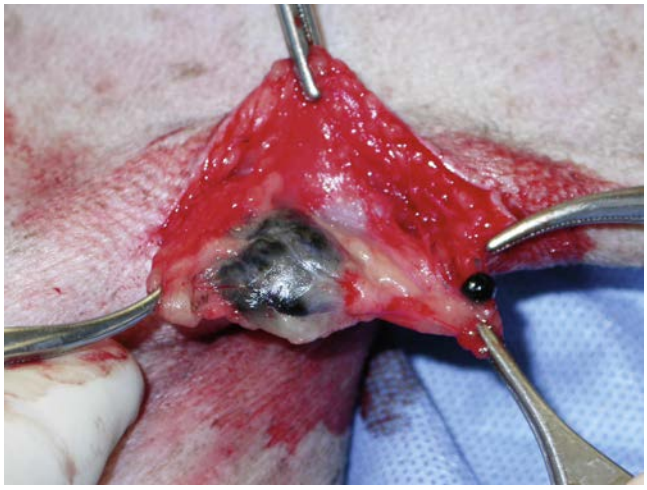
VetBooks.ir

ulcerated, and rapidly growing tumors can make surgical excision challenging. In the latter example, incisional biopsy and IHC can be an important part of the diagnostic workup, particularly if the mass is nonpigmented, to allow other tumor types to be ruled out and a diagnosis of melanoma confirmed.

Clinical staging tests routinely include evaluation of the regional LNs and assessment of the thoracic cavity with either three-view thoracic radiographs or thoracic CT scan. The regional LNs should be assessed whether lymphadenomegaly is present or not. LN metastasis is present in approximately 70% of dogs with lymphadenomegaly (Fig. 20.2) but, more importantly, in approximately 40% with normal sized LNs.[109] FNA cytology of the ipsilateral regional LNs has been recommended to assess for nodal metastasis; however, the only accessible regional LN is the mandibular LN. This may provide misleading information, as the lymphatic drainage of the head is complex and metastases to contralateral LNs has been documented. Furthermore, the mandibular LN can be normal when other LNs, such as the medial retropharyngeal or parotid LN, are metastatic.[110,111] Although earlier studies showed a high concordance of cytology and histopathology in dogs with melanomas,[111] a recent study highlighted discordance between cytology findings and histopathology, with a low correlation between the final cytology and histopathology reports in dogs with melanocytic neoplasia.[112] As a result, histologic examination of the LN is recommended either through excision of the major LNs of the head and neck or sentinel LN (SLN) mapping.

Nondiscriminate extirpation of the regional LNs of the head and neck has been described in dogs with and cats with malignant oral tumors.[113,114] One approach describes ipsilateral extirpation of the parotid, mandibular, and retropharyngeal LNs, but this requires an extensive dissection and does not investigate the contralateral LNs.[113] A second approach involves extirpation of the left and right mandibular and medial retropharyngeal LNs through a single incision, but does not investigate the parotid LNs.[114] The limitations of both approaches include more extensive dissections and incomplete testing of the regional LNs, and hence there is a risk of postoperative complications and missed metastatic LNs.

SLN mapping allows identification of the direct lymphatic drainage pathway from the tumor to the first draining LN. This LN can then be targeted for selective lymphadenectomy and histopathologic testing. Selective lymphadenectomy avoids the indiscriminate extirpation of multiple LNs and, because it is a less extensive surgical dissection, reduces the risk of postoperative complications. The use of SLN mapping and lymphadenectomy has been proven to be of diagnostic, prognostic, and clinical benefit in human melanoma.[115] Relatively few investigations have been reported to date for SLN mapping and/or excision for dogs with malignancies,[116–123] and the authors strongly encourage additional investigation and clinical adoption in this area.



Although not commonly described, abdominal ultrasonography or CT scans should be considered in dogs with melanomas arising from the oral cavity, digits, or pads because of the risk of metastasis to the abdominal LNs, liver, adrenal glands, and other intraabdominal sites. The use of novel staging modalities, such as gallium citrate scintigraphy, requires further investigation.[124]

Cross-sectional imaging (i.e., computed tomography [CT] scans or magnetic resonance imaging [MRI]) is critical for surgical planning for oral melanoma, especially melanomas involving the maxilla and caudal mandible. This allows for assessment of the extent of tumor, invasion into soft tissues, bone and the nasal cavity, and assessment of regional LNs, particularly the nonpalpable medial retropharyngeal, parotid, and buccal LNs.

Treatment

Surgery

Surgery continues to be the most effective local treatment modality for melanoma. There are few objective data available to guide decision making for appropriate surgical margin width for resection of melanomas. Benign cutaneous tumors are typically completely excised with 1-cm skin margins (and ideally one fascial plane for deep margins). Given the invasive nature of MMs, wide margins (2–3 cm) are ideal whenever possible; however, for oral melanomas, wide margins may not possible because of the limited amount of adjacent normal tissues. In these cases, surgery may need to be combined with RT for adequate local tumor control. In the authors' experience, 1- to 2-cm margins are usually adequate for complete histologic excision of MMs with well-defined borders (Fig. 20.3). Wide margins are usually possible with cutaneous and digit melanomas.

• **Fig. 20.2** Extirpation of a popliteal lymph node from the dog in Fig. 20.7. Note the effaced node overtaken with pigmented cells and the smaller nodule within the lymphatic vessel slightly distal to the node.

• **Fig. 20.3** Amelanotic melanoma involving the rostral aspect of the right lip; 1- to 2-cm lateral margins resulted in complete histologic excision.

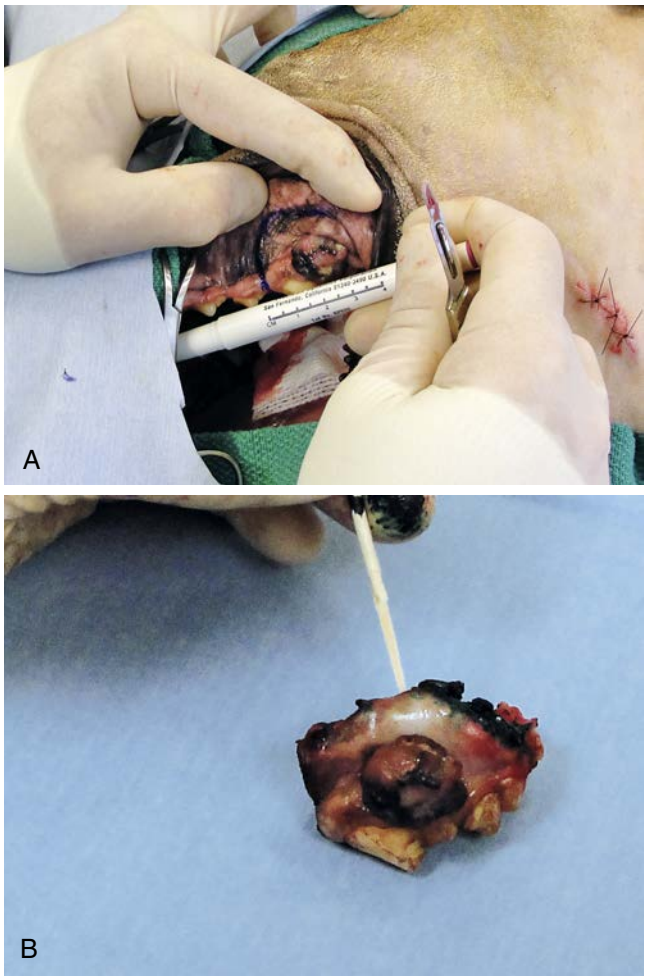
VetBooks.ir

• **Fig. 20.4** Local tumor recurrence after incomplete histologic excision and postoperative radiation of a gingival melanoma dorsal to the right carnassial tooth (caudal is to the left and the right canine tooth can be seen in the lower right-hand corner). When first treated, the mass was reportedly less than 1 cm in diameter and wide resection (i.e., partial maxillectomy) was not performed.

Partial mandibulectomy or maxillectomy is often required for resection of oral melanomas arising from the gingiva or mucosa in close proximity to the bone.[125] A common error is to resect a gingival mass without taking underlying bone simply because bone invasion is not observed. Owing to the proximity of the gingiva to the underlying bone, this approach typically leaves residual microscopic disease that leads to local recurrence (Fig. 20.4). Occasionally, tumors do occur in mucosal areas that are not adjacent to bone (e.g., buccal mucosa) or originate in the lip or tongue (Fig. 20.5) and are amenable to excision of the soft tissues only. Complete histologic excision of oral tumors has been shown to significantly affect prognosis in some studies (Fig. 20.6).[126–128] Dogs with incomplete histologic excision are 3.6 times more likely to die of tumor-related causes compared with dogs with complete histologic excision.[128] In this study, dogs with tumors caudal to the third premolar tooth (PM3) were 4.3 times more likely to die of tumor-related causes compared with dogs with tumors located rostral to PM3. For more specific surgical approaches to oral melanoma please see Chapter 23, Section A on oral tumors.

With the widespread access to cross-sectional imaging, improvements in surgical techniques (e.g., combined dorsal and intraoral approach for caudal maxillary tumors), and increased availability of surgical oncologic training, complete histologic excisions are more likely to be achieved than previously reported. The surgical goals should be driven by tumor location, clinical stage, owner preferences, and the ability of the surgeon to perform a wide resection in locations where surgery is difficult (e.g., large caudal tumors). Unplanned or limited attempts at excision should not be made, as these will often leave either residual gross or microscopic disease and result in rapid tumor recurrence. The first chance to operate with undisrupted anatomy is often the best chance to achieve tumor-free margins. For patients that undergo surgical excision with either a mandibulectomy or maxillectomy, quality of life is usually very good, and most dogs resume eating within 3 days of surgery. Furthermore, owner satisfaction with functional and cosmetic results after mandibulectomy and maxillectomy is high.[129] The functional outcome of single digit amputation is excellent and partial foot amputations (requiring excision

• **Fig. 20.5** (A) Lingual melanoma near the midline of the tongue of a dog. These masses are often superficial and can be easily excised with 1- to 2-cm lingual mucosal margins and a layer of muscle fibers deep to the mass. (B) Closure results in little disruption of the lingual architecture and postoperative function is excellent.



of more than one digit; see Fig. 20.7) are also tolerated very well and result in a good functional outcome.[130,131]

For tumors that are not amenable to wide resection or for which resection results in incomplete histologic margins, the combination of surgery with RT or other adjuvant therapies should be considered. Historically, surgery has not been recommended in the presence of metastatic disease (e.g., a positive LN is discovered during tumor staging); however, the role of adjuvant therapy (chemotherapy or immunotherapy) in conjunction with cytoreductive surgery is being investigated for metastatic melanoma in people and such approaches are now being explored in dogs.[132–134]

Radiation Therapy

RT plays an important role in the management and treatment of canine and feline oral melanomas. As with most tumor types, RT is used for the purpose of achieving locoregional tumor control. RT has been described as both a primary and adjuvant therapy, and both hypofractionated and definitive protocols have been described (Table 20.1).[26,106–108, 135–141]

Melanoma is thought to be a relatively radioresistant tumor type necessitating a higher dose in each fraction to achieve local

• **Fig. 20.6** (A) Intraoperative photograph of a melanoma confined to the lateral aspect of the caudal dental arcade. Surgical margins in this case were approximately 1.5 cm around the rostral, dorsal, and caudal borders of the tumor. The incision along the hard palate was made just medial to the dental arcade. (B) Surgical margins are inked with a green surgical ink and histopathologic assessment showed complete histologic excision.

• **Fig. 20.7** Malignant melanoma in the interdigital webbing between digits 3 and 4 (same dog as in Fig. 20.2). Surgical margins were between 1 and 2 cm. Complete histologic excision was achieved in this case after partial foot amputation.

control, although this is somewhat controversial.[142] Most published protocols in dogs and cats have used higher dose per fraction protocols, although the relative radiosensitivity of melanoma in companion animal species has not been determined and nor has the ideal dose per fraction in hypofractionated protocols been determined.

Hypofractionated protocols have the advantage of fewer treatments with fewer anesthetic episodes, lower cost, and less time commitment for the owner. These protocols also result in less severe acute effects. The main disadvantage of hypofractionated protocols is a lower overall and biologic equivalent dose, which theoretically results in lower rates of local control and an increased risk for late side effects. For dogs with a better prognosis, lower dose per fraction protocols can be used to decrease the risk of late effects. For a discussion of radiation effects, see the section on radiation side effects in Chapter 13.

When planning for RT, most radiation oncologists will treat both the primary tumor and the regional LN, including the mandibular and medial retropharyngeal LNs (Fig. 20.8). These LNs are included because, as noted earlier in this chapter, normal sized LNs do not preclude the possibility of metastasis.[109]

The reported range of partial and complete responses to RT are 25% to 67% and 19% to 69%, respectively, yielding an overall response rate of 82% to 94%, although one recent study reported a 0% complete and partial response rates and a 73% overall response rate when including stable disease in this measure.[107,136–138,140,141] When treating gross disease, responses are generally rapid and dramatic decreases in tumor volume can be seen within several weeks of starting therapy (Fig. 20.9). The PFS ranges from 3.6 to 8.6 months.[107,108,135,136] Interestingly, the longest reported PFS was from a study in which all dogs had surgery as part of their treatment protocol.[135] Local recurrence rates after RT vary and are confounded by different radiation protocols and adjuvant therapies used in these studies: local recurrence rates of 26% and 27% have been reported after the treatment of microscopic disease, whereas local progression was reported in 45% of dogs after the irradiation of macroscopic disease.[107,135]

The reported MSTs for dogs treated with RT range from 4.5 to 14.7 months (see Table 20.1).[106–108,135-138,139–141] The majority of these studies are retrospective and use different RT equipment, protocols, and adjuvant therapies, making it difficult to determine an ideal treatment regimen. Reported protocols include 2 to 4 Gy fractions daily for 12 to 19 treatments (45.6–57 Gy),[107,108] 4 Gy per fraction three times weekly for 4 weeks (48 Gy), 6 Gy per fraction twice weekly for 2.5 (30 Gy) or 3 weeks (36 Gy),[135,136,141] 6 Gy per fraction once weekly for 4 weeks (24 Gy),[135] 6 Gy once weekly for 6 fractions (36 Gy),[106,141] 8 Gy per fraction once weekly for 3 (24 Gy) or 4 fractions (32 Gy),[135,137,141] 9 Gy per fraction once weekly for 4 fractions (36 Gy),[107,138,139] and 10 Gy per fraction once weekly for 3 fractions (30 Gy).[107]

Five cats with oral melanoma and treated with RT have been reported.[26] There was one complete response and two partial responses with an MST of 146 days. Three cats were treated adjuvantly: one cat with carboplatin, one cat with carboplatin and mitoxantrone, and one cat with a DNA-based vaccine as an adjuvant to RT.

Chemotherapy may have a role in the management of dogs and cats with MMs treated with RT, either as a radiation sensitizer and/or because of the risk of metastatic disease. In one study, 39 dogs with incompletely excised oral melanomas were treated with either cisplatin (10–30 mg/m^2 IV) or carboplatin (90 mg/m^2 IV) once weekly approximately 1 hour before receiving RT.[106] The

TABLE 20.1 Published Studies on the Treatment of Oral Melanoma with Radiation Therapy

Study, Study Type (Year Published)	Species (No.)	Source and Dose/Protocol of Radiation	Outcomes	Chemotherapy
Bateman et al, Prospective single-arm trial (1994)[137]	Canine (18)	Cobalt-60; 24 Gy in three once-weekly fractions of 8 Gy.	One dog died during treatment, 9/18 had a complete response, 5/18 had a partial response, 3/18 had no response, MST: 7.9 months.	
Blackwood et al, Prospective single-arm trial (1996)[138]	Canine (36)	4 MV linear accelerator ($n = 29$), 250 kVp orthovoltage unit ($n = 1$), combination of the two machines ($n = 4$) 36 Gy in four once-weekly fractions of 9 Gy.	25/36 dogs had a complete response, 9/36 had a partial response, overall MST not reported (range, 5–213 weeks), MST for dogs that died of tumor-related causes: 21 weeks.	
Theon et al, Prospective single-arm trial (1997)[108]	Canine (38)	Cobalt-60; 48 Gy in 12 4-Gy fractions on a Monday–Wednesday–Friday schedule.	PFS 7.9 months, MST not reported.	
Proulx et al, Retrospective case series (2003)[107]	Canine (140)	Cobalt-60: 36 Gy in four once weekly 9-Gy fractions ($n = 54$); 30 Gy in 3 once-weekly 10-Gy fractions ($n = 69$), or 45.6–57 Gy in 12 to 19 2–4 Gy fractions ($n = 17$).	45/86 dogs had a complete response and 27/86 dogs had a partial response. Median time to first event (metastasis, local recurrence, or death): 5.0 months, MST: 7.0 months.	80 dogs received chemotherapy (carboplatin [$n = 60$], cisplatin [$n = 3$], melphalan [$n = 17$]). Chemotherapy did not affect time to first event or survival.
Freeman et al, Retrospective case series (2003)[106]	Canine (39)	Cobalt-60 and 4 MV linear accelerator: 36 Gy in 6 once-weekly 6-Gy fractions.	MST: 363 days.	Dogs received cisplatin (10–30 mg/m^2 IV) or carboplatin (90 mg/m^2 IV) chemotherapy 60 minutes before radiation delivery.
Farrelly et al, Retrospective case series (2004)[26]	Feline (5)	Cobalt-60: 24 Gy in three once-weekly 8-Gy fractions.	One complete response, two partial responses, MST: 146 days.	Two cats received chemotherapy, one received carboplatin, one carboplatin and mitoxantrone, and one was treated with a DNA-based vaccine. One cat had additional radiation after initial failure.
Murphy et al, Retrospective two-arm study (2005)[139]	Canine (28)	4 MV linear accelerator: 36 Gy in four once weekly 9-Gy fractions.	No chemotherapy group, MST 307 days. Chemotherapy group, MST 286 days.	No chemotherapy, 13 dogs. Chemotherapy group, 15 dogs treated with carboplatin (planned dose: 300 mg/m^2 IV every 21 days).
Dank et al, Retrospective case series (2012)[135]	Canine (17); 11 dogs treated with surgery, chemotherapy, and radiation; 6 dogs treated with surgery and chemotherapy	Radiotherapy sources not indicated. 32 Gy in four once-weekly 8-Gy fractions ($n = 5$), 36 Gy in six twice-weekly 6-Gy fractions ($n = 4$), 30 Gy in three once-weekly 10-Gy fractions ($n = 1$), and 24 Gy in four once-weekly 6-Gy fractions ($n = 1$).	PFS radiotherapy group, 259 days; PFS no radiotherapy group, 210 days. MST radiotherapy group, 440 days; MST no radiotherapy group, 387 days. No significant difference between groups.	Carboplatin (median dose of 300 mg/m^2 IV).
Kawabe et al, Retrospective case series (2015)[140]	Canine (111)	Orthovoltage 300 Kvp ($n = 68$), 4 MV linear accelerator ($n = 34$) or combined ($n = 5$); electron therapy, energy not reported ($n = 4$). The median total radiation dose was 37.8 Gy (range, 6.3–74.3 Gy).	38/87 dogs had a complete response and 36/87 dogs had a partial response. MST: 171 days; MST for orthovoltage-treated dogs, 122 days; MST for megavoltage-treated dogs, 233 days. This was statistically different.	66 dogs had chemotherapy: either intralesional cisplatin (0.5mg/dog q1–2wks; $n = 26$), carboplatin IV (180–250 mg/m^2 q3wks; $n = 26$), or both ($n = 14$).

TABLE 20.1 Published Studies on the Treatment of Oral Melanoma with Radiation Therapy—cont'd

Study, Study Type (Year Published)	Species (No.)	Source and Dose/Protocol of Radiation	Outcomes	Chemotherapy
Cancedda et al, Prospective multicenter, non-randomized, two-arm clinical trial (2016)[136]	Canine (27)	Linear accelerator using photons or electrons. Energy not specified. 30 Gy in five fractions over 2.5 weeks.	Radiation therapy alone group: 3/15 dogs had a complete response and 10/15 dogs had a partial response; PFS 110 days; MST: 192 days. RT and temozolamide group: 2/15 dogs had a complete response and 8/15 dogs had a partial response. PFS of 205 days. MST: 401. Statistically significant difference for PFS but not MST.	No chemotherapy given to 15. 12 received temozolomide at 60 mg/m^2 PO once daily for 5 days every 4 weeks.
Tollett et al, Retrospective case series (2016)[141]	Canine (11)	6 MV linear accelerator. 32 Gy in four once-weekly 8-Gy fractions (n = 9) or 36 Gy in six once- or twice-weekly 6-Gy fractions (n = 2).	0/11 dogs had a complete or partial response. MST: 134 days.	

IV, Intravenous; *MST*, median survival time; *PFS*, progression-free survival; *PO*, per os.

• **Fig. 20.8** Postcontrast axial computed tomography (CT) image of a dog with metastasis to the left mandibular lymph nodes (A, *arrows*) and the enlarged left medial retropharyngeal lymph node (B, *arrow*). Note the heterogeneous contrast enhancement in both lymph nodes.

radiation protocol consisted of six once-weekly 6 Gy fractions. Local recurrence was reported in 15% of dogs, the median time to metastasis was 10.2 months, and the MST was 11.9 months. These results may have been favorably biased because the majority of dogs had either T1 (56.4%) or T2 (35.9%) stage melanomas.

Several studies have looked at using adjuvant chemotherapy in addition to RT. Administered drugs included carboplatin, cisplatin, or melphalan. Adding chemotherapy to the radiation protocol did not improve outcomes.[107] However, two studies suggest that there may be a role for chemotherapy in the treatment of oral melanoma in combination with RT. In a multicenter retrospective study of 17 dogs with oral melanoma treated with surgery and carboplatin, including 11 dogs also treated with RT, the overall median PFS (259 days) and MST (440 days) for dogs did not significantly change when RT was added to the treatment protocol.[135] The proportion of dogs with local recurrence, however, was lower in the RT group (27%) compared with dogs not treated with RT (67%). The authors concluded that there may be a role

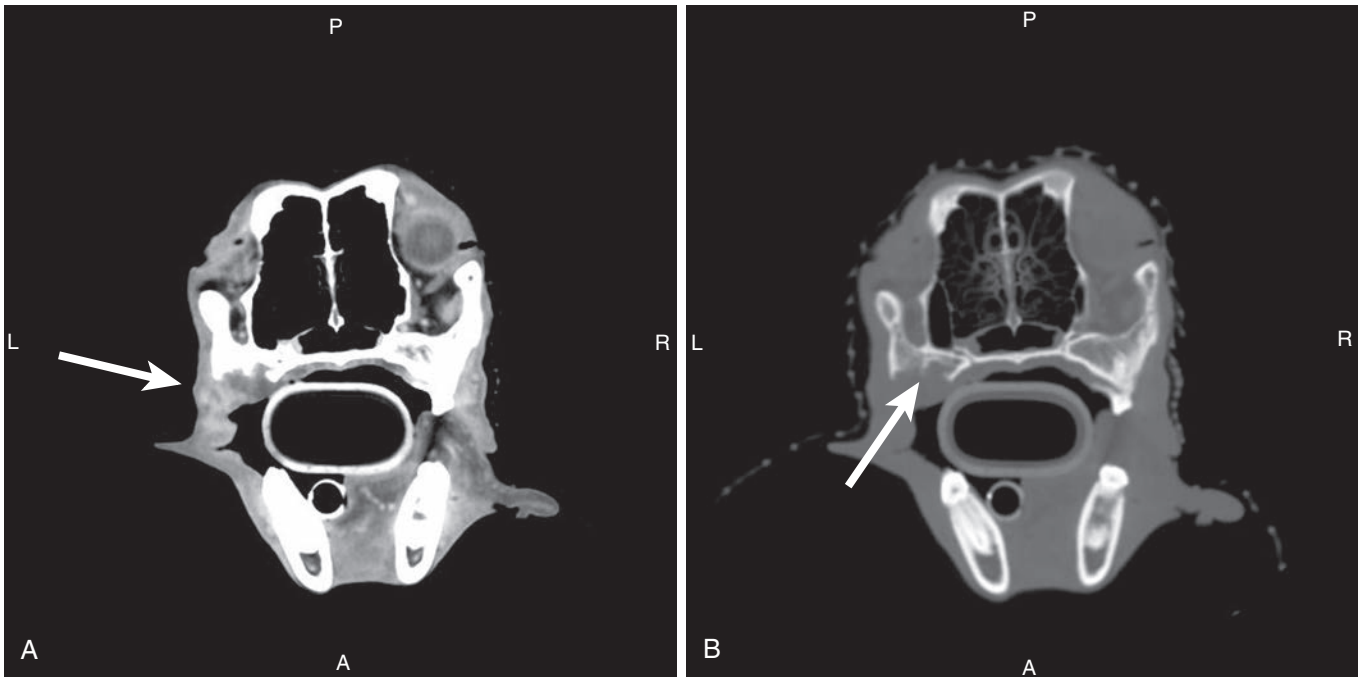
• **Fig. 20.9** A dog with an oral melanoma treated with a hypofractionated protocol of 8 Gy per fraction once weekly on the first day of therapy (A) and before the fourth and final fraction of radiotherapy (B). This dog went on to have a complete response.

for carboplatin in the multimodal treatment of dogs with oral melanomas because of the relatively long PFS and MST in this study. This may be related to the dose intensity of carboplatin used in this study with the majority of dogs not having dose reductions from the intended 300 mg/m^2 dose of carboplatin.

In a prospective study of 27 dogs with malignant melanoma in oral and nonoral sites, 15 dogs were treated with RT only and 12 dogs were treated with RT and adjuvant temozolomide.[136] The RT protocol used in all dogs was 5 fractions of 6 Gy delivered over 2.5 weeks; temozolomide was administered at 60 mg/m^2 PO once daily for 5 days and repeated every 28 days for dogs in the chemotherapy group. Both groups had similar overall response rates of 86.7% and 81.1%, respectively. The median time to progression (TTP) was significantly longer in dogs treated with RT and temozolomide (205 days) compared with dogs treated with RT alone (110 days). The MSTs, however, were not statistically significant different with MSTs of 192 days and 402 days for dogs treated with RT alone and RT and temozolomide, respectively.[136] Given the small number of dogs, it is possible that temozolomide may have an effect on MST and further clinical trials will be necessary to evaluate this.

Radiation-Associated Prognostic Factors

Several prognostic factors have been identified in dogs with oral melanoma treated with RT. These factors must be viewed with caution because some of the data are conflicting and most are derived from retrospective case series without the use of control groups.



Similar to the situation after surgery, the size of the irradiated oral melanoma is prognostic in several studies. In one study of 105 dogs with oral tumors, 38 of which were MM, treated with 4 Gy per fraction on a Monday–Wednesday–Friday schedule to a total dose of 48 Gy, the overall median PFS was 7.9 months.[108] Dogs with T1 lesions had a median PFS of 11.3 months whereas dogs with T2 and T3 lesions had median PFSs of 6.0 and 6.7 months, respectively. The most common cause of failure in this study was distant metastasis rather than local tumor recurrence. In another study of dogs with oral melanomas treated with a 9 Gy per fraction once weekly for 4 weeks, dogs with tumors less than 5 cm^3 were more likely to achieve a complete response and have significantly better MST than dogs with larger tumors.[138] The MSTs were 86 weeks, 16 weeks, and 21 weeks for dogs with tumors less than 5 cm^3, 5 to 15 cm^3, and greater than 15 cm^3, respectively. Tumor size also affects times to first event, pulmonary metastasis, and death. In a study in which dogs were treated with a variety of different radiation protocols and adjuvant treatments, dogs with stage I disease had a significantly longer MST (758 days) compared with dogs with stage II (278 days), stage III (163 days), and stage IV (80 days) disease; however, these results contrast with other studies in which tumor size was not found to be prognostic.[137]

In one study, dogs without radiographic evidence of bone invasion had significantly longer times to first event and overall survival times than dogs with radiographic evidence of bone changes.[107] However, bony involvement has been reported in up to 92% of dogs with melanoma (Fig. 20.10).[106]

The role of vascular endothelial growth factor (VEGF) in the response and clinical outcome of melanomas to RT has been investigated, although its clinical effect has not been completely elucidated.[143] Several studies have found that dogs with oral melanoma have higher plasma VEGF concentrations than normal control dogs.[53,144] In a preliminary study investigating plasma VEGF levels in a variety of tumor types treated with hypofractionated RT, four dogs diagnosed with melanoma had the highest mean plasma VEGF levels of all tumor types, although no significant changes in VEGF levels were noted over the course of treatment.[145] The effect of VEGF levels had on patient outcome has also been investigated in 39 dogs, six of which were diagnosed with melanoma.[145,146] VEGF levels did not significantly increase over the course of RT in these dogs; however, dogs with higher plasma VEGF levels treated with hypofractionated protocols had a shorter time to treatment failure and a shorter MST.

Chemotherapy and Immunotherapy

Systemic therapy is indicated in dogs with a moderate to high metastatic risk, such as dogs with oral, digit or pad melanomas, and dogs with cutaneous MM with a high tumor score and/or increased proliferation index through increased Ki67 expression. Chemotherapy does not seem to have a role in the management

• **Fig. 20.10** (A) Postcontrast axial CT image of a dog with a maxillary oral melanoma. Note the heterogeneously contrast enhancing soft tissue mass *(arrow)*. Precontrast axial image at the same level as the image in (A). (B) Note the bone destruction of the maxillary bone and the invasion of the soft tissue mass into the nasal cavity *(arrow)*.

of dogs with MM. Overall response rates for dogs with measurable disease are largely disappointing, especially with single-agent dacarbazine, melphalan, vinorelbine, or doxorubicin,[147–150] with the highest reported response rates response being 18% for dogs treated with cisplatin and piroxicam[151] and 28% for dogs treated with carboplatin.[152] Furthermore, the majority of responses are short lived. More recently and importantly, five retrospective studies investigating the role of chemotherapy in the adjuvant setting after either surgery or RT found no significant differences in outcomes with the addition of chemotherapy to the treatment protocol.[104,107,127,139,153] Other nonimmunologic antiproliferative and/or prodifferentiation approaches have included lupeol or targeting SET/I2PP2A, proteasomes, and SINE (selective inhibitor of nuclear export).[154–158] Although it can be effectively argued that the studies performed to date to evaluate the activity of chemotherapy in an adjuvant setting for canine melanoma have been suboptimal for a variety of reasons, the human literature is extensive and this suggests melanoma is an extremely chemotherapy-resistant tumor.[135,159] It is clear that new approaches to the systemic treatment of this disease are desperately needed.

One potential clinical therapy avenue that has been minimally reported on to date in canine or feline melanoma is the use of cyclooxygenase (COX)-2 inhibitors. A number of authors have investigated the expression of COX-2 and neurokinin-1 (NK-1) in canine melanoma and/or melanoma cell lines and found positive correlations of expression to proliferation and survival.[79,160–165] Studies investigating the clinical responsiveness of canine melanoma to COX-2 inhibitors (and potential correlation to COX-2 expression) and/or NK-1 antagonists, such as maropitant, are required. Other modalities reported for local tumor control as case reports and/or case series include intralesional cisplatin implants, intralesional bleomycin with electronic pulsing, and many others, but widespread use has not been reported to date.[166–168]

Immunotherapy represents one potential systemic therapeutic strategy for the adjuvant treatment of malignant melanoma. A variety of immunotherapeutic strategies for the treatment of human melanoma have been reported with typically poor outcomes because of a lack of breaking tolerance. Immunotherapy targets and strategies to date in canine melanoma have used autologous tumor cell vaccines (with or without transfection with immunostimulatory cytokines and/or melanosomal differentiation antigens); allogeneic tumor cell vaccines transfected with interleukin-2 (IL-2) or granulocyte macrophage colony-stimulating factor (GM-CSF); liposomal-encapsulated nonspecific immunostimulators (e.g.. L-MTP-PE); intralesional Fas ligand DNA; siRNA (small interfering) against the *survivin* and/or *Bcl-2* genes; bacterial superantigen approaches with GM-CSF or IL-2 as immune adjuvants; polyethylene glycol (PEG) ylated TNF-no suicide gene therapy; adenovector CD40 ligand; chondroitin sulfate proteoglycan 4 (CSPG4); IL-12; interferon-beta (IFN-beta); and lastly canine dendritic cell vaccines loaded with melanosomal differentiation antigens.[17,158,169–189] Although these approaches have produced some clinical antitumor responses, the methodologies for the generation of these products are often expensive, time consuming, sometimes dependent on patient tumor samples being established into cell lines, and fraught with the difficulties of consistency, reproducibility, and other quality control issues, and none are currently commercially available. Furthermore, we now more fully understand the native immune dysregulation potentially induced by the malignancy through increased T regulatory (Treg) cells that suppress antitumor responses.[190–193]

The advent of DNA vaccination circumvents many of the previously encountered hurdles in vaccine development. DNA is relatively inexpensive and simple to purify in large quantities. The antigen of interest is cloned into a bacterial expression plasmid with a constitutively active promoter. The plasmid is introduced

VetBooks.ir

into the skin or muscle with an intradermal or intramuscular injection. Once in the skin or muscle, professional antigen-presenting cells, particularly dendritic cells, are able to present the transcribed and translated antigen in the proper context of major histocompatibility complex and costimulatory molecules. Although DNA vaccines have induced immune responses to viral proteins, vaccinating against tissue-specific self proteins on cancer cells is clearly a more difficult problem. One way to induce immunity against a tissue-specific differentiation antigen on cancer cells is to vaccinate with xenogeneic antigen or DNA that is homologous to the cancer antigen. Vaccination with DNA encoding cancer differentiation antigens is ineffective when self DNA is used, but tumor immunity can be induced by orthologous DNA from another species.[194]

A xenogeneic DNA vaccine program for melanoma was developed in collaboration with human investigators from Memorial Sloan-Kettering Cancer Center.[195,196] Preclinical and clinical studies showed that xenogeneic DNA vaccination with tyrosinase family members (e.g., tyrosinase, GP100, GP75) produced immune responses resulting in tumor rejection or protection with prolonged survival times, whereas syngeneic vaccination with orthologous DNA did not induce an immune response.[197] Although tyrosinase may not appear to be a preferred target in amelanotic canine melanoma because of poor expression when assessed by IHC,[32] more appropriate and/or sensitive PCR-based studies and other IHC-based studies document significant tyrosinase overexpression in melanotic and amelanotic melanomas across species.[16,39,198–201] These studies provided the impetus for development of a xenogeneic tyrosinase DNA vaccine program in canine MM. The antibody and T-cell responses in dogs vaccinated biweekly for a total of four vaccinations with human tyrosinase (huTyr) demonstrated antigen-specific IFN-γ T-cells with 2- to 5-fold increases in circulating antibodies to huTyr which can cross react to canine tyrosinase, suggesting the breaking of tolerance.[202,203] The clinical results with prolongation in survival have been reported previously.[195,196]

The results of these trials demonstrate that xenogeneic DNA vaccination in canine MM: (1) is safe; (2) leads to the development of antityrosinase antibodies and T cells; (3) is potentially therapeutic; and (4) is an attractive candidate for further evaluation in an adjuvant, minimal residual disease phase II setting for canine MM. Based on these studies, a multiinstitutional safety and efficacy trial compared 58 prospectively enrolled dogs with surgically resected stage II and III oral melanomas treated with adjuvant HuTyr-based canine melanoma vaccine (Oncept, Merial, Inc.) to a historical control group of 53 dogs.[204] Dogs treated with Oncept had a significantly better outcome; the MST for dogs in the historical group was 324 days compared with an MST that was not reached in the vaccinated group because only 26% of vaccinated dogs died as a result of their disease.[204] A number of clinical case series have not found a significant difference in outcome with the addition of Oncept after surgical resection of oral MMs.[104,126,205–208] Compared with the aforementioned prospective study, conclusions are more difficult to make from these studies, as they are retrospective, noncontrolled, include a high proportion of stage I oral melanomas, include a wide variety of other treatments utilized in both the nonvaccinate and vaccinate groups, had small numbers of patients investigated, and/or the cause of death and/or progression of disease was not reported.

The concurrent use of RT and Oncept has been investigated in dogs with oral MM.[209] This pilot study determined that concurrent use was well tolerated with no unexpected toxicities. Oncept also appears to be safe for use in cats.[210] Human clinical trials utilizing various xenogeneic melanosomal antigens as DNA (or peptide with adjuvant) vaccination have begun and the preliminary results look favorable.[197,211,212]

Further evidence for the efficacy of immunotherapy for the treatment of canine oral melanoma has been shown in clinical trials with the CSPG4 vaccination.[184,213] In a controlled prospective study of dogs with stage II or III oral MM, 19 dogs were treated with surgical resection only and 23 dogs were treated with surgical resection and adjuvant CSPG4 vaccination. The outcomes were significantly better in the vaccinated group. The median disease-free interval, MST, and 1- and 2-year survival rates in the vaccinated group were 477 days, 684 days, and 73.9% and 30.4%, respectively, compared with 180 days, 200 days, and 26.3% and 5.3%, respectively, in the nonvaccinated group.[184]

The role of xenogeneic DNA vaccination in the adjuvant management of dogs with digit MM has also been investigated.[214] A staging scheme was developed based on tumor size, tumor depth, bone involvement, and presence of nodal and distant metastatic disease. A T1 digit melanoma was defined as less than 2 cm diameter and superficial or exophytic; a T2 tumor was defined as 2 to 5 cm in diameter with minimal invasion; a T3 digit melanoma was defined as greater than 5 cm or invading the subcutaneous tissue; and a T4 tumor was defined as invading into fascia or bone. Stage I was defined as nonmetastatic T1 digit melanoma; stage II as nonmetastatic T2 digit melanoma; stage III as nonmetastatic T3 or T4 digit melanoma and/or LN metastasis; and stage IV was defined as distant metastasis.[214] Treatment of dogs with digit melanoma with digit amputation and adjuvant Oncept resulted in significantly improved outcomes compared with historical outcomes with digit amputation only.[214] Dogs presenting with metastatic disease had a significantly worse MST (105 days) than dogs without evidence of metastatic disease at presentation (533 days), with a 3-year survival rate of 48% in the latter group. The clinical staging scheme was also prognostic, with MSTs of greater than 952 days, greater than 1093 days, 321 days, and 76 days for dogs with stage I, II, III, and IV disease, respectively.[214]

Mast Cell Tumors

CHERYL A. LONDON AND DOUGLAS H. THAMM

The neoplastic proliferation of mast cells (MCs) referred to as mast cell tumor (MCT; mastocytoma, MC sarcoma) represents the most commonly encountered cutaneous tumor in the dog and the second most common cutaneous tumor in the cat.[1–5] Systemic forms of the disease are often referred to as *mastocytosis.* Canine and feline forms of the disease are considered separately in this chapter, as many differences exist with regard to histologic type, biologic behavior, therapy, and prognosis.

Canine Mast Cell Tumors

Biology of Canine Mast Cells

MC precursors leave the bone marrow and migrate to various tissues throughout the body where they undergo differentiation into mature MCs with their characteristic cytoplasmic granules, which stain metochromatically with Geimsa and toluidine blue.[6] These granules contain a number of bioactive substances including heparin, histamine, preformed tumor necrosis factor-alpha (TNF-α), and several proteases.[6] The nature and composition of MC granules is highly influenced by the microenvironment in which the MC mature. For example, in dogs, MCs in the gastrointestinal (GI) tract express primarily chymase whereas MCs in the skin express both chymase and tryptase.[7] On stimulation, MCs can rapidly produce a variety of proteases (chymase, tryptase), cytokines (TNF-α, interleukin-6 [IL-6]), chemokines (CCL2, CXCL1), growth factors (vascular endothelial growth factor [VEGF], basic fibroblast factor [bFGF]), and lipid mediators (prostaglandin D_2 [PGD_2], leukotriene C_4 [LTC_4]).[6] Through this process, MCs participate in several biologic activities, including wound healing, induction of innate immune responses, antiparasite activity, and modulation of reaction to insect and spider venoms.[6,8]

Normal canine MCs can be generated from bone marrow derived hematopoietic precursors.[9,10] These cells, known as canine bone marrow derived MCs (cBMMCs), have been used to characterize the functional properties of MCs in this species. As with normal human MCs, their differentiation requires the presence of the growth factor stem cell factor (SCF), and can be influenced by the presence of other cytokines.[9,10] On stimulation, these cells rapidly release histamine, monocyte chemoattractant protein-1 (MCP-1), TNF-α, and tryptase, and they produce several additional cytokines and chemokines including IL-3, IL-13, granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage inflammatory protein-1 alpha (MIP-1α).[9,10] Interestingly, the cBMMCs are extremely sensitive to chemical degranulation, which may help explain why dogs exhibit such a high degree of hypersensitivity to several chemical agents including polysorbate 80, cremaphor EL, and doxorubicin.[9] The function of cBMMCs can be modulated by cytokines, steroids, and nonsteroidal antiinflammatory drugs.[9–11]

Incidence and Risk Factors

MCT is the most common cutaneous tumor in the dog, accounting for between 16% and 21% of all cutaneous tumors.[1,3,5,12] Although MCTs are primarily a disease of older dogs (mean age approximately 8–9 years), they have also been reported in younger dogs and there is no apparent sex predilection.[1,3,5] Most occur in mixed breeds; however, several breeds are at increased risk for MCTs, including dogs of bulldog descent (boxer, Boston terrier, English bulldog, pug), Labrador and golden retrievers, cocker spaniels, schnauzers, Staffordshire terriers, beagles, Rhodesian ridgebacks, Weimaraners, and Chinese shar-pei.[1,5,13–15] The increased incidence of MCTs in certain breeds suggests the possibility of an underlying genetic cause.[14] A recent genome-wide association study in golden retrievers identified polymorphisms in the *GNAI2* gene and multiple genes associated with hyaluronic acid synthesis as risk factors for MCT development.[16] Interestingly, although dogs of bulldog ancestry are at higher risk for MCT development, it is generally accepted that MCTs in these dogs are likely to be less aggressive.[1,17] In contrast, anecdotal evidence suggests that Chinese shar-pei develop MCTs that may be more biologically aggressive (A. Avery, personal communication). Spontaneously regressing MCTs in young animals have been described in cats, pigs, horses, and humans. Multiple cutaneous MCT that all regressed within 27 weeks was reported in a 3-week-old Jack Russell terrier.[18] This syndrome of spontaneous regression in young animals may indicate a hyperplastic or dysplastic syndrome rather than a true neoplastic lesion.

The etiology of MCTs in dogs is for the most part unknown. Historically, MCTs have been associated with chronic inflammation or the application of skin irritants; however, the epidemiology of disease in dogs does not support the role of a topical carcinogen.[19–21] Unequivocal evidence is lacking for a viral etiology, although MCTs have been transplanted to very young or immunocompromised laboratory dogs using tumor cell tissues and rarely by cell-free extracts.[22–24] No C-type or other identifiable virus particles have been observed, and no epidemiologic evidence exists to

VetBooks.ir

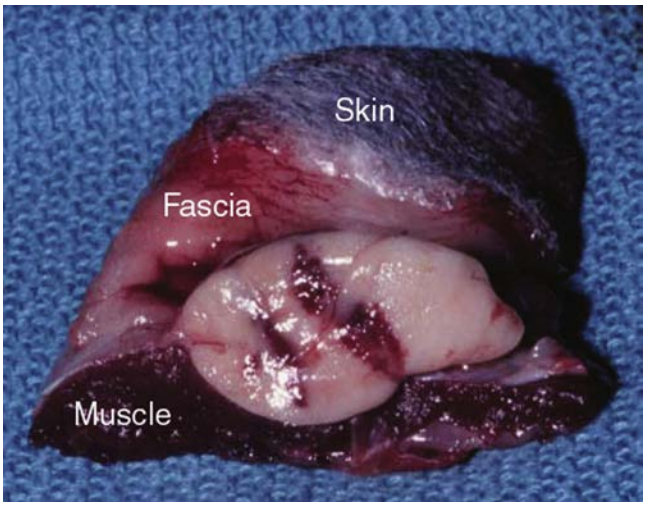
suggest horizontal transmission. Chromosomal fragile site expression, a phenomenon thought to genetically predispose humans to develop certain tumors, was shown to be increased in boxer dogs with MCT[25]; however, the control population for this study was young, non–tumor-bearing boxers, and the increased expression of chromosomal fragile sites may be due to this age difference.

The genetic changes that predispose to canine MCTs are incompletely understood. Alterations in the p53 tumor suppressor pathway have been identified in some canine MCTs,[26–28] but p53 sequencing in a limited number of cases has revealed no mutations.[29] Perturbations in expression of the proteins p21 and p27, cyclin-dependent kinase inhibitors that contribute to regulation of the cell cycle, have been identified in many canine MCTs.[30] Cytosolic receptors for estrogen and progesterone have also been detected in canine MCTs,[31] but their role in the etiopathogenesis of MCTs is poorly understood. One European study reported that female dogs with MCTs had a more favorable prognosis with chemotherapy.[32] Although the majority of studies performed in North America have failed to detect such an association, the relatively higher frequency of intact females present in the European population may have allowed the effect of sex hormones to have a greater statistical effect on biologic behavior. Expression of the angiogenic growth factor VEGF and its receptor VEGFR2 has been demonstrated in many canine MCTs, and preliminary evidence suggests that VEGFR2 activation may be associated with inferior postsurgical outcomes.[33,34]

Perhaps the best-described molecular abnormality in canine MCTs involves the receptor tyrosine kinase (RTK) KIT. KIT is expressed normally on a variety of cells including hematopoietic stem cells, melanocytes, and MCs, among others.[35–37] The ligand for KIT, SCF, induces KIT dimerization, subsequent phosphorylation, and generation of intracellular signaling that promotes the proliferation, differentiation, and maturation of normal MCs.[35–37] SCF is essential for the differentiation of mature MC from CD34+ hematopoietic stem cells in vitro, and inhibition of KIT signaling induces apoptosis of cBMMCs.[10,36,37] KIT expression has been demonstrated on canine MCTs, and aberrant cytoplasmic localization and/or increased phosphorylation of KIT in MCTs may be associated with dysregulated KIT function.[38–42] A significant minority of canine MCTs possess somatic mutations in the c-*kit* gene involving either the juxtamembrane domain (exons 11–12) or extracellular domain (exons 8–9).[43–47] These mutations result in SCF-independent activation of KIT and subsequent unregulated KIT signal transduction.[45,46] In dogs, the c-*kit* mutations appear to be associated with 25% to 30% of intermediate- and high-grade MCTs, and evidence suggests that they are linked to increased risk of local recurrence, metastasis, and a worse prognosis.[43,46,48–50]

More recently, studies have been undertaken to better characterize copy number variation (CNV), gene expression profile, and proteomic profile of canine MCTs to identify those pathways that contribute to aggressive biologic behavior. In one study of CNVs found in MCTs from dogs that survived <6 and >12 months, regions of loss in phosphatase and tensin homolog (PTEN), FAS*, and regions of gains in MAPK3, WNT5B, FGF, FOXM1, and RAD51 were detected in those tumors with shorter survival times (STs).[51] In another study, CNVs were found to increase as tumor grade increased, and tumors with c-*kit* mutations showed genome-wide aberrant CNVs often involving genes in the p53 and rB pathways, whereas CNVs were very limited in tumors with wild-type c-*kit*.[52] Gene expression profiling comparing MCTs from dogs cured with surgery versus those that died of disease revealed differential expression of genes associated with drug metabolism and cell cycle pathways including members of solute carrier transporter and UDP glucuronosyltransferase gene families.[53] In contrast, another study found that expression of 13 specific transcripts divided samples into two categories (differentiated and undifferentiated), harboring a different prognosis. Among these, a significant association was found between expression of FOXM1, GSN, FEN1, and KPNA2 and MCT-related mortality.[54] Using proteomic profiling, four stress response proteins (HSPA9, PDIA3, TCP1A, and TCP1E) were found to be significantly upregulated in high-grade tumors, whereas proteins mainly associated with cell motility and metastasis had either increased (WDR1, ACTR3, ANXA6) or decreased (ANXA2, ACTB) expression levels.[55] Lastly, overexpression of micro-RNA-9 was associated with MCT metastasis, potentially through the induction of an invasive phenotype.[56] It is likely that future work to more definitely characterize the canine MCT genome will help clarify how the abnormalities described earlier influence tumor biologic behavior.

History and Clinical Signs



The vast majority of MCTs in dogs occur in the dermis and subcutaneous tissue,[5,57] and most are solitary in nature, although 11% to 14% of dogs present with multiple lesions.[58,59] Approximately 50% of cutaneous MCTs occur on the trunk and perineal region, 40% on the limbs, and 10% on the head and neck.[20,60] MCTs have also been reported to occur in other sites including the conjunctiva, salivary gland, nasopharynx, larynx, oral cavity, ureter, and spine.[61–65] A visceral form of MCT, often referred to as disseminated or systemic mastocytosis, has also been documented, although it is usually preceded by an aggressive primary lesion.[66–70] Infiltration of abdominal lymph nodes (LNs), spleen, liver, and bone marrow is commonly observed in dogs with visceral disease, and pleural/peritoneal effusions containing neoplastic MCs have been documented. A case series of dogs with primary GI MCT was reported in which most dogs presented for vomiting, diarrhea, and melena. Only 40% dogs were alive at 30 days after first admission and fewer than 10% were alive at 6 months.[28]

It is important to note that cutaneous MCTs have an extremely varied range of clinical appearances and they are sometimes inadvertently mistaken for nonneoplastic lesions. Well-differentiated MCTs tend to be solitary, small, slow-growing tumors that may have been present for several months. They are not typically ulcerated, but overlying hair may be lost. Undifferentiated MCT tend to be rapidly growing, ulcerated lesions that cause considerable irritation and attain a large size. Surrounding tissues may become inflamed and edematous. Small satellite nodules may develop in surrounding tissues. Tumors of intermediate differentiation fill the spectrum between these two extremes. A subcutaneous form of MCT that is soft and fleshy on palpation is often misdiagnosed clinically as a lipoma (Fig. 21.1).

The history and clinical signs of dogs with MCTs may be complicated by signs attributable to release of histamine, heparin, and other vasoactive amines from MC granules. Occasionally, mechanical manipulation during examination of the tumor results in degranulation and subsequent erythema and wheal formation in surrounding tissues. This phenomenon has been referred to as

*Fas or FasR, also known as apoptosis antigen 1 (APO-1 or APT), cluster of differentiation 95 (CD95) or tumor necrosis factor receptor superfamily member 6 (TNFRSF6) is a protein that is encoded by the *FAS* gene. Fas was first identified using a monoclonal antibody generated by immunizing mice with the FS-7 cell line. Thus, the name Fas is derived from FS-7-associated surface antigen.

• **Fig. 21.1** Subcutaneous mast cell tumor from the shoulder of a dog. This mass was originally misdiagnosed as a lipoma based on palpation alone. Wide surgical excision to include the deep muscle layer was necessary to achieve complete surgical margins.

• **Fig. 21.2** Erythema and wheal formation occurred in surrounding skin after manipulation of this cutaneous mast cell tumor. This phenomenon resulting from release of vasoactive amines from mast cell granules is known as Darier's sign. (Courtesy D. Vail, University of Wisconsin–Madison.)

"Darier's sign" (Fig. 21.2).[71] This can also occur spontaneously, and dog owners may describe the tumor as periodically increasing and decreasing in size. GI ulceration has been documented in 35% to 83% of dogs with MCTs that underwent necropsy.[72,73] The incidence of GI ulceration may be overrepresented owing to the fact that more aggressive forms of the disease likely end up in necropsy surveys. Histamine released from MCT granules is thought to act on parietal cells via H_2 receptors, resulting in increased hydrochloric acid secretion. Plasma histamine concentrations have been shown to be high in dogs with measurable high-grade MCTs, and there is preliminary information that monitoring of plasma histamine concentrations may be useful in assessing disease progression.[74] These dogs also have decreased concentrations of plasma gastrin, which is normally released by antral G cells in response to increased gastric hydrochloric acid concentrations, acting as a negative feedback loop. Dogs with substantial MCT burden (i.e., large tumors, metastatic disease, systemic disease) are much more likely to present with clinical signs related to the release of MC mediators. These may include vomiting, diarrhea, fever, peripheral edema, and rarely collapse.

Perioperative degranulation of MCTs and subsequent release of histamine and other less characterized vasoactive substances may also result in potentially life-threatening hypotensive events during surgery. It is thought that prostaglandins in the D series secreted by tumor cells may mediate the hypotensive effects observed in humans with MC diseases.[75,76] Coagulation abnormalities, also reported in dogs with MCTs, are likely due to heparin release from MC granules.[68,77] Although clinical evidence of systemic hemorrhage is not typically associated with this phenomenon, localized excessive bleeding at the time of biopsy or surgery due to degranulation after tumor manipulation can be a complication, even in the presence of normal presurgical coagulation parameters.

Prognostic Factors

A discussion of prognostic factors associated with canine MCTs will precede sections on diagnosis and treatment, as steps followed in those sections are predicated on the presence or absence of these prognostic factors. Table 21.1 lists factors known to be predictive of biologic behavior and clinical outcome in dogs with MCTs. It is important to note that no one factor is entirely predictive of biologic behavior and, as such, all prognostic indicators should be taken into consideration when evaluating a patient.

Histologic grade is considered the most consistent and reliable prognostic factor available for dogs with MCTs, although it will not predict the behavior of every tumor.[13,57,78,79] Several investigators have applied histologic grading systems to canine MCTs based on degree of differentiation (Table 21.2). The number grades used in these studies are at odds. Therefore for the sake of clarity, the three differentiation groups should be simply referred to as undifferentiated (high) grade, intermediate grade, and well-differentiated (low) grade. Table 21.3 lists the relative distribution of MCT grades encountered in larger series. STs after surgical excision based on histologic grade are presented in Table 21.4. The vast majority of dogs with well-differentiated MCTs (80%–90%) and approximately 75% of dogs with intermediate-grade MCTs experience long-term survival after complete surgical excision.[58,78,80–83] Metastatic rates for undifferentiated MCT range from 55% to 96%, and most dogs with these tumors die of their disease within 1 year.[57,84] The majority disseminate first to local LNs, then to spleen and liver. Other visceral organs may be involved; however, lung involvement is rare. Neoplastic MCs may be observed in the bone marrow and peripheral blood in cases of widespread systemic dissemination.[68]

The current histopathologic grading system does not detect a small percentage of those well- or intermediately differentiated MCTs that result in death of affected dogs, and this is complicated by the fact that there is disagreement in tumor grading schemes among pathologists. In one study, there was significant variation among pathologists in grading a specific set of MCTs, although this was found to be less so if all pathologists strictly employed the system described by Patnaik.[13,85,86] Recently, an attempt was

TABLE 21.1 Prognostic Factors for Mast Cell Tumors in Dogs

Factor	Comment
Histologic grade	Strongly predictive of outcome. Dogs with undifferentiated tumors typically die of their disease after local therapy alone, whereas those with well-differentiated tumors are usually cured with appropriate local therapy.
Clinical stage	Stages 0 and 1, confined to the skin without local lymph node or distant metastasis, have a better prognosis than higher-stage disease.
Location	Subungual, oral, and other mucous membrane sites are associated with more high-grade tumors and worse prognosis. Preputial and scrotal tumors are also associated with a worse prognosis. Subcutaneous tumors have a better prognosis. Visceral or bone marrow disease usually carries a grave prognosis.
Cell proliferation rate	Mitotic index, relative frequency of AgNORs, and percent PCNA or Ki-67 immunopositivity are predictive of postsurgical outcome.
Growth rate	MCTs that remain localized and are present for prolonged periods of time (months or years) without significant change are usually benign.
Microvessel density	Increased microvessel density is associated with higher grade, a higher degree of invasiveness, and a worse prognosis.
Recurrence	Local recurrence after surgical excision may carry a more guarded prognosis.
Systemic signs	The presence of systemic illness (e.g., hyporexia, vomiting, melena, GI ulceration) may be associated with a higher stage of disease.
Age	Older dogs may have shorter median disease-free intervals when treated with radiation therapy than younger dogs.
Breed	MCTs in boxers (and potentially other brachycephalic breeds) tend to be of low or intermediate grade and are thus associated with a better prognosis.
Sex	Male dogs had a shorter survival time than female dogs when treated with chemotherapy.
Tumor size	Large tumors may be associated with a worse prognosis after surgical removal and/or radiation therapy.
c-*kit* mutation	The presence of an activating mutation in the c-*kit* gene is associated with a worse prognosis.
DNA copy number variation	Higher CNVs are observed in tumors of higher grade and those with a worse prognosis.

AgNORs, Argyrophilic nucleolar organizer regions; *CNV*, copy number variation; *GI*, gastrointestinal; *MCTs*, mast cell tumors; *PCNA*, proliferating cell nuclear antigen.

TABLE 21.2 Histologic Classification of Mast Cell Tumors in Dogs

Grade	Bostock Grading	Patnaik Grading	Microscopic Description
Anaplastic, undifferentiated (high grade)	1	3	Highly cellular, undifferentiated cytoplasmic boundaries, irregular size and shape of nuclei; frequent mitoses, sparse cytoplasmic granules
Intermediate grade	2	2	Cells closely packed with indistinct cytoplasmic boundaries; nucleus-to-cytoplasmic ratio lower than anaplastic; infrequent mitoses; more granules than anaplastic
Well differentiated (low grade)	3	1	Clearly defined cytoplasmic boundaries with regular, spherical or ovoid nuclei, mitoses rare or absent; cytoplasmic granules large, deep staining, and abundant

made to develop a new grading system that would separate tumors into "high" or "low" grade based on one of four features identified on histopathologic evaluation, in an attempt to minimize interpathologist disagreement and still provide useful prognostic information.[87] In this setting, tumors were classified as high grade if they possessed (1) at least 7 mitotic figures/10 HPF, (2) at least 3 multinucleated cells/10 HPF, (3) at least 3 bizarre nuclei/10 HPF, or (4) karyomegaly. In a series of 95 dogs evaluated by both the Patnaik and this alternative system, the alternative system was somewhat better at predicting which dogs would be more likely to die of disease[87]; at least one follow-up study has confirmed the utility of this two-tiered system.[88] There remains incomplete information to confirm whether two-tiered system is truly better than the Patnaik three-tiered system for predicting the biologic behavior of MCTs. The authors prefer to receive grades according to both schemes on MCT histopathology reports.

Several markers of proliferation have been evaluated to assist in determining whether an MCT is likely to behave in a more aggressive manner.[49,79,89–97] Ki-67 is a protein found in the nucleus, the levels of which appear to correlate with cell proliferation and patient survival.[90,91] Silver colloid staining of paraffin-embedded sections can be used to determine the relative presence

of argyrophilic nucleolar organizer regions (AgNOR), another surrogate marker of proliferation. These have been correlated with histologic grade and postsurgical outcome.[79,98] Finally, proliferating cell nuclear antigen (PCNA), another indicator of cell proliferation, has been used to determine the biologic behavior of MCTs, although this is probably not as reliable as the other markers.[79,98,99] The previously discussed markers of proliferation all require the use of special stains. In contrast, mitotic index (MI, number of mitoses per 10 HPF) in hematoxylin and eosin–stained sections has been used to assess the biologic behavior of canine MCTs. In one study, those dogs with tumors possessing an MI <5 had a median ST (MST) of 80 months compared with 3 months for those possessing a MI >5, suggesting that MI is a strong predictor of overall survival for dogs with MCTs.[100] Additional studies have also found a role for MI in MCT prognosis.[87,97,101–103]

Other cellular assessments have been employed to evaluate the biologic behavior of MCTs. A study of DNA ploidy determined by flow cytometric analysis suggested a trend toward shorter survival and higher clinical stage of disease in aneuploid tumors compared with diploid tumors.[104] Complementary to this, increases in DNA CNV also appear to be associated with higher grade and shorter postsurgical ST.[51,52] Studies have found a correlation between intratumor microvessel density and invasiveness, MI, and prognosis,[89,105] and a correlation between nuclear characteristics (assessed by computerized morphometry) and outcome and grade.[106,107]

The potential role of KIT dysregulation in MCT prognosis was investigated by assessing KIT immunohistochemical staining patterns on histopathologic specimens.[108] Three distinct patterns were identified: membrane, focal/stippled, and diffuse cytoplasmic staining. Although there was some evidence that dogs with diffuse cytoplasmic KIT staining patterns did not live as long as those with other patterns, no group reached an MST and most dogs in each of the KIT staining groups evaluated experienced extremely long postoperative STs.[108] The presence of c-*kit* activating mutations has been associated with a higher rate of local recurrence, metastasis, and death from disease, suggesting that KIT dysregulation confers a more aggressive phenotype to MCT.[43,48,49] Finally, investigators have attempted to correlate histologic grading of MCT with a combined Ki67/PCNA/AgNOR/KIT immunohistochemical scoring.[109] No significant correlation was found for KIT staining and MCT grade, but high Ki67/PCNA/AgNOR scores all positively correlated with tumor grade (i.e., higher scores for higher grade). This suggests that proliferation indices increase with increasing grade and are ultimately reflected in the eventual biologic behavior of the tumor.

Tumor location has been investigated as a potential prognostic indicator.[58,110–114] Tumors in the preputial/inguinal area, subungual (nail bed) region (Fig. 21.3), and other mucocutaneous sites, including the oral cavity and perineum, historically have been associated with aggressive behavior. Two reports did not show a poorer prognosis for tumors occurring in the inguinal

TABLE 21.5 World Health Organization Clinical Staging System for Mast Cell Tumors

Stage	Description
0	One tumor incompletely excised from the dermis, identified histologically, without regional lymph node involvement a. Without systemic signs b. With systemic signs

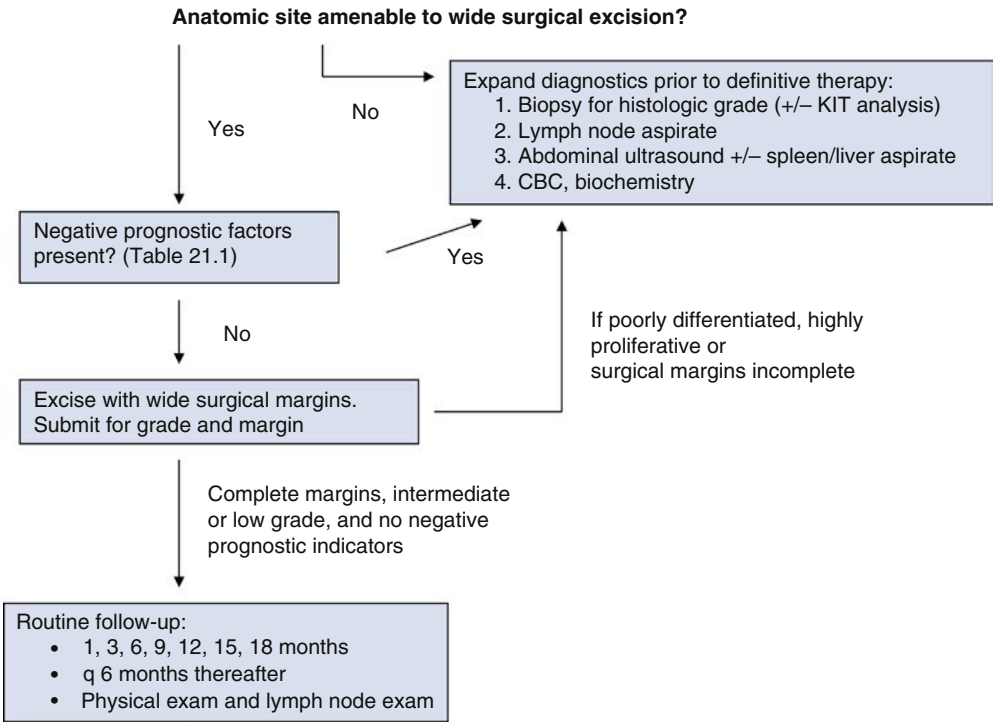
II	One tumor confined to the dermis, with regional lymph node involvement a. Without systemic signs b. With systemic signs
III	Multiple dermal tumors; large, infiltrating tumors with or without regional lymph node involvement a. Without systemic signs b. With systemic signs
IV	Any tumor with distant metastasis, including blood or bone marrow involvement

and perineal region; however, when preputial and scrotal regions were specifically evaluated, they were indeed associated with worse outcomes.[111,112] Approximately 50% to 60% of dogs with MCTs located in the muzzle present with regional LN metastasis.[113,115] Interestingly, this does not necessarily indicate a worse long-term prognosis, as the MST for dogs with metastatic disease was 14 months.[113] MCTs that originate in the viscera (GI tract, liver, spleen) or bone marrow carry a grave prognosis.[67,68] Recent data indicate that MCTs arising in the subcutaneous tissues have a favorable prognosis with extended STs and low rates of recurrence and metastasis. In one study of 306 dogs with subcutaneous MCTs, metastasis occurred in 4% of dogs and 8% experienced local recurrence.[103] The estimated 2- and 5-year survival probabilities were 92% and 86%, respectively. Decreased survival was linked to MI >4, infiltrative growth pattern, and presence of multinucleation.[103] Lastly, conjunctival MCTs were found to have a good prognosis, with 15 of 32 dogs disease-free at a mean of 21.4 months postsurgery; no dogs in this study died of MCT-related disease.[116]

Clinical stage, represented in Table 21.5, is also predictive of outcome.[32,57,104,110,117,118] There is controversy regarding the effect of multiple MCTs on prognosis and, as such, this part of the staging scheme may not accurately correlate with outcome. Several studies indicate that there is no difference in outcome between patients with a single cutaneous MCTs and those with multiple MCTs,[58,114,119,120] whereas others have suggested an inferior outcome in dogs with multiple tumors.[102,121] It is uncertain whether this phenomenon represents an atypical form of metastasis or multiple, unrelated tumors arising independently, although one study demonstrated a clonal origin for two distant cutaneous tumors arising over years.[122] The effect of LN metastasis on prognosis is also somewhat controversial. In two studies, the presence of MCs in the regional LNs was a negative prognostic factor for disease-free interval (DFI) and survival[120,123]; however, an additional study revealed that dogs with intermediately differentiated MCTs and LN metastasis treated with postoperative radiation therapy (RT) achieved long-term survival.[124] Other studies have shown that dogs with intermediately differentiated MCTs with LN metastasis may have a good prognosis if the affected LN is removed and adjuvant chemotherapy and/or RT is administered.[114,120,125] For poorly differentiated tumors, the presence of LN metastatic disease resulted in an MST of 194 days compared with 503 days for dogs with no metastasis.[84] For these dogs, treatment of the LN improved MST (240 days) compared with those dogs whose LNs were not treated (42 days).[84] As with all cases, clinical judgment regarding LN metastasis is probably important.

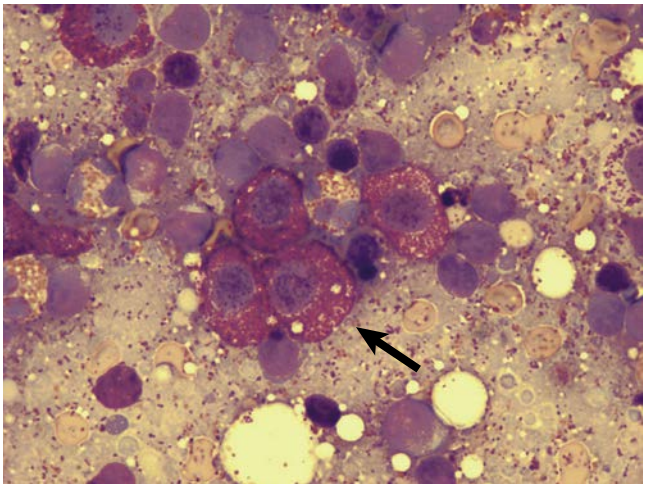


Several miscellaneous factors have been linked to prognosis in dogs with MCTs. Certain breeds of dogs such as boxers, pugs, and dogs of bulldog descent appear to develop MCTs that often behave in a more benign fashion.[1,17,57,126] Recent rapid growth has been associated with a worse outcome. For example, in one study, 83% of dogs with tumors present for longer than 28 weeks before surgery survived for at least 30 weeks compared with only 25% of dogs with tumors present for less than 28 weeks.[57] Systemic signs of hyporexia, vomiting, melena, widespread erythema, and edema associated with vasoactive substances from MC degranulation are more commonly associated with visceral forms of MCT and, as such, carry a more guarded prognosis.[58,68,127] In recent retrospective studies of visceral or disseminated MCT, STs were short and nearly all dogs with follow-up died of their disease.[69,70,128] Local tumor ulceration, erythema, or pruritus has been associated with a worse prognosis in some studies.[58,120] Lastly, recurrence of MCTs after surgical excision has also been associated with a more guarded prognosis.[92,118,120,129] Thus appropriate aggressive therapy at the time of first presentation, rather than at the time of recurrence, may improve the long-term prognosis in patients with MCTs.

Diagnostic Technique and Workup

MCTs are initially diagnosed on the basis of fine-needle aspiration (FNA) cytology. Rowmanovsky's or rapid hematologic-type stains used in most practices will suffice. MCs appear as small- to medium-sized round cells with abundant, small, uniform cytoplasmic granules that stain purplish red (metachromatic) (see Figs. 7.2 and 7.5 of Chapter 7).[1,130] A small percentage of MCTs have granules that do not stain readily, giving them an epithelial or macrophage-like appearance that has often been referred to as giving a "fried-egg" impression (Fig. 7.2, Chapter 7). In these cases, a Wright–Giemsa or toluidine blue stain will often reveal granules; however, histologic assessment may ultimately be necessary. Highly anaplastic, agranular MCTs can sometimes be challenging to definitively diagnose by routine light microscopy. Immunohistochemical techniques have been applied in an attempt to differentiate these from other anaplastic round cell tumors. MCTs are vimentin positive and the majority are tryptase and CD117 (KIT) positive.[38,131–133] Other markers that could potentially be useful include chymase, MCP-1, and IL-8.[9,10]

Historically, preoperative diagnostic tests have included a minimum database (complete blood count [CBC], serum biochemistry profile), a buffy coat smear to document peripheral mastocytosis, cytologic assessment of regional LNs, abdominal ultrasound (US) with cytologic assessment of spleen or liver if warranted, thoracic radiographs, and a bone marrow aspirate. It is now likely that an extensive workup is unnecessary for dogs with MCTs that do not exhibit the previously discussed negative prognostic factors. Fig. 21.4 illustrates the diagnostic steps and the order in which they are pursued in the authors' practice.



VetBooks.ir

• **Fig. 21.4** Suggested diagnostic steps for canine cutaneous mast cell tumors.

If the MCT is in a location amenable to wide surgical excision and no negative prognostic indicators are present (see Table 21.1), no further tests other than minimum database and FNA of the regional LN (if possible) are performed before wide surgical excision. If there is ambiguity regarding the location of the regional LNs, sentinel LN mapping may be performed to facilitate identification (see Chapter 9 for more information). Although cytologic methods for assigning a grade have been recently described,[134–136] histologic assessment after excision remains critical to provide guidance regarding necessary further diagnostics and therapeutics.

If the tumor presents at a site that is not amenable to wide surgical excision or primary closure (e.g., distal extremity) or if negative prognostic factors exist in the history or physical examination, ancillary diagnostics to further stage the disease are recommended before definitive therapy. An incisional/needle biopsy may be performed at this point for determination of histologic grade. The minimum staging that is advisable in those cases requiring presurgical staging consists of a minimum database, FNA cytology of the regional LN (even if normal in size), and abdominal US. With respect to cytologic evaluation of LNs, definitive criteria for metastatic disease can be challenging if MCs are present in low numbers; this is because MCs are normally found in LNs and their numbers can be increased in the presence of infection and ulceration, which are sometimes observed in MCTs. For example, in 56 healthy beagle dogs, approximately 24% of LN aspirates contained MCs (range of 1–16 MCs/slide, mean of 6.4/slide).[137] Therefore an occasional solitary MC is not indicative of metastasis; rather, clustering and aggregates are more worrisome (Fig. 21.5).[117] Surgical removal of a cytologically suspicious LN for histologic assessment may be necessary to accurately determine whether MCs present in the LN truly represent metastatic disease. A histologic grading scheme has been described for "degree of LN metastasis" to account for the varying levels of LN involvement that can be observed histologically (from scattered, isolated MCs to complete effacement with tumor cells).[138] Dogs with high histologic node (HN) scores had shorter STs than dogs with low HN scores.[138] Abdominal US is now considered an important diagnostic test for the evaluation of dogs with potentially aggressive MCT. Although FNA cytology of structurally normal livers or spleens is generally unrewarding,[139,140] the presence of negative prognostic indicators (metastatic LN, clinical signs, etc.) is sufficient justification to perform cytologic evaluation of these organs even if they appear ultrasonographically normal.[141]

• **Fig. 21.5** Regional lymph node aspirate from a dog with a cutaneous mast cell tumor. Note clustering of mast cells in a background of lymphocytes more indicative of true metastasis.

Thoracic radiographs rarely demonstrate metastasis; however, it is reasonable to procure them before an expensive or invasive procedure to rule out occult cardiopulmonary disease that could complicate anesthesia or unrelated disease processes (primary lung tumor, etc.). Occasionally, thoracic lymphadenomegaly may be

observed as a result of MCT metastasis. Knowledge of the extent of MCT margins before surgery, usually accomplished by digital palpation, can be enhanced with the use of diagnostic US or computed tomography (CT). In dogs with cutaneous MCT or soft tissue sarcomas the extent of local tumor margins was upgraded in 19% and 65% of cases when imaged by US and CT, respectively.[142] Such information allows more appropriate planning of definitive surgery or RT. The cost-effectiveness of such a study depends on the location of the tumor and whether wide excision is technically simple or difficult.

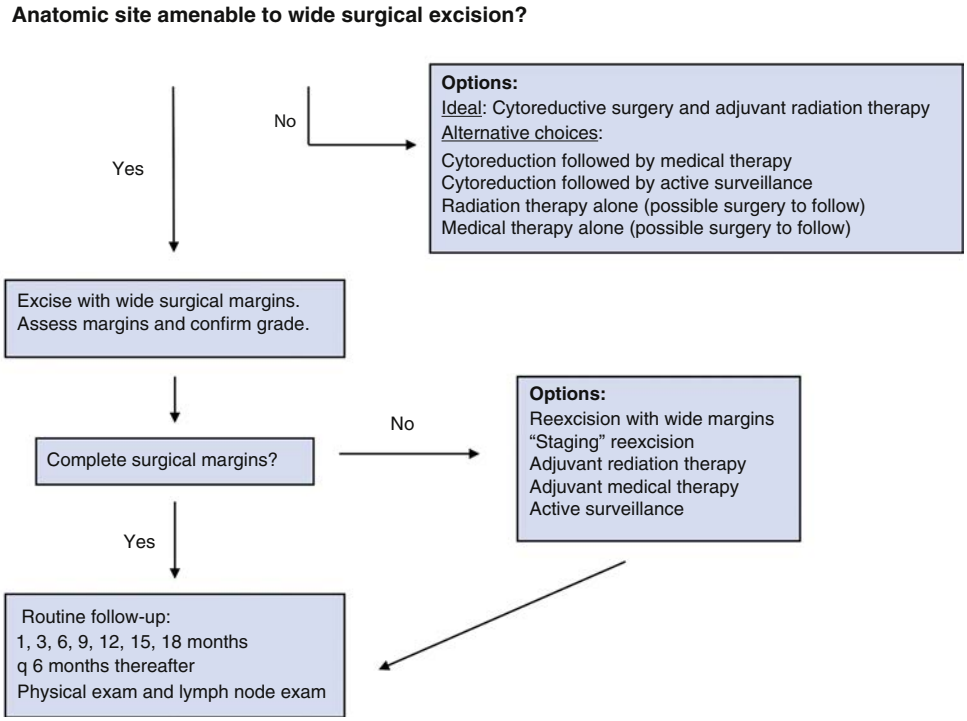
With respect to evaluation of buffy coat smears for evidence of systemic MC disease, peripheral mastocytosis (1–90 MCs/μL) is reported in dogs with acute inflammatory disease (in particular parvoviral infections), inflammatory skin disease, regenerative anemias, neoplasia other than MCT, and trauma.[143–145] One study revealed that peripheral mastocytosis is actually more likely to occur and may be more dramatic in dogs with diseases other than MCT.[144] Therefore this test is no longer routinely performed in the staging of MCT patients. In a report evaluating 157 dogs with MCT, the incidence of bone marrow infiltration at initial staging was only 2.8%.[146] Although the presence of bone marrow involvement is indicative of systemic MC disease, it is usually easier to find evidence of systemic involvement in other organs (liver, spleen).[68] This is in contrast to dogs that present with visceral MCT, in which 37% of buffy coat smears are positive for MC and 56% of bone marrow aspirates reveal MC dissemination[128]; however, these constitute a small minority of all MCT cases. Therefore with the exception of the extremely rare case of primary mastocytic leukemia,[147,148] involvement of bone marrow or peripheral blood in the absence of disease in regional LN or abdominal organs is unlikely and the routine performance of bone marrow aspirates for clinical staging has fallen out of favor.[146]

Treatment

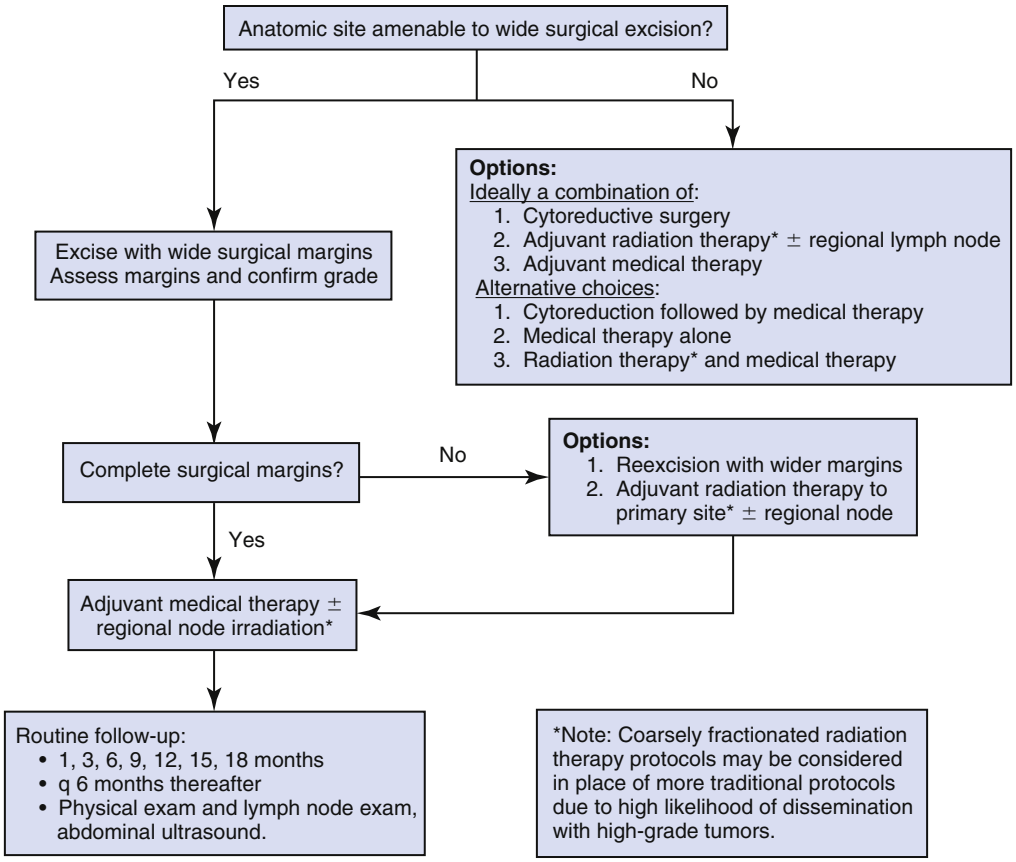
Treatment decisions are predicated on the presence or absence of negative prognostic factors and on the clinical stage of disease. In tumors localized to the skin in areas amenable to wide excision, surgery is the treatment of choice. Historically, surgical excision to include a 3-cm margin of surrounding normal tissue has been recommended. However, this recommendation was largely anecdotal. More recently, surgical margins have been evaluated for the excision of low- and intermediate-grade MCTs less than 5 cm diameter, and two different approaches have been described. The metric approach uses a prescribed metric distance, with lateral margins of 1 cm and 2 cm for low- and intermediate-grade MCTs, respectively.[149,150] The proportional approach uses lateral margins proportional to the maximum dimension of the MCT.[151] For both approaches, deep margins include removal of one uninvolved fascial plane in continuity with the tumor. If necessary, muscle layers may also be removed deep to the tumor. In 100 dogs with 115 resectable MCT (primarily low- and intermediate-grade), no local recurrence or metastasis was noted for greater than 2 years after excision with lateral histologic margins 10 mm or greater and deep histologic margins 4 mm or greater,[83] although the "quality" of the margin (e.g., fascia vs loose connective tissue vs fat) needs to be considered for deep margin evaluation. It should be noted that these microscopic, formalin-fixed margin parameters may not accurately reflect margin size at surgery; tissue shrinkage (up to 30% for cutaneous tissues) can occur subsequent to formalin fixation.[152–154] Considering that the majority of naïve dermal MCTs encountered in practice are of low or intermediate grade, it can be said that most MCTs can be adequately treated with surgery alone provided the site is amenable to adequate surgical resection. All surgical margins should be evaluated histologically for completeness of excision. For tumors in which wide surgical excision is not possible because of size, geographic constraints, or owner concerns, a biopsy to determine histologic grade maybe helpful before definitive therapy to determine whether smaller lateral margins may be sufficient for complete histologic excision (i.e., 1 cm lateral margins for a low-grade MCTs).

The management of MCTs in locations where primary closure after wide excision is difficult to impossible, such as the distal extremities, can be challenging. Options include tailoring the surgical approach according to preoperative determination of histologic grade, wide excision followed by reconstruction of the subsequent defect, limb amputation, and primary closure of a marginally excised MCTs followed by either RT or chemotherapy. Histologic grade can be accurately diagnosed based on preoperative biopsies,[155] and histologic grade can be used to determine the lateral margins required for complete histologic excision of low- to intermediate-grade MCTs; 1-cm and 2-cm lateral margins are usually sufficient for grade I and grade II MCTs, respectively.[149] If primary closure is not possible regardless of the width of the lateral margins, then the two basic options include wide excision, with or without chemotherapy depending on histologic grading, or marginal excision followed by adjuvant therapy. Wide excision with 2-cm lateral margins,[149,150] or proportional lateral margins[151] is still feasible despite an inability to close the resultant defect primarily. Options for management of these defects include closure with random or axial pattern flaps or free-meshed skin grafts, or healing by second intention. In one study of 31 dogs managed with second-intention healing after excision of soft tissue sarcomas with 2-cm lateral margins, 93.5% of resulting wounds healed completely after a median time of 53 days.[156] Limb amputation is the most aggressive option; however, although wide margins are guaranteed, it results in the least functional outcome and is generally not recommended given the availability of other effective therapies.

Marginal excision of low- to intermediate-grade MCTs is also an acceptable approach if followed by treatment with RT. In this situation, the MCT must be able to be excised with no evidence of gross residual disease and the wound closed primarily. If this is possible, then adjuvant RT is associated with long-term tumor control. Two-year control rates of 85% to 95% can be expected for stage 0 tumors of low- or intermediate-grade MCTs.[110,123,157–159] If RT is either not available or declined, then two studies have demonstrated a low rate of recurrence in dogs with incompletely excised MCTs that receive some form of postoperative chemotherapy[160,161]; however, both studies were single-arm retrospective studies with low case numbers and hence these results should be regarded with caution. There is also information to suggest that some low- or intermediate-grade MCTs will not recur even if no adjuvant therapy is employed.[162] Although this approach is not considered optimal, it can be used in cases in which RT is unavailable or unaffordable. Regardless of the local therapy chosen, dogs with low- and intermediate-grade tumors should be reevaluated regularly (so-called *active surveillance*) for local recurrence and regional and distant metastasis. Local site and regional LN evaluation, complete physical examination, and FNA of any new cutaneous masses or enlarged LNs are performed at these intervals. More complete staging, including abdominal US, should be included if the dog has an MCT with negative prognostic factors.



• **Fig. 21.6** Reexcision of a mast cell tumor from the skin of a golden retriever. The first surgery resulted in incomplete surgical margins. Three-cm margins are taken around and deep to the previous incision and the entire sample is again submitted for margin analysis by the pathologist.



Some authors advocate prophylactic irradiation of cytologically negative regional LNs (prophylactic nodal irradiation [PNI]).[114,123,124,163] Owing to the generally low risk of postsurgical metastasis in low- to intermediate-grade tumors, PNI is probably unwarranted in this group of patients, and at least one study has demonstrated no advantage in terms of disease-free or overall survival when PNI is employed[159]; however, in MCTs at high risk for metastasis, PNI may provide improvement in outcome over local site irradiation only.[114,163]

For cases in which planned curative excisional surgery is unsuccessful and histologic margins are incomplete, further local therapy is generally warranted. If possible, a second excision of the surgical scar with additional wide margins should be performed (Fig. 21.6); however, some evidence suggests that marginal, "staging" reexcision of dirty surgical scars may be associated with an acceptable likelihood of achieving tumor-free margins.[78,162,164] Alternatively, adjuvant RT can be used in cases in which reexcision is not an option. Not all MCTs with surgically incomplete margins will recur; in some studies only 10% to 30% of MCTs with histologically confirmed incomplete margins did so.[92,162,165] One study suggests that measurement of proliferation indices (Ki67 and PCNA) via IHC may be useful in predicting likelihood of recurrence after incomplete resection of intermediate-grade MCTs.[92] Although recurrence rates vary by study, several studies have demonstrated increased local recurrence rates and/or decreased overall STs in dogs with incompletely resected MCTs.[28,78,80,120] Fig. 21.7 summarizes the treatment recommendations for clinical stage 0 and I, histologically low- or intermediate-grade MCTs.

Alternative local therapies for MCTs have been reported and include hyperthermia in combination with RT,[166] intralesional brachytherapy,[167] photodynamic therapy,[168,169] intralesional corticosteroids,[170,171] cryotherapy, and electrochemotherapy.[172–175] Although some have advocated the use of intralesional deionized water at the site of an incompletely excised MCT, clinical data indicate that this approach is not effective at preventing local

• **Fig. 21.7** Suggested treatment approach for clinical stage 0 and 1 canine mast cell tumors of low or intermediate grade.

• **Fig. 21.8** Suggested treatment approach for high-grade, biologically aggressive canine mast cell tumors.

recurrence and therefore should not be used.[176–181] It is important to note that none of these alternative local therapies are as thoroughly investigated, clinically effective, or practical as surgery, RT, or a combination of the two. Lastly, despite its common use, there are no published studies to suggest that adjuvant corticosteroid or antihistamine therapy is of benefit in cases of individual intermediate-grade MCTs that have been either excised completely or treated with postoperative RT.

The treatment of anaplastic or undifferentiated MCTs remains frustrating. This designation includes dogs with intermediate-grade tumors with regional or distant metastasis, high-grade tumors, MCTs with high proliferative activity as assessed by special stains, and mucous membrane or mucocutaneous junction MCTs. There is some evidence to suggest that intermediate-grade tumors with only regional LN involvement have a better prognosis than high-grade tumors.[113,114] In the authors' opinion, until convincing evidence exists, such tumors should still be treated as if they have a high potential for metastasis. Fig. 21.8 summarizes the treatment recommendations for high-grade MCTs. The long-term prognosis for such dogs is less favorable, as regional and distant metastasis is more likely.

Poorly differentiated and metastatic MCT will, in most instances, progress to kill the dog in the absence of effective post-surgical intervention. Systemic adjuvant therapy should be offered in such cases in an attempt to decrease the likelihood of systemic involvement, or at least potentially improve DFIs. Corticosteroids, such as prednisone, have been reported for many years in preclinical or anecdotal settings to be of some benefit.[182–186] Although corticosteroids can inhibit canine MCT proliferation and induce tumor cell apoptosis in vitro,[187] they may also contribute to apparent antitumor response by decreasing peritumoral edema and inflammation. The Veterinary Cooperative Oncology Group (VCOG) studied the efficacy of single-agent systemic prednisone therapy for intermediate- and high-grade canine MCTs.[186] Of 21 dogs receiving 1 mg/kg daily PO, only one complete response (CR) and four partial responses (PRs) were noted, and these were short lived, lasting only a few weeks in the majority of cases. More recent studies have reported 70% to 75% response rates; however, tumors were excised or irradiated after short-term prednisone treatment and thus duration of response was not evaluable.[185,188] One report found that response of MCTs to corticosteroids was dependent on expression of the glucocorticoid receptor; those dogs with tumors that expressed low levels of receptor had MCTs that were resistant to prednisolone therapy.[189] These data suggest that a subset of MCTs may indeed benefit from corticosteroid therapy if there is adequate expression of the glucocorticoid receptor.

Recently a number of studies have evaluated the response rates of measurable canine MCTs to various cytotoxic chemotherapy drugs and protocols (see Table 21.6).[32,120,125,190–196] Objective response rates as high as 64% have been reported, and accumulating evidence suggests that multiagent protocols may confer a higher response rate than single-agent therapy.[32,120,125,193,195,197] It is important to note that, in most instances, the response of bulky MCT to any chemotherapy protocol tends to be short lived, stressing the need for local control of disease before the institution of adjuvant therapy.

TABLE 21.6 Responses to Available Agents in Measurable Canine Mast Cell Tumors

[a]Excludes patient that experienced a CR; euthanized without evidence of disease after 440 days.

A few single-arm studies have attempted to evaluate the efficacy of chemotherapy for "high-risk" MCT in the postsurgical setting. One study evaluated the use of postoperative prednisone and vinblastine (VBL) for dogs with MCTs considered to be at high risk for metastasis (LN positive, mucous membrane origin, or high histologic grade). In this study, dogs with high-grade MCTs had an MST of 1374 days.[114] A second study reported 70% 1- and 2-year disease-free survival rates after prednisone–VBL in dogs with high-grade MCTs.[198] A combination of prednisone, lomustine, and VBL has been used for residual microscopic disease in dogs at high risk for dissemination. Dogs with microscopic disease had a median progression-free ST of 35 weeks and an overall ST of 48 weeks.[193] Combination therapy using cyclophosphamide, VBL, and prednisone also yielded promising results in the microscopic residual disease setting for dogs considered at high risk of recurrence or metastasis. The reported progression-free and overall STs were 865 days and >2092 days, respectively.[125] Most studies described earlier used a dose of 2 mg/m^2 of VBL. There is now information suggesting that dogs may tolerate higher doses[199–202]; however, it remains to be seen if dose-escalation of VBL will translate into improved efficacy.

As previously discussed, virtually all canine MC neoplasms express the KIT RTK, and a large minority of canine MCT (20%–40%) possess a mutation in the c-*kit* gene, which renders the KIT protein constitutively active.[43,46,50,203] Orally available molecules have been developed that inhibit signaling through KIT called small molecule tyrosine kinase inhibitors (TKIs). The two veterinary-approved TKIs in this class are toceranib (TOC; Palladia, Zoetis) and masitinib (MAS; Masivet, AB Science), and limited studies have also been performed with the human KIT inhibitor imatinib (Gleevec, Novartis).

After encouraging in vitro and early-phase clinical trials,[47,204,205] a multicenter, placebo-controlled, double-blind, randomized study of TOC was performed in dogs with recurrent or metastatic intermediate- or high-grade MCTs.[206] During the blinded phase of the study, the objective response rate in TOC-treated dogs (n = 86) was 37.2% (7 CRs and 25 PRs) versus 7.9% (5 PRs) in placebo-treated dogs. When all 145 dogs that received TOC were analyzed, including those in which placebo was switched to TOC, the objective response rate was 42.8% (21 CRs and 41 PRs) with an additional 16 dogs experiencing stable disease for an overall biologic activity of 60%.[206] The median duration of objective response and time to tumor progression were 12.0 and 18.1 weeks, respectively.[206] Interestingly, dogs whose MCT harbored activating mutations in the c-*kit* gene were roughly twice as likely to respond to TOC than those with wild-type c-*kit* (69% vs 37%), although more recent studies have failed to confirm a higher response rate to TOC in c-*kit* mutant MCT.[129,207] In fact, TOC-treated c-*kit* mutant MCTs had an inferior PFS time compared with ***c-kit*** wild-type MCT (hazard ratio = 2.34) in one study.[207] GI toxicity, in the form of hyporexia, weight loss, diarrhea, and occasionally vomiting or melena, were the most common adverse effects and were generally manageable with symptomatic therapy, drug holidays, and dosage reductions as necessary. Hypertension, generally manageable with standard hypertensive agents (e.g., enalapril, amlodipine), has also been

VetBooks.ir

reported after initiation of TOC therapy in dogs and blood pressure monitoring and intervention is advised.[208] Other adverse effects reported include mild to moderate leukopenia, proteinuria (with or without hypertension), and muscle pain.[206,208] Recent clinical experience with TOC suggests that equivalent antitumor activity and reduced adverse effects may be observed if dosages lower than the label dosage are employed. A dosage of 2.5 to 2.75 mg/kg every other day or 3 days per week (Monday, Wednesday, Friday) is currently used by many oncologists.[209]

A clinical trial of similar design was completed with MAS in dogs with recurrent or unresectable MCT.[210] This study demonstrated significantly improved time to progression in MAS-treated dogs versus placebo-treated dogs, and, again, outcome was improved in dogs with MCT harboring activating c-*kit* mutations. Subsequent follow-up of patients treated with long-term MAS identified an increased number of patients with long-term disease control compared with those treated with placebo (40% vs 15% alive at 2 years),[211] underscoring the potential for long-term disease stabilization with TKIs. GI adverse effects (vomiting or diarrhea) were most common but were mild and self-limiting in the majority of cases. Myelosuppression was also observed and was mild in most cases. A small percentage of dogs developed a protein-losing nephropathy leading to edema. Increases in urea and creatinine were observed in some dogs, and hemolytic anemia was also observed rarely.[210]

Lastly, small studies have evaluated the efficacy of imatinib for the treatment of measurable canine MCT.[212–214] Imatinib was well tolerated and objective antitumor responses were observed in dogs with both c-*kit* mutant and wild-type MCTs. It is important to note that no studies have yet been performed in dogs with MCTs to assess the pharmacokinetics of imatinib, and thus current dosing recommendations are based on observed clinical activity, not pharmacokinetic and pharmacodynamic relationships.

There are now several published studies regarding the safety and efficacy of combination therapy with KIT inhibitors and standard forms of therapy, such as RT or cytotoxic chemotherapy; however, evidence of benefit when used in the postoperative setting has yet to be demonstrated. Combinations of continuously or intermittently administered TOC with lomustine and VBL have been evaluated.[215–218] In all of these studies, significant reductions in chemotherapy drug dosage and/or frequency were required to avoid additive myelosuppression. Another study investigated the combination of TOC, prednisone, and hypofractionated RT in dogs with unresectable and/or metastatic MCTs. The overall response rate was 76.4%, with 58.8% of dogs achieving CRs and 17.6% PRs. The overall MST was not reached with a median follow-up of 374 days. The combination of hypofractionated RT and TOC was well tolerated and demonstrated efficacy in the majority of dogs, indicating that this may be a viable treatment option for dogs with unresectable MCTs.[219]

Novel medical approaches that may hold promise for the future treatment of MCT include JAK2/STAT5 inhibitors,[220] histone deacetylase inhibitors,[221–223] HSP90 inhibitors,[224,225] retinoids,[226–228] TRAIL,[229] and polo-like kinase-1 inhibitors.[230] A recent study evaluated a KIT-targeting monoclonal antibody for the treatment of canine MCT; KIT protein activation was blocked in vivo and multiple objective responses were observed.[231]

Ancillary therapy to address the systemic effects of MC mediators is sometimes warranted in dogs with MCT. Minimizing the effects of histamine release can be accomplished by administering the H_1 blockers diphenhydramine (2–4 mg/kg PO q12hrs) or chlorpheniramine (0.22–0.5 mg/kg q8hrs) and the H_2 blockers cimetidine (4–5.5 mg/kg PO q8hrs), famotidine (0.5–1 mg/kg q12hrs), or ranitidine (2 mg/kg q12hrs). Omeprazole (0.5–1 mg/kg q12–24hrs), a proton pump inhibitor, may be more effective, particularly in the setting of bulky MC disease. These agents are generally used in the setting of gross disease, particularly those cases in which (1) systemic signs are present; (2) the tumor is likely to be entered or manipulated at surgery (i.e., cytoreductive surgery); or (3) treatment is undertaken where gross disease will remain and degranulation is likely to occur in situ (e.g., RT or medical therapy for tumors that are not surgically cytoreduced). For cases with active evidence of GI ulceration, the addition of sucralfate (0.5–1.0 g PO q8hrs) and occasionally misoprostol (2–4 µg/kg PO q8hrs) to histamine blockers is prudent. Some experimental data suggest that the use of H_1 and H_2 blockers could also be beneficial for the prevention or resolution of histamine-mediated wound breakdown,[232–234] but this has not been systematically evaluated. The use of protamine sulfate, a heparin antagonist, has been mentioned by some for use in cases of severe hemorrhage.[128]

Feline Mast Cell Tumors

Unlike MCTs in the dog, which are primarily cutaneous/subcutaneous in nature, MCTs in the cat typically occur in three distinct syndromes, although there is some overlap among them. These are cutaneous MCT, splenic/visceral MC disease, and intestinal MCT. The etiology of feline MCT is currently unknown and appears unrelated to viral infection[235]; however, it is now evident that feline MCTs also possess somatic activating mutations in c-*kit*.[175,236–238] In one study, 42 of 62 (67%) of cutaneous and splenic/visceral MCT had c-*kit* mutations that were primarily present in exons 8 (28/62) and 9 (15/62), both of which encode the fifth immunoglobulin domain of KIT.[239] Similar to the canine juxtamembrane domain mutations, these feline c-*kit* mutations induce ligand independent activation of KIT, which can be inhibited by imatinib in vitro.[238]

The granules present in feline MCTs stain blue with Giemsa and purple with toluidine blue.[1,2,4] As in the dog, granules present in feline MCs contain vasoactive substances such as heparin and histamine.[2,240] In culture, feline MCs express surface-bound immunoglobulins and are capable of secreting histamine, heparin, and probably other vasoactive compounds when appropriately stimulated.[240] Feline MCs also have phagocytic capability and can endocytose erythrocytes in both experimental models and in clinical samples.[241] Complications associated with degranulation of MCTs can also occur in the cat, including coagulation disorders, GI ulceration, and anaphylactoid reactions.[2,242,243] Given that the biologic behaviors of the three feline MCT syndromes are different, they will be described individually.

Cutaneous Feline Mast Cell Tumors

MCTs represent the second most common cutaneous tumors in the cat, accounting for approximately 20% of cutaneous tumors in cats in the United States.[2,4,12] The incidence of MCTs in cats appears to have increased dramatically since 1950.[2] Interestingly, MCTs appear to occur much less frequently in the United Kingdom than in the United States, accounting for only 8% of all cutaneous tumors.[1] The typical feline cutaneous MCT is a solitary, raised, firm, well-circumscribed, hairless, dermal nodule between 0.5 and 3.0 cm in diameter.[2,4,244,245] They are often white in appearance, although a pink erythematous form is occasionally

TABLE 21.7 Histologic Classification of Mast Cell Tumors in Cats

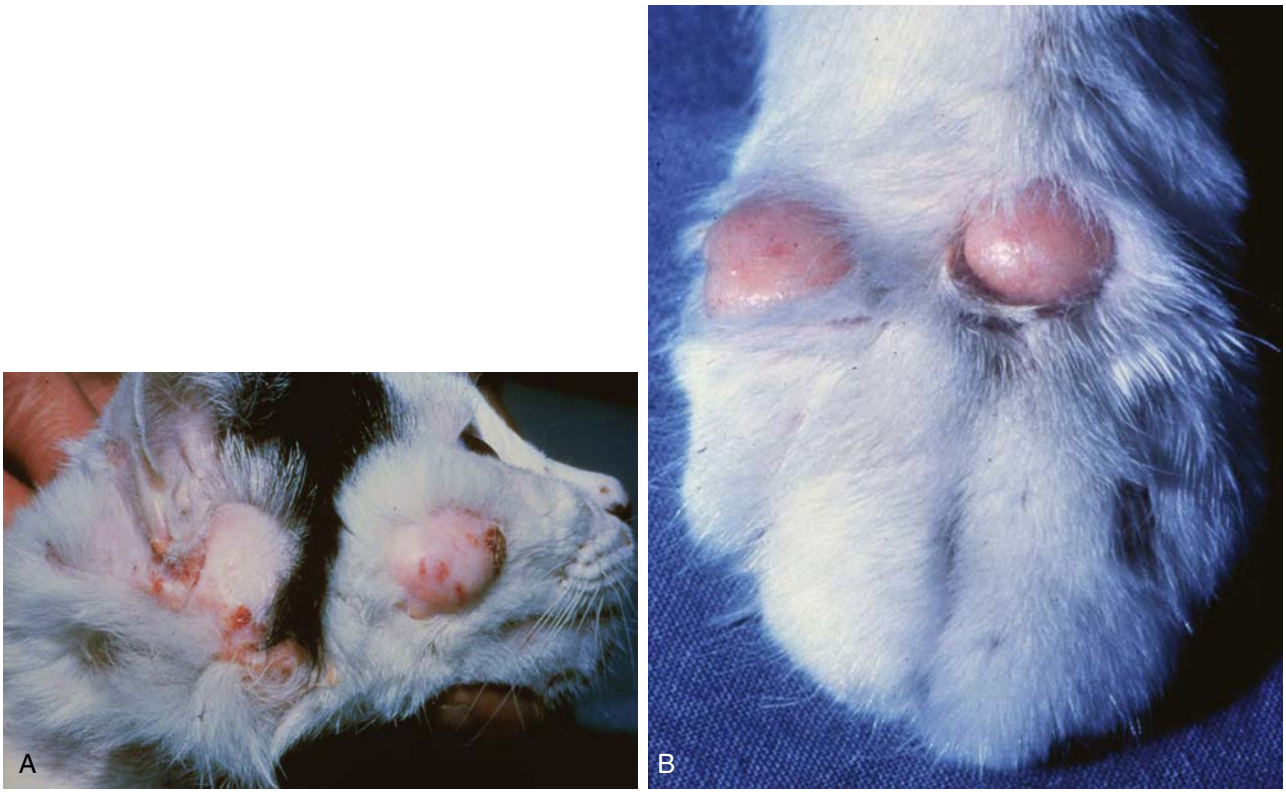
Type	Subtype	Microscopic Description
Mastocytic	Compact (well-differentiated)	Homogeneous cords and nests of slightly atypical mast cells with basophilic round nuclei, ample eosinophilic cytoplasm and distinct cell borders. Eosinophils conspicuous in only half of cases.
	Diffuse (anaplastic)	Less discrete, infiltrated into subcutis. Larger nuclei (>50% cell diameter), 2–3 mitoses/high-power field. Marked anisocytosis, including mononuclear and multinucleated giant cells. Eosinophils more commonly observed.
Histiocytic		Sheets of histiocyte-like cells with equivocal cytoplasmic granularity. Accompanied by randomly scattered lymphoid aggregates and eosinophils. Granules lacking in some reports, others report granules readily demonstrable.

encountered. Approximately 20% are multiple, although one series reported multiple lesions in the majority of cases.[1] Superficial ulceration is present in approximately 25% of cases. Other clinical forms that have been described include a flat pruritic plaque-like lesion, similar in appearance to eosinophilic plaques, and discrete subcutaneous nodules.

Two distinct types of cutaneous MCTs in the cat have been reported (Table 21.7): (1) the more typical mastocytic MCT, histologically similar to MCT in dogs; and (2) the less common histiocytic MCT, with morphologic features characteristic of histiocytic MC and that may regress spontaneously over a period of 4 to 24 months.[239,245] An overall mean age of 8 to 9 years is reported for cats with MCTs; however, the mastocytic and histiocytic forms occur at mean ages of 10.0 and 2.4 years, respectively.[2,4,244] Siamese cats appear to be predisposed to development of MCT of both histologic types.[2,4,239,244,245] The histiocytic form of MCT in cats is reported to occur primarily in young (<4 years of age) Siamese cats, including two related litters.[239] In contrast to these reports, Siamese cats were not more likely to develop the histiocytic form of MCT than the mastocytic form in another series of cases.[4] Earlier studies reported a male predilection for development of MCT[243,244]; however, larger, more recent series have failed to confirm this predilection.[2,4]

The mastocytic form can be further subdivided on histologic appearance into two categories, previously referred to as compact (representing 50%–90% of all cases) and diffuse (histologically anaplastic), which may have prognostic significance.[2,239,246] Well-differentiated compact tumors tend to behave in a benign manner and metastasis is uncommon.[244,247,248] In contrast, anaplastic tumors may have a high MI, marked cellular and nuclear pleomorphism, and infiltration into the subcutaneous tissues.[245] Although these have been reported to behave in a more malignant manner with metastasis to LNs and the abdomen, a more recent study evaluating pleomorphic cutaneous MCTs from 15 cats found that the majority were behaviorally benign, with only one cat euthanized because of disease progression.[249]

Unlike in the dog, the head and neck are the most common site for MCTs in the cat, followed by the trunk, limbs, and miscellaneous sites (Fig. 21.9A, B).[2,4,244] Those on the head often involve the pinnae near the base of the ear. They rarely occur in the oral cavity. Intermittent pruritus and erythema are common, and self-trauma or vascular compromise may result in ulceration. Darier's sign, the erythema and wheal formation after mechanical manipulation of the tumor, has been reported in the cat.[243] Affected cats are usually otherwise healthy. The spontaneously regressing histiocytic form of cutaneous MCT usually presents as multiple, nonpruritic, firm, hairless, pink, and sometimes ulcerated subcutaneous nodules (Fig. 21.10).[4,239]



As with canine tumors, most feline MCTs are usually easily diagnosed by cytologic examination of FNAs. In contrast, the uncommon histiocytic form of feline MCT is more challenging to diagnose both by FNA and histopathology.[239,245] MCs may comprise only 20% of the cells present, with the majority being sheets of histiocytes that lack distinct cytoplasmic granules and are accompanied by randomly scattered lymphoid aggregates and eosinophils. In contrast, one report readily demonstrated metachromatic granules in seven cases of the histiocytic subtype. These tumors can be initially misdiagnosed as granulomatous nodular panniculitis or deep dermatitis.

Cats with cutaneous MCTs should be evaluated for evidence of additional cutaneous and splenic tumors, as one study found that 3 of 41 cats with cutaneous MCTs also had splenic disease.[247] In addition, a minimum database is recommended along with careful examination of regional LNs for evidence of lymphadenopathy. Interestingly, unlike dogs, cats rarely exhibit evidence of circulating MCs on buffy coat smears when healthy or ill from non–MCT-related causes.[250] In contrast, one study demonstrated that 43% of cats with MC disease had positive buffy coats, although most of these cats tended to have splenic/visceral MCTs.[251]

Feline MCT are usually positive for vimentin, α-1 antitrypsin, and KIT.[252,253] Although the histologic grading system described for canine MCTs has provided no prognostic information for cats in several series and is not used,[243,254] tumors with a high MI appear to be at greatest risk for local recurrence and metastasis, suggesting that this histopathologic feature may be useful for predicting biologic behavior, and as in dogs, a cutoff of 5/10 HPF has been suggested.[245,249,255,256] In recent studies evaluating the prognostic value of histologic and immunohistochemical features in feline cutaneous MCT, MI, and KIT immunoreactivity score/localization were the strongest predictive variables.[255,257,258]

The definitive treatment for cutaneous feline MCT is surgical excision. In a series of 32 cats with cutaneous MCT, five cats developed local recurrence after surgical excision, although none of the cats in this study died of their disease. In this study, completeness of excision and histopathologic factors, such as nuclear pleomorphism and MI, were not associated with tumor recurrence.[248] In a more recent series of cats with MCT of the eyelids, local tumor control in 19 of 23 (83%) cats was achieved with surgery alone and another three cats had local tumor control with surgery and adjuvant RT or cryotherapy; the MST was 945 days.[259] Despite the fact that only 50% of the tumors were completely excised, no cats developed either local tumor recurrence or metastatic disease and only one cat developed disseminated cutaneous tumors.[259] Other reports have demonstrated local recurrence rates after excision between 0% and 24%.[2,244,245,247,249] These data suggest that most cutaneous feline MCTs are behaviorally benign and wide

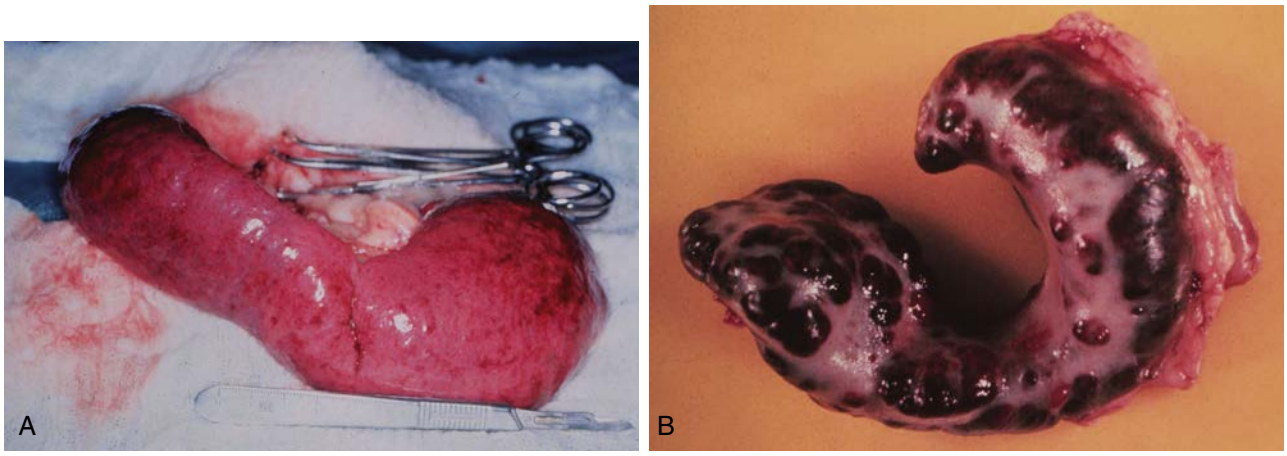
• **Fig. 21.9** (A) Multiple mast cell tumors on the head of a cat. The head and neck are the most commonly encountered location for mast cell tumors in the cat. They often involve the area near the base of the ear. (B) Mast cell tumors in the cat are less common on the limbs. (Courtesy S. Helfand, Oregon State University.)



• **Fig. 21.10** Histiocytic mast cell tumors on the head of a young Siamese cat. This form of mast cell tumors in cats typically regress spontaneously, as was the case in the cat pictured here. (Courtesy Dr. K. Moriello, University of Wisconsin–Madison.)

surgical margins may not be as critical as in the dog. Frequency of systemic spread after surgical excision varies from 0% to 22%, although those that metastasize are more likely to be anaplastic tumors.[244,245,247–249] Therefore for histologically anaplastic tumors or those with a high MI more likely recur postoperatively or metastasize, a more aggressive approach similar to that used for canine MCT may be prudent.[249,260] After biopsy confirmation, conservative resection or active surveillance may be taken with the histiocytic form in young cats with multiple masses, as these may spontaneously regress.[2,4,239]

RT may be considered for tumors that are incompletely excised. In one study of feline cutaneous MCT, a 98% control rate was achieved with strontium-90 irradiation with an MST greater than 3 years.[261] Limited information exists concerning the utility of chemotherapy in cats with MCT. It is generally believed that feline MCTs are less responsive to prednisone than dogs; biologic activity of corticosteroids in cats with the histiocytic variant was found to be equivocal.[239] Objective responses to lomustine (CCNU) have been reported in cats.[262,263] Of 20 cats with cutaneous MCTs, two had a CR and eight cats had a PR with lomustine.[263] The authors have observed evidence of clinical activity in cats treated with prednisone and VBL. Some investigators have utilized a combination of prednisone and chlorambucil to treat metastatic or multiple tumors. This is generally well tolerated, although its effectiveness is not known.

Biologic activity of imatinib has been observed in cats with MCT expressing activating mutations in c-*kit,* although the responses were all partial.[237,238,264] Studies in healthy cats have demonstrated that MAS may be safe to administer to clinically normal cats, and plasma concentrations associated with MCT inhibitory activity are likely achievable.[265] Cats should be monitored very closely for neutropenia, proteinuria, and increases in creatinine.[266,267] TOC has been evaluated in multiple feline tumor types, including MCT. Tolerability appears good at the canine label dose and objective responses have been observed in some cats with MCTs.[268,269]

Splenic/Visceral Feline Mast Cell Tumors

MCT represents the most common differential for splenic disease in cats, accounting for 15% of submissions in a series of 455 pathologic specimens.[270] This disease affects primarily older animals (mean age, 10 years), with no sex or breed predilection.[2,247,270] The majority of cats with splenic MCTs do not have a history of cutaneous MCT, although recent evidence suggests that some cats with multiple cutaneous MCTs may also have splenic involvement.[247] Although the spleen is the primary site, other organs may also be involved.[2,242] Necropsy data on 30 cats with splenic MCT revealed dissemination in the following organs in decreasing order of frequency: liver (90%), visceral LN (73%), bone marrow (40%), lung (20%), and intestine (17%).[2] Up to one-third of cases have peritoneal and pleural effusions rich in eosinophils and MCs.[2,242] Peripheral blood mastocytosis has been reported in 40% to 100% of cats with peripheral MC counts up to 32,000 cells/μL.[2,251] In one clinical report of 43 cats with splenic MCT, 23% had bone marrow involvement.[242]

Cats with splenic MCTs may present with signs of systemic illness including vomiting, hyporexia, and weight loss.[2,242] Dyspnea may be evident if pleural effusion is present. Abdominal palpation usually reveals a markedly enlarged spleen and/or liver. Other common differential diagnoses for splenomegaly in the cat include lymphoma, myeloproliferative disease, accessory spleen, hemangiosarcoma, hyperplastic nodules, and splenitis.[270] Clinical signs associated with the release of MC mediators, such as GI ulceration, hemorrhage, hypotensive shock, and labored breathing may also be noted. Cats with suspected splenic MCTs should undergo a standard workup including minimum database, abdominal US, and thoracic radiographs. FNA cytology is usually diagnostic for splenic MCT, as is cytologic evaluation of thoracic or abdominal fluid. Anemia is a common hematologic finding, with eosinophilia less likely to be observed.[2,242] In one report of 43 cats with splenic MCTs, 90% had an abnormal coagulation profile, although this did not appear to be of clinical significance.[242]

Splenectomy is the treatment of choice for cats with splenic MCTs, even if involvement of other organs is noted. Pretreatment with H_1 and H_2 blockers before surgery may be indicated to avoid possible anesthetic complications associated with the release of MC mediators. Two gross forms of splenic involvement are possible: a diffuse smooth form and a less common nodular form (Fig. 21.11).[139,271] Surprisingly, even in the face of significant bone marrow and peripheral blood involvement, long-term survival with good quality of life is the norm after splenectomy, with MSTs from 12 to 19 months reported,[2,242,265,272–275] although one study reported an MST of only 132 days after splenectomy.[276] Hyporexia, significant weight loss, and male sex were found to be negative prognostic indicators in one study.[242] Peripheral mastocytosis often declines significantly and may completely resolve after therapy.[274] Cats should be followed postoperatively with complete blood cell counts (CBCs) and peripheral blood smears because an increase in the number of circulating MCs may indicate disease progression. Adjunctive chemotherapy with prednisone, VBL, lomustine, and/or chlorambucil has been attempted in a limited number of cases, but it is not clear if postoperative chemotherapy improves postsplenectomy outcome.[274,275] As discussed earlier, recent data indicate that cats with MCTs may respond to the KIT inhibitors imatinib and TOC.[237,238,268,269]

Feline Intestinal Mast Cell Tumors

Intestinal MCT is the third most common primary intestinal tumor in cats after lymphoma and adenocarcinoma.[2] No breed or sex predilection is known. Older cats appear to be at risk, with a mean age of 13 years; however, cats as young as 3 years have been reported.[277] Most cats have a history of vomiting, diarrhea, and hyporexia, and a solitary palpable abdominal mass is usually evident on physical examination.[2,277] Intestinal MCT more commonly involves the small intestine (equally divided among duodenum, jejunum, and ileum), with colonic involvement reported in fewer than 15% of cases; lesions can be solitary or multiple.[2,277,278] Diarrhea, with or without hematochezia, is commonly observed with the intestinal form, and fever may be present. Affected cats may be ill for several months before diagnosis. As metastasis is common with intestinal MCT, enlarged mesenteric LNs and/or hepatosplenomegaly may be noted. A peritoneal effusion may be present, and this often contains MCs and eosinophils. Diagnosis is usually made by FNA cytology of the mass or involved organs; MCs from intestinal lesions are often less differentiated than those of skin MCTs, and cytoplasmic granules may be less prominent, making diagnosis challenging in certain cases. Cats with intestinal MCT should be staged with a minimum database, thoracic radiographs, and abdominal US, which may be required to determine the extent of intestinal involvement and presence of visceral

dissemination. Buffy coat smear may also be performed although, unlike in splenic MCT, peripheral mastocytosis is rarely associated with intestinal MCT and only two reports of peripheral eosinophilia exist in the literature.[277]

Intestinal MCT in cats often carries a poor prognosis because metastasis is common at the time of diagnosis and many cats either die or are euthanized soon after diagnosis.[2,277–279] However, two recent reports totaling 48 cats suggest a more favorable outcome for cats with intestinal MCT.[279,280] MSTs after surgical and/or medical (TKIs/corticosteroids) management were approximately 1.5 years. Histologic differentiation and MI were found to be prognostic, whereas c-*kit* mutation was not prognostic.[279] Surgery is the treatment of choice and wide surgical margins are necessary (5–10 cm), as the tumor typically extends histologically well beyond the gross disease.[2,277] Undifferentiated tumors and those with a MI >2 may have worse postsurgical outcomes.[279] Recently, a variant of feline intestinal MCT, termed sclerosing MCT, was described in 50 cats.[278] Metastatic disease to the LN and/or liver was present in 23 of 36 cats evaluated. Of the 25 cases with clinical follow-up information, 23 died or were euthanized within 2 months of diagnosis.[278] Limited information exists regarding the use of chemotherapy and/or TKIs for the treatment of feline intestinal MCT, although responses to lomustine and TOC have been reported.[263,268]

Comparative Aspects of Mast Cell Tumors

Neoplastic diseases of MCs are rare in people and present as three main clinical entities.[281–285] Cutaneous mastocytosis, also known as urticaria pigmentosa, is a benign disease in which MC infiltration is confined to the skin. It occurs primarily in young children and usually regresses spontaneously before progression into adulthood. Systemic mastocytosis (SM) occurs primarily in adults and includes four major subtypes: (1) indolent SM, the most common form involving mainly skin and bone marrow that does not progress to aggressive disease; (2) a unique subcategory termed SM with an associated non-MC clonal hematologic disease; (3) aggressive SM usually presenting without skin lesions; and (4) MC leukemia, probably representing the rarest variant of human leukemias. Lastly, rare localized extracutaneous MCT (either benign or malignant) have been reported. Dysregulation of KIT is also found commonly in human neoplastic MC diseases and is primarily driven by a point mutation in exon 17 of c-*kit* that induces ligand-independent activation.[282,286] More recently, mutations have also been identified in exons 8 to 11, most of which are also activating.[282,286]

Treatment of the benign human MC disorders is focused primarily on supportive therapy, including H_1 and H_2 antagonists, and topical or systemic therapy with corticosteroids. Unfortunately, an effective treatment protocol for people with aggressive mastocytosis or MC leukemia has not been identified. Treatment with interferon-alpha and/or cladribine is often used, although response rates are typically low.[281,286] Most of the currently available small molecule KIT inhibitors, including imatinib, nilotinib, and dasatinib, have been ineffective in treating human mastocytosis.[286] This may in part be due to the fact that inhibiting phosphorylation of KIT expressing activating exon 17 mutations is extremely challenging. More recently, the protein kinase C inhibitor midostaurin has demonstrated activity in human MC disease.[286]

Soft Tissue Sarcomas

JULIUS M. LIPTAK AND NEIL I. CHRISTENSEN

Incidence and Risk Factors

Soft tissue sarcomas (STSs) are a heterogeneous population of mesenchymal tumors that comprise 15% and 7% of all skin and subcutaneous tumors in the dog and cat, respectively.[1] The annual incidence of STSs in companion animals is about 35 per 100,000 dogs at risk and 17 per 100,000 cats at risk.[2] In dogs, sarcomas have been associated with radiation, trauma, foreign bodies, orthopedic implants, and the parasite *Spirocerca lupi*.[3–9]

Most STSs are solitary tumors in middle-aged to older dogs and cats, except for rhabdomyosarcomas which occur in young dogs.[10,11] There is no specific breed or sex predilection for STSs. STSs tend to be overrepresented in large-breed dogs.[10]

Pathology and Natural History

STSs are typically regarded as a heterogeneous group of tumors whose classification is based on similar pathologic appearance and clinical behavior; however, this may be an overly simplistic interpretation. Sarcomas arise from mesenchymal tissues and have features similar to those of the cell type of origin. These tumors originate in connective tissues, including muscle, adipose, neurovascular, fascial, and fibrous tissue, and can give rise to benign and malignant entities. STSs can arise at any anatomic location, but they most commonly involve the skin and subcutaneous tissues. For simplicity and consistency, a number of sarcomas arising from soft tissue are excluded from the umbrella term of cutaneous and subcutaneous STSs because of differences in anatomic location, biologic behavior (such as a higher metastatic rate and/or a different distribution of metastasis), and histologic features.[12] These include histiocytic sarcoma (HS), synovial cell sarcoma (SCS), hemangiosarcoma (HSA), lymphangiosarcoma, rhabdomyosarcoma, oral fibrosarcoma (FSA), and peripheral nerve sheath tumors (PNSTs) of the brachial and lumbar plexi.[12] HS, SCS, HSA, and oral FSA are covered in other chapters, with this chapter concentrating primarily on malignant STSs.

The majority of cutaneous and subcutaneous STSs have a similar biologic behavior. This is characterized by a locally expansile mass growing between fascial planes, but STSs can also be infiltrative. STSs are often surrounded by a pseudocapsule formed by the compression of peritumoral connective tissue, which may contain or be confluent with neoplastic tissue.[12,13] Overall, cutaneous and subcutaneous STSs have a low to moderate local recurrence rate after surgical excision, with or without adjuvant radiation therapy (RT), and a low metastatic rate. The likelihood of local recurrence is dependent on tumor size, degree of infiltration, completeness of histologic excision, and histologic grade; the likelihood of metastasis is dependent primarily on histologic grade.

STS is a general term encompassing a heterogenous group of tumors, but STSs can be subclassified according to the tissue of origin or phenotype.[12] These include FSA, perivascular wall tumor (PWT), PNST (nonbrachial plexus), liposarcoma, myxosarcoma, pleomorphic sarcoma (or malignant fibrous histiocytoma), malignant mesenchymoma, and undifferentiated sarcoma.[12,14,15] These can be difficult to differentiate histologically because common components include an intercellular collagen matrix and spindle or fusiform mesenchymal cells forming bundles, streams, and whorls.[12] STSs may be characterized histologically by areas of mature tissue or via immunohistochemistry (IHC) by the expression of certain cellular markers to determine phenotype (Table 22.1).[12,16–21] However, STSs may display more than one histologic pattern, and histologic patterns and IHC features may not be exclusive to a single cell type of origin or phenotype.[12] STSs are sometimes referred to by alternate names such as spindle cell tumors of soft tissue because of the complexity of phenotypic differentiation, the use of the term "sarcoma" for tumors that have a low metastatic potential, and the difficulty in differentiating benign from low-grade malignant variants of some mesenchymal tumors of soft tissue (Table 22.2).[12,22–25] Histologic distinction of tumor type may not be clinically important because most STSs have a similar biologic behavior (i.e., locally aggressive with a low to moderate risk of distant metastasis); however, this may be an overly simplistic approach as there is increasing evidence that discernible differences in presentations and outcomes may exist between different types of STSs.

Specific Tumor Types

Tumors of Fibrous Tissue

Nodular Fasciitis (Fibromatosis, Pseudosarcomatous Fibromatosis)

Nodular fasciitis is a benign nonneoplastic lesion arising from the subcutaneous fascia or superficial portions of the deep fascia in dogs. These lesions are usually nodular, poorly circumscribed, and very invasive.[26] Histologically, nodular fasciitis is characterized by large plump or spindle-shaped fibroblasts in a stromal network of variable amounts of collagen and reticular fibers with scattered lymphocytes, plasma cells, and macrophages.[26] The morphologic and pathologic characteristics of nodular fasciitis can result in these lesions being misdiagnosed as FSA. Infantile desmoid-type

VetBooks.ir

TABLE 22.1 Types of Cutaneous and Subcutaneous Soft Tissue Sarcomas with Distinctions Based on Histogenesis, Phenotype, Histologic Features, and Immunohistochemistry

Type	Tissue of Origin	Phenotype	Histologic Features	Immunohistochemistry
Fibrosarcoma	Fibrous tissue	Fibroblast, fibrocyte	Interwoven bundles, herringbone pattern, pronounced collagenous stroma	
Myxosarcoma	Fibrous tissue	Fibroblast, fibrocyte	Stellate- or spindle-shaped cells in mucinous stroma	
Pleomorphic sarcoma (malignant fibrous histiocytoma)	Fibrous tissue	Primitive mesenchymal cells (fibroblast or myofibroblast)	Mixture of fibroblastic cells and karyomegalic, cytomegalic, or multinucleate histiocytoid cells in storiform patterns with variable inflammatory infiltrate	Positive: lysozyme (29%–100%), MHC II (70%), desmin (86%), vimentin Negative: S-100, CD18
Perivascular wall tumor	Perivascular wall cells	Pericyte, myopericyte, smooth myocyte	Vascular growth patterns including staghorn, placentoid, perivascular whirling, and bundles from tunica media	Positive: calponin, pan actin, smooth muscle actin (50%) Negative: S-100, NSE, GFAP, myoglobin
Peripheral nerve sheath tumor	Peripheral nerve	Schwann cell, neurofibroblast	Interwoven bundles, whorls around collagen bundles, Antoni A and B patterns	Positive: NSE (45%–82%), S-100 (50%–100%), neurofilament (82%), NGFR (47%), myoglobin (64%), GFAP (0%–35%)
Liposarcoma	Adipose tissue	Lipoblast, lipocyte	Polygonal cells with distinctly vacuolated cytoplasm	Positive: MDM2 (67% of well-differentiated and 75% of dedifferentiated), CDK4 (88% well-differentiated, 71% myxoid, 67% pleomorphic, and 100% dedifferentiated)[84]
Rhabdomyosarcoma	Skeletal muscle	Skeletal myoblast, skeletal mycoyte	Cytoplasmic striation, racket and strap cells	Positive: desmin, S-100 (75%), NSE (50%), GFAP (50%)
Lymphangiosarcoma	Lymph tissue		Irregular, anastomosing, and arborizing vascular channels and trabeculae lined by a single layer of flattened, elongate to plump spindle-shaped cells with scant cytoplasm supported on a collagenous stroma; with lumina characterized by a paucity of erythrocytes.[91]	Positive: *PROX-1* (80%–88%),[90,91] Factor VIII-related antigen (100%), LYVE-1 (80%)[91]
Mesenchymoma	Any mesenchymal tissue	Multiple cell types	Multiple soft tissue mesenchymal cell types and matrix components including osteoid, chondroid, and collagen	

GFAP, Glial fibrillary acidic protein; *LYVE-1*, lymphatic vessel endothelial receptor-1; *MDM2*, mouse double minute 2 homolog; *MHC*, major histocompatibility complex; *NGFR*, nerve growth factor receptor; *NSE*, neuron specific enolase; *PROX-1*, prospero-related homeobox gene 1.

Modified from Dennis et al, *Vet Pathol*, 2011.[12,84,90,91]

TABLE 22.2 Soft Tissue Sarcoma Grading System

Score	Differentiation	Mitosis[a]	Necrosis
1	Resembles normal adult mesenchymal tissue	0–9	None
2	Specific histologic subtype	10–19	<50% necrosis
3	Undifferentiated	>20	>50% necrosis

Grade I: Cumulative score of ≤4 for the 3 categories.

Grade II: Cumulative score of 5–6.

Grade III: Cumulative score of ≥7.

[a]Mitosis is calculated as the number of mitotic figures/10 HPF.

fibromatosis is a variant of nodular fasciitis and is characterized by fibroblast proliferation with a dense reticular fiber network and mucoid material.[27] Wide excision of both nodular fasciitis and infantile desmoid-type fibromatosis lesions is usually curative.[28] Local recurrence is possible with incomplete resection. These tumors do not metastasize.[26]

Fibrosarcoma

FSAs arise from malignant fibroblasts in any location, but most commonly in the skin, subcutaneous tissue, and oral cavity. Similar to other STSs, FSAs can range from well differentiated to anaplastic.[29] FSAs tend to occur in older dogs and cats with no breed or sex predilection; however, a there was higher predilection in golden retrievers and Doberman pinschers in one study[30] and

VetBooks.ir

dogs with FSAs were significantly younger than dogs with other histologic subtypes of STSs in another study.[31] FSAs are more likely to recur after incomplete histologic excision and have higher mitotic rates than other histologic subtypes of STSs[32–35] but, conversely, are more likely to be low grade.[31]

Pleomorphic Sarcoma (or Malignant Fibrous Histiocytoma)

Malignant fibrous histiocytoma (MFH) is a tumor with histologic characteristics resembling histiocytes and fibroblasts.[36] According to the World Health Organization classification of soft tissue tumors, the preferred term for MFH is undifferentiated pleomorphic sarcoma because electron microscopic and IHC analyses of these tumors have shown that the term "fibrohistiocytic" is a misnomer.[37] Pleomorphic sarcomas are typically diagnosed in middle-aged to older dogs. There is no sex predilection, although in one report 70% of dogs with the giant cell variant of pleomorphic sarcoma were female.[38] Flat-coated retrievers, Rottweilers, and golden retrievers are overrepresented.[38,39] Pleomorphic sarcomas is most commonly diagnosed in the subcutaneous tissues of the trunk and pelvic limbs and the spleen in dogs. Computed tomography (CT) and magnetic resonance imaging (MRI) characteristics of pleomorphic sarcomas have been described in humans but not in dogs.[40] In people, pleomorphic sarcomas are typically characterized as a large lobulated inhomogeneous hypo- to isodense mass with inhomogeneous enhancement on CT and hypo- to isointense on T1-weighted images, with inhomogeneous enhancement, hyperintensity, and hypointense areas on T2-weighted images on MRI.[40] Four histologic subtypes of pleomorphic sarcoma are described: storiform–pleomorphic, myxoid, giant cell, and inflammatory.[40] Definitive IHC staining patterns have not been established, but pleomorphic sarcomas will typically be vimentin positive and CD18 negative.[39] Histologic subtype has prognostic significance in people, with the giant cell subtype having a higher local recurrence rate than storiform–pleomorphic subtype and a higher metastatic rate than the inflammatory subtype.[41] Giant cell pleomorphic sarcomas have been described in 10 dogs: they were highly metastatic to subcutaneous tissue, lymph nodes (LNs), liver, and lungs; and the median survival time (MST) in these dogs was only 61 days.[38] Canine pleomorphic sarcomas are significantly more likely to be high grade and have metastases at the time of diagnosis compared with other histologic subtypes of STSs.[31]

Myxosarcoma

Myxosarcomas are neoplasms of fibroblast origin with an abundant myxoid matrix composed of mucopolysaccharides. These rare tumors occur in middle-aged or older dogs and cats. The majority are subcutaneous tumors of the trunk or limbs,[29] but there are reports of myxosarcomas arising from the heart, eye, and brain.[42–44] These tumors tend to be infiltrative growths with ill-defined margins.[29]

Tumors of the Vascular Wall

Perivascular Wall Tumor

PWTs are derived from the different cellular components of the vascular wall, excluding the endothelial lining.[45] The components of the vascular wall depend on the type of vessel. Capillaries are composed of endothelium, pericytes, and basement membrane; large veins and arteries are composed of endothelium, subendothelial lining cells, basement membrane, a medial layer of smooth muscle cells, and an adventitial layer of myofibroblasts and fibroblasts.[45] PWTs are characterized by the amounts and types of cytoplasmic contractile proteins, which progressively increase from pericytes in capillaries to myopericytes and smooth muscle myocytes in the vascular subendothelial lining of larger vessels.[45] PWTs have a characteristic cytologic appearance with moderate to high cellularity, cohesion of spindle cells, presence of capillaries, and multinucleate cells.[45] They are diagnosed histologically based on vascular growth patterns (e.g., staghorn, placentoid, perivascular whirling, bundles of media) and are further characterized by IHC staining patterns.[45] Pericytes express vimentin and variable amounts of pan and α-smooth muscle actin; myopericytes are characterized by the additional expression of desmin and calponin; and smooth muscle cells express smoothelin and heavy caldesmon.[45] Based on IHC staining, canine PWTs have been classified similarly to human PWTs, with the following being recognized: myopericytoma, angioleiomyoma, angioleiomyosarcoma, hemangiopericytoma, angiofibroma, and adventitial tumor.[45,46] PWTs are differentiated from PNSTs by both histology and IHC.[45,47] PWTs are characterized by a less aggressive biologic behavior, with significantly lower rates of local recurrence than other histologic subtypes.[34]

Tumors of Peripheral Nerves

Peripheral Nerve Sheath Tumor

PNSTs are tumors of nerve sheath origin, arising from Schwann cells, perineural cells, or perineural or endoneural fibroblasts.[47] Benign and malignant variants have been described.[48] The most common benign PNSTs are schwannomas and neurofibromas, and these tend to be well circumscribed, located in the skin and subcutaneous tissue, with an equal distribution of Antoni A and B histologic patterns.[48] Malignant PNSTs are often subcutaneous, poorly circumscribed, and invasive into deeper tissues, and associated with high local tumor recurrence rates and relatively poor survival times.[47,48] Malignant PNSTs can be differentiated from PWTs based on IHC staining; malignant PNSTs stain positive with S-100, vimentin, glial fibrillary acidic protein (GFAP), nerve growth factor receptor, and neuron-specific enolase.[47–49] In additional, PNSTs have significantly higher Ki67 index than PWTs.[49]

Regardless of nomenclature, these tumors can occur anywhere in the body. Despite appearing encapsulated at surgery, they are similar to FSAs and are usually poorly defined without histologic encapsulation.[48] Most are adherent to deeper tissues and may infiltrate underlying fascia, muscle, and skin.[48] Although PNSTs are considered malignant, they have a modest metastatic rate. Local recurrence is common after conservative surgery.[48] PNSTs tend to grow slowly and can range in size from 0.5 cm to greater than 12 cm in diameter. In some cases, they can easily be confused with lipomas on initial clinical examination.[29]

PNSTs of macroscopic nerves, which are not considered part of the conventional classification of STSs in dogs, are classified as peripheral, root, or plexus.[50] Peripheral PNSTs involve macroscopic nerves distant to either the brain or spinal cord, and this form is much more amenable to treatment than either the root or plexus PNSTs. Plexus PNSTs can involve either the brachial or lumbrosacral plexus.[50] The vast majority of cases will show signs of unilateral lameness, muscle atrophy, paralysis, and pain.[50] They can invade the spinal cord, especially high-grade root and plexus PNSTs.[50] Treatment options include surgery, surgery with adjuvant RT, or RT alone. Surgical excision typically involves forequarter amputation,[50] although limb-sparing nerve-specific compartmental resection is occasionally possible.[51]

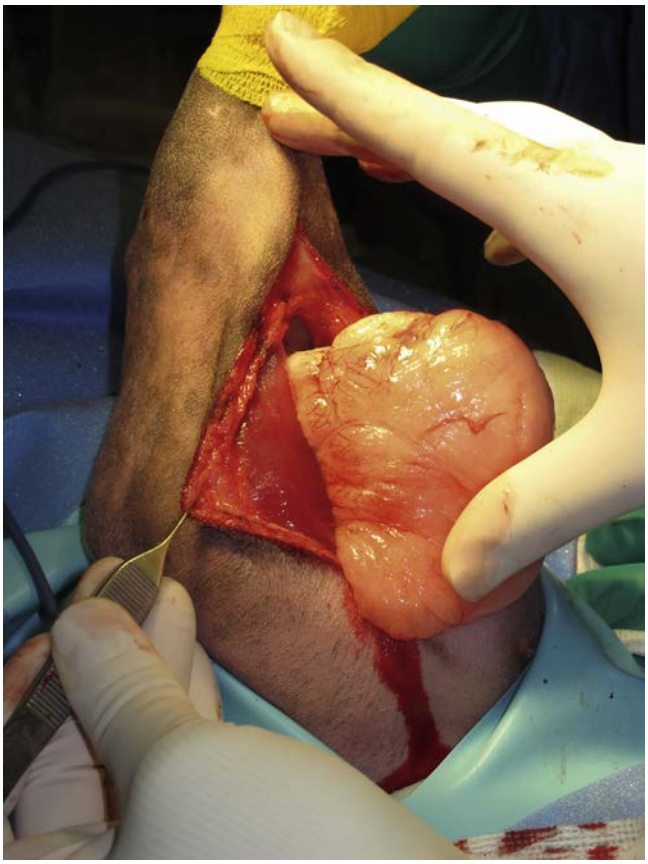
VetBooks.ir

In one study of 16 dogs with brachial plexus PNSTs treated with limb-sparing compartmental resection, the overall MST was 1303 days and was significantly better for dogs with complete histologic excision (MST 2227 days) compared with dogs with incomplete excision (MST 487 days).[51] For peripheral nerve tumors extending through the foramen, hemilaminectomy may be required in addition to forequarter amputation for adequate tumor excision.[50] Stereotactic RT has been described in 10 dogs with brachial plexus tumors with partial or complete resolution of neurologic signs in all dogs.[52] The mean progression-free survival (PFS) and overall survival times (OSTs) were 240 days and 371 days, respectively, with progression reported in 90% of dogs.[52] Regardless of histologic grade, local disease usually limits survival before metastasis occurs.[50,52]

Tumors of Adipose Tissue

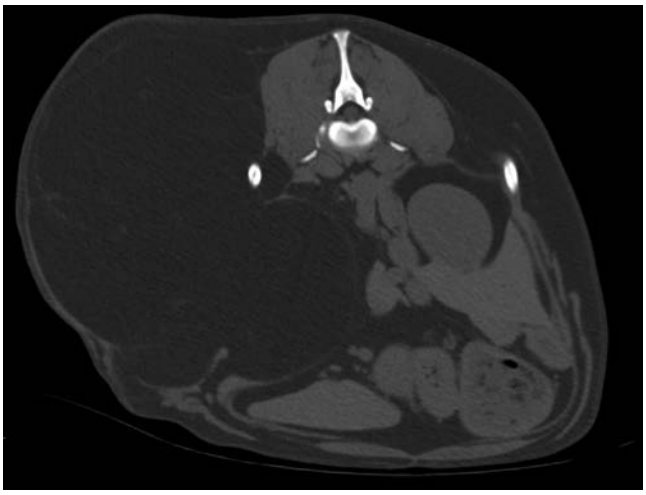
Lipoma

Lipomas are benign tumors of adipose tissue, and can be differentiated from liposarcomas based on morphologic, CT, and histologic appearance.[53] There are three morphologic types of lipomas: regular, infiltrative, and intermuscular.[53–59] Histologically, lipomas have indistinct nuclei and cytoplasm resembling normal fat, whereas liposarcomas are characterized by increased cellularity, distinct nuclei, and abundant cytoplasm with one or more droplets of fat.[60] Histologic variants of lipomas have been reported and include angiolipoma and angiofibrolipoma.[61]



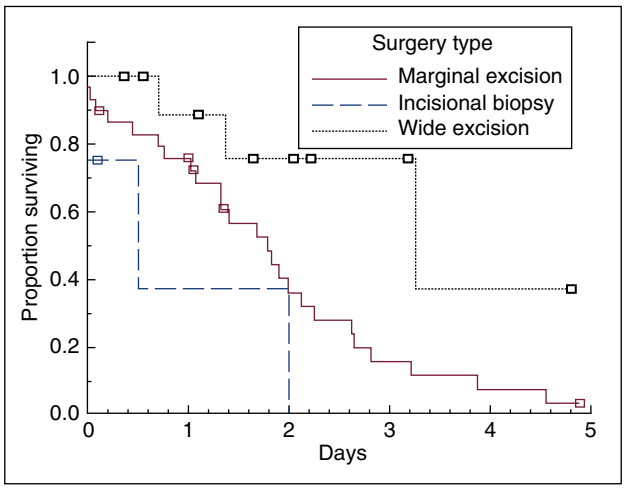
Regular lipomas are relatively common in older dogs, especially in subcutaneous locations, and are rarely symptomatic. They have been reported in the thoracic cavity, abdominal cavity, spinal canal, and vulva and vagina of dogs, and can cause clinical abnormalities secondary to either compression or strangulation.[60,62–69] Marginal excision is recommended for lipomas that interfere with normal function; however, the majority are asymptomatic and do not require surgical intervention. Liposuction and intralesional triamcinolone have also been reported with variable results.[70,71] Surgical resection is usually curative, but local recurrence has been reported.[68]

Intermuscular Lipoma



Intermuscular lipomas are a variant of the subcutaneous lipoma and are located between muscle bellies. The most common location is the caudal thigh of dogs, particularly between the semitendinosus and semimembranosus muscles (Fig. 22.1), but they have also been reported in the axilla.[72,73] Clinically, intermuscular lipomas appear as a slow-growing, firm, and fixed mass in either the axillary or caudal thigh region and may occasionally cause lameness.[72,73] Cytologic analysis of fine-needle aspirates is usually diagnostic. The recommended treatment is surgical resection, involving blunt dissection and digital extrusion, and placement of a negative-suction drain. Seromas are a common complication in dogs in which a drain is not used.[72] The prognosis is excellent with no recurrence reported after surgical excision in two published papers totaling 27 dogs.[72,73]

Infiltrative Lipoma



Infiltrative lipomas are uncommon tumors composed of well-differentiated adipose cells without evidence of anaplasia. These tumors cannot be readily distinguished from the more common simple lipoma by cytology or small biopsy specimens. They are considered "benign" and do not metastasize; however, infiltrative lipomas are locally aggressive and commonly invade adjacent muscle, fascia, nerve, myocardium, joint capsule, and even bone.[55,74,75] CT is used to better delineate these tumors and they can be differentiated from regular lipomas based on differences in shape, margins, and type of attenuation[53]; however, they do not contrast enhance and differentiating infiltrative lipomas from normal fat can be problematic (Fig. 22.2).[72] One retrospective analysis of 16

• **Fig. 22.1** An intermuscular lipoma arising from between the semitendinosus and semimembranosus muscles. Surgical dissection and removal was curative.

• **Fig. 22.2** A CT scan of an infiltrative lipoma of the chest wall in a dog. Differentiating an infiltrative lipoma from normal fat can be difficult on CT, but extension of the lipoma through the chest and body wall into the thoracic and abdominal (pictured) cavities is characteristic of an infiltrative lipoma.

• **Fig. 22.3** Kaplan–Meier survival curve of 56 dogs with liposarcoma treated with either incisional biopsy, marginal resection, or wide excision. The median survival time is significantly longer, at 1188 days, after wide surgical resection than less aggressive techniques. (Reprinted with permission from Baez JL, Hendrick MJ, Shofer FS, et al: Liposarcomas in dogs: 56 cases (1989–2000), *J Am Vet Med Assoc* 224:887, 2004.)

cases reported a 4:1 female-to-male ratio.[57] Aggressive treatment, including amputation, may be necessary for local control. RT can be considered either alone or in combination with surgical excision. Complete and partial responses have been reported in the gross disease setting after external beam RT.[59]

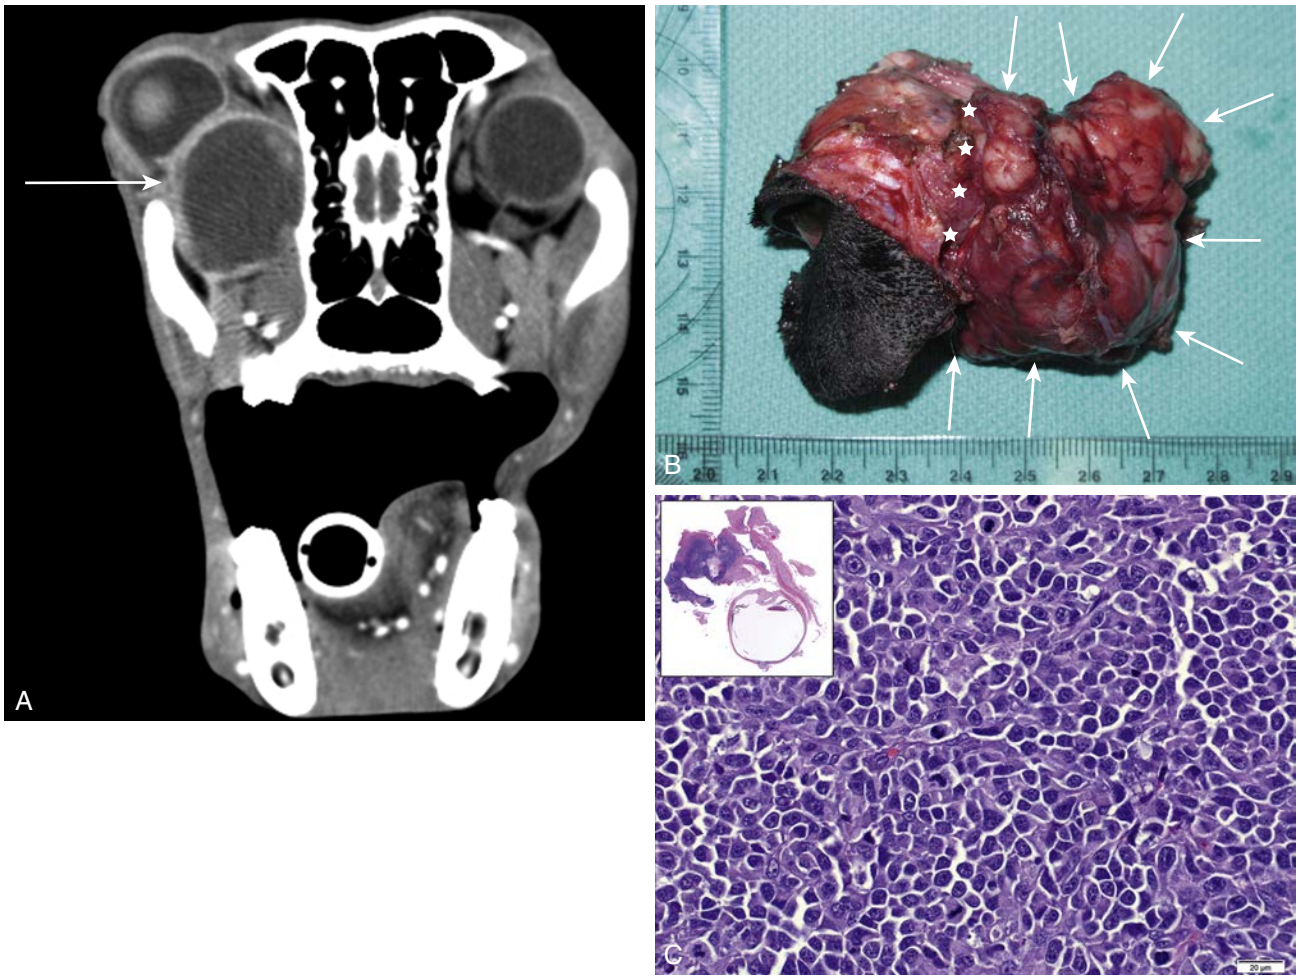
Liposarcoma

Liposarcomas are uncommon malignant tumors originating from lipoblasts and lipocytes in older dogs.[76] Liposarcomas are usually firm and poorly circumscribed. They are locally invasive with a low metastatic potential. Metastatic sites include the lungs, liver, spleen, and bone.[29,76] Liposarcomas do not arise from malignant transformation of lipomas. Specific causes are not known, but foreign body–associated liposarcoma has been reported in one dog.[5] There is no breed or sex predilection.[76] They are commonly reported in subcutaneous locations, especially along the ventrum and extremities, but can also occur in other primary sites such as bone, spleen, and the abdominal cavity.[76–78] Liposarcomas are differentiated from lipomas based on morphologic appearance, cytologic findings, and CT characteristics. Staining cytologic samples with Oil Red O can be useful to differentiate liposarcomas from other soft tissue saromas by staining lipid.[79] Liposarcomas appear as mixed-attenuating, heterogeneous, multinodular, contrast-enhancing masses on precontrast CT images, and these features can be used to differentiate liposarcomas from regular and infiltrative lipomas.[53,80]

The prognosis for liposarcoma is good with appropriate surgical management. The MST after wide surgical excision is 1188 days; this is significantly better than either marginal excision or incisional biopsy, which have MSTs of 649 days and 183 days, respectively (Fig. 22.3).[76] Liposarcoma is histologically classified as well-differentiated, myxoid, round cell (or poorly differentiated), pleomorphic, or dedifferentiated. This classification scheme has clinical and prognostic importance in humans because pleomorphic liposarcomas have a high metastatic rate, myxoid liposarcomas are more likely to metastasize to extrapulmonary soft tissue structures, and well-differentiated liposarcomas are unlikely to metastasize.[81–83] In a retrospective study in dogs, histologic subtype was not prognostic, but metastatic disease was more common in dogs with pleomorphic liposarcomas.[76] A revised classification scheme has been proposed on the basis of IHC expression of MDM2 and CDK4. In one study, MDM2 and CDK4 were expressed in 67% and 88% of well-differentiated liposarcomas, 14% and 71% of myxoid liposarcomas, 0% and 67% of pleomorphic liposarcomas, and 75% and 100% of dedifferentiated liposarcomas.[84] Furthermore, Ki67 index also correlated with histotype and was lowest in well-differentiated liposarcomas and highest in dedifferentiated liposarcomas.[84] These results parallel the human data to some degree and suggest that not only are well-differentiated and dedifferentiated liposarcomas distinct entities, but that this classification scheme may have prognostic significance.[84]

Tumors of Skeletal Muscle

Rhabdomyosarcoma



Rhabdomyosarcomas are rare malignant tumors originating from myoblasts or primitive mesenchymal cells capable of differentiating into striated muscle cells.[85] In dogs, rhabdomyosarcomas are most frequently reported to arise from skeletal muscle of the urinary bladder, retrobulbar musculature (Fig. 22.4), larynx, tongue, and myocardium.[86,87] They are locally invasive with a low to moderate metastatic potential. Metastatic sites include the lungs, liver, spleen, kidneys, and adrenal glands.[85]

Rhabdomyosarcomas are histologically classified as embryonal, botryoid, alveolar, and pleomorphic.[86] The histologic diagnosis of rhabdomyosarcoma is difficult (see Fig. 22.4C), and IHC staining for vimentin, skeletal muscle actin, myoglobin, myogenin, and myogenic differentiation (MyoD) may be required for definitive diagnosis.[88] Embryonal rhabdomyosarcomas have a predilection for the head and neck region, such as the tongue, oral cavity, larynx, and retrobulbar musculature.[86,87] In contrast, botryoid rhabdomyosarcoma commonly arises in the urinary bladder of young, female large-breed dogs, with Saint Bernard dogs possibly being overrepresented in one data set.[85] Botryoid tumors are characterized by their grapelike appearance. The histologic classification scheme for rhabdomyosarcoma has prognostic significance in humans.[85,89] In humans, botryoid rhabdomyosarcoma has a good prognosis, embryonal rhabdomyosarcoma has an intermediate prognosis, and alveolar rhabdomyosarcoma has a poor prognosis.[85,89] In dogs, botryoid rhabdomyosarcomas have a 27% metastatic rate whereas embryonal and alveolar rhabdomyosarcomas have a 50% metastatic rate.[86] Metastatic disease is more common in younger dogs, with the majority of dogs with metastatic disease being less than 2 years of age in one study[86] and, in another study, all dogs less than 4 years of age died of metastatic disease or local tumor recurrence (with an MST of 2.5 months), whereas no dog older than 4 years of age died of tumor-related reasons.[87]

Tumors of Lymphatic Tissue

Lymphangiosarcoma

Lymphangiosarcoma is a rare tumor arising from lymphatic endothelial cells.[29,90] They are usually soft, cystic-like, and edematous, usually occurring in the subcutis (Fig. 22.5).[29] In most cases, clinical signs are associated with extensive edema and drainage of lymph through the skin or a cystic mass, or nonhealing, discharging wounds.[90] Lymphangiosarcoma and HSA can be difficult to differentiate using histopathology and immunohistochemical markers for vascular endothelium, such

• **Fig. 22.4** (A) Postcontrast axial CT image at the level of the cribriform plate from a 12-month-old Belgian Turvuren. A hypoattenuating mass with a contrast enhancing rim (*arrow*) is causing significant dorsal displacement of the right eye. The dog developed local recurrence and pulmonary metastatic disease despite surgery and postoperative radiation therapy within 2 months after diagnosis. as factor VIII–related antigen and CD31.[29,91] IHC staining with the lymphatic endothelial cell-specific markers lymphatic vessel endothelial receptor-1 (LYVE-1) and propsero-related homeobox gene-1 (*PROX-1*) successfully differentiated lymphangiosarcoma from HSA in the majority of dogs.[91] In one series of 12 dogs with lymphangiosarcoma, the MST was 168 days (range, 60–876 days) for three dogs with no treatment and 487 days (range, 240–941 days) for five dogs treated with surgery alone; one dog treated with surgery, RT, and chemotherapy had an ST of 574 days.[90] All dogs treated surgically had incomplete histologic excision and all dogs were euthanized because of recurrent or progressive local disease.[90]

Tumors of Uncertain Histogenesis

Malignant Mesenchymoma

Malignant mesenchymomas are rare STSs comprising a fibrous component with two or more different varieties of other types of sarcoma.[26] Malignant mesenchymomas have been reported in the heart, lungs, thoracic wall, liver, spleen, kidney, digits, and soft

VetBooks.ir

• **Fig. 22.6** The typical gross appearance of a canine soft tissue sarcoma with a firm, well-circumscribed, expansile subcutaneous mass.

tissue.[92–101] They have a slow rate of growth and can grow very large. Metastasis has been reported.[96–100] The outcome for dogs with splenic mesenchymomas is better than for those with other types of splenic sarcomas, with a MST of 12 months and a 1-year survival rate of 50%.[96]

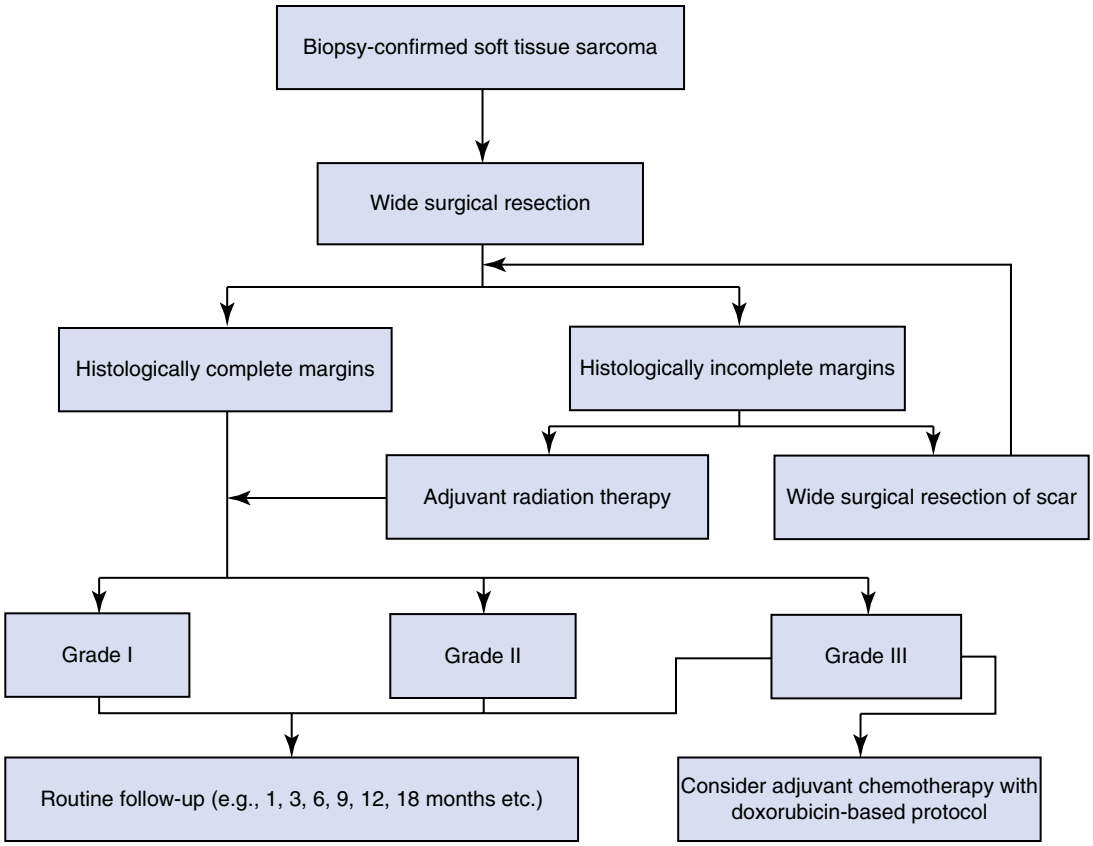
History and Clinical Signs

STSs generally present as slow-growing expansile masses. Rapid tumor growth, intratumoral hemorrhage, or necrosis can be seen in some cases. Symptoms are directly related to site of involvement and tumor invasiveness, with the vast majority of subcutaneous and cutaneous STSs causing no clinical signs. There is marked variability in the physical features of STS, but they are generally firm and well circumscribed (Fig. 22.6). They can be either mobile or adherent (fixed) to skin, muscle, or bone. STSs can also be soft and lobulated, mimicking lipomas.

Diagnostic Techniques and Workup

Fine-needle aspiration (FNA) is recommended for a cytologic diagnosis; however, cytologic evaluation may not be sufficient for a definitive diagnosis because variable degrees of necrosis and poor exfoliation of cells may result in a nondiagnostic sample.[26] The cytologic accuracy of correctly diagnosing an STS varies from 63% to 97%.[32,102] Cytologic preparations should be assessed by a board-certified cytopathologist because a disproportionate number of false-negative cytologic results were associated with in-house cytologic assessments compared with evaluation by a board-certified cytopathologist in one study.[33] Even in the absence of a definitive diagnosis, FNA cytology can exclude the diagnosis of readily exfoliating tumors such as epithelial and round cell tumors, and this may be sufficient for the suspected diagnosis of an STS by exclusion.[102,103]

Biopsy methods for definitive preoperative diagnosis of STSs include needle-core, punch, incisional, or excisional biopsies. The biopsy should be planned and positioned so that the biopsy tract can be included in the curative-intent treatment without increasing the surgical dose or size of the radiation field. Although needle-core and incisional biopsies will typically provide sufficient tissue for a definitive diagnosis of STS, the determination of histologic grade from preoperative biopsies was incorrect in 41% of dogs compared with the definitive surgical sample, with histologic grade underestimated in 29% of dogs and overestimated in 12% of dogs.[104] Excisional biopsies are *not* recommended because they may not be curative and the subsequent surgery required to achieve complete histologic margins is often more aggressive than surgery after core or incisional biopsies, resulting in additional morbidity and treatment costs. Furthermore, multiple attempts at resection, including excisional biopsy, before definitive therapy have a negative effect on ST in dogs with STSs.[105]



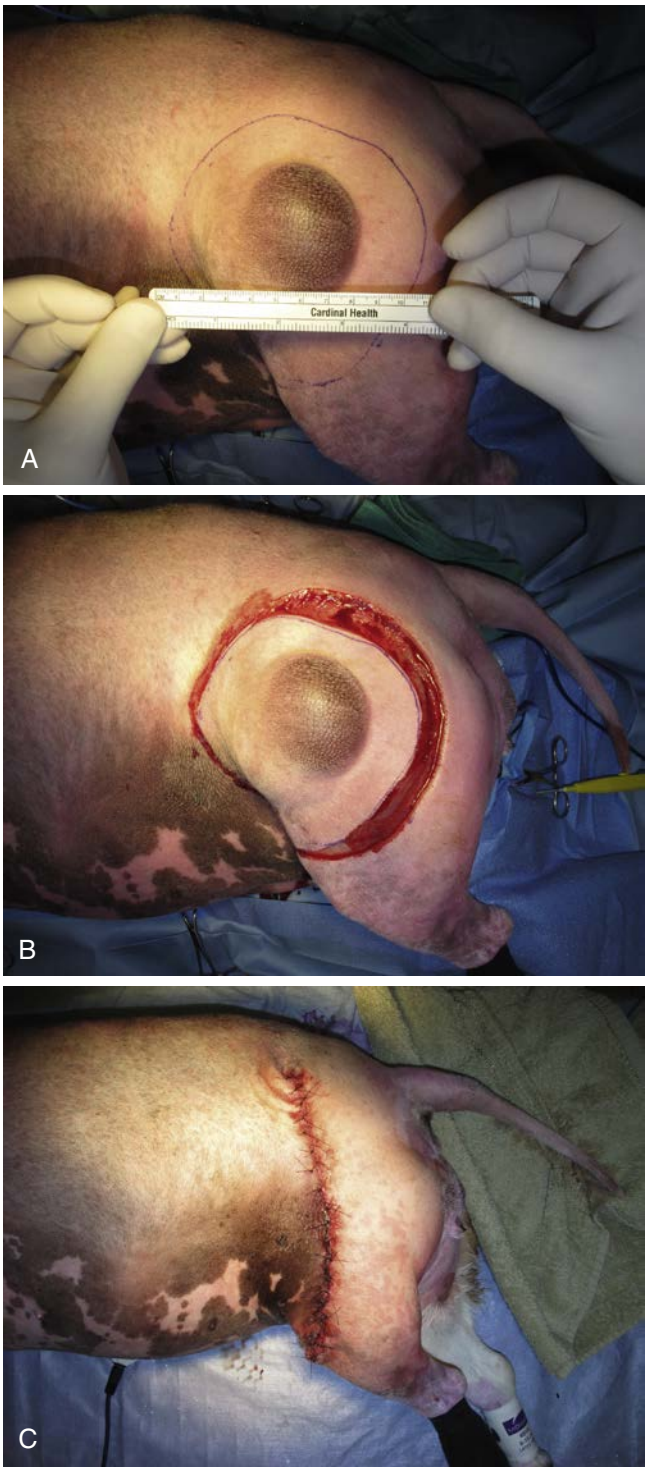
Diagnostic tests performed for workup and clinical staging include routine hematologic and serum biochemical blood tests, three-view thoracic radiographs, abdominal ultrasonography or advanced imaging, FNA or biopsy of the regional LNs, and regional imaging of the STS. Three-view thoracic radiographs should be performed before definitive treatment because the lungs are the most common metastatic site for typical STSs.[35] Although LN metastasis is uncommon, FNA or biopsy of regional LNs should be performed in dogs with clinically abnormal LNs, grade III STSs, or suspected nonconventional STSs with a high rate of metastasis to regional LNs (e.g., HS).[106] Abdominal imaging is recommended for the assessment of metastasis to intraabdominal organs in animals with high-grade pelvic limb STS. Imaging studies of the local tumor may be required for planning of the surgical approach or RT if the tumor is fixed to underlying structures or located in an area that may make definitive treatment difficult, such as the pelvic region. Three-dimensional (3D) imaging techniques such as CT and MRI are particularly useful for staging local disease.[107] Other imaging modalities for staging of the local tumor include survey radiographs and ultrasonography.[108]

Clinical Staging

A modified staging system has been described for STSs in dogs.[26] The American Joint Committee on Cancer (AJCC) staging system currently used in humans with STSs has been substantially modified from the original staging system, on which the modified animal staging system is based. The most important change to AJCC staging is categorization of local disease, with less emphasis on tumor size, which is an arbitrary assignment, and greater emphasis on depth of invasion.[81,109] A superficial tumor is defined as an STS located above the superficial fascia and that does not invade the fascia, whereas a deep tumor is located deep to the superficial fascia, invades the fascia, or both.[109]

Treatment

The predominant challenge in the management of cutaneous and subcutaneous STSs is local tumor control. As such, surgical resection is the principal treatment for dogs with STSs. RT may also play a significant role in local tumor control, especially for incompletely resected and unresectable STSs. However, definitive treatment options depend on tumor location, clinical stage, histologic grade, and completeness of histologic margins.[10,26,110] A suggested algorithm for managing dogs with STSs is presented in Fig. 22.7.

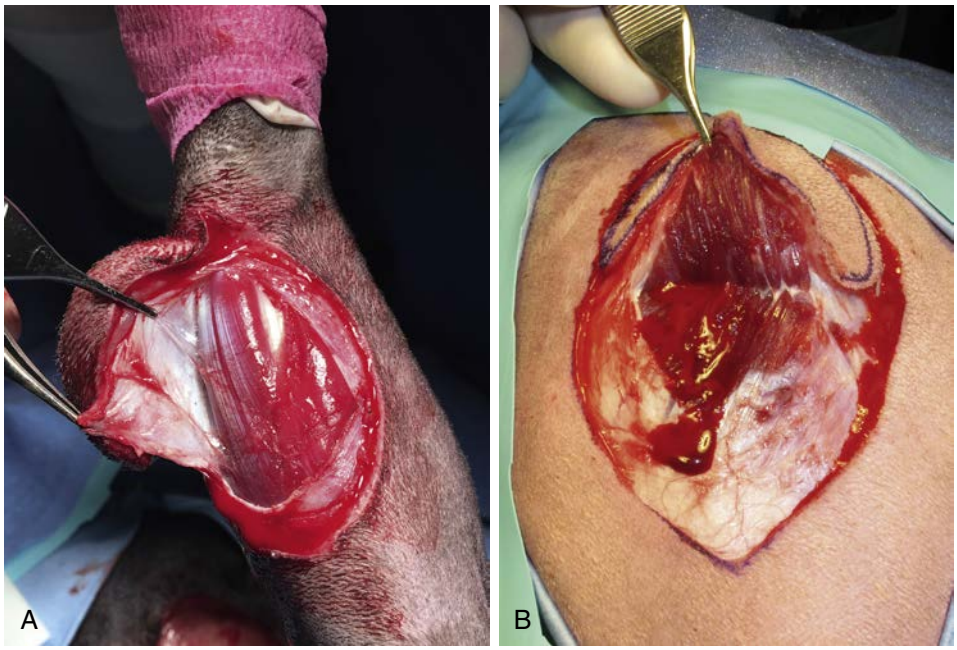


• **Fig. 22.7** Suggested algorithm for the treatment of soft tissue sarcomas in dogs.

Surgery

The surgical options for management of STSs include marginal resection, wide resection, or radical resection, and the preferred surgical approach can be tailored to each individual patient depending on location, size, degree of infiltration, histologic grade of the STS, and the outcome goals of the client. The majority of STSs are characterized by a locally expansile mass, but they can also be infiltrative.[111] This was supported by a histologic study showing that grade I and II STSs were significantly less invasive than low-grade mast cell tumors in both circumferential and deep directions.[112] STSs are often surrounded by a pseudocapsule formed by the compression of peritumoral connective tissue that may contain or be confluent with neoplastic tissue.[12,26] The pseudocapsule can give the false impression of a well-encapsulated tumor; however, surgical removal of the encapsulated mass without adequate margins may result in incomplete histologic margins and a higher risk of local tumor recurrence.[35] The minimum recommended margins for wide surgical resection of STSs are 2 to 3 cm lateral and one fascial layer deep to the tumor (Fig. 22.8),[10,13,103,110,113,114] although this is an arbitrary recommendation and does not account for tumor size, patient size, tumor location, or local tumor characteristics.[10,103,110,113,114] In one study of 22 dogs with 24 subcutaneous STSs, all STSs were completely excised with mean lateral and deep margins of 22.23 mm (range, 6–50 mm) and 7 mm (1–24 mm), respectively, with all deep margins including an uninvolved fascial plane (Fig. 22.9).[113] A proportional margin system, where the lateral surgical margins are equal to the maximal diameter of the tumor as validated for the resection of low-grade mast cell tumors,[115] may also be appropriate for the resection of STSs in dogs because incomplete histologic excision is significantly more likely after surgical resection of larger tumors and tumors in smaller patients [46,116] Biopsy tracts and any areas of fixation, including bone and fascia, should be resected en bloc with the tumor using the recommended surgical margins. Radical surgery such as limb amputation or hemipelvectomy may be required to achieve adequate histologic margins and local tumor control, especially for fixed and invasive STSs. Wide excision of STSs is associated with a significantly increased likelihood of complete histologic excision,[32] and dogs with complete histologic excision are 10.5 times less likely to have local tumor recurrence compared with dogs with incompletely excised STSs.[35]

Marginal excision may be an acceptable treatment option for well-circumscribed, noninfiltrative STSs less than 5 cm in diameter, and located on the limbs at or below the elbow or stifle. STSs in these locations tend to be less infiltrative and more well-circumscribed than STSs in other locations, such as the upper limbs and trunk (Fig. 22.10).[46,117] In one study of 236 dogs with subcutaneous STSs treated with excisional biopsy, the local recurrence rate was 0% for completely excised tumors and dependent on histologic grade for incompletely excised tumors, with 7% of grade I and 34% of grade II incompletely excised STSs developing local tumor recurrence.[118] Similar results have been reported in other studies after marginal excision of STSs from nonreferral practices and low-grade PWTs. In a study of 35 dogs with marginal excision of 37 low-grade STSs, the local recurrence rate was 11% and no prognostic factors for local recurrence were identified.[117] In a study of 104 canine STSs managed with surgery alone in nonreferral practices, which did not include undifferentiated



• **Fig. 22.8** Wide resection of a grade II soft tissue sarcoma from the craniolateral thigh of a dog. (A) Planned lateral surgical margins are indicated with a sterile marker pen 3 cm in all directions around the soft tissue sarcoma. (B) An incision is then performed along the marked margins, and continued deeply to include an uninvolved fascial layer. (C) Primary closure after wide resection of the soft tissue sarcoma.

STSs and liposarcomas, fewer than 10% were excised with 3 cm lateral margins, and local tumor recurrence was reported in 28% of dogs (29% of marginal excisions, 17% of narrow excisions, and 5% of wide excisions); local tumor recurrence was significantly more likely to occur with fixed and invasive STSs.[25] In two studies of dogs with PWTs, the local recurrence rate was 18% to 20.0% despite 60% to 63% of these tumors being incompletely excised.[46,111] The only prognostic factor for local recurrence in both studies was tumor size, with local recurrence up to 7.0 times more likely for PWTs greater than 5 cm diameter with the risk of local tumor recurrence increasing by up to 1.3 times for every 1 cm increase in tumor size.[46,111] In a study of 350 canine STSs treated surgically in nonreferral practices, the local recurrence rate was 21% despite only 5% of these STSs being excised with wide surgical margins.[34] Histologic grade was the only prognostic factor for local tumor recurrence in this study, with grade III STSs having a 5.8-fold increased risk for local recurrence compared with grade I and II STSs.[34] Taken in totality, these studies suggest that acceptable local tumor control rates are achievable with less aggressive surgical approaches; however, they also illustrate that the traditional consideration of STSs having a similar biologic behavior is overly simplistic. The ideal treatment for dogs with cutaneous and subcutaneous STSs should not necessarily be standardized but rather tailored to each individual case according to location, tumor size, degree of infiltration, histologic subtype, histologic grade, and completeness of excision. If insufficient information is available before surgery to individualize treatment options, then wide surgical resection (with 2–3 cm lateral margins and one fascial layer for deep margins) is the preferred surgical approach.

The resected tumor should be pinned out to the original dimensions to prevent shrinkage during formalin fixation[119]; the lateral and deep margins should be inked to aid in histologic identification of surgical margins; and any areas of concern should be tagged with suture material, inked in a different color, or submitted separately for specific histologic assessment. Histologic margins and histologic grade are important in determining the need and type of further treatment.

There are a number of limitations with our current ability to assess the adequacy of the completeness of the excision and risk of local tumor recurrence, and thus our ability to determine which patients require further therapy and which patients may benefit from monitoring. These include sample shrinkage after excision and during formalin fixation, the techniques used to assess margins histologically, the lack of information on the definition of a "narrow" histologic margin, and the significance of narrow margins on the risk of local tumor recurrence.[13,120] Perhaps most important is that histopathology is an examination of excised tissue ex vivo and not residual tissue in vivo, and that this assessment is made days after surgery rather than in real time. A number of advancements are being made in both veterinary and human surgical oncology in the real-time assessment of the wound bed after excision of STSs for residual neoplastic disease.[121–125] Hopefully, as these real-time in vivo assessment methods are validated and become available for clinical use, there will be an improvement in the rate of complete histologic excision and local tumor control.

The treatment options for incompletely excised STSs include active surveillance (i.e., frequent observation for local tumor recurrence and appropriate treatment if the tumor recurs), staging surgery, wide excision (i.e., revision surgery), RT, metronomic chemotherapy, and electrochemotherapy. The first surgery provides the best opportunity for local tumor control, as the management of incompletely resected tumors increases patient morbidity and treatment costs, increases the risk of further local tumor recurrence, and potentially decreases ST.[10,31,34,35,105,110,126–130] Active surveillance may be appropriate

• **Fig. 22.9** (A) Wide and marginal resection of soft tissue sarcomas should include an uninvolved fascial layer for deep margins or, (B) if a defined anatomic fascia layer is not present, then either partial or full thickness muscle.

for dogs with grade I and possibly grade II STSs with favorable local characteristics, such as well-circumscribed tumors, less than 5 cm in diameter, and located on either the thoracic or pelvic limb at or below the elbow or stifle.[25,34,46,110,111,117,118] Active surveillance may be appropriate in these cases because, as discussed earlier, local recurrence rates are relatively low (7% and 34% for incompletely excised grade I and II STSs, respectively)[118] and further aggressive treatment may be unnecessary in up to 93% of dogs (with incompletely grade I STSs), with an associated increased risk in morbidity and costs.

Staging surgery is a decision-making surgery. The surgical scar is excised with minimal margins (<1 cm), with the aim being to determine whether there is histologic evidence of residual tumor cells.[33] In one study in which the surgical scar was excised with 0.5- to 3.5-cm lateral margins, histologic evidence of residual tumor was identified in only 22% of 39 dogs with incompletely excised STSs.[33] If there is no evidence of tumor cells, then no further treatment is required and these dogs should be monitored regularly for local tumor recurrence. If there is evidence of residual tumor cells, then wide resection of the surgical scar should be performed with the same margins recommended for primary STSs (2–3 cm lateral to the tumor and one fascial layer deep to the tumor[10,13,103,110,113,114]) or the entire surgical scar should be irradiated.[128,129] Surgery is preferred to RT for the management of incompletely resected STSs in humans because local tumor control is better with repeat surgical resection than adjunctive RT alone.[128,129]

Metronomic (or low-dose) chemotherapy is another option for the management of dogs with incompletely excised STSs. The administration of piroxicam and low-dose cyclophosphamide in 30 dogs with incompletely excised STSs resulted in a significantly prolonged disease-free interval (DFI) compared with a nonrandomized control group of 55 dogs with incompletely excised STSs and no metronomic chemotherapy.[131] Of note, the control population used in this study experienced recurrence rates much greater than what is expected in the general population based on the preponderance of current data, perhaps weakening the generalizability of this study. Metronomic chemotherapy has been much less thoroughly studied than wide excision or postoperative RT, and should not be considered an equivalent substitute for these other modalities at this time. Additional studies are needed to confirm the efficacy of metronomic chemotherapy in the management of dogs with incompletely excised STSs.

Electrochemotherapy has also been investigated in the management of incompletely excised high-grade STSs in 22 dogs.[132] Bleomycin was injected into the tumor bed followed by sequential application of trains of biphasic electrical pulses. The local recurrence rate was 36% with a mean time to recurrence of 730 days.[132] Wound dehiscence was reported in 14% of dogs.

Surgery and Radiation Therapy

RT is often recommended in the management of dogs with STSs, particularly after incomplete histologic excision, and adjuvant RT has a documented role in improving local tumor control in people with STSs.[103,114,128,129] The evidence is less robust in veterinary medicine because all published studies of adjuvant RT in the management of dogs with incompletely excised STSs are retrospective and, more importantly, lack a control group. Local recurrence rates are similar in studies of dogs treated with marginal resection alone, compared with recurrence rates occurring in dogs with either marginal resection or incomplete histologic excision treated with adjuvant RT (fractionated or hypofractionated) or intralesional chemotherapy (Table 22.3); however, it is important to recognize that study results cannot be compared because of differences in study populations and methodologies. Furthermore, because canine STSs have a biologic behavior similar to that of low-grade STSs in people and because RT significantly improves local tumor control in people with incompletely excised STSs, RT should still be considered in the management of dogs with STSs.[114,128,129] RT can be used as an adjunct to surgery after either planned marginal resection or unplanned incomplete histologic excision. Marginal surgical

• **Fig. 22.10** (A) Marginal resection of a well-circumscribed, noninfiltrative, grade I soft tissue sarcoma below the level of the stifle in a dog. (B) Freely movable skin over the soft tissue sarcoma is carefully dissected away from the mass to avoid iatrogenic penetration of the tumor capsule and (C, D) permit primary closure of the subsequent wound defect. This soft tissue sarcoma was resected with complete histologic margins and the dog remains tumor-free 2 years postoperatively.

TABLE 22.3 Comparison of Local Tumor Control Outcomes for Dogs with Cutaneous and Subcutaneous Soft Tissue Sarcomas Between Different Treatment Modalities

	Local Recurrence Rate	Median Disease-Free Interval	1-Year Disease-Free Rate	2-Year Disease-Free Rate	3-Year Disease-Free Rate
Surgery[25,32,34,46,111,113,117,118]	Wide: 0%–5% Marginal: 11%–29%	368 days to not reached	89%–93%	78%–82%	66%–76%
Surgery[a] and fractionated radiation therapy[135–138]	17%–39%	412 days to not reached	71%–84%	60%–81%	57%–81%
Surgery[a] and hypofractionated Radiation therapy[140,141]	18%–21%	698 days to not reached	81%	73%	73%
Marginal surgical resection and intralesional chemotherapy[162–164]	17%–31%	264 days to not reached	81%–100%	69%–89%	59%–84%

VetBooks.ir

• **Fig. 22.11** Planned marginal resection of a soft tissue sarcoma in a dog. Marginal resection followed by full-course postoperative radiation therapy provides excellent local tumor control and preserves both the limb and limb function. Radiation therapy should not involve the limb circumferentially to preserve both lymphatic and venous drainage of the distal extremity. If close but clean margins were obtained for a grade I soft tissue sarcoma, observation alone may be an acceptable alternative.

resection combined with full-course postoperative RT is an attractive alternative to limb amputation for extremity STS (Fig. 22.11). This multimodality approach requires additional planning and costs, but preserves the limb and limb function. Surgery involves completely removing all grossly visible tumor and then marking the lateral, proximal, and distal extents of the surgical field with radiopaque clips to assist in planning of RT.[133] Migration of the radiopaque clips has been reported but does not significantly influence the planned radiation field.[133]

RT should be started a minimum of 7 days postoperatively to minimize the risk of radiation-induced complications with the surgical wound, such as delayed healing and dehiscence.[134] Full-course fractionated protocols are recommended, with reported schedules including 3.0- to 4.2-Gy fractions on a Monday-to-Friday or Monday–Wednesday–Friday schedule for a total dose of 42 to 63 Gy.[135–138] The optimal fractionation and total dose schemes for canine STS have not been determined, but cumulative doses greater than 50 Gy are recommended because local tumor control is better with higher cumulative doses.[135] Acute side effects of RT, such as moist desquamation, are relatively mild and transient.[136]

Local tumor control and ST are very good when incompletely resected STSs are treated with postoperative, definitively fractionated RT with local tumor recurrence reported in 16.7% to 36.8% of dogs,[135–137] and 1-, 2-, 3-, and 4-year local control rates of 71% to 84%, 60% to 81%, 57% to 81%, and up to 81%, respectively.[135,136,138] The local tumor recurrence rates may have been adversely affected by the inclusion of incompletely excised oral FSAs in one study.[135] The median time to local recurrence is 412 days to more than 798 days.[105,135–137] The median time to recurrence was significantly shorter in dogs with grade III STSs (78 days) compared with dogs with grade I and II STSs (>1416 days) in one study.[135] The overall MST for incompletely resected nonoral STSs treated with postoperative RT is 2270 days, with survival rates ranging from 80% to 87% at 1 year, 72% to 87% at 2 years, 92% at 3 years, and 76% at 5 years.[135–139] In one study, dogs with STSs with a mitotic index greater than 9 per 10 high-power fields (HPFs) were more likely to have local recurrence and shorter ST.[139]

Hypofractionated RT after either incomplete or close complete (<3 mm) histologic excision of STSs has also been reported with encouraging results.[140,141] Protocols reported have utilized weekly fractions of 6 to 9 Gy to a total dose of 24 to 36 Gy.[140] An 18% to 21% local recurrence rate was reported in these studies; however, the majority of STSs were initially small (median size 3.6 cm) and either grade I or II (83%).[140,141] Acute toxicity was mild, but late toxicities, although uncommon, were noted in both studies.[140.141] An increased risk of late toxicity generally occurs with larger radiation doses per fraction and this risk must be considered in a group of patients who are expected to survive for prolonged periods after RT. Progression-free intervals (PFIs) in these studies were 698 days to not reached, and the probability of being free of local tumor recurrence at 1, 2, and 3 years was 81%, 73%, and 73%, respectively.[140,141] In one study, delaying hypofractionated RT for more than 4 weeks after surgery was associated with an improved outcome, with local recurrence nine times more likely in dogs in which RT was started less than 4 weeks after surgical excision.[140] Histologic grade was prognostic for both median PFS and OST in one study.[141] Median PFS times were 1904 days, 582 days, and 292 days for dogs with grade I, II, and III STSs, respectively; the median tumor-specific OST was not reached for dogs with grade I and II STSs, but was 940 days for dogs with grade III STSs.[141]

Radiation Therapy for Gross Disease

RT can also be used a single modality, usually for palliation of clinical signs. RT alone, using a cumulative dose of 50 Gy, resulted in 1- and 2-year tumor control rates of 50% and 33%, respectively.[142] Measurable and palpable (i.e., macroscopic) STSs are resistant to long-term control with conventional doses of radiation alone (40–48 Gy).[143,144] Although one study reported a 30% complete response rate with RT alone,[145] these tumors do not rapidly regress after RT and, if there is significant tumor shrinkage, it is not usually a durable response.

Hypofractionated RT has been reported for the treatment of macroscopic STSs using a number of different protocols, including 3 to 4 fractions of 8 Gy once weekly for a total dose of 24 to 32 Gy, 5 to 6 fractions of 6 Gy once to twice weekly for a total dose of 30 to 36 Gy, and 5 fractions of 4 Gy for a total dose of 20 Gy.[146–150] The results of hypofractionated RT are similar to those of full-course RT in the gross disease setting. In two studies, the overall response rate was 46% to 50%,[146,148] whereas stable disease was more common in two other studies.[147,149] The median PFI ranged from 155 to 419 days.[146–150] Prognostic factors for median PFI include tumor location and previous surgeries. The median PFI is significantly better for limb STSs (466 days) than STSs located on the head or trunk (110 days), and dogs treated with more than one surgery had a significantly decreased median PFI (105 days) compared with dogs treated with one or no surgery (420 days).[148] The MST after hypofractionated RT for macroscopic STS is 206 to 513 days.[146–150] STS location has a significant effect on MST, with STSs located on the limbs (579 days) having a better outcome than those on the head (195 days) or trunk (190 days).[148] In this study, 40% of dogs were also treated with metronomic chemotherapy. Metronomic chemotherapy did not improve median PFIs, but this adjunctive treatment did significantly improve MSTs (757 days compared with 518 days for dogs not treated with metronomic chemotherapy).[148]

Preoperative RT is becoming commonplace in veterinary oncology. The rationale and advantage of administering RT before surgery are that (1) the radiation field is smaller because, after

surgery, the entire surgical site must be included in the field plus a margin of normal tissue and this may contribute to local toxicity; (2) a large number of peripheral tumor cells are inactivated (with reduced contamination of the surgical site); and (3) tumor volume reduction may make surgical resection less difficult.[15,151–153] In a randomized phase III human trial of preoperative compared with postoperative RT, wound complications were found to be higher in people treated with preoperative RT (35% vs 17%); however, OST was found to be marginally improved in patients treated with preoperative RT.[154] Other studies, including a meta-analysis of 1098 patients, have confirmed these findings and further suggested that both local recurrence rates and ST may be improved in patients treated with preoperative RT.[155] Lower doses of preoperative RT (<50 Gy) are generally used to reduce the risk of surgical complications.

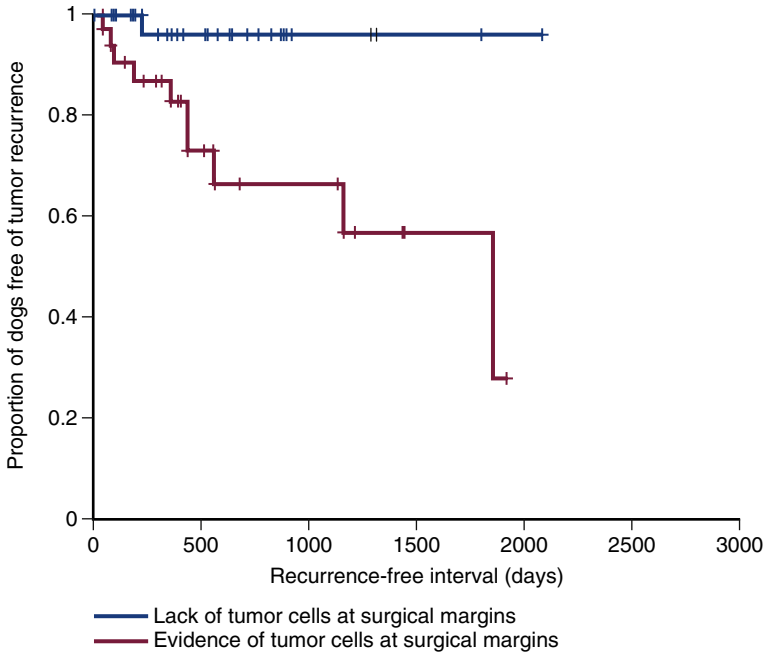
Chemotherapy

The role of chemotherapy in the management of dogs with STS is controversial. The metastatic rates for dogs with grade I, II, and III cutaneous STSs are 0% to 13%, 7% to 27%, and 22% to 44%, respectively.[31,35,156] Metastasis often occurs late in the course of disease, with a median time to metastasis of up to 365 days,[35] and this may minimize the beneficial effects of postoperative chemotherapy on the development of metastatic disease. In one retrospective study of 39 dogs with grade III STSs arising from various locations, including noncutaneous and subcutaneous sites, treated with either surgery alone (n = 18) or surgery and doxorubicin (DOX) (n = 21), there was no significant difference in survival outcomes with the addition of DOX to the treatment protocol.[156] An alternating protocol of DOX and ifosfamide was reported in 12 dogs with various STSs after surgical excision, but survival outcomes were not investigated because of low case numbers.[157] DOX and ifosfamide are the most effective single agents in the management of STS in humans, but meta-analyses show that single- and multiple-agent chemotherapy protocols do not significantly increase OST compared with surgery alone in people.[158,159]

Although adjuvant chemotherapy has not shown the same effect on local tumor control in dogs with STSs as it does in people,[158] metronomic and local chemotherapy protocols may be effective in decreasing the rate of local tumor recurrence and improving DFIs in dogs with STSs. Metronomic chemotherapy improves local tumor control in experimental and human studies by inhibiting tumor angiogenesis and suppressing regulatory T cells, and a similar effect was demonstrated in dogs with STSs treated with low-dose cyclophosphamide at a dose of 15.0 mg/m^2/day, but not 12.5 mg/m^2/day.[160] Clinically, metronomic chemotherapy improved ST in dogs with macroscopic STSs treated with hypofractionated RT.[148] Although not investigated clinically, there may be a role for tyrosine kinase inhibitors in the management of STS because increased vascular endothelial growth factor (VEGF) and VEGF receptor expression has been demonstrated in the peri- and intratumoral regions of canine STSs.[161–163] Furthermore, VEGF has been postulated to have a role in the angiogenesis of canine STSs because serum VEGF levels decrease after STS excision.[164]

The effect of the local release of chemotherapy on local tumor recurrence rates after marginal excision of STSs has been investigated in dogs. Intralesional chemotherapy agents include cisplatin, released locally from either a biodegradable polymer or calcium sulfate and dextran sulfate beads implanted into the surgical bed, and 5-fluorouracil, injected weekly for a minimum of six treatments.[165–168] Local recurrence was reported in 17% to 31%, and this was significantly more likely for dogs with grade III STSs.[162–164] Wound complications are common after treatment with intralesional chemotherapy and are reported in 47% to 84% of dogs.[163–167]

Prognosis



Local Tumor Recurrence

Local tumor control is often the most challenging aspect of managing STSs, but this is dependent on a number of factors including tumor size, local tumor characteristics such as well-circumscribed or infiltrative, tumor location, histologic grade, completeness of histologic excision, and treatment methods. The overall local recurrence rates are 0% to 5% after wide resection,[25,113] 11% to 29% after marginal resection,[25,34,46,111,117,118] 17% to 37% after incomplete histologic excision and fractionated RT,[135–137] and 18% to 21% after incomplete histologic excision and hypofractionated RT (see Table 22.2).[140,141] The DFIs and local tumor control rates are also similar between the different treatment options, with a median DFI of 368 to 637 days to not reached and disease-free rates of 89% to 93%, 78% to 82%, and 66% to 76% at 1, 2, and 3 years, respectively, after surgery alone[32,34,35,46,113]; a median DFI of 412 to more than 798 days and disease-free rates of 71% to 84%, 60% to 81%, 57% to 81%, and up to 81% at 1, 2, 3, and 4 years, respectively, for incomplete excision and fractionated RT[135,136,138]; and a median DFI of 698 days to not reached and disease-free rates of 81%, 73%, and 73% at 1, 2, and 3 years, respectively, after incomplete excision and hypofractionated RT.[140,141] Poor prognostic factors for local tumor control include large tumor size (>5 cm), infiltrative tumors, tumors in locations other than the limbs at or below the elbow or stifle, histologic subtypes, grade III STSs, and incomplete surgical margins.

In one study of 75 dogs, the local tumor recurrence rate after incomplete histologic excision was 28% and 11 times more likely compared with STSs resected with complete histologic margins (Fig. 22.12).[35] Complete histologic excision is significantly more likely when STSs are treated with wide resection rather than more conservative approaches,[31,32] and complete histologic excision is associated with long-term survival in up to 98% of dogs with STSs.[31,32,35,113] Despite the importance of complete histologic excision in the management of dogs with STSs, incomplete excision has infrequently been identified as a prognostic factor for local tumor recurrence after marginal resection,[25,118] with the majority of studies showing no significant association between incomplete histologic excision and local tumor recurrence.[34,46,111,117]

Histologic grade has an effect on local tumor recurrence both overall and after incomplete histologic excision. Grade III STSs have a six-fold greater risk for local recurrence compared with low-grade tumors.[34] In one study of 236 dogs with subcutaneous STSs treated with excisional biopsy, the local recurrence rate was 0% for STSs excised with complete histologic margins and 19% overall for incompletely excised STSs.[118] The recurrence rate for incompletely excised grade I, II, and III STSs was 7%, 34%, and 75% (three of four) respectively.[118]

Histologic subtype may also be associated with local tumor recurrence; however, it is important to recognize that differentiating histologic subtypes of STSs can be problematic, even with IHC.[12,114] PWTs are often associated with a low risk of local tumor recurrence,[12,34] whereas FSAs have been associated with a higher local recurrence rate.[32–34]

• **Fig. 22.12** Kaplan–Meier curve for disease-free interval in 39 dogs with complete surgical removal of soft tissue sarcomas and 36 dogs with incomplete surgical margins. (Reprinted with permission from Kuntz CA, Dernell WS, Powers BE, et al: Prognostic factors for surgical treatment of soft-tissue sarcomas in dogs: 75 cases (1986–1996), *J Am Vet Med Assoc* 211:1147, 1997.)

Local tumor characteristics also influence local tumor control. Tumor size has been reported to have a negative effect on local tumor control, especially for incompletely excised STSs.[35,46,111] Local tumor recurrence is up to 7.0 times more likely after marginal resection of PWTs greater than 5 cm diameter and the risk of local tumor recurrence increases by up to 1.3 times for every 1 cm increase in tumor size.[46,111] This may be because a large tumor size influences the ability to achieve complete histologic excision or because a larger tumor size may indicate a more aggressive biologic behavior.[46,116] Tumor size has not been identified as a prognostic factor in other studies,[32,33,139,169] and does not influence local tumor control in dogs treated with surgery and adjuvant RT or RT alone.[142,169,170] Dogs with fixed or invasive STSs have significantly decreased DFIs and STs.[34] Invasive or fixed tumors are associated with a two-fold increased risk for local recurrence compared with well-circumscribed STSs after marginal resection,[25] and PWTs invasive into muscle were eight times more likely to recur after marginal resection.[32,111]

Local tumor recurrence has been associated with an increased risk of tumor-related death and decreased STs in some studies.[31,34] In one study of 350 dogs with STSs managed in nonreferral practices, local tumor recurrence was associated with a 5-fold risk of death.[34] Although many dogs can live with recurrent STSs, local recurrence is more difficult to manage and may result in owners electing euthanasia rather than pursuing further treatment. The median postrecurrence ST for dogs euthanized because of their local tumor recurrence is 256 days and this is significantly worse than the 945 days median postrecurrence ST for dogs with local recurrence that die of unrelated reasons.[34] This underscores the importance of wide excision of STSs initially, as the management of recurrent STSs is usually more difficult with curative-intent treatment of recurrent STSs requiring a more aggressive approach, resulting in increased treatment-related morbidity with the potential for shorter DFIs, higher metastatic rates, and poorer STs.[32,113,126–130] Local tumor recurrence is still possible after either complete resection or incomplete resection combined with adjunctive RT.[35,135–138] Consequently, examination of the treatment site is recommended at regular intervals, such as monthly for the first 3 months, then every 3 months for the first 12 months, and then every 6 months thereafter.[10,110] The median time to local tumor recurrence varies from 368 to greater than 798 days, which emphasizes the need for long-term follow-up in these cases.[32,34,35,46,113,135–137,140,141]

Metastasis

The overall metastatic rate in dogs with STS varies from 0% to 31%, with a median time to metastasis of 230 to 365 days.[31–34,35,46,113,135–138,141] Factors that increase the risk of metastatic disease include histologic grade, number of mitotic figures, percentage of tumor necrosis, and local tumor recurrence. The metastatic rates for dogs with grade I, II, and III STSs are 0% to 13%, 7% to 27%, and 22% to 44%, respectively.[31,35,156] Metastasis is significantly more likely in dogs with pleomorphic and undifferentiated sarcomas compared with FSAs, PNSTs, myxosarcomas, and liposarcomas.[31] Metastasis is five times more likely when tumors have a mitotic rate of 20 or more mitotic figures/10 HPF compared with fewer than 20 mitotic figures/10 HPF.[35] In one study, no dog with a STS at or below the level of the elbow or stifle developed metastatic disease.[35]

Survival

The MST for dogs with STS ranges from 1013 to 1796 days after surgery alone to 2270 days with surgery and adjunctive RT for nonoral STSs.[25,34,35,135,136] However, the majority of studies report MSTs that cannot be calculated because only 9% to 33% of dogs eventually die of tumor-related causes after curative-intent

VetBooks.ir

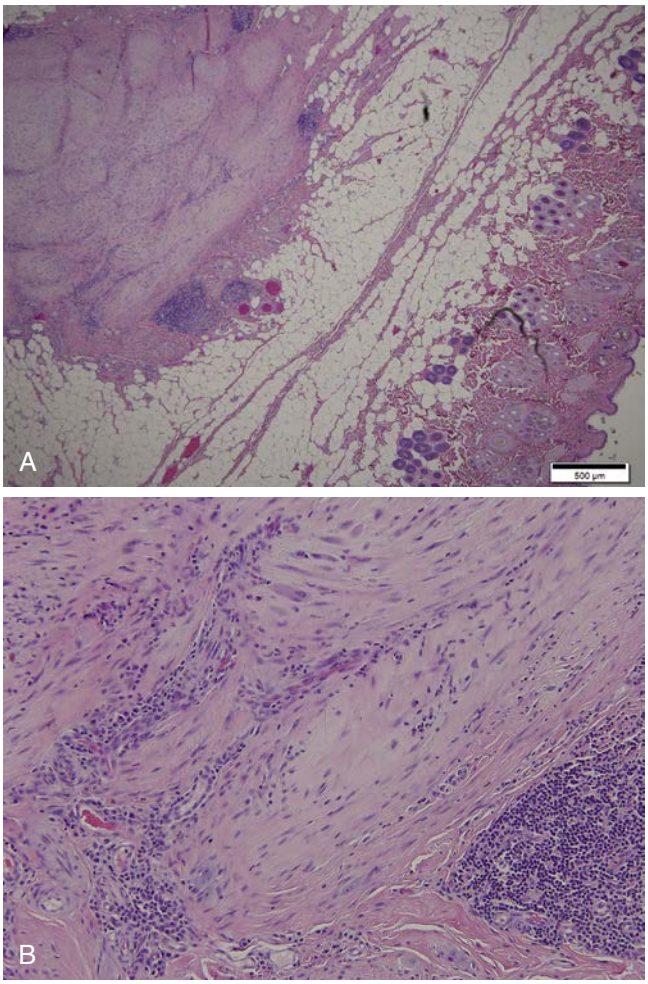
treatment.[25,31–35,113,117,118,136,140,141] The 1-, 2-, 3-, 4-, and 5-year survival probabilities are 80% to 94%, 72% to 87%, 61% to 81%, 81%, and 76% respectively.[34,141]

Clinical factors associated with decreased ST include tumor invasiveness, surgical approach, completeness of excision, and local tumor recurrence, all of which may be related to some degree. Dogs with grossly invasive and fixed STSs have a 5-fold increased risk of tumor-related deaths,[25,34] presumably because of greater difficulty in achieving complete excision of their STSs. Dogs treated with wide surgical resection have a MST of greater than 1306 days compared with 264 days for dogs treated with non–curative-intent surgeries.[31] The MST for dogs with incompletely excised STSs is 657 days, and this is significantly worse than the MST of greater than 1306 days for dogs with completely excised STSs.[31] Dogs with local tumor recurrence have a 5-fold risk of tumor-related death.[34]

Histologic and IHC features associated with survival include tumor necrosis, mitotic rate, histologic grade, argyrophilic nucleolar organizer region (AgNOR) score, and Ki67 score.[31,34,35] Tumor-related deaths are three times more likely with greater than 10% tumor necrosis and three times more likely with a mitotic rate of 20 or more mitotic figures/10 HPFs.[35] The MSTs for dogs with 10 or fewer, 10 to 19, and 20 or more mitotic figures/10 HPFs are 1444 days, 532 days, and 236 days, respectively.[35] Histologic grade was prognostic in two adjuvant RT studies with an MST not reached and greater than 1461 days for dogs with grade I and II STSs compared with 78 days for dogs with grade III STSs in one study of incompletely excised STSs treated with fractionated RT,[135] and a 940-day MST for dogs with grade III STSs compared with an MST not reached for dogs with grade I and II MSTs in dogs treated with incomplete excision and hypofractionated RT.[141] The MSTs and survival rates for dogs with STSs with AgNORs below and above the median AgNOR scores were greater than 1188 days and 76% versus greater than 1306 days and 53%, and dogs with an increased AgNOR score are 77 times more likely to die as a result of their disease.[31] Similarly, MSTs and survival rates for dogs with STSs with Ki67 scores below and above the median AgNOR scores were MST greater than 1188 days with 94% survival versus 657 days, and dogs with an increased Ki67 score are 12 times more likely to die as a result of their disease.[31]

Feline Sarcomas and Injection-Site Sarcomas

Epidemiology and Risk Factors



The following events are linked to the development of postvaccinal sarcomas in the cat. The prevalence of feline rabies led to the enactment of a law in Pennsylvania in 1987 requiring rabies vaccinations for cats.[171] In addition, two changes in vaccines occurred in the mid-1980s: development of a killed rabies vaccine licensed for subcutaneous administration and a killed vaccine for feline leukemia virus (FeLV). Epidemiologic studies have shown a strong association between the administration of inactivated feline vaccines, such as rabies and FeLV, and subsequent development of STSs at vaccination sites.[172–179] This is further supported by the significant decrease in interscapular injection-site sarcomas (ISSs) and significant increase in body wall and left and right pelvic limb ISSs since the recommendations of the Vaccine-Associated Feline Sarcoma Task Force (VAFSTF) were published in 2001.[180,181] Some authors report the reaction to vaccines was additive and this increased the likelihood of sarcoma development with multiple vaccines given at the same site simultaneously.[175] The prevalence of sarcoma development of at sites of vaccine administration has been estimated between 1 to 4/10,000 cases,[176,182,183] but as high as 13 to 16/10,000 cases.[177,184,185] The ratio of ISSs to non-ISSs has increased from 0.5 in 1989 to 4.3 in 1994.[186]

The time to tumor development postvaccination has been reported to be 4 weeks to 10 years, and is associated with a robust inflammatory reaction around the tumor.[176] Adjuvant-containing vaccines have been proposed to be more likely to cause a vaccine site reaction and/or develop into an ISS[176]; however, three large epidemiologic studies did not provide evidence that aluminum-containing vaccines pose a greater risk,[175,178,187] and thus it remains unclear whether nonadjuvanted vaccines are safer.[180,187,188] A multicenter study of cats in the United States and Canada found that no single vaccine manufacturer or vaccine type had a higher association with the development of ISSs.[178] Cats with pelvic limb ISSs are significantly more likely to have been vaccinated with an inactivated rabies vaccine than a recombinant rabies vaccine, and cats with interscapular ISSs were more likely to have received long-acting corticosteroid injections.[187] Vaccination practices such as needle gauge, syringe reuse, use and shaking of multidose vials, mixing vaccines in a single syringe, and syringe type had no role in the development of tumors.[178]

Although no vaccine type has been associated with a higher risk of ISS development, nonadjuvanted vaccines are associated with less tissue inflammation compared with adjuvanted vaccines.[180] ISSs are hypothesized to develop from an inflammatory reaction induced by injectable medications that leads to uncontrolled fibroblast and myofibroblast proliferation and eventual tumor formation, either alone or in association with immunologic factors.[189–193] The thought that inflammation precedes tumor development is supported by histologic identification of transition zones from inflammation to sarcoma and microscopic foci of sarcoma located in areas of granulomatous inflammation (Fig. 22.13). A similar phenomenon of intraocular sarcoma development exists in cats after trauma or chronic uveitis.[194–197] ISSs have also been reported to arise at sites of injections other than vaccines such as lufenuron, long-acting steroids, nonsteroidal antiinflammatory drugs, cisplatin, vascular access ports, deep nonabsorbable sutures, and microchips,[187,198–204] and for this reason the term ISS is preferred to vaccine-associated sarcoma.

Growth factors regulate the cellular events involved in granulation tissue formation and wound healing. When these factors are added to fibroblast cultures, the cells develop a neoplastic phenotype. IHC identification and localization of growth factors and their receptors are being investigated in ISSs. ISSs are immunoreactive for platelet-derived growth factor (PDGF), epidermal growth factor and its receptors, and transforming growth factor (TGF)-β. Conversely, non–injection-site FSAs are negative or faintly positive for these factors and their receptors.[205,206] Lymphocytes in ISSs are positive for PDGF, but lymphocytes in non–injection-site FSAs and normal LNs are negative for PDGF.[205] Regional macrophages also stain positively for PDGF receptor (PDGFR). Neoplastic cells that are closest to lymphocytes in these tumors have the strongest staining for PDGFR, which has led to a hypothesis that lymphocytes in ISSs may secrete PDGF, recruit macrophages, and lead to fibroblast proliferation.[205,206] The expression of c-*jun*, a proto-oncogene coding for the transcriptional protein AP-1, has also been examined in ISSs. c-*jun* was found to be strongly positive in ISSs and not expressed in non–injection-site FSAs.[205,206] FeLV and the feline sarcoma virus are not involved in the pathogenesis of feline ISSs.[207]

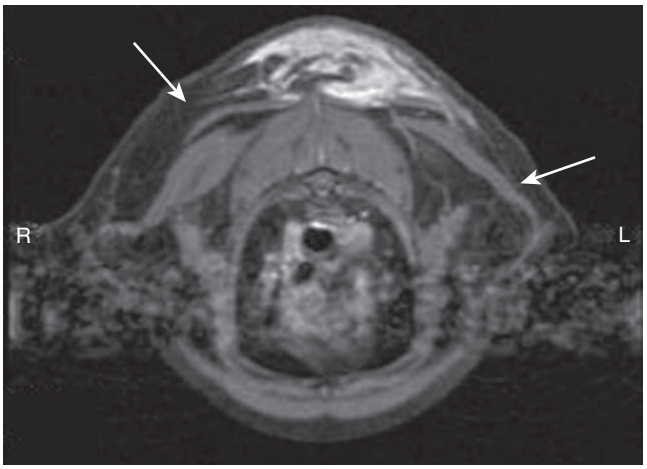
Studies have attempted to link growth factors with development of ISSs in cats. Continued immunohistochemical probing of feline ISSs documents expression of growth-regulating proteins: p53 protein, basic fibroblast growth factor, and TGF-α.[208] Researchers recently concluded that PDGF and PDGFR play an important role in the in vitro growth of ISS cell lines, both alone and in the presence of chemotherapeutic agents.

Pathology

There are many similarities between histologic subtypes and biologic behavior of STSs in cats and dogs. The three principal exceptions in cats are ISSs, virally induced multicentric FSA, and the relative rarity of PNST, SCS, and HS.[192,209] There are significant differences between ISSs and non-ISSs. Clinically, ISSs are usually large with a rapid growth rate and typically arise from the subcutis at sites consistent with the administration of vaccines and other injections, such as the interscapular region, body wall, and pelvic limbs (Fig. 22.14), whereas non-ISSs are smaller, slower growing, and will often arise from the skin rather than



• **Fig. 22.14** The typical gross appearance of a feline injection-site sarcoma with a firm, large, multilobulated subcutaneous or cutaneous mass arising at a location consistent with the administration of a vaccine or other injections, such as the interscapular region, body wall, or pelvic limbs (pictured).

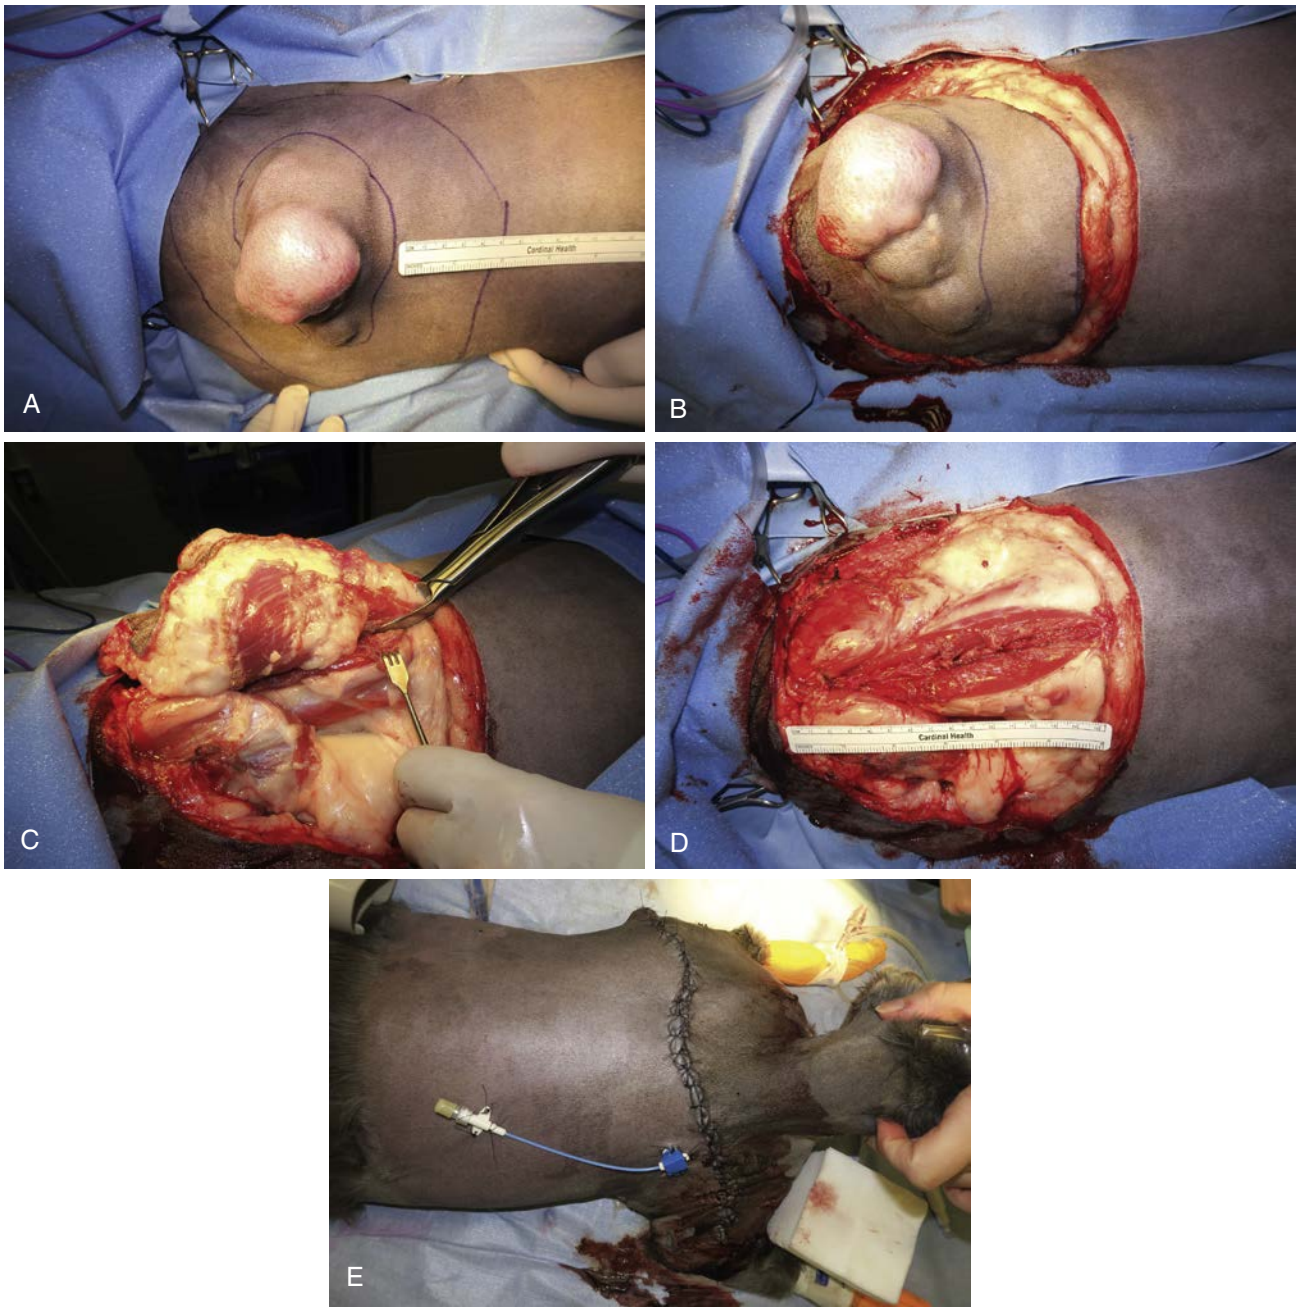
subcutaneous tissue.[174,210,211] ISSs are typically mesenchymal in origin and include FSAs, rhabdomyosarcomas, MFHs, undifferentiated sarcomas, and extraskeletal osteosarcomas and chondrosarcomas.[205,212,213] ISSs have histologic features consistent with a more aggressive biologic behavior than non–ISSs, such as marked nuclear and cellular pleomorphism, increased tumor necrosis, high mitotic activity, multinucleate giant cells, and the presence of a peripheral inflammatory cell infiltrate consisting of lymphocytes and macrophages.[172,185,186,193,205] In a series of 91 cats with histologically confirmed and graded ISSs, the prevalence of high-grade lesions was substantially higher than reported in dogs,[35] with 59% of cats diagnosed with grade III tumors and only 5% with grade I tumors.[214] Microscopically, areas of transition between inflammation and tumor development are frequently observed in cats with ISS.[205,215] The macrophages in these peripheral inflammatory cell infiltrates often contain a bluish-gray foreign material that has been identified as aluminum and oxygen by electron probe x-ray microanalysis.[192] Aluminum hydroxide is one of several adjuvants used in currently available feline vaccines.[192] Although nonadjuvanted vaccines are currently available for FeLV and rabies, it is unknown if these vaccines are less likely to result in sarcoma formation, especially as studies have shown that all vaccines have the potential to cause ISSs.[180,187,188] ISSs are histologically similar to mesenchymal tumors arising in the traumatized eyes of cats, which suggests a common pathogenesis of inflammation and the development of STSs in these cats.[196,197,206] The presence of inflammatory cells, fibroblasts, and myofibroblasts in and adjacent to ISSs supports this hypothesis.[26,216,217]

Diagnosis and Workup

The diagnostic techniques and clinical staging tests recommended for cats with suspected ISSs are similar to those described in dogs earlier in this chapter. Advanced imaging, such as contrast-enhanced CT or MRI, is recommended for local staging of the tumor because these 3D imaging modalities provide essential information for proper planning of surgery and/or RT (Fig. 22.15).[192,218–223] The volume of tumor based on contrast-enhanced CT is larger than the volume measured using calipers during physical examination.[191,223] Furthermore, the presence

• **Fig. 22.15** Contrast-enhanced magnetic resonance imaging of a cat with an injection-site sarcoma. Note the fingerlike projections of the tumor (*arrows*).

of skip metastases on CT scans was significantly associated with local tumor recurrence.[222] Although CT and MRI are both very sensitive for the detection of the peritumoral extent of disease in cats with suspected ISSs, up to 59% of these peritumoral lesions are nonneoplastic when examined histologically.[221] Moreover, the low-field MRI characteristics of ISSs can vary and this may be influenced by previous incisional or excisional biopsies.[218] For interscapular ISSs, it is important to perform postcontrast CT scans with the thoracic limbs extended cranially and caudally along the body to permit better evaluation of the relationship between the ISS and the adjacent tissue.[219] Accurate pretreatment knowledge of the extent of disease is important because ISSs are very invasive, are frequently located in areas in which regional anatomy can complicate an aggressive surgical approach (e.g., interscapular area, body wall, and proximal pelvic limb), and have a high rate of local tumor recurrence, especially if incompletely excised. Excisional biopsy of a suspected ISS is not recommended because the risk of local tumor recurrence is increased, and DFI and ST are significantly decreased.[224,225]



Treatment

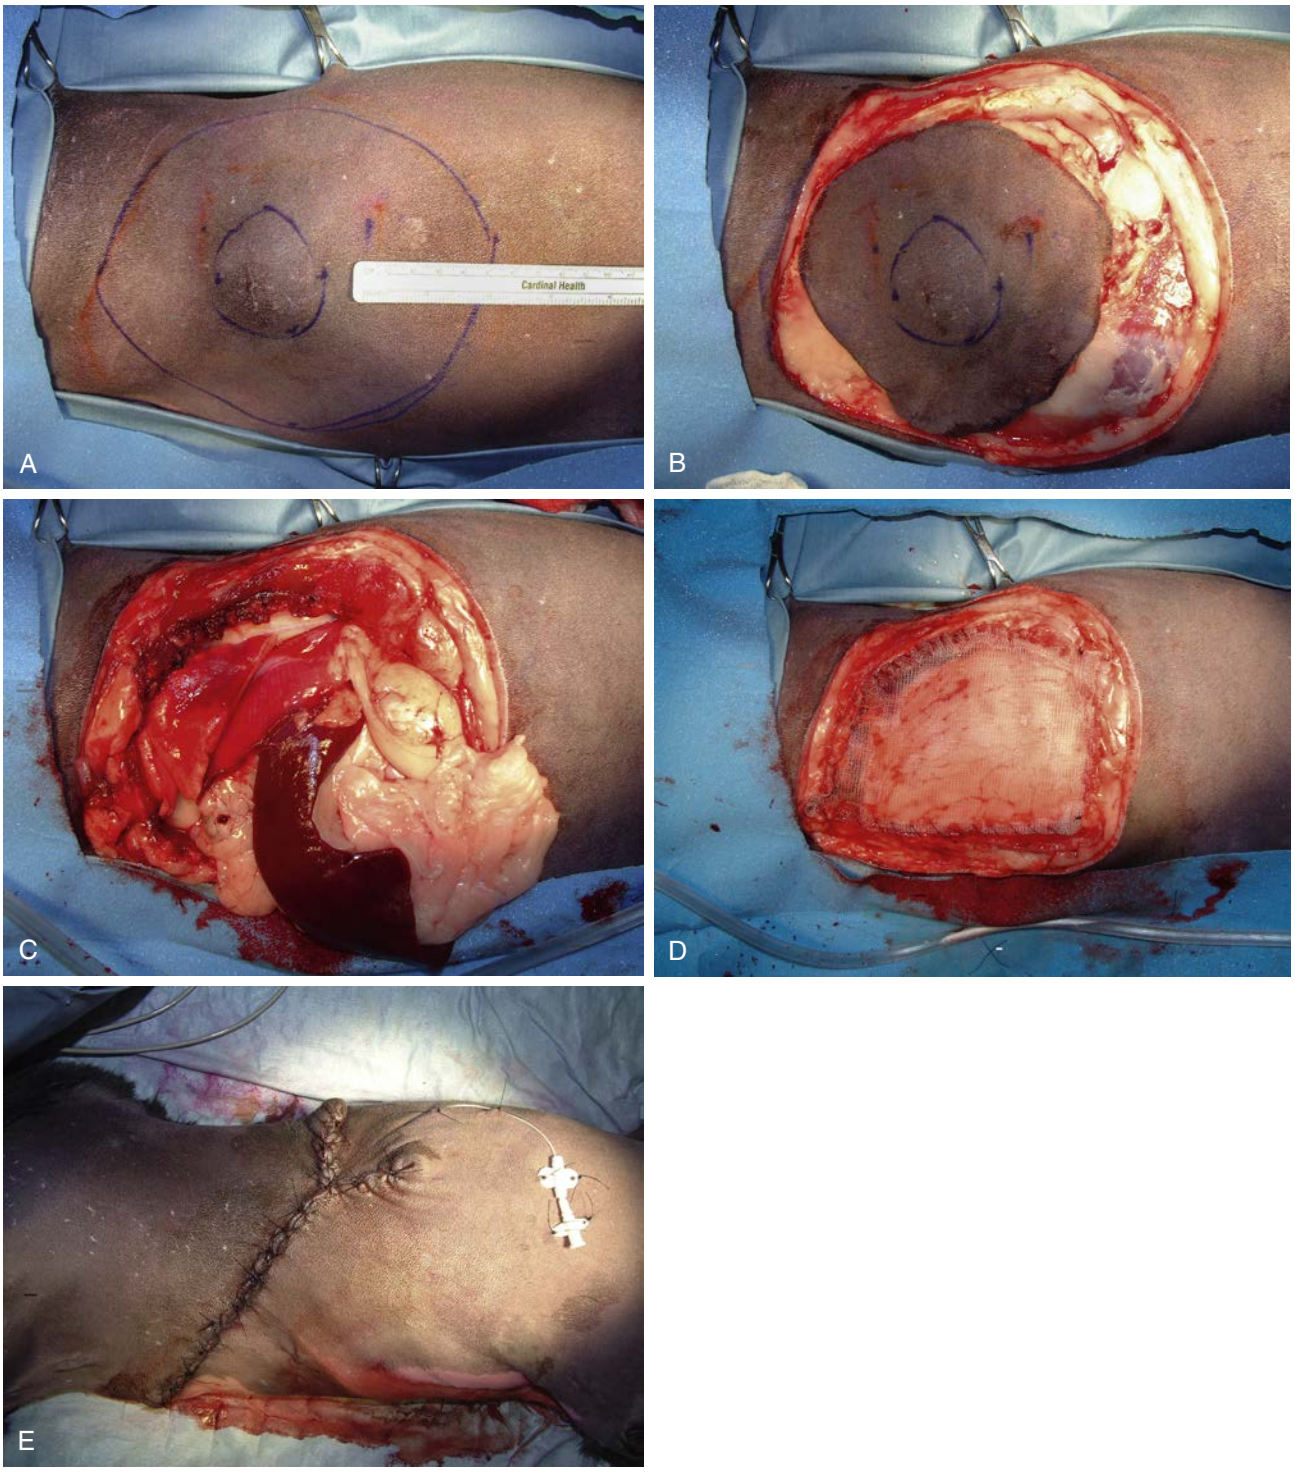
Surgery

ISSs are poorly encapsulated tumors with extension and infiltration along fascial planes.[215,216] The VAFSTF has recommended surgical resection with a minimum of 2 cm margins both lateral and deep to the tumor[192]; however, this recommendation is now considered inadequate. The preferred approach is based on how the extent of the ISS is assessed, with 5-cm lateral margins and two fascial layers for deep margins recommended when the extent of disease is based on gross palpation, whereas 3-cm lateral margins and one fascial layer for deep margins are recommended when the extent of disease is based on contrast-enhanced CT scans.[214,226,227] Only 50% of ISSs are completely excised when resected with 2- to 3-cm lateral margins compared with 95% to 97% when excised with 4- to 5-cm lateral margins.[214,224–226] Marginal resection or excisional biopsy should not be attempted. The median DFI and MST are significantly decreased with marginal resection, with more than one attempt at surgical resection, and if surgery is performed by nonreferral surgeons.[214,224,225] The median time to first recurrence after marginal resection is 79 days compared with 325 to 419 days for wide resection or radical surgery.[224] In addition, the median time to first recurrence is only 66 days when the first surgery is performed at a nonreferral institution compared with 274 days at referral institutions.[224] Inadequate biopsy planning, preoperative staging, and/or attempts at first surgery will result in an increase in tumor margins and may make further surgical treatment more difficult to impossible. The first attempt at surgical management of cats with ISSs should be performed by a referral surgeon with experience in aggressive resection, especially in the interscapular, body wall, or pelvic regions, to increase the chance of a successful outcome.[214,224–228] Similar to dogs with STSs, biopsy tracts and any areas of fixation, including bone and fascia, should be resected en bloc with the tumor. In cats with ISSs, wide surgical resection of tumors located in the interscapular region will often involve excision of dorsal spinous processes (Fig. 22.16), whereas thoracic or body wall resection is often required for truncal tumors (Fig. 22.17).[224,225] Limb amputation or hemipelvectomy is usually required to achieve adequate surgical margins and local tumor control for ISSs located on the extremity.[214]

Local tumor control is very good if the ISS is treated aggressively with 5-cm lateral margins and one to two fascial layers for deep margins, or compartmental resections. When the VAFSTF recommendations of 2- to 3-cm lateral margins and one fascial layer for deep margins are used, complete resection is achieved in fewer than 50% of cats and overall 1- and 2-year disease-free rates are only 35% and 9%, respectively.[224,225] In comparison, the complete excision rate is 97% and the local recurrence rate is 14% at 3 years when ISSs are resected with 5-cm lateral margins and two fascial layers for deep margins, including ISSs located in the interscapular region, body wall, and extremities.[214] These findings are supported by an earlier study of 57 cats treated with 4- to 5-cm lateral margins and one fascial layer for deep margins, in which complete histologic excision was achieved in 95% of cats.[226] Chest wall and body resection, using a minimum of 3-cm margins, was well tolerated in six cats and local tumor recurrence was not reported in any of these cats at a minimum of 12 months postoperatively.[228] Compartmental resections of interscapular ISSs, in combination with neoadjuvant epirubicin, resulted in a local recurrence rate of 14% in 21 cats after a median follow-up time of 1072 days.[229] Despite these aggressive approaches, major wound healing complications are relatively uncommon, with wound dehiscence reported in 11% to 17% of cats.[214,227] Wound dehiscence is more common after wide resection of interscapular ISSs compared with other locations[214] and in overweight cats, cats with larger tumors, ISSs that required longer anesthetic and surgical times for surgical resection, and wound defects which were closed in an X-shape rather than linearly.[227] Real-time in vivo assessment of residual tumor in the wound bed has been investigated with good initial results in 12 cats with ISSs,[230] and local tumor control rates may be improved when this technology becomes commercially available.

Neoadjuvant chemotherapy or RT may have benefits when combined with surgery. In people, both preoperative chemotherapy and RT have resulted in the conversion of the tumor pseudocapsule into a thick, collagenized capsule with no viable tumor cells.[114] Clinically, this may result in a better defined tumor that is more amenable to complete histologic excision. In one study, there was no difference in local recurrence rates or STs in 49 cats treated with neoadjuvant DOX and surgery compared with 20 cats treated with surgery alone.[231] However, in another study,

• **Fig. 22.16** Aggressive resection of injection-site sarcomas, with 5-cm lateral margins and one to two uninvolved fascial layers for deeps margins, is required for the best opportunity for complete histologic excision and local tumor control. (A) Planned lateral surgical margins are indicated with a sterile marker pen 5 cm in all directions around an interscapular injection-site sarcoma. (B) An incision is then performed along the marked margins, and continued deeply to include two uninvolved fascial layers. (C) In this cat, ostectomy of the dorsal spinous processes was performed with bone cutters to achieve deep surgical margins and compartmental resection of the injection-site sarcoma. (D) The wound defect after these aggressive wide resections can be large, but primary closure is almost always achievable (E).



neoadjuvant chemotherapy with three doses of epirubicin followed by compartmental resection of interscapular ISSs resulted in an overall local recurrence rate of 14% in 21 cats after a median follow-up time of 1072 days.[229]

Surgery and Radiation Therapy

Although aggressive surgical resection is recommended for the management of cats with ISSs, this may not always be feasible. In these cases, multimodality therapy with either preoperative or postoperative RT results in better rates of local tumor control than more conservative surgical approaches alone.[213,232–236]

In two studies investigating preoperative RT, local tumor recurrence was reported in 40% to 45% of cats at a median of 398 to 584 days postoperatively.[232,234] In both studies, complete resection significantly improved the time to local recurrence, with a 700- to 986-day median DFI for completely excised tumors and 112- to 292-day median DFI for tumors resected with incomplete margins.[232,234] However, complete resection after preoperative RT does

VetBooks.ir

• **Fig. 22.17** Aggressive resection of injection-site sarcomas, with 5-cm lateral margins and one to two uninvolved fascial layers for deeps margins, is required for the best opportunity for complete histologic excision and local tumor control. (A) Planned lateral surgical margins are indicated with a sterile marker pen 5 cm in all directions around a body wall injection-site sarcoma. (B) An incision is then performed along the marked margins. (C) Deep margins of two uninvolved fascial layers included chest (seven ribs) and body wall. not appear to improve local control rates because local tumor recurrence was reported in 42% of 59 cats with complete histologic excision and 32% of 28 cats with incomplete histologic excision.[234]

The outcome after postoperative RT is similar to preoperative RT. In one study of 79 cats treated with surgery and curative-intent RT, the MST was significantly longer in cats treated with postoperative rather than preoperative RT; however, the practice at this institution was to treat larger tumors with preoperative RT and hence this finding may be due to a selection bias.[236] In one study, local tumor recurrence was reported in 41% of 76 cats at a median of 405 days

VetBooks.ir

postoperatively.[232] In another study investigating the effects of chemotherapy in cats treated with surgery and postoperative RT, local tumor recurrence occurred in 28% of 25 cats with a median time to first recurrence not reached in cats treated with surgery and RT alone and 661 days in cats also treated with DOX.[233] In a study of 46 cats treated with surgery and curative-intent postoperative RT, the median PFI was 37 months, with 1- and 2-year progression-free rates of 63% and 60%, respectively.[235] In comparison, 27 cats treated with postoperative palliative hypofractioned protocols had a median PFI of 10 months and a MST of 24 months.[235] Importantly, RT should start 10 to 14 days postoperatively as DFI and ST decreases as the interval between surgery and starting RT increases.[213] Local tumor recurrence does not influence ST and, regardless of the timing of RT relative to surgery, survival data are encouraging with MSTs of 600 to 1307 days and 1-, 2-, and 3-year survival rates of 86%, 44% to 71%, and 28% to 68%, respectively.[213,232–235]

Local tumor control is still disappointing with 28% to 45% of tumors recurring after multimodality treatment with surgery using 2- to 3-cm lateral margins and RT.[213,232–236] The radiation field used in these studies typically included a minimum of 3-cm margins around the tumor or surgical scar. The majority of tumors recur within the radiation field, although tumors have been reported to recur outside the radiation field.[234] Similar to surgery alone, a more aggressive approach may be warranted to improve local tumor control, such as higher radiation doses, larger radiation fields, and more aggressive surgical resections.

Radiation Therapy for Gross Disease

Although RT alone is rarely effective for the management of cats and dogs with measurable STSs, RT may have a role in the palliative setting for cats with large and unresectable ISSs. In a pilot study of 10 cats with ISSs, 7 cats achieved partial responses and 2 cats had complete responses after treatment with liposomal DOX as a radiation sensitizer and irradiation with a median of 5 fractions of 4 Gy for a total dose of 20 Gy; however, PFIs were not durable (median of 117 days).[237] Similar findings were reported in 17 cats with gross disease treated with 4 fractions of 8 Gy for a total dose of 32 Gy in which the median PFI was 4 months and MST was 7 months.[235] Stereotactic RT (SRT) has also been reported in a series of 11 cats.[238] These cats were treated with variable protocols (most commonly 3 fractions of 10 Gy) with three complete and five partial responses documented. The median PFI was 242 days and the MST was 301 days.[238] A margin for subclinical microscopic disease was not utilized in these patients and thus the intent of SRT alone cannot be considered definitive; however, it may facilitate surgical resection or result in palliation of clinical signs.

Chemotherapy

The role of chemotherapy in the management of cats with ISS remains undefined. Metastasis has been reported in 0% to 26% of cats with ISSs, despite the aggressive histologic appearance and prevalence of high-grade lesions in these tumors, with a median time to metastasis of 265 to 309 days.[209,210,220–222,228,230] ISS cell lines have shown in vitro sensitivity at clinically relevant doses to DOX, mitoxantrone, vincristine, lomustine, and paclitaxel.[239–241] Clinically, partial and complete responses to DOX, either alone or in combination with cyclophosphamide, or lomustine have been reported in 25% to 50% of cats with gross tumors, but these responses are often short-lived with a median duration of 83 to 125 days.[242–244] However, MSTs are significantly prolonged in cats that respond to chemotherapy: 242 days for responders and 83 days for nonresponders.[242] Furthermore, MSTs are significantly increased for cats with gross residual disease after surgical excision and treated with postoperative RT and chemotherapy with an MST of 29 months compared with 5 months for cats treated with surgery and postoperative RT.[235]

Postoperative chemotherapy has minimal effect on survival in cats treated with curative-intent surgery and RT.[214,226,232,233,243] Chemotherapy may, however, have beneficial effects on local tumor control and time to local tumor recurrence. DOX and liposome-encapsulated DOX significantly prolonged DFI after surgery, with a median DFI of 393 days for cats receiving chemotherapy and 93 days for those in which chemotherapy was not administered.[243] The completeness of surgical margins may be a confounding factor in this analysis because the median DFI was greater than 449 days in cats with complete surgical margins compared with 281 days after incomplete resection.[243] Chemotherapy has also been reported to affect MST but not DFI in cats treated with hypofractionated RT for gross disease.[235] Carboplatin was associated with an insignificant but numerically superior median DFI of greater than 986 days in cats treated with preoperative RT and surgery.[234] Other studies have shown no effect of adjunctive chemotherapy on either local tumor control or ST.[232,233]

The tyrosine kinase inhibitors toceranib phosphate (Palladia), masitinib mesylate (Kinavet/Masivet), and imatinib mesylate (Gleevec) have also been investigated for the therapy of ISSs in cats based on dysregulation of PDGFR in feline ISS cell lines.[245,246,247,248] Imatinib has been shown to result in inhibition of the PDGF/PDGFR pathway and results in chemosensitization of feline ISS cells.[245] Masitinib also resulted in inhibition of PDGFR and cellular proliferation in feline ISS cell lines, but at doses that were higher than those readily achievable clinically.[246] Masitinib was also investigated as a radiation sensitizer in feline ISS cell lines, but was not found to result in sensitization in vitro.[247] Finally, toceranib was administered to 18 cats with unresectable ISSs and, although well tolerated at doses commonly administered in dogs, responses were not documented.[248]

Novel treatments such as electrochemotherapy and immunotherapy are also being investigated with some encouraging results. In one study, cats with high-grade STSs were treated either intraoperatively or postoperatively with intratumoral bleomycin followed by eight biphasic pulses of up to 1300 V/cm.[249] The median time to local tumor recurrence in the control (surgery only) group was 4 months compared with 12 months for cats treated intraoperatively and 19 months for cats treated postoperatively. Of further interest, the metastatic rate was only 1.7%.[249] In a second study, 64 cats with FSA were treated postoperatively with two rounds of electrochemotherapy utilizing cisplatin.[250] The local recurrence rate was 29%. Minimal systemic toxicity, including pulmonary, renal, or cutaneous toxicity, was documented in these cats.[250] It should be noted that cisplatin cannot be administered systemically in cats because cisplatin causes fatal pulmonary edema even at relatively low doses.[251]

Immunotherapy, using recombinant viruses expressing interleukin-2 (IL-2), has shown some promise in improving local tumor control rates in cats with ISSs. After surgical resection and iridium-based brachytherapy, the 1-year local tumor recurrence rate was 61% in cats receiving no adjunctive treatment, 39% in cats administered human IL-2 using a vaccinia virus vector, and 28% with feline IL-2 using a canary pox virus vector.[252] In a randomized trial by the same group comparing surgery and brachytherapy with surgery and brachytherapy combined with high- and low-dose IL-2 vaccine, the frequency of relapse was significantly reduced in the groups receiving the IL-2 vaccine at both 12 (52% vs 28%) and 24 months (59% vs 28%).[253] This product is now commercially available in the United States and European Union for the postoperative treatment of feline ISSs. In a phase I trial, two doses of intratumoral feline IL-2, interferon-gamma

VetBooks.ir

(IFN-γ), and granulocyte-macrophage colony-stimulating factor (GM-CSF) followed by magnetofection before surgical resection resulted in a 1-year local recurrence rate of 24%.[254] In another phase I trial by the same research group, two doses of intratumoral GM-CSF followed by magnetofection before surgical resection resulted in a 1-year local recurrence rate of 50% and minimal treatment-related toxicities.[255] Other immunotherapeutic agents such as IL-12 and acemannan have been investigated with less favorable results.[256–258]

Prognosis

Local Recurrence

Local tumor control is the most challenging aspect of managing cats with ISS. The best results are achieved after complete histologic excision, and complete histologic excision is more likely after aggressive surgical resection. The rate of complete histologic excision is less than 50% when ISSs are excised with 2- to 3-cm lateral margins,[224,225] compared with 95% to 97% when excised with 4- to 5-cm lateral margins.[214,226] The local tumor recurrence rate is 14% to 22% after complete histologic excision compared with 58% to 69% after incomplete excision.[214,229,243,259] Incomplete histologic excision of ISSs is associated with a 10-fold increased risk of local tumor recurrence.[259] Overall, the 1- and 2-year disease-free rates are 35% and 9%, respectively, after wide resection with 2- to 3-cm lateral margins,[224,225] compared with a 3-year disease-free rate of 86% after wide resection with 5-cm lateral margins or compartmental resections.[214,229]

When surgical resection is combined with either preoperative or postoperative RT, the local recurrence rates are 28% to 45% with median DFIs of 13 to 37 months.[213,226,228,232–234,260] Similar to surgical management of ISSs, complete histologic excision results in a significant improvement in time to local recurrence for cats treated with surgery and RT, with a 700- to 986-day median DFI for completely excised tumors and 112- to 292-day median DFI for tumors resected with incomplete margins.[232,234] However, complete excision after preoperative RT does not appear to improve local control rates because local tumor recurrence was reported in 42% of 59 cats with complete histologic excision and 32% of 28 cats with incomplete histologic excision.[234]

Prognostic factors for local recurrence include tumor size, surgical dose or aggressiveness, completeness of histologic excision, and histologic grade. In one study of 24 cats with ISSs, local recurrence was significantly more likely after wide resection of larger tumors; and for each unit increase in tumor size, cats were two times more likely to develop local recurrence and two times more likely to have a tumor-related death.[261] A number of studies have shown the importance of an aggressive surgical approach in the management of cats with ISSs, but this most likely is related to the ability to achieve complete histologic excision rather than the surgical approach specifically. The median time to first recurrence after marginal resection is 79 days compared with 325 to 419 days for wide resection or radical surgery.[225] In addition, the median time to first recurrence is only 66 days when the first surgery is performed at a nonreferral institution compared with 274 days at referral institutions.[224,225] In another study of 57 cats with wide resection of ISSs, the local recurrence rate was 39% and significantly more likely with grade III ISSs compared with either grade I or II ISSs.[226]

Metastasis

Metastasis is relatively uncommon in cats with ISSs. The metastatic rate varies from 0% to 24%.[209,213–215,225,226,232,234,261,262] Metastasis is significantly more likely in cats with grade III ISSs[226]; and the metastatic rates for cats with grade I, II, and III ISSs are 0% to 17%, 15% to 19%, and 22% to 100%.[214,226] The lungs are the most common site of metastasis, with other sites including regional lymph nodes, kidney, liver, spleen, intestines, and epidural and ocular infiltration.[214,215,225,226,232]

Survival

The overall prognosis for cats with ISSs is often very good despite their propensity for local tumor recurrence. The overall MST is 804 to 901 days to not reached for cats treated with wide surgical resection of 4-cm to 5-cm lateral margins and one to two fascial layers for deep margins.[214,226,229] For cats treated with less aggressive surgery, the overall MST varies from greater than 395 days to 608 days.[224,225,262] For cats treated with surgery and RT, regardless of the timing of RT, the overall MSTs range from 520 to 1307 days with 1-, 2-, and 3-year survival rates of 62% to 86%, 42% to 71%, and 28% to 68%, respectively.[213,232–236,260]

Prognostic factors associated with survival in cats with ISSs include anemia, tumor size, treatment type, histologic subtype, mitotic rate, local tumor recurrence, and metastatic disease. For cats treated with surgery and either preoperative or postoperative RT, anemia with a packed cell volume (PCV) less than 25% was associated with decreased ST.[236] The MSTs for cats with a PCV less than and greater than or equal to 25% were 308 days and 760 days, respectively, with a 2-fold increased risk of tumor-related death for cats with a PCV less than 25%.[236] The 1- and 2-year survival rates for cats treated with a PCV less than 25% were 40% and 24%, respectively, whereas the 1- and 2-year survival rates for cats with a PCV greater than or equal to 25% were 72% and 50%, respectively.[236] Tumor size was associated with prognosis in two studies of cats treated with surgery alone. Cats with STSs smaller than 2 cm in diameter had an MST of 643 days, which was significantly longer than the MSTs of 558 days for cats with tumors 2 to 5 cm in diameter and 394 days for cats with STSs larger than 5 cm in diameter.[262] In another study, cats with ISSs greater than 3.75 cm had a significantly decreased ST.[261] Although most studies do not show differences in outcomes between cats treated with surgery and either preoperative or postoperative RT, the outcome was significantly worse for cats treated with preoperative RT (MST 310 days) than postoperative RT (MST 705 days) in one study, and cats treated with preoperative RT had a 2-fold increased risk of tumor-related death.[236] The 1- and 2-year survival rates for cats treated with preoperative and postoperative RT were 42% and 29%, and 70% and 47%, respectively.[236] In another study of 52 cats treated with surgery alone, including eight cats with presumed ISSs, histologic subtype was prognostic with MSTs for cats with FSA (640 days) and PNST (645 days) significantly better than for cats with MFH (290 days).[262] Survival was significantly associated with mitotic rate in one study of 24 cats with a 994-day MST for cats with mitotic count greater than 20 mitoses per 10 HPFs compared with an MST that was not reached in cats with a mitotic rate less than or equal to 20 mitoses per 10 HPFs.[261] The MST for cats with local tumor recurrence was 327 to 499 days compared with 1098 to 1461 days to not reached for cats without local tumor recurrence.[214,226,261] The estimated 2-year survival rates for cats without and with local recurrence are 75% and 37%, respectively.[261] The MST for cats without distant metastasis was 929 to 1528 days compared with 165 to 388 days for the 20% to 21% of cats that developed distant metastasis.[214,226] Distant metastasis increased the risk of tumor-related death by three times.[226]

Prevention

The recommendations on preventing ISSs in cats are controversial. These include changing the sites of vaccine administration, decreasing the use of polyvalent vaccines, using nonadjuvanted

VetBooks.ir

vaccines, avoiding the use of aluminum-based adjuvants, and increasing the interval between vaccinations.[26,177,263,264]

The VAFSTF has recommended that no vaccine be administered in the interscapular region, rabies vaccines be administered in the distal aspect of the right pelvic limb, FeLV vaccines be administered in the distal aspect of the left pelvic limb, and all other vaccines be administered in the right shoulder.[26,192] The location of each injection, the type of vaccine, and the manufacturer and serial number of the vaccine should be documented in the patient records. These recommendations are intended to provide epidemiologic information rather than prevent ISSs. Vaccines should be administered into the distal, rather than mid to proximal, aspects of the limb to aid in earlier detection and increase the chance of achieving complete resection. Subcutaneous and intramuscular administration can both cause local inflammatory reactions and result in the development of ISSs.[26] Subcutaneous administration is preferred to intramuscular injection because ISSs developing from subcutaneous sites are more readily palpable and diagnosed earlier in the course of disease. The VAFSTF has recommended that masses at vaccination sites be interrogated if the mass is evident 3 or more months after vaccination, is larger than 2 cm in diameter, or is increasing in size more than 1 month after vaccine administration (3–2–1 Rule).[191,192] Unfortunately, feline ISSs are still occurring at sites not recommended by the VAFSTF.[178,179,181,185] Vaccination in the tail has been recommended by some investigators because masses are more readily visible and palpable in the tail than other sites and the tail is relatively simple to amputate with good margins and minimal effect on the function and quality of life of cats, especially compared with other locations such as interscapular resections, body wall resections, and limb amputations or hemipelvectomies.[265] In a pilot study, vaccination in the tip of the tail was well tolerated and did not require sedation or restraint.[265]

Traditionally, annual boosters have been recommended for most vaccines in cats. The U.S. Department of Agriculture–Animal Plant Health Inspection Service (USDA-APHIS) does not require duration of immunity studies for licensing of vaccines; however, if a duration of immunity study has not been performed, the USDA-APHIS requires that vaccine labels include a recommendation for annual revaccination.[192] Vaccine practices have been questioned by the profession and this has been supported by duration of immunity studies. The duration of immunity for a single commercially available inactivated, adjuvanted combination of feline panleukopenia, herpesvirus, and calicivirus is greater than 7 years, with persistent antibodies against all three viruses for more than 3 years.[266–268] Local and state requirements often mandate annual rabies boosters, despite a duration of immunity of at least 3 years, because of the significant public health concern of rabies infection.[192] The VAFSTF has recommended that the administration of vaccines is a medicinal procedure and vaccination protocols should be customized for individual cats.[192] A vaccine should not be administered until the medical importance and zoonotic potential of the infectious agent, risk of exposure, and legal requirements have been considered and balanced against the risk of ISSs and other adverse effects.[192]

Comparative Aspects

In general, STSs have a similar pathologic appearance, clinical presentation, and behavior in humans and animals. However, a higher incidence is seen in young people as opposed to young companion animals, with the exception of rhabdomyosarcoma, which is seen in young dogs. The distribution of STS in humans is similar to animals. In humans, 43% are in the extremities, with two-thirds occurring in the lower limb, and 34% are intraperitoneal, with 19% visceral in origin and 15% retroperitoneal. STSs of the trunk occur in 10% of human patients, and the remaining 13% occur at other sites. Metastasis is generally hematogenous and appears to be more common in human STS than in dogs, which may partially be explained by the higher numbers of nerve sheath tumors (with lower metastatic rate) seen in the dog.

Most sarcomas recognized in humans are also diagnosed in animals, although the specific incidences may vary markedly. There are many more histologic subtypes recognized in humans, which are often site dependent. With the exception of benign smooth muscle tumors and subcutaneous lipomas, there is little evidence that these lesions arise from their mature (differentiated) tissue counterparts. One current theory is that switching on a set of genes that programs mesenchymal differentiation in any mesenchymal cell may give rise to any type of mesenchymal tumor. Common subtypes of STSs seen in the extremities of humans are liposarcomas, MFHs, SCS, and FSAs. In the retroperitoneal location, liposarcomas and leiomyosarcomas are the most common histotypes noted in humans. The most common subtype noted viscerally are gastrointestinal stromal tumors (GISTs). Overall, leiomyosarcoma is the most common genitourinary sarcoma. Up to 15% of all sarcomas occur in children, and the subtypes most commonly represented are rhabdomyosarcomas, Ewing's sarcomas, and primitive neuroectodermal tumors.

Prognostic variables in humans include clinical stage, histologic grade, necrosis, site, size, LN involvement, and aggressiveness of surgery or RT. The histopathologic grading system used and shown to be predictive for metastasis in dogs is a grading system adopted from human pathology that is also predictive for survival.[26] In addition, it appears that histologic grade is the predominant predictor of early recurrence, whereas tumor size plays a more important role for late recurrence. It is unclear whether age plays a prognostic role in human STS.

Surgical treatment is the mainstay of therapy for STS in the control of local disease. The definition of the surgical approach varies between different organizations, with 1- to 4-cm lateral margins considered a wide resection and those 5 cm or greater termed a curative resection; however, tissue barriers are also taken into account in determining surgical margins, with thin and thick tissue barriers being considered equivalent to 2 cm and 3 cm of margins, respectively.[13] Surgery can be combined with neoadjuvant chemotherapy, neoadjuvant RT, and/or adjuvant RT to improve local tumor control.[114] Amputation is reserved for patients with unresectable tumors, no evidence of metastasis, and the potential for good long-term rehabilitation. Local recurrence is greater in those patients undergoing limb-sparing therapies compared with amputation; however, there is no difference in disease-free survival between the two groups. Distant metastasis is more common in people with STS; however, chemotherapy is not routinely used because of either a lack of or small but significant improvements in tumor control and survival outcomes with adjuvant chemotherapy.[114] Ifosfamide is currently the most active salvage agent for patients who have failed DOX-based protocols, but tyrosine kinase inhibitors are also used. Permanent local control with the first treatment is related to long-term survival. High-risk STS patients are treated with combined chemoradiation before surgical resection. The chemotherapy protocol often used is DOX, ifosfamide, mesna, and dacarbazine. In human patients with metastatic disease, combination chemotherapy produces response rates of 20%, and most of these patients are candidates for investigational agents.

Cancer of the Gastrointestinal Tract

SECTION A: ORAL TUMORS

JULIUS M. LIPTAK

Incidence and Risk Factors

Oral tumors are common in both cats and dogs, with cancers of the oral cavity accounting for 3% to 12% and 6% of all tumors in these species, respectively.[1–5] Oropharyngeal cancer is 2.6 times more common in dogs than in cats, and male dogs have a 2.4 times greater risk of developing oropharyngeal malignancy compared with female dogs.[6,7] A male sex predisposition has also been reported for dogs with malignant melanoma (MM), tonsillar squamous cell carcinoma (SCC), and peripheral odontogenic fibromas,[8,9] and a female sex predisposition has been reported for dogs with axial osteosarcoma (OSA).[10] Dog breeds with the highest risk of developing oropharyngeal cancer include the cocker spaniel, German shepherd dog, German shorthaired pointer, Weimaraner, golden retriever, Gordon setter, miniature poodle, Chow Chow, and boxer.[3,8,11] In one study, German shepherd dogs and boxers had a decreased risk of developing oral melanoma.[11]

In dogs, the most common malignant oral tumors are, in descending order, MM, SCC, and fibrosarcoma (FSA),[12–24] although in other studies SCC is more common than MM.[25] SCC is the most common oropharyngeal cancer in cats, followed by FSA, which accounts for 13% of feline oral tumors.[5] Other malignant oral tumors in dogs include OSA, chondrosarcoma, anaplastic sarcoma, multilobular osteochondrosarcoma (MLO), intraosseous carcinoma, myxosarcoma, hemangiosarcoma, lymphoma, mast cell tumor, and transmissible venereal tumor.[12–28] Tumors or tumor-like lesions of unusual sites, types, and biologic behavior (e.g., peripheral odontogenic fibroma, acanthomatous ameloblastoma [AA], odontogenic tumors, tonsillar SCC, tongue tumors, malignancy of young dogs, viral papillomatosis, canine and feline eosinophilic granuloma complex, and nasopharyngeal polyps) will be covered at the end of this chapter. A general summary of the common oral tumors is found in Table 23.1.

Pathology and Natural Behavior

The oral cavity is a very common site for a wide variety of malignant and benign cancers. Although most cancers are fairly straightforward histologically, some have confusing nomenclature or extenuating circumstances that warrant discussion.

Malignant Melanoma

In comparison to other malignant oral tumors, MM tends to occur in smaller body weight dogs. Cocker spaniel, miniature poodle, Anatolian sheepdog, Gordon setter, Chow Chow, and golden retriever are overrepresented breeds.[11] The mean age at presentation is 11.4 years.[11] MM occurs in cats, but is uncommon.[29]

MM can present a confusing histopathologic picture if the tumor or the biopsy section does not contain melanin (Fig. 23.1A), and amelanotic melanomas (see Fig. 23.1B) represent up to 38% of cases.[30] A histopathologic diagnosis of undifferentiated or anaplastic sarcoma or even epithelial cancer should be viewed with suspicion for possible reclassification as melanoma. Several immunohistochemical antibodies can be applied to biopsy specimens to help differentiate melanoma from other poorly differentiated tumors and an immunodiagnostic cocktail using antibodies against PNL2, Melan A, TRP-1, and TRP-2 was found to have 100% specificity and 94% sensitivity and may be helpful in differentiation.[11,31]

Melanoma of the oral cavity is a highly malignant tumor with frequent metastasis to the regional lymph nodes (LNs) and then the lungs.[9,30–68] There is a small subset of dogs with well-differentiated oral melanomas and these may have a more benign biologic behavior.[41,69] The metastatic rate is site, size, and stage dependent and reported in up to 80% of dogs.[12,20,30–68] The World Health Organization (WHO) clinical staging system for oral tumors in dogs may have prognostic significance in dogs with oral melanoma (Table 23.2).[30–68,70] MM is a highly immunogenic tumor, and molecular and immunomodulatory approaches to treatment are active areas of research and treatment.[56–68] A review of the biology and molecular mechanisms of canine melanoma development and progression is provided in Chapter 20.[71,72]

Squamous Cell Carcinoma

SCC is the most common oral tumor in cats (Fig. 23.2) and the second most common in dogs.[1,4,5,20–24] There are five different histologic subtypes of SCC in dogs: conventional, papillary, basaloid, adenosquamous, and spindle cell.[73] Papillary SCCs typically occur in the rostral oral cavity of dogs less than 9 months old, although cases in older dogs have also been reported.[73–77] The metastatic rate for nontonsillar SCC in dogs is 5% to 29%,[43,76–85] but the metastatic risk is site dependent, with the rostral oral cavity having a low metastatic rate and the caudal tongue and tonsil having a high metastatic potential.[77]

TABLE 23.1 Summary of Common Oral Tumors in the Dog and Cat[a]

	CANINE				FELINE	
	Malignant Melanoma	SCC	Fibrosarcoma	Acanthomatous Ameloblastoma	SCC	Fibrosarcoma
Frequency	30%–40%	17%–25%	8%–25%	5%	70%–80%	13%–17%
Median age (years)	12	8–10	7–9	8	10–12	10
Sex predisposition	None to male	None	Male	None	None	None
Animal size	Smaller	Larger	Larger	None	—	—
Site predilection	Gingival, buccal, and labial mucosa	Rostral mandible	Maxillary gingiva and hard palate	Rostral mandible	Tongue, pharynx, and tonsils	Gingiva
Lymph node metastasis	Common (41%–74%)	Rare (<40%) Tonsil SCC up to 73%	Occasional (9%–28%)	None	Rare	Rare
Distant metastasis	Common (14%–92%)	Rare (<36%)	Occasional (0%–71%)	None	Rare	Rare (<20%)
Gross appearance	Pigmented (67%) or amelanotic (33%), ulcerated	Red, cauliflower, ulcerated	Flat, firm, ulcerated	Red, cauliflower, ulcerated	Proliferative, ulcerated	Firm
Bone involvement	Common (57%)	Common (77%)	Common (60%–72%)	Common (80%–100%)	Common	Common
Surgery response	Fair to good	Good	Fair to good	Excellent	Poor	Fair
Local recurrence	0%–59%	0%–50%	31%–60%	0%–11%		
MST	5–17 months	9–26 months	10–12 months	>28–64 months	45 days	
1-Year survival rate	21%–35%	57%–91%	21%–50%	72%–100%	<10%	
Radiation response	Good	Good	Poor to fair	Excellent	Poor	Poor
Response rate	83%–94%	—	—	—		
Local recurrence	11%–27%	31%–42%	32%	8%–18%		
MST	4–12 months	16–36 months	7–26 months	37 months	90 days	
1-Year survival rate	36%–71%	72%	76%	>85%		
Best treatment	Surgery and/or radiation ± chemotherapy ± immunotherapy	Surgery and/or radiation	Surgery and/or radiation	Surgery	Surgery and radiation ± sensitizer	Surgery and/or radiation
Prognosis	Fair to good	Good to excellent	Good	Excellent	Poor to fair	Fair
MST	<36 months	26–36 months	18–26 months	>64 months	14 months	
Cause of death	Distant disease	Local or distant disease	Local disease	Rarely tumor related	Local disease	Local disease

MST, Mean survival time; *SCC*, squamous cell carcinoma.

[a]References 11–21, 28–32, 37, 53, 57–60, 78, 84–86, 104–111.

In cats, the risk of developing oral SCC is significantly increased by 4-fold with the use of flea collars and high intake of either canned food in general or canned tuna fish specifically.[86] Exposure to household tobacco smoke increases the risk of oral SCC by 2-fold in cats,[86] and although this was not statistically significant, smoke exposure is associated with a significant increase in expression of *p53* in SCC lesions compared with cats with oral SCC not exposed to environmental smoke.[87] For this reason, mutations of *p53* may be involved in the development and progression of smoke-related oral SCC in cats.

• **Fig. 23.1** (A) A malignant melanoma arising from the rostral mandible. (B) An amelanotic malignant melanoma arising from the caudal maxilla.

TABLE 23.2 Clinical Staging (TNM) of Oral Tumors in Dogs and Cats[70]

Clinical Staging System for Oral Tumors

Primary Tumor (T)
Tis Tumor in situ
T1 Tumor <2 cm in diameter at greatest dimension
T1a Without evidence of bone invasion
T1b With evidence of bone invasion
T2 Tumor 2–4 cm in diameter at greatest dimension
T2a Without evidence of bone invasion
T2b With evidence of bone invasion
T3 Tumor >4 cm in diameter at greatest dimension
T3a Without evidence of bone invasion
T3b With evidence of bone invasion

Regional Lymph Nodes (N)
N0 No regional lymph node metastasis
N1 Movable ipsilateral lymph nodes
N1a No evidence of lymph node metastasis
N1b Evidence of lymph node metastasis
N2 Movable contralateral lymph nodes
N2a No evidence of lymph node metastasis
N2b Evidence of lymph node metastasis
N3 Fixed lymph nodes

Distant Metastasis (M)
M0 No distant metastasis
M1 Distant metastasis [specify site(s)]

Stage Grouping	Tumor (T)	Nodes (N)	Metastasis (M)
I	T1	N0, N1a, N2a	M0
II	T2	N0, N1a, N2a	M0
III	T3	N0, N1a, N2a	M0
IV	Any T	N1b	M0
	Any T	N2b, N3	M0

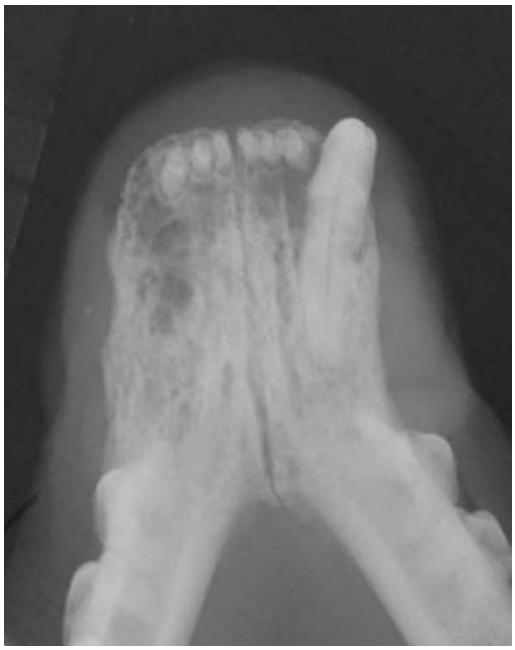
SCC frequently invades bone in both cats and dogs, and bone invasion is usually severe and extensive in the cat. Increased tumor expression of parathyroid hormone–related protein in cats with oral SCC may play a role in bone resorption and tumor invasion.[88] Control of local disease is the most challenging aspect in cats with oral SCC because of the extent of the local tumor[89–112]; [not superscript] however, metastasis has been reported to the mandibular LNs and lungs in 31% and 10% of cats, respectively,[95] and hence treatment for this metastatic potential may be warranted for cats in which local tumor control is achieved.

Fibrosarcoma

Oral FSA is the second most common oral tumor in cats and the third most common in dogs.[2,5, 20–24,90] In dogs, oral FSA tends to occur in large breed dogs, particularly golden and Labrador retrievers.[20–24,113–117] The median age at diagnosis is 7.3 to 8.6 years and there may be a male predisposition.[113–116] Oral FSA may look surprisingly benign histologically and, even with large biopsy samples, the pathologist can find it difficult to differentiate fibroma from low-grade FSA.[113] This syndrome, which is common on the hard palate (Fig. 23.3) and maxillary arcade between the canine and carnassial teeth



• **Fig. 23.2** Typical appearance of an oral squamous cell carcinoma in a cat. Although these can be proliferative and firm, ulceration is more common.

of large-breed dogs, has been termed *histologically low-grade but biologically high-grade FSA.*[113] Even with a biopsy result suggesting fibroma or low-grade FSA, the treatment should be aggressive, especially if the cancer is rapidly growing, recurrent,

VetBooks.ir

• **Fig. 23.3** Typical appearance of a biologically high-grade but histologically low-grade fibrosarcoma. These often appear histologically benign or low-grade, but have an aggressive local behavior. Wide surgical resection and possibly postoperative radiation therapy are required for adequate local tumor control.

• **Fig. 23.4** An intraoral radiograph of the rostral mandible of a cat with a squamous cell carcinoma. Note the extensive bone lysis resulting in tooth loss, which is very common in cats with this type of tumor.

or invading bone. FSA is locally invasive, but metastasis to the lungs and occasionally regional LNs occurs in fewer than 30% of dogs.[12,20–24,43,113–117]

Osteosarcoma

OSA of axial sites is less common than appendicular OSA and represents approximately 25% of all cases.[10] Of the axial OSA, the mandible and maxilla are involved in 27% and 16% to 22% of cases, respectively.[10,118] OSA is the fourth most common malignant oral tumor in dogs. The metastatic potential for axial OSA is less than appendicular OSA.[10,119–122] A female sex predisposition has been reported.[10]

Peripheral Odontogenic Fibroma

Peripheral odontogenic fibroma is the preferred term for a group of benign tumors previously known as epulides.[123] Four types of epulides have been described in the dog: acanthomatous, fibromatous, ossifying, and giant cell.[123–135] Acanthomatous epulis has been renamed acanthomatous ameloblastoma, and the fibromatous and ossifying epulides have been renamed peripheral odontogenic fibroma.[123] Peripheral odontogenic fibromas are relatively common in dogs, but rare in cats.[135] Multiple epulides have been described in cats, with 50% of cases occurring in cats younger than 3 years.[135] They are benign gingival proliferations arising from the periodontal ligament and appear similar to focal fibrous hyperplasia of the gingiva.[123] Unlike AAs, they do not invade into underlying bone. The mean age at presentation for dogs with peripheral odontogenic fibromas is 8 to 9 years, and a male predisposition has been reported.[123–127] Peripheral odontogenic fibromas are slow-growing, firm masses and usually are covered by intact epithelium. They have a predilection for the maxilla rostral to the third premolar teeth.[123–127]

Acanthomatous Ameloblastoma

AA is a benign tumor, but has an aggressive local behavior and frequently invades bone of the underlying mandible or maxilla. Medium- to large-breed dogs are most commonly affected, and Shetland sheepdogs, Old English sheepdogs, and golden retrievers are overrepresented.[123–130] The mean age at presentation is 7 to 10 years, and a sex predisposition is unlikely, with three studies reporting conflicting results.[125,128–130] The rostral mandible is the most common site, representing 51% of all cases in one study of 263 dogs with AA, with other sites being the caudal mandible (22%), rostral maxilla (22%), and caudal maxilla (6%).[128,129] They do not metastasize. AA is the preferred term, but some pathologists will refer to these tumors by their previous terminology of *acanthomatous epulis* or *adamantinoma.*[124]

History and Clinical Signs

Most cats and dogs with oral cancer present with a mass in the mouth noticed by the owner. Cancer in the caudal pharynx, however, is rarely seen by the owner and the animal will present with signs of increased salivation, exophthalmos or facial swelling, epistaxis, weight loss, halitosis, bloody oral discharge, dysphagia or pain on opening the mouth, or occasionally cervical lymphadenopathy (especially SCC of the tonsil).[20–24,91] Loose teeth, especially in an animal with generally good dentition, should alert the clinician to possible underlying neoplastic bone lysis (Fig. 23.4), particularly in the cat. Although paraneoplastic syndromes associated with oral tumors are rare, hypercalcemia has been reported in two cats with oral SCC[87] and hyperglycemia in a cat with a gingival vascular hamartoma.[136]

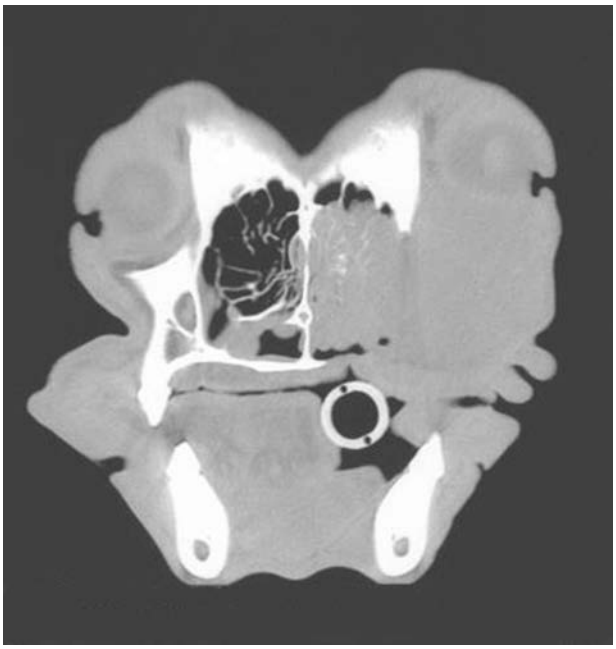
Diagnostic Techniques and Workup



The diagnosis and clinical staging of animals with oropharyngeal masses is imperative before definitive surgical excision. A biopsy is required for definitive diagnosis and this will assist the clinician in determining biologic behavior and prognosis. Clinical staging consists of evaluating the extent of the local tumor and the presence of metastatic disease. The regional LNs and lungs are the two most common sites of metastasis in cats and dogs with oral tumors.[30–68,76–85,89–122] The procedures required for the diagnosis and clinical staging of animals with oral cancer can usually be performed under a short general anesthesia.

Diagnosis

A large incisional biopsy is often required for a definitive diagnosis. Fine-needle aspirate (FNA) or impression smear cytology has traditionally been considered unrewarding because many oral tumors are associated with a high degree of necrosis and inflammation; however, one prospective study of 114 cats and dogs with oral masses showed that, in comparison to definitive histopathologic results, FNA cytology had a diagnostic accuracy rate of 98% in dogs and 96% in cats, and impressions smear cytology had a diagnostic accuracy rate of 92% in dogs and 96% in cats.[137] Dogs with exophytic or ulcerated masses will generally tolerate a deep wedge or core punch biopsy without general anesthesia. Biopsy is recommended in the diagnostic workup of cats and dogs with an oral mass to differentiate benign from malignant disease, for owners basing their treatment options on prognosis, and when other treatment modalities, such as radiation therapy (RT), may be preferable. Oral cancers are commonly infected, inflamed, or necrotic, and it is important to obtain a large representative specimen. Cautery may distort the specimen and should be used for hemostasis only after blade incision or punch biopsy. Large samples of healthy tissue at the edge and center of the lesion will increase the diagnostic yield, but care must be taken not to contaminate normal tissue, which cannot be removed with surgery or included in the radiation field. Biopsies should always be performed from within the oral cavity and not through the lip to avoid seeding tumor cells in normal skin and compromising curative-intent surgical resection. For small lesions (e.g., epulides, papillomas, or small labial mucosal melanoma), curative-intent resection (excisional biopsy) may be undertaken at the time of initial evaluation. However, accurate notes should be included in the medical records, and/or photographic evidence, to detail the size and anatomic location of the mass if excision is incomplete and further treatment is required. For more extensive disease, waiting for biopsy results is recommended so that appropriate treatment plans can be formulated.

Clinical Staging: Local Tumor

Tumor size is an important prognostic factor for some types of oral tumors, such as MM, SCC, and tongue tumors,[40,41,78,138–142] and hence an accurate measurement of tumor size should be recorded. Cancers that are adherent to or arising from bones of the mandible, maxilla, or palate should be imaged under general anesthesia to determine the presence of bone lysis and the extent of local disease. Regional radiographs include open mouth, intraoral, oblique lateral, and ventrodorsal or dorsoventral projections. Bone lysis is not radiographically evident until 40% or more of the cortex is destroyed and hence apparently normal radiographs do not exclude bone invasion. Advanced imaging modalities are now widely available and these are recommended for imaging of oral tumors, particularly tumors arising from the maxilla, palate, and caudal mandible (Fig. 23.5).[143–145] Computed tomography (CT) scans are generally preferred to magnetic resonance imaging (MRI) because of superior bone detail, but both CT or MRI scans will provide more information on the local extent of the tumor than regional radiographs. In one study, invasion into adjacent structures was noted in only 30% of dogs imaged with radiographs compared with more than 90% of dogs imaged with contrast-enhanced CT.[145] In another study, MRI provided more accurate information on invasion into adjacent structures, MRI and CT showed similar accuracy in assessing bone invasion, and calcification and cortical bone erosion were better assessed with CT scan.[144] Although not widely available, positron emission tomography (PET)/CT provided valuable information on the extent of soft tissue infiltration and presence of LN metastasis in cats with oral SCC in comparison to CT.[146,147] This information is important for planning the definitive surgical procedure (or RT if indicated).

• **Fig. 23.5** A computed tomography image of a dog with a maxillary fibrosarcoma. Advanced imaging allows better planning of surgery and radiation therapy, as the extent of bone involvement and extension into the nasal cavity is often much greater than can be appreciated grossly.

Clinical Staging: Regional Lymph Nodes

Regional LNs should be carefully palpated for enlargement or asymmetry. However, caution should be exercised when making clinical judgments based on palpation alone because LN size is not an accurate predictor of metastasis. In one study of 100 dogs with oral MM, 40% of dogs with normal sized LNs had metastasis and 49% of dogs with enlarged LNs did not have metastasis.[34] Furthermore, the regional LNs include the mandibular, parotid, and medial retropharyngeal LNs; but the parotid and medial retropharyngeal LNs are not externally palpable.[148–151] In addition,

VetBooks.ir

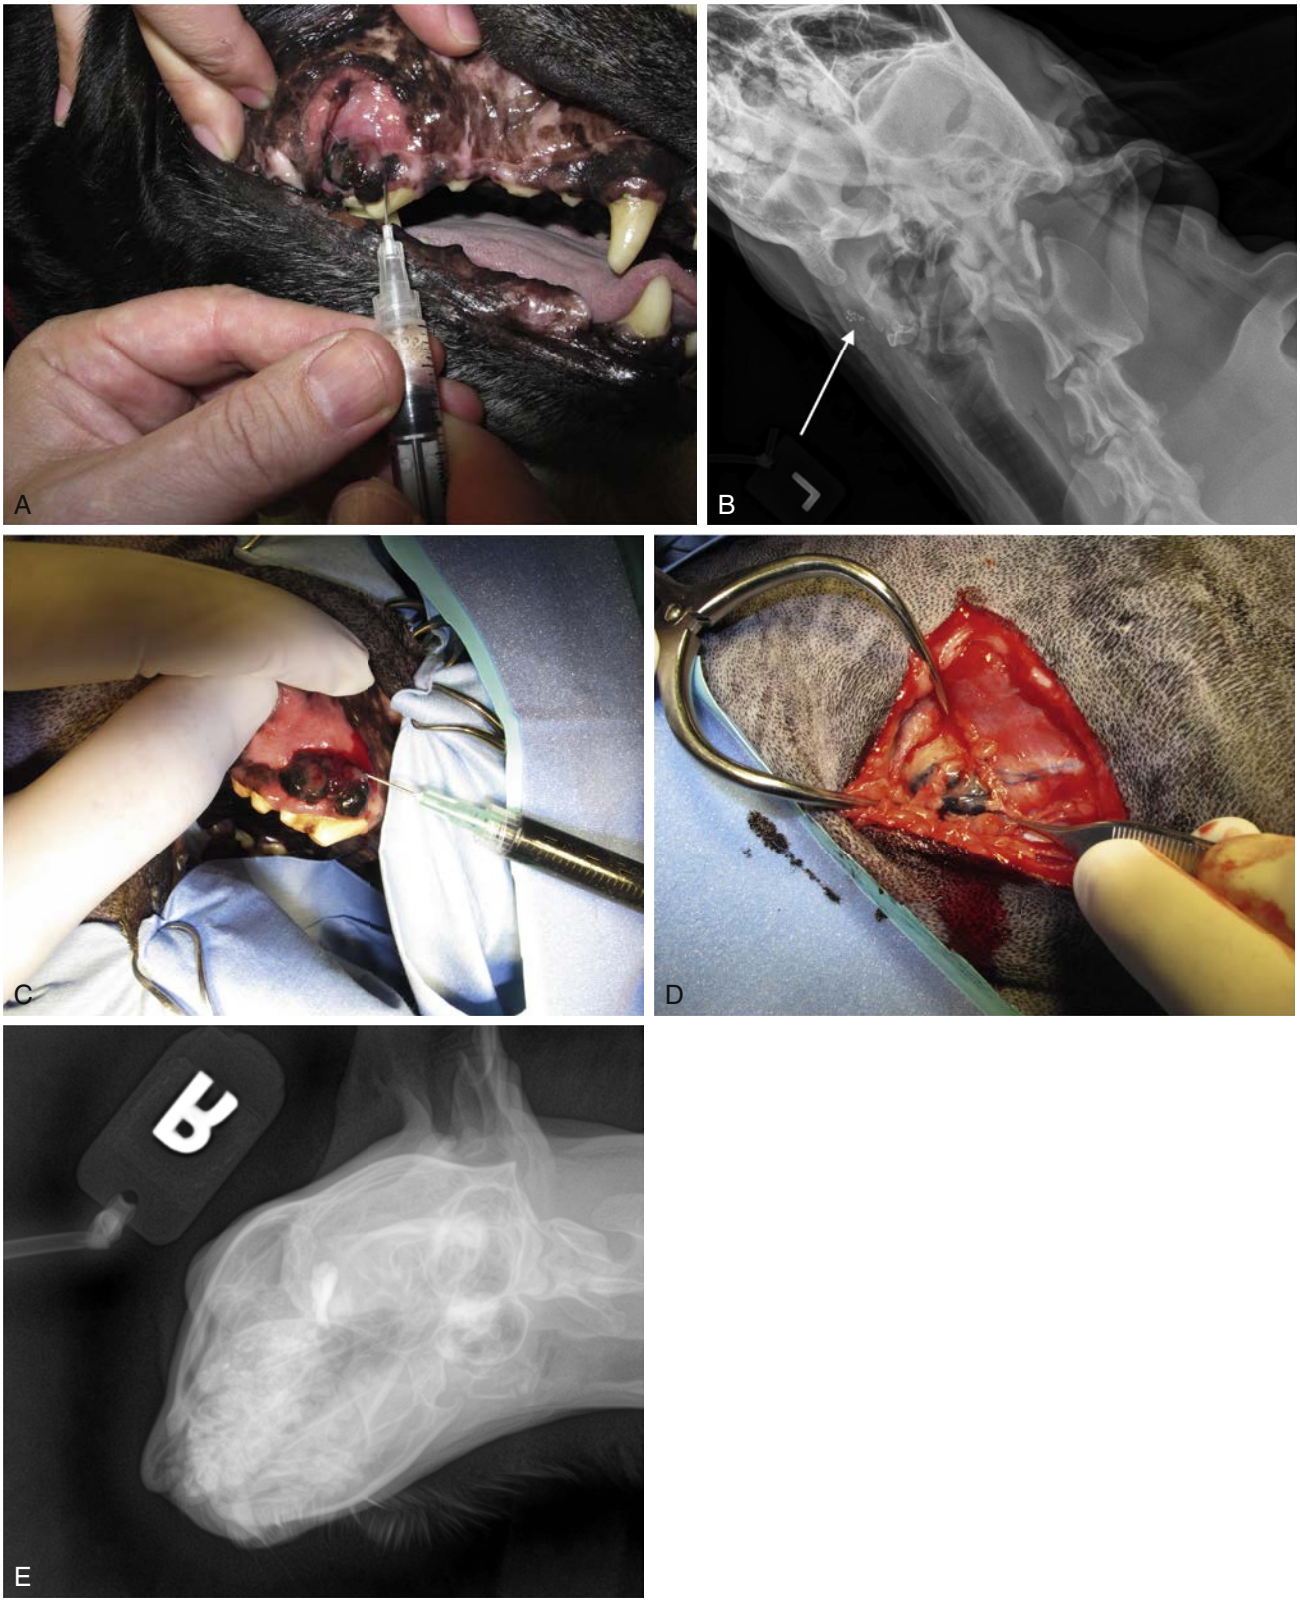
only 55% of 31 cats and dogs with metastasis to the regional LNs had metastasis to the mandibular LNs.[149] CT and PET/CT can be useful to determine LN metastasis and guide further diagnostics.[143,147,148] LN aspiration should be performed in all animals with oral tumors, regardless of the size or degree of fixation of the LNs.[34,149] The accuracy of LN aspirates for the detection of metastatic cancer in cats and dogs is 77%.[152] Resection of some or all of the regional LNs has been described and, although the therapeutic benefit of this approach is unknown, it may provide valuable staging information.[148–151] The major concerns with nontargeted LN resection are the possibility of missing a metastatic lesion and the potential morbidity associated with excision of multiple LNs. Lymphatic drainage of the oral cavity is highly variable in humans and likely in dogs and cats,[151] and the first draining LN can be ipsilateral or contralateral to the tumor and include any one of the mandibular, medial retropharyngeal, parotid, or minor LNs, such as the buccal LN.[149,151] For these reasons, sentinel LN (SLN) mapping and biopsy is becoming the preferred technique for LN staging of oral tumors.

SLN mapping and biopsy is the assessment of LN metastasis without more aggressive en bloc surgical excisions of the regional LNs. The SLN is the first draining LN and the status of this LN is representative of the entire LN bed. Furthermore, the SLN is not necessarily the regional anatomic LN. In one study of dogs with cutaneous mast cell tumors, the SLN was different from the regional anatomic LN in 40% of dogs.[153] Methods to detect SLN in people with head and neck cancer include lymphoscintigraphy, intraoperative blue dyes, and intraoperative gamma probes.[154] Lymphoscintigraphy, intraoperative dyes, and contrast-enhanced ultrasonography have been described in dogs with various tumors, including head and neck cancer.[154,155] The use of lipid-soluble and water-soluble contrast agents has also been reported as methods of detecting the location of the SLN preoperatively, and then combining this with methylene blue to aide in the identification of the SLN intraoperatively (Fig. 23.6).[156] The advantage of this latter technique is that radioactive materials are not required and hence this is a more widely applicable SLN mapping technique.

Clinical Staging: Distant Metastasis

The final step in the clinical staging of animals with oral tumors is imaging of the thoracic cavity for metastasis to the lungs. Three-view thoracic radiographs (right and left lateral projections, and either dorsoventral or ventrodorsal projection) are generally recommended. CT scans should be considered for animals with highly metastatic tumor types, such as oral MM, as they are significantly more sensitive in detecting pulmonary metastatic lesions compared with radiographs.[157–160] Based on these diagnostic steps, oral tumors are then clinically staged according to the WHO staging scheme (see Table 23.2).[70]

Treatment



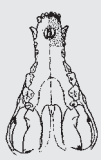
Surgery

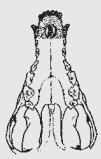
Surgery and RT are the most common treatments used for the local control of oral tumors. Surgical resection is the most economic, expeditious, and curative treatment. The type of oral surgery depends on tumor histology and location. Except for peripheral odontogenic fibromas, most oral tumors have some underlying bone involvement and surgical resection should include bony margins to increase the likelihood of local tumor control. More aggressive surgeries such as mandibulectomy, maxillectomy, and orbitectomy are generally well tolerated by cats and dogs. These procedures are indicated for all aggressive and/or invasive oral tumors, particularly lesions with extensive bone invasion, with poor sensitivity to RT (Tables 23.3 and 23.4).[13–24,161–164] Margins of at least 2 cm are generally necessary for malignant cancers such as SCC, MM, FSA, and OSA in the dog. If possible, FSA in the dog and SCC in the cat should be treated with surgical margins greater than 2 cm because of high local recurrence rates. Bone reconstruction after bony resection has been described,[165–172] but is rarely necessary in dogs because of good postoperative function and cosmetic appearance with mandibulectomy alone.[13–24] Furthermore, a high complication rate has been reported after reconstruction and these complications often require revision surgeries for their management.[24,172] In contrast to dogs, cats frequently have poor postoperative function after mandibulectomy[90] and hence mandibular reconstruction may improve postoperative functional outcome in cats.[173] Rostral and segmental resections (e.g., mandibulectomy and maxillectomy) may be sufficient for benign lesions and rostral SCC in dogs. Rim resections, in which the ventral cortex of the mandible is preserved, may be possible for small benign tumors localized to the alveolar margin of the mandible (Fig. 23.7).[174–176] Larger resections, including hemimandibulectomy, hemimaxillectomy, orbitectomy, and radical maxillectomy, are necessary for more aggressive tumors, especially FSA, and malignant tumors with a more caudal location.[13–24,161–164] Although these large resections carry some morbidity, owner satisfaction with the cosmetic and functional outcomes is in excess of 85%.[13–24,90,161–164] Cosmesis is usually very good after most mandibulectomy and maxillectomy procedures (Fig. 23.8), but can be challenging with aggressive bilateral rostral mandibulectomies and radical maxillectomies.[13–24,161–164,177] Blood loss and hypotension are the most common intraoperative complications, particularly during caudal or aggressive maxillectomy procedures.[21,162,177] Postoperative complications include incisional dehiscence and oronasal fistula formation, epistaxis, increased salivation, mandibular drift and malocclusion, lip trauma, infection, and difficulty prehending food, particularly after bilateral rostral mandibulectomy caudal to the second premolar teeth.[13–24,161–164,177] Elastic training, consisting of an orthodontic elastic rubber chain between an orthodontic button on the lingual aspect of the intact mandible tooth and buccal aspect of the maxillary fourth premolar tooth, has been described to maintain occlusion and prevent mandibular drift after mandibulectomy in dogs.[178] Enteral feeding tubes are not usually required after oral surgery in dogs; however, they are recommended for cats treated with any type of mandibulectomy because eating can be difficult for 2 to 4 months after surgery and 12% of cats never eat voluntarily after mandibulectomy.[89,90]

Local disease control is the goal of treatment for most animals with oral tumors. Regional LN resection has been described in cats and dogs; although it adds to clinical staging information, its effectiveness in controlling local and metastatic disease is unknown.[148–151]

Radiation Therapy

RT can be effective for locoregional control of oral tumors. RT can be used as a primary treatment, with either palliative or curative intent, as an adjunct for incompletely resected tumors, or as an adjunct for locally aggressive tumors regardless of the completeness of excision, such as oral FSA. MM,[42–49] canine oral SCC,[80,81,179]





• **Fig. 23.6** Indirect lymphography for sentinel lymph node mapping. (A) A lipid-soluble, radio-opaque contrast agent is being injected peritumorally in four quadrants around a malignant melanoma in a dog. (B) The lipid-soluble contrast agent is taken up slowly into the lymphatics. A regional radiograph is taken 24 hours postinjection to identify the sentinel lymph node, which was the ipsilateral mandibular lymph node in this case *(arrow)*. (C) To confirm the sentinel lymph node, methylene blue is injected in four quadrants peritumorally during surgery. (D) Methylene blue is rapidly taken up into the lymphatics. A surgical approach is made to the sentinel lymph node identified radiographically. Blue discoloration of the afferent lymphatics and lymph node assist in identifying this node as the sentinel lymph node. The sentinel lymph node is submitted for histopathologic assessment to determine whether there is evidence of metastatic disease. (E) Regional radiograph of a cat with a malignant melanoma of the lip 24 hours after peritumoral injection of a lipid-soluble contrast agent. The sentinel lymph node is the buccal lymph node. Note that the mandibular lymph nodes are the only palpable regional lymph nodes; however, malignant oral tumors can metastasize the ipsilateral or contralateral mandibular, medial retropharyngeal, parotid, and minor lymph nodes. Aspiration or excision of only the mandibular lymph node may result in metastatic lymph nodes being missed.

TABLE 23.3 Various Mandibulectomies

Mandibulectomy Procedure	Indications	Comments	
Unilateral rostral	Lesions confined to rostral hemimandible; not crossing midline	Most common tumor types are squamous cell carcinoma and adamantinoma that do not require removal of entire affected bone; tongue may lag to resected side.	
Bilateral rostral	Bilateral rostral lesions crossing the symphysis	Tongue will be "too long," and some cheilitis of chin skin will occur; has been performed as far back as PM4 but preferably at PM1.	
Vertical ramus	Low-grade bony or cartilaginous lesions confined to vertical ramus	These tumors are variously called *chondroma rodens* or *multilobular osteosarcoma*; temporomandibular joint may be removed; cosmesis and function are excellent.	
Complete unilateral	High-grade tumors with extensive involvement of horizontal ramus or invasion into medullary canal of ramus	Usually reserved for aggressive tumors; function and cosmesis are good.	
Segmental	Low-grade midhorizontal ramus cancer, preferably not into medullary cavity	Poor choice for highly malignant cancer in medullary cavity because growth along mandibular artery, vein, and nerve is common.	

TABLE 23.4 Various Maxillectomies

Maxillectomy Procedure	Indications	Comments	
Unilateral rostral	Lesions confined to hard palate on one side	One-layer closure.	
Bilateral rostral	Bilateral lesions of rostral hard palate	Needs viable buccal mucosa on both sides for flap closure.	
Lateral	Laterally placed midmaxillary lesions	Single-layer closure if small defect, two-layer if large.	
Bilateral	Bilateral palatine lesions	High rate of closure dehiscence because lip flap rarely reaches from side to side; may result in permanent oronasal fistula.	

• **Fig. 23.7** Rim resection of an acanthomatous ameloblastoma in a dog. The rim resection has been performed with a 24-mm biradial saw to preserve the ventral cortex of the mandibular body and hence prevent postoperative mandibular drift.

• **Fig. 23.8** The typical appearance of a dog 6 months postoperatively after subtotal unilateral mandibulectomy for an osteosarcoma. The tongue will often hang out and the remaining hemimandible will drift toward the resected side.

and some benign tumors, such as AA,[130–132] are known to be radiation responsive, and RT should be considered in the primary treatment of these tumors. RT can also be used for the palliation of oral SCC in cats and a variety of hypofractionated, accelerated, and stereotactic RT protocols have been described.[96–106]

Acute effects are common but self-limiting. These include alopecia and moist desquamation, oral mucositis, dysphagia, and ocular changes, such as blepharitis, conjunctivitis, keratitis, and uveitis.[43,80,81,116,117,130] The acute effects of coarse fractionation are less than experienced with the full-course protocols used for oral SCC and dental tumors and usually resolve rapidly.[44–49,96–104] Late complications are rare, occurring in fewer than 5% of cases, but can include permanent alopecia, skin fibrosis, bone necrosis and oronasal fistula formation, development of a second malignancy within the radiation field, keratoconjunctivitis sicca, cataract formation, xerostomia, and retinal atrophy.[43,130–132] Orthovoltage radiation may be associated with a higher incidence of second malignancies and bone necrosis than megavoltage irradiation.[32,130,131]

Chemotherapy

The major problem with most oral tumors is control of local disease; however, chemotherapy may be indicated for some tumors with higher metastatic potential, especially oral MM in dogs,[9,30–68] tonsillar SCC in cats and dogs, OSA in dogs,[122] and possibly oral SCC in cats.[89–112]

Prognosis

Clinical series of more than 750 dogs with various oral malignancies treated with either mandibulectomy or maxillectomy have been described.[13–24,161–164] The majority of cases were treated with surgery alone. Unfortunately, the methods of reporting and outcome results vary with each paper. Overall, the lowest rates of local tumor recurrence and best survival times (STs) are reported in dogs with AA and SCC, whereas FSA and MM are associated with the least favorable results.[13–24] Most of these reports suggest that histologically complete resection, smaller diameter, and a rostral location are favorable prognostic factors.[24] In two studies of 142 dogs treated with either mandibulectomy or maxillectomy, tumor-related deaths were 10 to 21 times more likely with malignant tumors, up to five times more likely with tumors located caudal to the canine teeth, and two to four times more likely after incomplete resection.[22,23] Rostral locations are usually detected at an earlier stage and are more likely to be resectable with complete surgical margins. Local tumor recurrence is more frequent after incomplete resection with 15% to 22% and 62% to 65% of tumors recurring after complete and incomplete excision, respectively.[22,23] Recurrent disease negatively affects ST because further treatment is more difficult and the response to treatment is poorer.[31] FSA continues to have high local recurrence rates in most studies, and more aggressive surgical approaches or adjuvant therapies, such as postoperative RT, should be considered.[24,115] On the other hand, MM is controlled locally in 75% of cases, but metastatic disease requires more effective systemic adjuvant therapy.

Malignant Melanoma

The prognosis for dogs with oral MM is guarded. Metastatic disease is the most common cause of death, with metastasis to the lungs reported in 14% to 67% of dogs.[9,13–24, 30–68] Surgery or RT can provide good local control, but the majority of dogs will fail treatment because of metastatic disease and hence the search for effective adjuvant immunotherapy holds the most promise to ultimately improve outcomes.

Surgery is the most common treatment for management of the local tumor. The median survival time (MST) for untreated dogs with oral MM is 65 days,[31] whereas tumor control and STs are significantly better when surgery is included in the treatment plan.[32] The overall local tumor recurrence rate after surgery is up to 45%,[24,40,41] with local tumor recurrence rates of 22% after mandibulectomy and 48% after maxillectomy.[7,18,19] The median ST (MST) for dogs with MM treated with surgery alone varies

TABLE 23.5 Prognostic Factors for Dogs with Oral Malignant Melanoma Treated with Surgery, with or without Radiation Therapy, Chemotherapy, and/or Immunotherapy

Prognostic Factor	Median Progression-Free Survival	Median Survival Time
Age[40]	—	630 days if <12 years 224 days if ≥12 years
Tumor size[56]	—	511 days if >2 cm 164 days if >2 cm
Tumor size[40]	—	630 days if <2 cm 240 days if 2–4 cm 173 days if >4 cm
Tumor size[41]	>567 days if <3 cm 245 days if >3 cm	874 days if <3 cm 396 days if >3 cm
Metastasis at diagnosis[41]	567 days if no metastasis 187 days if metastasis	818 days if no metastasis 131 days if metastasis
Clinical stage[40,41]	>567 days for stage I >187 days for stage II 245 days for stage III	874 days for stage I 818 days for stage II 207 days for stage III
PDGFRs-α and -β coexpression[30]	239 days if no coexpression 159 days if no coexpression	335 days if no coexpression 183 days if no coexpression
Ki67[30]	484 days if Ki67 <19.5% 188 days if Ki67 >19.5%	484 days if Ki67 <19.5% 224 days if Ki67 >19.5%

PDGFR, Platelet-derived growth factor receptor.

considerably from 150 to 874 days with 1-year survival rates less than 35%.[9,13–24,30–68] In a recent study, the median progression-free interval (PFI) and MST after surgery alone for oral MM were greater than 567 days and 874 days, respectively.[41] Variables which are known to have prognostic significance in dogs treated with surgery alone or in combination with other modalities include age, tumor size, clinical stage, the ability of the first treatment to achieve local control, and histologic and immunohistochemical criteria such as the degree of differentiation, mitotic index, nuclear atypia score, pigment quantification, COX-2 expression, PDGFR expression, Ki67 expression, and c-*kit* expression (Table 23.5).[9,13–24,30–68] In some studies, tumor location has prognostic importance with rostral mandibular and caudal maxillary sites having a better prognosis than other sites.[32,37,53] MSTs are significantly shorter for dogs with recurrent oral MM compared with dogs with previously untreated oral MM.[31] In one study, dogs treated with adjunctive RT had significantly longer STs, but this result may have been confounded by age, which was also prognostic in this study.[40] In 64 dogs with surgically treated well-differentiated melanomas of the lips and oral cavity, 95% of dogs were either alive or had died of unrelated causes at the end of the study period.[69] Prognostic information for melanocytic tumors in dogs has recently been reviewed.[39]

Oral melanoma is responsive to hypofractionated RT protocols. A number of different hypofractionated RT protocols have been described: (1) 3 weekly 8 to 10 Gy fractions for a total dose of 24 to 30 Gy,[44,47] (2) 4 weekly fractions of 9 Gy for a total dose of 36 Gy,[45,47] (3) 6 weekly 6 Gy fractions for a total dose of 36 Gy,[46] (4) 5 fractions of 6 Gy over 2.5 weeks,[49] and (5) 8 weekly 6 Gy fractions for a total dose of 48 Gy.[42] Response rates are excellent, with 81% to 100% of tumors responding and a complete response observed in up to 70% of melanomas.[42–49] Local recurrence is reported in 15% to 26% of dogs experiencing a complete response with a median time to local recurrence of 139 days.[44–49] In one study progressive local disease was observed in all dogs that did not achieve a complete response.[44] The most common cause of death is metastasis, and this is reported in 58% of dogs with a median time of metastasis of 311 days.[46] The MST for dogs treated with RT is 192 to 401 days, with a 1-year survival rate of 36% to 48% and a 2-year survival rate of 21%.[44–49] Local tumor control and ST are significantly improved with rostral tumor location, smaller tumor volume, no radiographic evidence of bone lysis, postoperative irradiation of microscopic disease, and megavoltage irradiation.[43,45,47,48] In one series of 140 dogs with oral MM, the MST was 21 months if none of these risk factors were present compared with an MST of 11 months with one risk factor, 5 months with two risk factors, and three months with all three risk factors.[47]

Tumor size is important with median PFS for dogs with T1 oral melanomas of 19 months compared with less than 7 months for T2 and T3 tumors.[43] In one study of 111 dogs treated with either orthovoltage or megavoltage hypofractionated protocols, tumor size and clinical stage had a significant effect on outcome with MSTs for dogs with stage I, II, III, and IV oral malignant melanoma of 758, 278, 163, and 80 days, respectively.[48] In this study, there was a greater risk of death and decreased STs overall (MSTs of 233 days compared with 122 days) and for dogs with stage III melanoma (MSTs of 210 days compared with 99 days) when treated with orthovoltage rather than megavoltage RT.[48] The median PFI was significantly prolonged in one study of 27 dogs when hypofractionated RT was combined with adjuvant oral temozolomide compared with hypofractionated RT alone.[49] Hypofractionated RT has also been described in five cats with oral melanoma, resulting in a 60% response rate and MST of 146 days (range: 66–224 days).[29]

Effective systemic adjuvant therapies (e.g., immunotherapy, chemotherapy) are ultimately necessary for successful management

of dogs with oral MM owing to the high metastatic risk. Unfortunately, these tumors, in dogs and people, are generally poorly responsive to cytotoxic chemotherapy and effective immunotherapies that result in meaningful immunologic responses in the majority of patients are currently lacking.

In a small study of 17 dogs treated with surgery and adjuvant carboplatin, the median PFS was 259 days (with 41% of dogs developing local tumor recurrence and 41% of dogs developing metastasis) and the MST was 440 days.[52] However, two recent studies have shown no benefit in STs with the use of adjunctive chemotherapy,[40,41] with overall MSTs of 335 days and 352 days in dogs that were and were not treated with systemic adjuvant therapy.[41]

Immunotherapy holds the most promise for effective management in dogs with MM and this is an area of very active research in both veterinary and physician-based oncology. The use of DNA vaccinations with either murine or human tyrosinase in dogs with advanced stages of oral MM (clinical stage II–IV) results in MSTs of 224 to 389 days.[61–66] In one study of nine dogs treated with DNA vaccine encoded for human tyrosinase, complete response was observed in one dog with lung metastasis, two dogs with stage IV disease and bulky metastasis lived for greater than 400 days, and two dogs with stage II or III disease died of other causes approximately 500 days after treatment with no evidence of tumor at necropsy.[61] The MST is significantly improved to 589 days when the primary oral site and regional LNs are controlled with surgery or RT.[61] In a prospective study of dogs with surgically excised stage II or III oral MM that compared 58 dogs treated with DNA vaccine encoded for human tyrosinase with a historical control of 53 unvaccinated dogs, the MST was significantly longer for dogs in the vaccinated group (not reached compared with 324 days) with tumor-related deaths in only 26% of vaccinated dogs compared with 64% of unvaccinated dogs.[62] In two prospective studies investigating human recombinant chondroitin sulfate proteoglycan-4 DNA–based electrovaccination after surgical resection in dogs with stage II or III oral MMs, the survival outcomes were significantly longer in vaccinated dogs.[67,68] For vaccinated and unvaccinated dogs, respectively, the local recurrence rates were 21% to 35% and 39% to 42%; the metastatic rates were less than 36% and 79% to 90%; the 6-month survival rates were 96% to 100% and 63% to 69%; the 12-month survival rates were 64% to 74% and 15% to 26%; the 24-month survival rates were 30% and 5%; the median disease-free intervals (DFIs) were 477 days and 180 days; and the MSTs were 653 to 684 days and 200 to 220 days.[67,68] For vaccinated dogs, outcomes were significantly better for dogs weighing less than 20 kg.[68] A thorough discussion of MM and its prognosis after definitive treatment with surgery, RT, chemotherapy, and/or immunomodulatory agents is provided in Chapter 20.

The location of MM may also have some prognostic significance. Melanomas of the lip and tongue may have a lower metastatic rate, with survival more dependent on local control of the tumor. In one series of 60 dogs with oral MMs at various sites treated with combinations of surgery, RT, chemotherapy, and immunotherapy, the MST for dogs with lip and tongue MMs was 580 days and was greater than 551 days, respectively.[9] In comparison, the MST was 319 days for maxillary MMs and 330 days for MMs of the hard palate.[9] In another study, the MST was significantly longer for dogs with labial mucosal MMs (310 days) than mandibular and maxillary MMs (123 days).[38]

In another study, only 5% of 64 dogs with well-differentiated melanomas of the mucous membranes of the lips and oral cavities treated with surgery alone had died from tumor-related causes, with an overall MST of 34 months.[69] This improved prognosis may reflect the location of these lesions (lip compared with oral cavity) or the degree of differentiation. Nuclear atypia and mitotic index have also been shown to be prognostic in dogs with oral MM.[35]

Canine Oral Squamous Cell Carcinoma

The prognosis for dogs with oral SCC is good, particularly for rostral tumor locations. Local tumor control is usually the most important challenge, although metastasis to the regional LNs is reported in up to 10% of dogs and to the lungs in 3% to 36% of dogs.[24,43,76–85,179] In contrast, SCC of the tonsils and base of the tongue are highly metastatic, with metastasis reported in up to 73% of dogs, and locoregional recurrence is common.[138–141,180,181] Surgery and RT can both be used for locoregional control of oral SCC in dogs. Photodynamic therapy has also been reported with fair-to-good results in 11 dogs with smaller oral SCC.[182]

Surgery is the most common treatment for nontonsillar SCC.[13–24,74,78,79,179] Overall local recurrence rates vary from 18% to 23%[24,179] and, in one study, local recurrence was significantly associated with incomplete histologic excision.[24] After mandibulectomy, the local recurrence rate is 0% to 10% and the MST varies from 19 to 43 months with 88% to 100%, 79%, and 58% 1-, 2-, and 3-year STs, respectively.[20,74,78,79] In comparison, the local recurrence rate is 14% to 29% after maxillectomy, with an MST of 10 to 39 months and a 1-, 2- and 3-year survival rates of 57% to 94%, 69%, and 38%, respectively.[21,78,79] The reason for the higher local control and survival rates with mandibular resections is probably that the rostral mandible is the most common location for oral SCC in dogs and complete surgical resection is more likely for these rostral tumors. However, tumor location (both mandibular vs. maxillary and location within the oral cavity) was not prognostic after surgical excision in three recent studies.[77–79] In one study, the MST for untreated dogs was 54 days, with a 0% 1-year survival rate.[78] In comparison, the 1-year survival rate for dogs with surgically excised oral SCC was 94%, with MSTs not reached for dogs with stage I oral SCC and 420, 365, and 50 days for dogs with stage II, III, and IV oral SCC, respectively.[78] The presence of tumor-associated inflammation and risk score of 2 or ≥3 (combination of tumor-associated inflammation, lymphatic or vascular invasion, and peripheral nerve invasion) were associated with a significantly worse prognosis.[78] In two studies of dogs with surgically resected mandibular and maxillary SCC, overall median disease-free STs were not reached with 1- and 2-year disease-free survival rates of 75% to 79% and 61% to 76%, respectively.[76,179] The median disease-free survival was significantly shorter for dogs with grade III SCCs (138 days) and SCCs with a proliferating cell nuclear antigen expression greater than 65% (155 days) compared with dogs with grade II SCCs and SCCs with a proliferating cell nuclear antigen expression ≤65% (not reached).[77] In one study, incomplete histologic margins were associated with a significantly worse outcome (MST 1140 days compared with not reached for dogs with complete histologic excision), but dogs with incomplete histologic margins treated with adjuvant hypofractionated RT were significantly less likely to die of tumor-related reasons than dogs not treated with adjuvant RT.[179]

Full-course RT, either alone or as an adjunct after incomplete surgical resection, is also a successful treatment modality for the management of oral SCC in dogs.[43,80,81,179] The local tumor recurrence rate is 31%.[80,81] The MST for RT alone is 15 to 16 months and increases to 34 months when combined with surgery.[80,81]

VetBooks.ir

In one series of 39 dogs with oral SCC, the overall median PFS time was 36 months, with 1- and 3-year PFS rates of 72% and 55%, respectively.[43] Local tumor control was more successful with smaller lesions; the median PFS time for T1 tumors (<2 cm diameter) was not reached and greater than 68 months compared with 28 months for T2 tumors (2–4 cm diameter) and 8 months for dogs with T3 tumors (>4 cm diameter).[43] Other favorable prognostic factors for dogs receiving orthovoltage irradiation include rostral tumor location, maxillary SCC, and young age.[80] Rostral tumors (MST of 28 months compared with 2–10 months for caudal to extensive tumors), nonrecurrent tumors (MST 29 months compared with 7 months for recurrent SCC), portal size less than 100 cm^2/m^2 (MST 24 months compared with 7 months), and age less than 6 years (MST of 39 months compared with 10 months) are good prognostic factors for dogs treated with orthovoltage RT.[80] Younger age is also prognostic for dogs treated with megavoltage RT, as the MST of 315 days for dogs with oral SCC and older than 9 years is significantly shorter than the 1080 day MST for dogs younger than 9 years.[81]

Chemotherapy is indicated for dogs with metastatic disease, dogs with bulky disease, and when owners decline surgery and RT; however, although responses are noted in the macroscopic (gross disease) setting, durability of response is expected to be short (2–3 months). As the metastatic potential of oral SCC in dogs is relatively low, the role of adjuvant chemotherapy in minimizing the risk of metastatic disease is unknown. In a series of 17 dogs treated with piroxicam alone, the response rate was 17%, with one complete response and two partial responses.[82] The median PFI for dogs responding to piroxicam was 180 days and significantly longer than the 102 days for dogs with stable disease.[82] The outcome is better when piroxicam is combined with either cisplatin or carboplatin. In a series of nine dogs treated with piroxicam and cisplatin, the overall MST was 237 days, with the 56% of dogs responding to this chemotherapy protocol having a significantly better MST (272 days) than nonresponders (116 days).[83] However, renal toxicity was reported in 41% of dogs in this study and such toxicities limit the clinical usefulness of this protocol. In another small series of seven dogs with T3 oral SCC treated with piroxicam and carboplatin, a complete response was observed in 57% of dogs and this response was sustained in all dogs at the median follow-up time of 534 days.[84] Novel therapies under investigation include the combination of intralesional bleomycin and feline interleukin-12 (IL-12) DNA with translesional electroporation.[54]

Feline Oral Squamous Cell Carcinoma

The prognosis for cats with oral SCC is poor. There is no known effective treatment that consistently results in durable control or survival. Local control is the most challenging problem. In one series of 52 cats, the 1-year survival rate was less than 10%, with MSTs of 3 months or less for surgery alone, surgery and RT, RT and low-dose chemotherapy, or RT and hyperthermia.[91] However, 42% of these cats had SCC involving the tongue, pharynx, or tonsils. In another series of 54 cats treated in general practice, the MST was 44 days, with a 10% 1-year survival rate.[94] The oncologic outcome may be better for cats with mandibular SCC. The MST for seven cats treated with a combination of mandibulectomy and RT was 14 months, with a 1-year survival rate of 57%.[89] Local recurrence was the cause of failure in 86% of these cats between 3 and 36 months after therapy. In another series of 22 cats treated with mandibulectomy alone, the median DFI was 340 days.[90] Tumor location and extent of resection had prognostic importance, with an MST of 911 days for rostral mandibulectomies, 217 days after hemimandibulectomy, and 192 days when more than 50% of the mandible was resected.[90] Expansile, blastic, and discrete lesions are often more resectable than invasive, lytic, and ill-defined lesions. The use of esophagostomy or gastrostomy tubes may be necessary to provide supplemental nutrition in these cats for up to 4 months postoperatively.[90]

RT alone is generally considered ineffective in the management of cats with oral SCC. In nine cats treated with an accelerated radiation protocol (14 fractions of 3.5 Gy delivered twice daily for 9 days), the overall MST was 86 days and, although not significant, the MST for cats with a complete response was 298 days.[100] The combination of RT with radiation sensitizers or chemotherapy improves response rates and STs. Using the same accelerated radiation protocol with carboplatin resulted in a 52% complete and 22% partial response rate at 30 days with a MST of 163 days in 31 cats.[101] Intratumoral etanidazole, a hypoxic cell sensitizer, resulted in a 100% partial response rate in nine cats completing the RT course, with a median decrease in tumor size of 70% and a MST of 116 days.[96] Gemcitabine was used at low doses as a radiation sensitizer in eight cats with oral SCC, with an overall response rate of 75%, including two cats with complete responses, for a median duration of 43 days and an MST of 112 days.[98] However, gemcitabine is not recommended as a radiosensitizer in cats because of significant hematologic and local tissue toxicities.[99] The combination of RT with mitoxantrone holds some promise; in two series of 18 cats, a complete response was observed in 73%, with a median duration of response of 138 to 170 days and an MST of 184 days.[97,107] Tumor location, clinical stage, and the completeness of response are reported prognostic factors.[101,103] Location was a prognostic factor in this study, with significantly longer MSTs in cats with SCC of the tonsils (not reached, mean 724 days) and cheek (not reached) than other locations.[101] A complete response at 30 days was also associated with a significantly longer ST (379 days) than non- or partial responders (115 days).[101]

Hypofractionated RT has also been reported in cats with oral SCC. An overall response rate of 81%, with an MST of 174 days, was reported in 21 cats treated with an accelerated hypofractionated RT protocol consisting of 10 daily fractions of 4.8 Gy for a total dose of 48 Gy.[103] In 54 cats treated with 8 to 10 Gy weekly fractions for a total dose of 24 Gy to 40 Gy, the radiation-induced adverse effects were considered mild, with the majority of owners reporting a subjectively improved quality of life.[104] The overall MST was 92 days and cats with sublingual SCCs had a longer MST (135 days) than cats with mandibular SCC (80 days).[104]

Palliative stereotactic RT has been investigated in 20 cats with a 39% overall response rate and a median PFI and MST of 87 and 106 days, respectively; however, there was a high complication rate with mandibular fracture in 6 of 11 cats, fibrosis in three of six cats with lingual SCC, and oronasal fistula in one of three cats with maxillary SCC.[105,106] In this study, cats with a low *Bmi-1* percentage, which is an oncogene responsible for suppression of cell-cycle inhibitors and confers resistance to both chemotherapy and RT, had a significantly better outcome with longer median PFI than cats with a higher *Bmi-1* percentage.[106] Other prognostic factors for cats with oral SCC treated with stereotactic RT include sex, tumor microvascular density, and degree of keratinization.[105]

Localized irradiation with strontium-90 may be effective for selected cats with very superficial disease.[183]

Chemotherapy appears to be largely ineffective in the management of cats with oral SCC. No responses were observed in 18 cats treated with liposome-encapsulated cisplatin or 13 cats treated

VetBooks.ir

with piroxicam.[108,110] However, nonsteroidal antiinflammatory drugs (NSAIDs) and toceranib have been shown to significantly improved outcomes in cats with measureable oral SCC.[94,111] In one study of 23 cats with oral SCC with no previous treatments, toceranib and/or an NSAID resulted in a biologic response rate of 57%, with a complete response in 4% of cats, partial response in 9% of cats, and stable disease in 43% of cats.[111] The MST of cats treated with toceranib and/or an NSAID (123 days) was significantly longer than the 45-day MST for cats not treated with toceranib.[111] Cats with a biologic response to treatment with toceranib and/or an NSAID had significantly better median PFS (112 days) and overall MSTs (202 days) than cats that did not respond to treatment (29 days and 73 days, respectively).[111] Cats treated with an NSAID also had a significantly improved MST (169 days) than cats not treated with an NSAID (55 days).[111] As most of these small case series are retrospective in nature, caveats as to the true efficacy of these therapeutic approaches await conformation in controlled, randomized trial settings.

Pamidronate, a bisphosphonate drug with antiosteoclastic activity, has been shown to reduce proliferation of feline cancer cells in vitro and palliate cats with bone-invasive tumors, including oral SCC.[112] In a pilot study of five cats with oral SCC treated with pamidronate, some of which were treated with other modalities including NSAIDs, the median PFS time and overall MST were 71 days and 170 days, respectively.[112]

Fibrosarcoma

The prognosis for dogs with oral FSA is guarded. These are locally aggressive tumors and local control is more problematic than metastasis. Metastasis is reported to the regional LNs in 19% to 22% of dogs and to the lungs in up to 27% of dogs. [12,20–24,43,113–117,179] Multimodality treatment of local disease appears to afford the best survival rates, with combinations of surgery and RT or RT and hyperthermia.[115]

Surgery is the most common treatment for oral FSA. Local recurrence has been reported in up to 54% of dogs overall,[24,179] up to 59% of dogs after mandibulectomy,[20] and up to 40% of dogs after maxillectomy.[21] However, a recent retrospective series reported local recurrence in 24% of 29 dogs with mandibular and maxillary FSA.[114] Local tumor recurrence was significantly associated with incomplete excision and breed (golden retriever or golden retriever mixed breed dogs).[114] Two of the seven dogs with local tumor recurrence developed recurrence after incomplete excision and adjunctive RT.[114] In older reports, the 1-year survival rates rarely exceed 50% with surgery alone;[13–23] however, the MST in a recent retrospective series was 743 days with a median PFI of greater than 653 days and 1- and 2-year survival rates of 88% and 58%, respectively.[114] The median DFI for five cats treated with mandibulectomy was 859 days.[90] The combination of surgery and RT may provide the best opportunity to control local disease in dogs regardless of completeness of excision.[115]

Oral FSAs are considered radiation resistant in the macroscopic (gross) disease setting.[116] The mean ST of 17 dogs treated with RT alone was only 7 months.[116] When RT is used as an adjunct to surgical resection, local tumor recurrence was reported in 32% of dogs overall and the MST increased to 18 to 26 months with a 1-year PFS rate of 76%.[43,117] In one study, 17 of 48 dogs with oral FSA were treated with adjuvant hypofractionated RT and RT did not provide a protective effect with significantly poorer STs in dogs treated with RT.[179] However, in another study, the addition of RT to surgery resulted in significantly longer median PFS (301 days compared with 138 days) and overall MSTs (505 days compared with 220 days) than mandibulectomy or maxillectomy alone.[115] A smaller tumor size improves the outcome after RT, with a median PFS time of 45 months for dogs with T1 tumors compared with 31 months and 7 months for T2 and T3 tumors, respectively.[43]

Osteosarcoma

OSA of axial sites is less common than appendicular OSA and represents approximately 25% of all cases.[10] Of the axial OSA, the mandible and maxilla are involved in 27% and 16% to 22% of cases, respectively.[10,118] The prognosis for dogs with oral OSA is better than for those with appendicular OSA because of an apparent lower metastatic potential.[10,119–122] In one study, only 4% of 183 dogs with maxillary, mandibular or calvarial OSA had evidence of metastasis at the time of diagnosis,[12] with distant metastasis reported in 32% to 46% of dogs after definitive treatment.[12,24]

The outcome after mandibulectomy alone is variable, with MSTs of 14 to 18 months and 1-year survival rates of 35% to 71%.[10,20,119] After mandibulectomy, local recurrence and metastasis has been reported in 15% to 28% and 35% to 58% of dogs, respectively.[20,121,122] The median metastasis-free interval and MST were 627 days and 525 days, respectively, in one study of 50 dogs.[122] After maxillectomy, local recurrence and metastasis were reported in 58% and 32% of 69 dogs, respectively.[121] The MST for dogs with maxillary OSA varies from 5 to 10 months, with a 1-year survival rate of 17% to 27% and with local tumor recurrence rather than distant metastasis being the most common cause of death.[10,21,118,121]

Local tumor control is the most challenging problem and resecting oral OSAs with complete surgical margins is imperative. The completeness of excision was prognostic for both local tumor recurrence and survival in multivariate analyses in one study.[121] The combination of surgery with either RT or chemotherapy has not resulted in improved outcomes in dogs with incompletely resected tumors, highlighting the necessity for an aggressive surgical approach.[120,121] These results are supported by another study of 45 dogs with axial OSA in which favorable prognostic factors included complete surgical excision, mandibular location, and smaller body weight dogs.[118] Other poor prognostic factors for dogs with mandibular, maxillary, and/or calvarial OSA include serum alkaline phosphatase levels greater than 140 units/L, increased monocyte counts, telangiectatic histologic subtype, mitotic index, histologic grade, and local tumor recurrence.[121,122] The role of chemotherapy in the management of dogs with oral OSA was considered controversial because local tumor recurrence was the most common cause of tumor-related deaths; however, adjuvant chemotherapy results in significantly longer metastasis-free intervals and STs in dogs with mandibular OSA.[122]

Peripheral Odontogenic Fibroma

The prognosis for dogs with peripheral odontogenic fibromas is excellent after treatment with either surgery or RT. These are benign tumors, and metastasis has not been reported; hence, local tumor control is the principal goal of therapy. The local tumor recurrence rate after surgical resection without bone removal varies from 0% to 17%,[125,126] whereas a 4% local recurrence rate was reported in one study of dogs treated with either mandibulectomy or maxillectomy.[24] RT is also effective, with an 3-year PFS

VetBooks.ir

rate of 86%.[131] However, definitive RT is usually not required, as these tumors can be adequately managed with simple surgical resection.[127] Local recurrence is common in cats with multiple peripheral odontogenic fibromas and is reported in 73% of 11 cats 3 months to 8 years after surgical resection.[135]

Acanthomatous Ameloblastoma

Surgery or RT is also used in the management of dogs with AA. Mandibulectomy or maxillectomy is required for surgical resection of AAs because of frequent bone invasion by this benign tumor. In one study, 91% of AAs recurred at a mean of 32 days after marginal excision.[127] Local recurrence rates after either mandibulectomy or maxillectomy with appropriate margins are less than 5%.[13–24,125,128,129] In one study of 263 dogs with AA, complete histologic excision was reported in 67%, 75%, and 100% of dogs with 1.0 cm, 1.5 cm, or 2.0 cm surgical margins, respectively. Despite incomplete histologic excision, the local recurrence rate was 0%, with a mean follow-up of 33 months.[129]

Megavoltage RT, consisting of an alternate day protocol of 4 Gy per fraction to a total of 48 Gy, results in a 3-year PFS rate of 80% in dogs with AAs.[131] The overall local recurrence rate with RT varies from 8% to 18% in two studies of 39 dogs and recurrence was eight times more likely with T3 tumors compared with T1 and T2 tumors.[130,131] The majority of tumors recur within the radiation field, which suggests a higher radiation dose may be required to achieve higher rates of local tumor control, particularly for tumors greater than 4 cm in diameter.[131] Other complications associated with RT include malignant transformation in 5% to 18% of dogs and bone necrosis in 6% of dogs.[130–132]

Intralesional bleomycin has been reported in two studies of dogs with AA.[133,134] In total, 10 dogs were treated with curative-intent intralesional bleomycin and all had complete responses. In one study of six dogs,[134] 1 to 16 (median, 5) intralesional injections were administered before a complete response was achieved. The median time to complete response was 1.5 months. There was no evidence of recurrence at 1 year in one study and after a median follow-up of 842 days in another study.[134]

Selected Sites or Cancer Conditions in the Oral Cavity

Tonsillar Squamous Cell Carcinoma

Tonsillar SCC is 10 times more common in animals living in urban versus rural areas, implying an etiologic association with environmental pollutants.[184] The most common tonsillar tumor is SCC.[185,186] Tonsillar SCC has a significantly higher proportion of grade III lesions and metastatic disease at diagnosis compared with oral SCC at other sites.[77] Lymphoma can affect the tonsils, but bilateral tonsillar involvement is more common and this is usually accompanied by generalized lymphadenopathy.[185,186] Other cancers, especially MM, can metastasize to the tonsils.[185,186] Cervical lymphadenopathy is a common presenting sign, even with very small primary tonsillar cancers. FNA of the regional LNs or excisional biopsy of the tonsil are required for definitive diagnosis. Up to 20% of cases have evidence of pulmonary metastasis at presentation. In spite of disease apparently confined to the tonsil, this disease is considered systemic at diagnosis in more than 90% of cats and dogs.[185,186] The CT features of pharyngeal neoplasia have been described, and these are useful in determining the extent of local disease and the presence of LN and distant metastasis.[185,186] If disease is localized to the tonsils and not infiltrative, then surgery should be considered as part of a multimodal treatment protocol. Simple tonsillectomy is almost never curative, but probably should be done bilaterally because of the high percentage of bilateral disease.[10] Cervical lymphadenectomy, especially if the regional LNs are large and fixed, is rarely curative and should be considered diagnostic only. Regional RT of the pharyngeal region and cervical LNs can achieve locoregional control in more than 75% of cases; however, survival still remains poor with 1-year survival rates of only 10%.[180,181] Local tumor control and STs were significantly improved in one study of 22 dogs with tonsillar SCC when RT was combined with a variety of different chemotherapy drugs.[181] Cause of death is local disease early and systemic disease (usually lung metastasis) later. To date, no known effective chemotherapeutic agents exist for canine or feline SCC, although cisplatin, carboplatin, doxorubicin, vinblastine, and bleomycin have been used with limited success.[85,181] In one study of 44 dogs with tonsillar SCC treated with surgery, RT, and/or chemotherapy, the MST was 179 days and dogs presenting with either anorexia or lethargy had significantly shorter STs.[187]

Lingual

Lingual tumors are uncommon in cats and dogs. In dogs, tongue tumors account for up to 4% of all oropharyngeal neoplasms.[188] Neoplasia accounts for up to 54% of canine lingual lesions with 64% of these being malignant tumors.[138,140,188] The majority of these tumors are located on the dorsal surface of the tongue, and are evenly distributed between the rostral, mid, and caudal portions of the tongue.[138,141] For unknown reasons, 16% of dogs and up to 29% of people with tongue tumors have a second primary tumor.[189] Hence, thorough physical examination and clinical staging are important in animals with tongue tumors. White dogs appear to be at higher risk for SCC, even though lack of pigment would not be intuitive as an etiologic contributor as it is in other more sunlight-exposed areas of the body (e.g., nose, eyelids, and ears).[139] Other reported breed predilections include Chow Chow and Chinese Shar-Pei for MM; poodle, Labrador retriever, and Samoyed for SCC; border collie and golden retriever for hemangiosarcoma and FSA; and cocker spaniel for plasma cell tumors.[188] The most common cancer of the canine tongue is SCC, accounting for up to 50% of cases, followed by MM, mast cell tumor, hemangiosarcoma and hemangioma, granular cell myoblastoma, FSA, adenocarcinoma, neurofibrosarcoma, leiomyosarcoma, rhabdomyoma and rhabdomyosarcoma, myxoma, and lipoma.[139,141,188,190] Feline tongue tumors are usually SCCs, and most are located on the ventral surface near the frenulum. Presenting signs are similar to those of other oral tumors. Ulceration is common with SCC.

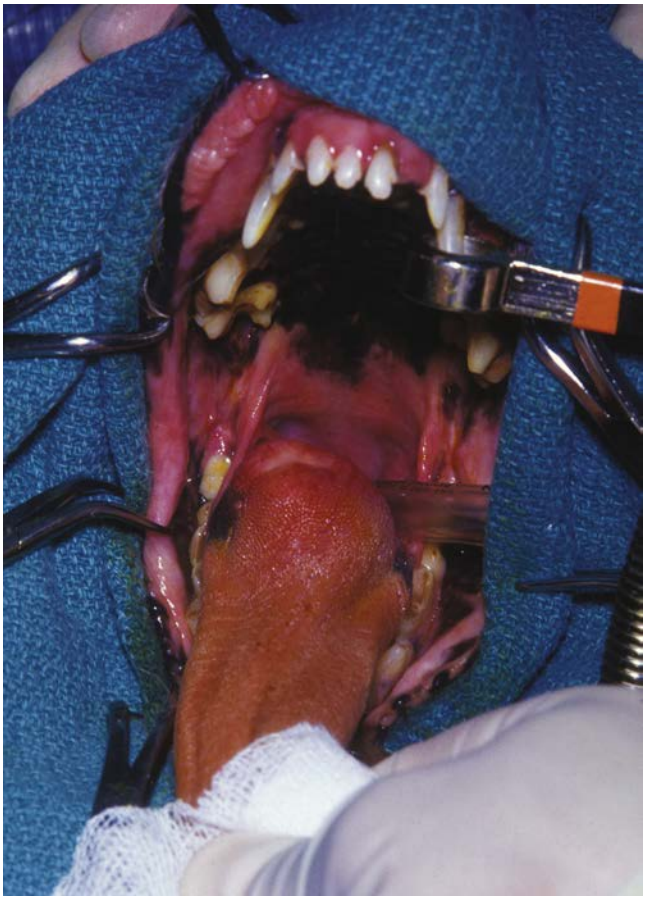
An incisional biopsy, such as a punch or wedge biopsy, is recommended for the diagnosis of tongue lesions in cats and dogs. A biopsy is necessary to differentiate malignant tumors from nonneoplastic lesions, such as eosinophilic granuloma and calcinosis circumscripta, and because a knowledge of the definitive diagnosis may change treatment options (i.e., surgical dose or multimodality therapy with either RT and/or chemotherapy) or the willingness of the owner to pursue curative-intent treatment. Ultrasonography can be useful in delineating the margins of tongue masses to determine surgical resectability.[191] Regional LNs should be aspirated for staging purposes and three-view thoracic radiographs evaluated for lung metastasis.

VetBooks.ir

Surgical resection is recommended,[141] whereas RT is reserved for MMs, inoperable cancer, or tumors metastatic to the regional LNs. Surgical resection, involving either marginal excision, subtotal glossectomy, or total glossectomy, was well tolerated in one study of 97 dogs.[141] Complications included postoperative bleeding (10%), partial tongue paralysis (2%), and incisional dehiscence (2%); and no dog had long-term prehension difficulties.[141] Resection of 50% to 100% of the tongue or avulsion of the tongue was reported in five dogs with minimal postoperative problems, which suggests that more aggressive resections may be possible without compromising quality of life.[189] Feeding tubes are recommended for enteral nutrition during postoperative recovery after total glossectomy but, in the long term, eating and drinking are usually only mildly impaired and good hydration and nutrition can be maintained postoperatively.[139,189] Hypersalivation is the most common complaint after aggressive resections.[189] Thermoregulation can be a problem in hot and humid environments. Grooming in cats will be compromised and may result in poor hair-coat hygiene.

The prognosis for tongue tumors depends on the site, size, type, and grade of cancer, completeness of excision, local tumor recurrence, and metastasis.[139–141] Cancer in the rostral tongue has a better prognosis, possibly because rostral lesions are detected at an earlier stage, the caudal tongue may have richer lymphatic and vascular channels to allow metastasis, and rostral tumors are easier to resect with wide margins.[139] Tumor size was prognostic in two studies. In one study, dogs with tongue tumors greater than 4 cm^2 were 10 times more likely to develop local recurrence and/or distant metastasis and up to 19 times more likely to die of their tongue tumor than dogs with tumors ranging from 1 cm^2 to 4 cm^2.[140] In another study, tumor size was the only variable prognostic on multivariate analysis; dogs with tumors less than 2 cm had a MST of 818 days compared with 207 days for dogs with tumors 2 cm or greater.[141]

Complete surgical excision was significantly more likely with smaller tumors and tumors located in the rostral free portion of the tongue.[139,140] Furthermore, complete surgical excision was significantly associated with increased STs and dogs with incomplete histologic margins were significantly more likely to develop local recurrence and/or distant metastasis and die of their tumor.[139,140] Local tumor recurrence has been reported in 26% to 28% of dogs after glossectomy, and is more likely with incomplete histologic excision, large tumors, and malignant tumors.[140,141] Dogs with local tumor recurrence were 33 times more likely to die as a result of their tumor than dogs without local recurrence.[140]



Dogs with benign tongue tumors have a significantly longer DFI and MST than dogs with malignant tongue tumors.[140] In one study, the MST for dogs with benign tongue tumors was not reached and greater than 1607 days compared with 286 days for dogs with malignant tongue tumors.[140] Dogs with malignant tongue tumors were eight times more likely to have local recurrence and/or distant metastasis and 15 times more likely to die of their tumor than dogs with benign tongue tumors.[140] Dogs with metastatic disease have a significantly worse outcome, with an MST of 241 days compared with a MST of 661 days for dogs without metastatic disease.[141]

Tongue SCCs in dogs are graded from I (least malignant) to III (most malignant) based on histologic features such as degree of differentiation and keratinization, mitotic rate, tissue and vascular invasion, nuclear pleomorphism, and scirrhous reaction.[139] The MST for dogs with grade I tongue SCC is 16 months after surgical resection, which is significantly better than the MSTs of 4 and 3 months reported for grade II and III SCC, respectively.[139] The 1-year survival rate is 50% after complete surgical resection and approaches 80% with complete histologic excision of low-grade SCCs.[139] Long-term control of feline tongue tumors is rarely reported with 1-year survival rates for tongue SCC less than 25%.

The MST for dogs with tongue MM is variable, with 222 days reported in one study,[140] but not reached and was greater than 551 days in another study.[9] The metastatic rate ranges from 29% to 45%.[9,138,140,141]

The overall MST for 20 dogs with surgically treated lingual hemangiosarcoma was 553 days.[142] Lingual hemangiosarcomas are typically small, located on the ventral aspect of the tongue, and low to intermediate histologic grade.[142] Prognostic factors included tumors causing clinical signs and larger tumors. Dogs with clinical signs associated with their lingual hemangiosarcoma had a significantly shorter MST (159 days) than asymptomatic dogs (633 days).[142] The MST for dogs with lingual hemangiosarcomas less than 2 cm (633 days) was significantly longer than for dogs with tumors 2 cm to 4 cm (150 days).[142]

Granular cell myoblastoma is a curable cancer.[192] These cancers may look large and invasive, but are almost always removable by conservative and close margins (Fig. 23.9). Permanent local control rates exceed 80%.[192] They may recur late, but serial surgeries are usually possible. Metastasis is rare with this cancer.

• **Fig. 23.9** This large granular cell myoblastoma was easily removed surgically. The dog had a recurrence 2 years postoperatively, which was resected again, and the dog is tumor free 3 years after the second surgery.

VetBooks.ir

Undifferentiated Malignancy of Young Dogs

Undifferentiated malignancy is seen in dogs under 2 years of age (range, 6–22 months).[193] Most dogs are large breeds and there is no sex predilection. The disease is manifest by a rapidly growing mass in the area of the hard palate, upper molar teeth, maxilla, and/or orbit.[193] Biopsies reveal an undifferentiated malignancy of undetermined histiogenesis. The majority of dogs present with metastasis to the regional LNs and distant sites. An effective treatment has not been identified, although chemotherapy would be necessary considering the high metastatic rate. Most dogs are euthanatized within 30 days of diagnosis because of progressive and uncontrolled tumor growth.[193]

Papillary SCC has been reported to occur in the oral cavity of young dogs (mean age, 3.9 years).[74] The most common location is the rostral maxilla, and bone invasion is frequently noted on CT.[74] Treatment recommendations include complete surgical resection or surgical cytoreduction and curettage followed by RT (40 Gy in 20 fractions). In two studies, no dogs developed either local tumor recurrence or regional or distant metastasis after treatment with either surgery alone or cytoreductive surgery and RT.[74,194]

Multilobular Osteochondrosarcoma

MLO is an infrequently diagnosed bony and cartilaginous tumor that usually arises from the canine skull, including the mandible, maxilla, hard palate, orbit, and calvarium.[27,28] Histologically, these tumors are characterized by multiple lobules with a central cartilaginous or bone matrix surrounded by a thin layer of spindle cells.[27,28] On imaging, MLO is characterized by a typical "popcorn" appearance (Fig. 23.10). Surgery is recommended for management of the local tumor. The overall rate of local recurrence after surgical resection is 47% to 58% and depends on completeness of surgical resection and histologic grade.[27,28] The median DFI for completely resected MLO is 1332 days and significantly better than the 330 days reported for incompletely excised tumors.[28] In terms of tumor grade, the local recurrence rate for grade III tumors is 78% and significantly worse than the recurrence rates of 30% and 47% for grade I and II MLO, respectively.[28] This tumor has a moderate metastatic potential (usually to the lung), which is grade dependent, but usually occurs late in the course of disease. Metastasis is reported in up to 58% of dogs with the median time to metastasis of 426 to 542 days.[27,28] Metastasis is significantly more likely after incomplete surgical resection with a 25% metastatic rate in completely excised tumors and 75% after incomplete resection.[28] Tumor grade also has a significant effect on metastatic rate with metastasis reported in 78% of grade III MLO compared with 30% of grade I and 60% of grade II tumors.[28] There is no known effective chemotherapy treatment for metastatic disease, but STs greater than 12 months have been reported with pulmonary metastasectomy because of the slow-growing nature of this tumor.[28] The overall MST is 21 months and is grade dependent, with reported MSTs of 50 months, 22 months, and 11 months for grade I, II, and III tumors, respectively.[27,28] Tumor location also has prognostic significance because the outcome for dogs with mandibular MLO is significantly better, with an MST of 1487 days compared with 587 days for these tumors at other sites.[28]

• **Fig. 23.10** A computed tomography image of a multilobular osteochondrosarcoma of the vertical ramus of the mandible. Note the characteristic "popcorn" appearance of the mass. After resection of the vertical ramus, this dog was tumor free 3 years after surgery.

Odontogenic Tumors

Odontogenic tumors originate from epithelial cells of the dental lamina. They account for up to 2.4% of all feline oral tumors,[5] but are rare in dogs. They are broadly classified into two groups depending on whether the tumors are able to induce a stromal reaction.[195,196] Inductive odontogenic tumors include ameloblastic fibroma, feline inductive odontogenic tumor, and complex and compound odontomas.[196] Ameloblastomas, AAs, and amyloid-producing odontogenic tumors are examples of noninductive odontogenic tumors.[195,196] Additional odontogenic tumor groups include tumors composed primarily of odontogenic ectomesenchyme (cementoma and cementifying fibroma), tumors derived from the periodontal ligament (peripheral odontogenic fibroma), cysts of the jaw (dentigerous cyst and radicular cyst), and tumor-like lesions (giant cell epulis and gingival hyperplasia.[196]

Inductive fibroameloblastoma is the most common odontogenic tumor in cats, usually occurs in cats less than 18 months of age, and has a predilection for the region of the upper canine teeth and maxilla.[5,124,195–197] Radiographically the tumor site shows variable degrees of bone destruction, production, and expansion of the mandibular or maxillary bones (Fig. 23.11). Teeth deformity is common. Smaller lesions are treated with surgical debulking and cryosurgery or premaxillectomy. Larger lesions will respond to RT. Local treatment needs to be aggressive, but control rates are good and metastasis has not been reported.[5,124]

Odontomas are benign tumors arising from the dental follicle during the early stages of tooth development.[198] Odontomas induce both enamel and dentin within the tumor. Odontomas have a biologic behavior similar to ameloblastomas.

Dentigerous cysts are nonneoplastic, circumscribed cystic lesions originating from islands of odontogenic epithelium.[195] They contain one or more teeth embedded in the cyst wall. Radiographs show a characteristic radiolucent halo surrounding the nonerupted tooth originating at the cementoenamel junction and enveloping the crown of the tooth.[199] Odontogenic cysts may represent an early stage of malignant epithelial tumors.[195] Surgical treatment is recommended, consisting of surgical removal of nonerupted teeth and the cyst lining with possible cancellous bone grafting, to prevent local tumor recurrence.[199]

VetBooks.ir

• **Fig. 23.11** An intraoral radiograph of the rostral mandible in a dog with an ameloblastoma. Note the expansile mandibular mass. The tumor was curetted and filled with cancellous bone graft and the dog was tumor free 1 year after surgery.

Osteomas

Osteomas have been described in both dogs and cats.[200,201] Osteomas are benign tumors of histologically normal mature compact and/or trabecular bone.[201] They are slow growing and rarely cause clinical signs unless the mass interferes with adjacent structures or prevents occlusion.[200,201] Radiographically, osteomas are typically proliferative masses with no evidence of bone lysis.[200,201] They are classified as peripheral, central, or extraskeletal in people, and peripheral and central osteomas have been described in dogs.[200,201] Surgical excision is usually curative.[200,201]

Comparative Aspects[202]

SCC accounts for the vast majority of oral cancer in humans. Oral tumors are associated with alcohol and tobacco use and usually occur in patients more than 40 years old. Patients with oral cancer have an increased risk of developing esophageal and lung cancer. Tumors are staged similar to animals and clinical stage influences both treatment options and prognosis.

Surgery and RT are the only options that provide the opportunity for a cure. Surgery and radiation are occasionally combined, especially because neither modality is likely to achieve a cure rate greater than 70% when used as sole therapy. Chemotherapy has a limited role for control of local disease but has shown promise, often in combination with radiation, for advanced stage cancer.

Prognosis is strongly correlated to histologic grade, stage, and site. Metastasis, particularly to the regional LNs, is more frequent with tonsillar and pharyngeal SCC and larger sized tumors. Tumors of the pharynx and caudal tongue are associated with a worse prognosis than cancers of the rostral tongue and oral cavity because of the higher incidence of nodal metastasis and difficulty in controlling disease once it has spread beyond the primary site.

SECTION B: SALIVARY GLAND NEOPLASIA

SARAH E. BOSTON

Incidence and Risk Factors

Salivary gland neoplasia in dogs and cats is rare; however, it is a significant cause of salivary disease. In a study of the histopathologic diagnosis of salivary gland biopsies in dogs and cats, 30% were diagnosed with neoplasia.[203] The second most common diagnosis in that study was sialadenitis (26%).

Pathology

Salivary gland neoplasms are primarily malignant epithelial tumors. Simple adenocarcinoma is the most common histopathologic diagnosis, with other types of carcinomas being represented second most commonly.[204] Other reported tumors in this location include oncocytoma[205] and carcinosarcoma in cats[206]; and pleomorphic adenoma,[207] myoepithelioma,[208] OSA,[209] and mast cell tumor in dogs[210]; however, these are single case reports and are rare.

History and Clinical Signs

Clinical signs of salivary neoplasia and sialadenitis may be similar. The most common presenting complaint in a retrospective of salivary gland neoplasia in dogs and cats was the presence of a mass.[204] Other presenting complaints included halitosis, weight loss, anorexia, dysphagia, exophthalmos, Horner's syndrome, sneezing, and dysphonia.[204] In one retrospective study of dogs and cats, there appeared to be a predilection for male sex and Siamese breed in cats.[204] In that study, the mandibular salivary gland was most commonly affected in cats and the parotid salivary gland was most commonly affected in dogs.[204]

Diagnostic Techniques and Workup

An FNA for cytology should be performed as a first step in attempting to distinguish between benign and malignant disease.[211] If this is not successful, a needle-core, incisional, or possibly an excisional biopsy can be considered for histopathology. Salivary gland adenocarcinoma is both locally aggressive and has metastatic potential, and hence local and distant staging should be considered before definitive treatment. Thoracic radiographs or CT can be performed to assess the lungs for metastatic disease. An ultrasound of the affected area can also be performed for initial staging and possibly to obtain an ultrasound-guided aspirate of the mass and/or regional LNs.[212] The medial retropharyngeal LNs are the primary lymphatic drainage center of the salivary glands and should be evaluated cytologically and/or biopsied for histopathology.[213] Ultimately, a CT scan of the head and thorax is recommended for staging and surgical planning.[212] In cases where surgery may not be possible, the patient should be positioned for a concurrent radiation planning CT for potential RT alone. In one retrospective study, cats presented at a more advanced stage of disease than dogs, suggesting that this disease may be more aggressive in cats.[204]

Therapy

Surgery is the mainstay of therapy. Using a CT scan for surgical planning, the affected salivary gland is removed. By definition,

this is a marginal excision. However, the degree of tumor encapsulation will help guide whether or not adjunctive RT is indicated. Regional LNs should be sampled for staging purposes.

The surgical approach to the affected mandibular or parotid salivary gland is generally straightforward. If the parotid salivary gland is removed, care must be taken to identify and protect the facial nerve. If this is not possible, facial nerve paralysis may occur. In rare cases of zygomatic salivary neoplasia,[214,215] the zygomatic salivary gland is approached via an orbitotomy and removal of the zygomatic arch.[214]

Prognosis

In one retrospective study of dogs and cats with salivary gland neoplasia, the median survival times were 550 days and 516 days for dogs and cats, respectively.[204] In that study, patients were treated with surgery alone or in combination with RT or chemotherapy.[204] The small number of patients treated with adjunctive therapy in that study makes it difficult to make a general recommendation for adjunctive therapy. Postoperative RT is generally recommended, especially in cases where the tumor is invasive and has extended beyond the capsule.[216] Recommendations for chemotherapy are less defined due to the paucity of information in the literature, but may be indicated in cases with evidence of metastatic disease and with highly malignant histopathology.

Comparative Aspects

Salivary gland adenocarcinoma has been reported in many other mammalian species other than dogs and cats.[217–225]

Treatment of salivary carcinoma in humans is commonly surgery followed by RT.[226–229] Factors that have been associated with a negative prognosis in one study included male sex, perineural invasion, high risk pathology, and late stage.[226] Another study found that age, sex, stage, site, and skin or bone invasion were significantly associated with survival.[227] The use of postoperative RT has been shown to improve locoregional control.[227] Local control has been shown to be significantly associated with tumor stage and treatment type, with the combination of RT and surgery being superior to surgery alone.[228] Tumor stage was significantly associated with survival.[228]

Five- and 10-year survival rates are 68%[229] and 50%, respectively.[227] A 20-year actuarial rate of local control of 57% was reported in one study with a 12-year probability of distant metastasis of 40%.[227]

SECTION C: ESOPHAGEAL TUMORS

PIERRE M. AMSELLEM AND
JAMES P. FARESE

Incidence and Risk Factors

Esophageal neoplasia is rare in dogs and cats. Esophageal sarcomas have been reported in association with infestation by the nematode *Spirocerca lupi*.[230–237] Although this parasite has been reported worldwide (South Africa, Kenya, India, Israel, the southeastern United States), *Spirocerca lupi*–associated esophageal granulomas and sarcomas are reported mainly in Israel.[230–237] Leiomyomas may have a genetic component, as a high incidence was reported in a colony of laboratory beagle dogs.[238] Most animals with esophageal tumors are middle-aged or older and there does not seem to be a gender predisposition.

Pathology and Behavior

It is postulated that with spirocercosis-associated sarcomas, a parasitic esophageal granuloma undergoes malignant transformation leading to the development of an esophageal sarcoma, typically in the caudal thoracic portion of the esophagus.[234] Histologic types of spirocercosis-associated sarcomas include OSAs, fibrosarcomas, and undifferentiated sarcomas.[239] Metastasis to the lungs was reported in 5 of 11 dogs at necropsy.[234] Additional metastatic sites included kidneys, adrenals, stomach, regional LNs, tongue, and the heart.[234] Complicating factors include the presence of megaesophagus and hypertrophic osteopathy.[234]

Plasmocytoma,[240] adenomatous polyp,[241] leiomyosarcoma,[242] carcinoma,[243] adenocarcinoma,[243] adenosquamous carcinoma,[244] and squamous cell carcinoma[245] have also been reported in dogs, but these are rare. Squamous cell carcinoma is the most common esophageal tumor in cats, typically occurring in the middle third of the esophagus just caudal to the thoracic inlet.[246,247]

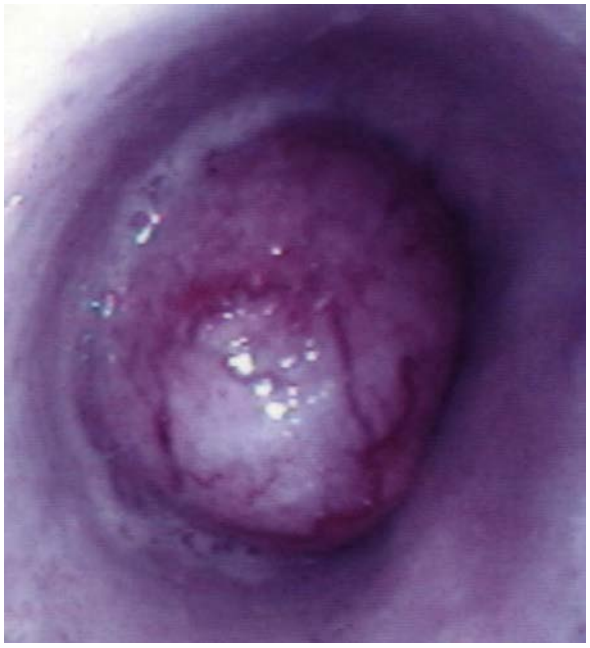
Leiomyomas are benign tumors of the muscularis of the esophagus. They have been reported in the distal esophagus near the gastroesophageal junction in dogs.[238,248] In some cases, multiple leiomyomas can occur in the distal esophagus and the stomach.[232,233] Leiomyomas do not invade the esophageal mucosa. In contrast, low-grade leiomyosarcomas occasionally penetrate the esophageal mucosa.[242]

Paraesophageal tumors, such as thyroid, thymic, or heart base tumors, can invade the esophagus.[249,250]

History and Clinical Signs

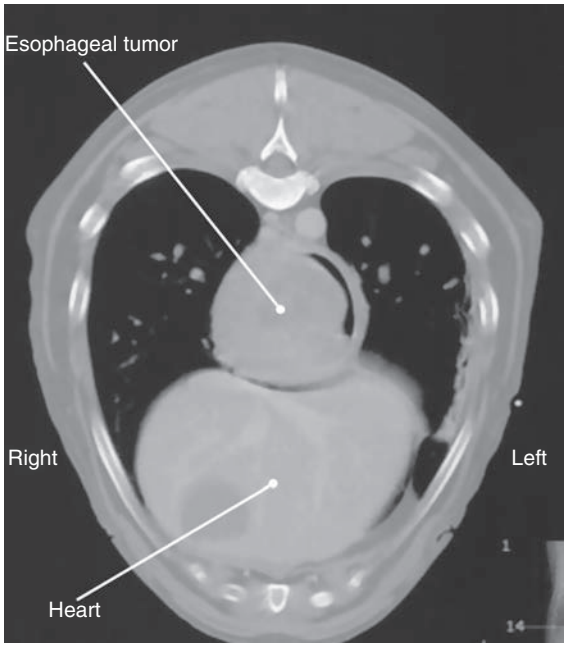
Clinical signs are usually related to obstruction of the esophagus, leading to regurgitation and weight loss. The presence of ulceration of the mass can cause melena and secondary anemia.

Respiratory signs can occur if aspiration pneumonia or metastatic disease develops.



Leiomyomas often are an incidental finding but can occasionally cause signs associated with esophageal obstruction.[232,233,243]

Diagnostic Tests and Workup



Diagnostic tests for esophageal masses usually include survey thoracic radiographs, contrast esophagram, esophagoscopy (Fig. 23.12), and CT scan (Fig. 23.13).[242] Survey radiographs may show retention of gas within the esophageal lumen, a mass, or esophageal dilatation proximal to the mass (Fig. 23.14). Spondylitis on the ventral aspect of the vertebral body T6 to T12 was detected radiographically in 12 of 15 dogs with spirocercosis-associated esophageal sarcoma.[234] A positive-contrast esophagram may show a stricture or mass lesion in the esophageal lumen. Ultrasound- or CT-guided aspirates can be performed for cytologic evaluation. Endoscopic biopsies of esophageal masses are possible; however, for smooth muscle tumors, such as leiomyomas and leiomyosarcomas, they are usually unrewarding, as these tumors do not penetrate the esophageal mucosa.[242,248] A surgical approach may be needed in these cases to obtain an incisional biopsy; however, given the invasive nature of the surgical approach, most biopsies are excisional.

A fecal flotation test may be performed in dogs with esophageal masses to test for *Spirocerca lupi* eggs, particularly in areas where the parasite is endemic. This is a poorly sensitive test; eggs were detected in only two of eight dogs in one study of spirocercosis-associated sarcomas.[234]

• **Fig. 23.13** Computed tomographic image of an esophageal leiomyosarcoma in a dog. (From Farese JP, Bacon NJ, Ehrhart NP, et al. Oesophageal leiomyosarcoma in dogs: surgical management and clinical outcome of four cases. *Vet Comp Oncol*. 20089;6(1):31–38.)

Treatment Options

Most esophageal cancers have extensive local involvement that typically precludes curative-intent therapy. In dogs with esophageal sarcomas, partial esophagectomy has been reported.[251] The authors' preferred approach is to perform an esophagotomy opposite to the esophageal mass to visualize the mass from within the esophageal lumen.[251] A full-thickness esophagectomy can then be performed to resect the mass with a minimum of 1-cm margins.[251] Endoscopic laser or electrocautery debulking of esophageal sarcomas has also been reported.[236] In one study, there was no difference in survival times between dogs treated with surgery and dogs treated with endoscopic ablation.[233]

• **Fig. 23.14** Lateral thoracic radiographic image of a large (8 cm long × 6 cm wide) leiomyosarcoma in the caudal esophagus, just cranial to the diaphragm. (From Farese JP, Bacon NJ, Ehrhart NP, et al. Oesophageal leiomyosarcoma in dogs: surgical management and clinical outcome of four cases. *Vet Comp Oncol*. 2008;6(1):31–38.)

Leiomyomas and low-grade leiomyosarcomas can be marginally excised via an intercostal thoracotomy or laparotomy.[248] Marginal excision appears to provide good long-term local tumor control for most dogs with esophageal leiomyomas. In contrast, marginal excision resulted in incomplete histologic excision in three of four dogs with esophageal leiomyosarcomas; however, local tumor recurrence was confirmed in only one dog and clinical signs of recurrence may not develop because of the slow-growing nature of this tumor.[242]

More aggressive excision with end-to-end resection of esophageal tumors can be curative,[240] but this is often not possible because of the extent of the resection required and/or the location of the mass. Resection of caudal esophageal masses is possible with gastric advancement through the diaphragm,[243] but persistent gastroesophageal reflux and esophagitis can occur.[250]

Nonsurgical treatment options for esophageal tumors have not been established. There are no published reports in dogs or cats documenting successful treatment with either chemotherapy or radiation therapy, either alone or as an adjuvant therapy.

Successful palliative treatment by placement of esophageal stents has been reported in the management of a squamous cell carcinoma[252] and of a leiomyoma in dogs.[253]

Prognosis

Except for leiomyoma and low-grade leiomyosarcomas, the overall prognosis for dogs and cats with esophageal tumors is guarded to poor because of the extent of local disease and/or the presence of metastasis at the time of diagnosis. In one study on 17 dogs with spirocercosis-associated esophageal sarcomas, five dogs treated with partial esophagectomy and adjuvant doxorubicin survived a median of 267 days.[234]

VetBooks.ir

The prognosis for dogs and cats with esophageal carcinomas seems to be poor, as most tumors are unresectable.[243,250] The prognosis for dogs with esophageal leiomyomas after marginal excision appears to be good in a small case series of three dogs[248] and an additional case report,[243] although local recurrence was reported in one dog. Similarly, dogs with low-grade leiomyosarcomas had good long-term resolution of clinical signs after marginal excision, despite incomplete histologic margins in three of four dogs.[242]

Comparative Aspects

A high mortality rate is associated with esophageal cancers in humans.[254] The American Cancer Society predicts that 17,290 new cases of esophageal cancers will occur in 2018, causing 15,850 deaths.[254] The most common esophageal cancer in the United States of America is adenocarcinoma followed by squamous cell carcinoma.[254] Adenocarcinoma has a predilection for the distal esophagus.[255] Risk factors include obesity, male gender, alcohol and tobacco consumption, gastroesophageal reflux, and Barrett esophagus.[255] Barrett esophagus consists of metaplasia of the esophageal mucosa secondary to severe gastroesophageal reflux and may be a preneoplastic lesion.[255]

SECTION D: EXOCRINE PANCREATIC CANCER

LAURA E. SELMIC

Incidence and Risk Factors

Cancer of the exocrine pancreas is very rare (<0.5% of all cancers) in the dog and the cat.[256,257] Incidence rates of pancreatic cancer have been estimated at 17.8 per 100,000 patient years for dogs and 12.6 per 100,000 patient years for cats.[258] Older female dogs and spaniels have been described as being at higher risk.[259–261] Experimentally, *N*-ethyl-*N*′-nitro-*N*-nitrosoguanidine has been shown to induce pancreatic duct adenocarcinoma when administered intraductally in dogs.[262]

Pathology and Natural Behavior

Almost all cancers of the pancreas are epithelial and most are malignant adenocarcinoma of ductular or acinar origin. Nodular hyperplasia is a common asymptomatic finding in older dogs and cats. Benign pancreatic pseudocysts and adenomas have been diagnosed by ultrasonography or surgery in dogs and cats.[256,263] In the vast majority of cases, malignant pancreatic cancer has metastasized to regional or distant sites before a diagnosis can be made.[260,264]

History and Clinical Signs

The history and clinical signs of exocrine pancreatic cancer are vague and nonspecific and may mimic or be accompanied by pancreatitis. Weight loss and anorexia (marked in cats),[265] paraneoplastic alopecia in cats,[266,267] vomiting, rare associated diabetes mellitus,[265,268] abdominal distension due to a mass effect or abdominal effusions secondary to tumor implantation on the peritoneum (i.e., carcinomatosis; common in cats), icterus (with common bile duct obstruction), and lethargy are common symptoms.[265] Alternatively, patients may present for symptoms of metastatic disease.

Diagnostic Techniques and Workup

Most hematologic and biochemical evaluations are nonspecific, but may include mild anemia, hyperglycemia, neutrophilia, and bilirubinemia (if occluding the common bile duct).[256] Elevations of serum amylase and lipase are inconsistent.[269] In extreme cases, signs of pancreatic insufficiency may be exhibited.[270]

In the dog, most tumors are not palpable through the abdominal wall. In the cat, late-stage, large palpable masses may be present.

Positive-contrast upper GI radiographs may reveal slowed gastric emptying and occasionally compression or invasion of the duodenum. Ultrasonography should be a useful diagnostic tool for localization of the primary tumor, documentation, and aspiration of fluid, as well as metastasis to liver and regional LNs.[271] Ascites may be a clinical sign and, when present, may reveal malignant cells on cytologic examination (carcinomatosis). A large (>2 cm) solitary mass is suggestive of pancreatic cancer rather than nodular hyperplasia in cats.[272] Contrast ultrasound has been assessed for distinguishing between pancreatic adenocarcinoma or insulinoma in four dogs.[273] In B-mode ultrasound, a hypoechoic nodule was present in the pancreas in three dogs, whereas heterogeneous pancreatic tissue was evident in the other dog. Contrast ultrasound could differentiate between the two tumors: adenocarcinomas appeared as hypoechoic and hypervascular lesions whereas insulinomas showed uniformly hypervascular lesions.[273] The utility of advanced imaging such as CT and MRI has not been documented for exocrine pancreatic tumors in veterinary patients. At present, most diagnoses are made at exploratory celiotomy. Immunohistochemical markers have been evaluated for aiding diagnosis of pancreatic carcinoma in dogs. More specifically, the expression patterns of claudin-4, a tight junction molecule, and claudin-5, an endothelium specific tight junction protein, were compared between well-differentiated and poorly differentiated pancreatic acinar cell carcinomas and normal pancreatic tissues.[274,275] Claudin-4 was present laterally in normal pancreatic acinar cells and intense apical lateral position in cells from a well-differentiated exocrine pancreatic carcinoma. Poorly differentiated exocrine pancreatic adenocarcinomas demonstrated a loss of claudin-4 expression.[274] The authors concluded claudin-4 immunohistochemistry may be useful to distinguish well-differentiated and undifferentiated exocrine pancreatic carcinomas.[274] Claudin-5 has also been evaluated in this manner with expression documented in lateral membranes of exocrine acinar cells and the endothelial cells of vessels and lymphatics within the stroma of the intact pancreas. The well- and poorly differentiated carcinomas showed loss of claudin-5 expression.[275]

Therapy

Most non–islet cell carcinomas of the pancreas are locally invasive and metastatic to regional LNs and liver at diagnosis. If liver, peritoneal cavity, or draining LNs are positive for tumor, aggressive surgery should generally not be performed. Total pancreatectomy or pancreaticoduodenectomy (Whipple's procedure) have been described in humans and dogs,[276] but carries a high operative morbidity and mortality without significant cure rates and is not recommended. Bypass procedures, such as gastrojejunostomy or cholecystoduodenostomy, are short-term palliative options for patients with

imminent or present gastrointestinal or common bile duct obstruction, respectively. Radiation therapy and chemotherapy have shown limited value in humans and animals. Occasionally, uncomfortable effusions from carcinomatosis can be diminished with systemic or intracavitary chemotherapy (see Chapter 12); however, the palliative response tends to be short lived.

Prognosis

The outlook for this disease in companion species is very poor because of its critical location and advanced stage at diagnosis. In a recent study evaluating the outcome for 34 cats with pancreatic carcinoma, the overall median survival time was 97 days and, for cats treated with either chemotherapy or surgery, the median survival time was 165 days.[265] Cats with abdominal effusion at diagnosis survived a median of 30 days.[265] Only three cats survived greater than 1 year.[265]

Comparative Aspects[277–279]

Pancreatic exocrine carcinoma accounted for an estimated 53,670 new cases and 43,090 deaths in the United States in 2017.[278] Several risk factors have been identified, including older age, inherited susceptibility, cigarette smoking, obesity, and diabetes mellitus. Most patients have disease progression beyond the pancreas at the time of initial diagnosis. Seventy-five percent are located in the head of the pancreas and the remainder in the body and tail of the pancreas. Direct extension to duodenum, bile duct, and stomach, as well as common metastasis to LNs and liver, make treatment difficult.

Treatments that are currently used include surgery (curative or palliative), radiotherapy (as an adjuvant or for treatment of advanced local disease), and systemic chemotherapy. Surgical resection is the mainstay of treatment for pancreatic carcinoma in humans, especially if the patient has a small tumor localized to the pancreas. Depending on the extent of disease within the pancreas, other surgical procedures include pancreaticoduodenectomy (Whipple's procedure) or total pancreatectomy. With recent advances in surgical technique, the mortality associated with these procedures has decreased; however, considerable patient morbidity still exists. Removal of the entire pancreas necessitates management of the patient for exocrine pancreatic insufficiency and diabetes mellitus. After surgery, chemotherapy is recommended to improve survival, but there is no superior single chemotherapeutic approach. In patients whose tumors are determined to be borderline resectable, chemotherapy is administered for 2 to 4 months and then, if the patient is still free from metastases, surgery or chemoradiation can be considered. Treatments for locally advanced or widely metastatic disease are palliative, but include chemotherapy alone or chemoradiation. If biliary outflow is obstructed, several procedures may be indicated including surgical bypass, endoscopic biliary stenting, or percutaneous biliary decompression. Palliative bypass of gastric outflow obstruction can be performed by open gastrojejunostomy, laparoscopic gastrojejunostomy, duodenal stenting, or decompressive gastrostomy tube. Despite recent developments and research into treatment of this disease, the prognosis remains poor, with overall 5-year survival rates for all patients less than 6%.[280]

SECTION E: GASTRIC CANCER

OWEN T. SKINNER

Incidence and Risk Factors

Gastric cancer is rare in small animals, comprising 0.16% of cancers in one large study.[281] The causes of gastric cancers have not been identified in dogs.[281–284] Gastric carcinoma has been experimentally induced in dogs with nitrosamines; however, the clinical relevance of these findings is unclear.[285] Hypergastrinemia is a risk factor in humans, typically associated with atrophic gastritis caused by *Helicobacter pylori*.[286] Although gastrin levels have not been reported to be increased in small populations of dogs with gastric carcinoma, individual dogs have been noted with substantial increases in serum gastrin.[287,288] *H. pylori* infection is rare in dogs.[289] Non–*H. pylori Helicobacter* species are highly prevalent in dogs, although the clinical significance of these organisms is uncertain, with both mild gastritis and asymptomatic presentations reported.[289–291]

Gastric carcinoma is the most common nonhematopoietic gastric tumor in dogs.[292–294] Breeds at higher risk of gastric carcinoma include the Tervueren, Bouvier des Flandres, Groenendael, collie, standard poodle, Norwegian elkhound, and Norwegian lundehund.[281,287,295–297] Mean age at presentation is typically 8 to 10 years.[281,283,284,293,294] Male dogs are consistently overrepresented, with a male-to-female ratio of approximately 1.5:1.[281,292–294,298] The most common mesenchymal tumors of the stomach are smooth muscle tumors (leiomyomas and leiomyosarcomas) and gastrointestinal stromal tumors (GISTs). These occur with similar frequency in male and female dogs, with a mean age at diagnosis of approximately 11 years.[299] Other reported canine gastric tumors include mast cell tumor (MCT),[300] histiocytic sarcoma,[301,302] plasmacytoma,[303] and undifferentiated sarcoma.[304]

Lymphoma is the most common primary gastric malignancy in cats.[305] Gastric carcinoma is rare in cats, representing fewer than 5% of feline gastrointestinal carcinoma cases.[306–308] Gastritis and *Helicobacter* have been proposed as risk factors for feline gastric carcinoma and lymphoma.[309,310] Other reported feline gastric tumors include MCT,[311] carcinoid,[312] hamartoma,[313] and polyps.[314]

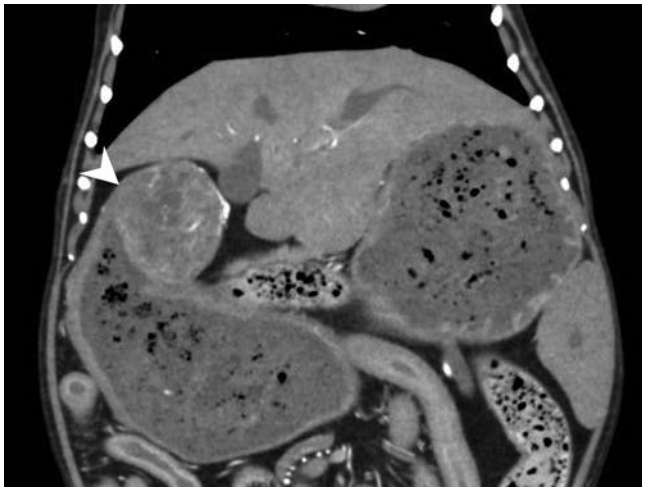
Pathology and Natural Behavior

Gastric carcinoma is classified as either "intestinal" (with papillary, acinar, or solid subtypes) or "diffuse" (with undifferentiated or glandular subtypes).[298,315] Intestinal type tumors in humans are thought to arise from sequential progression through gastritis, metaplasia, and dysplasia, whereas diffuse type tumors may be associated with mutation or methylation of CDH1.[316] The diffuse histologic type is more common in dogs.[283,287,298] Canine gastric carcinoma commonly arises in the pylorus or lesser curvature, although some carcinomas may lead to diffuse, firm thickening of the stomach (*linitis plastica*).[281,293,296,298,317] Ulceration is common and may progress to full-thickness perforation and peritonitis.[294] Metastasis to regional LNs is common (32% at presentation and 77% at postmortem), with liver and lungs less frequently affected.[292,298]

Many mesenchymal tumors previously diagnosed as leiomyosarcomas have been reclassified as GISTs.[299,304] Gastric leiomyoma and leiomyosarcoma are typically focal, with or

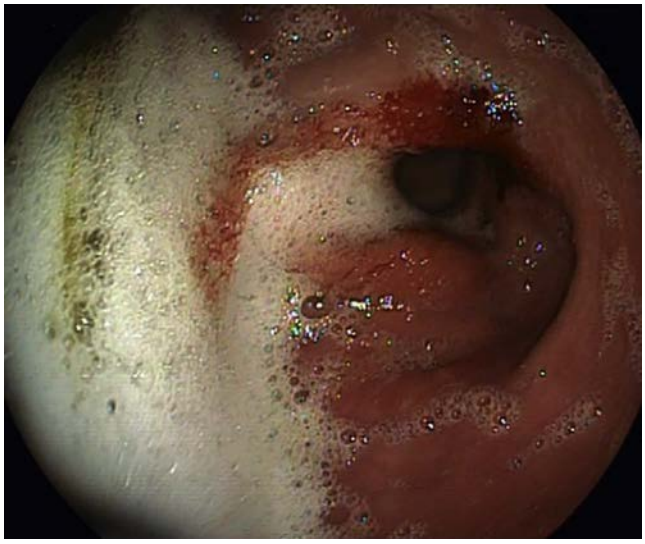
VetBooks.ir

without cavitating ulceration, and are most often found at the cardia or pylorus.[293,318–321] Paraneoplastic hypoglycemia has been reported with leiomyoma and leiomyosarcoma, possibly due to excessive release of IGF-2.[320,321] Although smooth muscle tumors are more common in the stomach, approximately 10% to 20% of GISTs arise at this site.[299,304,322] GISTs arise from the interstitial cells of Cajal, which normally express c-Kit (CD117) and may also express CD34, and hence immunohistochemistry (IHC) is required to differentiate leiomyosarcomas from GISTs.[322,323] Mutations in exon 11 of the c-*kit* gene are common in canine GIST and mutations in exon 9 have been reported.[299,324–327] GISTs are rare in cats.[328]



Gastric involvement of feline alimentary lymphoma is relatively uncommon.[329,330] Readers should refer to Chapter 33, Section B (Feline Lymphoma and Leukemia) for further information regarding gastric lymphoma.

History and Clinical Signs



Vomiting is the most common clinical sign, with or without associated hematemesis, in cats and dogs with gastric tumors.[284,292] Weight loss, anorexia, melena, diarrhea, and abdominal pain may also be encountered. Gastric cancer should be considered as a potential cause of septic peritonitis or pneumoperitoneum. Duration of clinical signs may vary widely, but is commonly in the order of 1 to 2 months.[292,294]

Diagnostic Techniques and Workup

Routine blood tests are not expected to be diagnostic, but may reveal anemia, hypoalbuminemia, thrombocytopenia, or thrombocytosis in patients with hemorrhage associated with ulceration.[284,292] Hepatocellular leakage enzymes may be increased with liver metastasis. Abdominal radiographs may identify changes such as a cranial abdominal mass, loss of serosal detail, or apparent thickening of the gastric wall. Contrast radiography may be helpful to identify delayed gastric emptying. Given the limited detail typically observed on radiographs, this modality has been largely superseded by abdominal ultrasound and, increasingly, CT (Fig. 23.15).[292,331–333] Gastric carcinomas tend to be broad-based on imaging, whereas mesenchymal tumors and benign lesions may be more focal or pedunculated.[314,334] Intraluminal gas can make ultrasonography challenging.[335] Thoracic imaging, whether radiographs or CT, should be assessed as part of the clinical staging protocol, but pulmonary metastasis at presentation is rare in patients with gastric cancer.[292,304] Gastroscopy can provide complementary information to the findings of diagnostic imaging (Fig. 23.16).[335] Multiple biopsies of any gastric lesions should be obtained, given the potential for acquisition of nondiagnostic samples in dogs and cats with gastric pathology.[336] If the disease process does not involve the mucosa, diagnosis from endoscopic biopsies can be challenging. Surgical biopsies may be considered if a diagnosis cannot be obtained with gastroscopy. Histopathology is the gold standard for diagnosis; however, squash preparation cytology, with assessment for the presence of signet ring cells and/or cytoplasmic microvacuolation, is sensitive (94%) and specific (94%) for gastric carcinoma.[337] IHC should be considered if there is doubt regarding tumor type.[299,304] FNA cytology of gastric masses has poor agreement (50%) with definitive histopathology in dogs and cats.[308]

• **Fig. 23.16** Ulcerated gastric carcinoma seen at gastroscopy in a dog.

Treatment

Resection of local disease may be considered in patients with solid tumors without evidence of either diffuse disease or distant metastasis. Surgery, if feasible, typically consists of various partial gastrectomy procedures. For tumors located in the pyloric region, surgical resection often requires a gastroduodenostomy (Billroth I).[293,338] Gastrojejunostomy (Billroth II) has been performed for patients with more extensive disease; however, outcomes are guarded because of persistent vomiting, poor appetite, and progressive disease with poor survival times of only 4 to 5 weeks.[293,339] Partial gastrectomy is recommended for tumors located in the gastric body. If surgery is pursued, complete abdominal exploration should be performed to assess for metastasis, with particular attention paid to all abdominal LNs and the liver. Benign lesions, such as leiomyomas, can be excised with a marginal approach.[319]

Adjuvant RT is used in humans after resection of gastric carcinomas, but RT has played a minimal role in dogs because of the proximity of sensitive tissues.[340]

VetBooks.ir

The role of chemotherapy for animals with solid gastric tumors is unclear. Response of carcinomas to chemotherapy has typically been poor, although multiple protocols have been attempted.[284,292,293] Expression of HER-2 is common in canine gastric carcinoma (58%), and this may represent a therapeutic target in dogs; however, clinical data are not available.[341] Responses to imatinib have been reported in dogs with GISTs, but large-scale studies are lacking.[324,325]

Prognosis

Gastric carcinoma typically carries a poor prognosis because of the difficulty in achieving local tumor control and a moderate-to-high metastatic rate. Long-term survival is possible after partial gastrectomy, but survival times are usually less than 6 months.[292–294,297,338,342,343] Given the challenges with controlling systemic disease, few dogs with gastric carcinoma are good surgical candidates and careful case selection is critical. Improvements in systemic therapies may increase the number of animals considered candidates for surgery. The median survival times for dogs with GIST, leiomyosarcoma, and undifferentiated sarcoma, provided they survive the perioperative period, are 37.4 months, 8 to 12 months, and 2.9 months, respectively.[304,318] The prognosis is excellent after surgical resection of leiomyoma, with the majority of dogs cured.[319,344] The median survival times for dogs and cats with gastrointestinal MCTs are less than 1 month[300] and 531 days, respectively.[311]

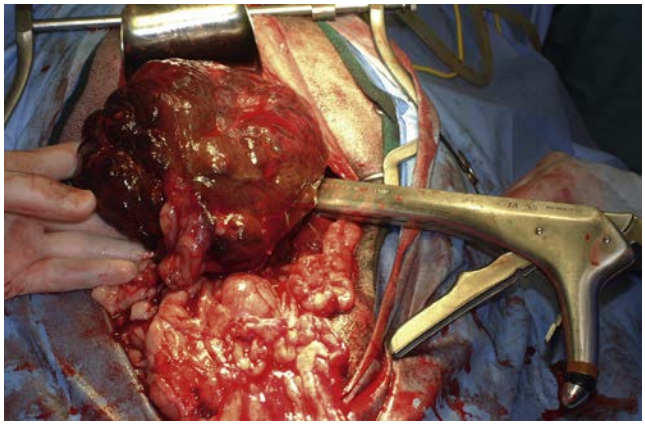
Comparative Aspects

In 2012 gastric cancer was the third most common cause of cancer-related death in men worldwide and the fifth most common cause of cancer-related death in women.[345] Men are approximately twice as likely to be affected as women.[346] Approximately 89% of noncardia gastric cancer in humans is associated with *H. pylori*.[347] Significant geographic differences are observed in the incidence of gastric carcinoma and this may be a result of *H. pylori* prevalence, socioeconomic status, and likely genetic susceptibility.[316,347] Mortality rates are approximately 60% to 80%, reflecting advanced disease at presentation and an aggressive disease course.[348] Treatment of local gastric tumors varies from endoscopic mucosal resection for superficial lesions to partial or total gastrectomy for more infiltrative and advanced lesions.[349,350] Adjuvant therapy, particularly chemoradiotherapy, is common in patients with advanced gastric cancer, although improvements in survival are often limited.[340,351] Targeted therapies, including trastuzumab targeting of HER-2, have shown promise, but improvements in outcome are still small for most patients.[352]

SECTION F: HEPATOBILIARY TUMORS

JULIUS M. LIPTAK

Incidence and Risk Factors



Primary hepatic tumors are uncommon and account for fewer than 1.5% of all canine tumors and 1.0% to 2.9% of all feline tumors, but up to 6.9% of nonhematopoietic tumors in cats.[353–356] Metastasis to the liver from nonhepatic neoplasia is more common and occurs 2.5 times more frequently than primary liver tumors in dogs, particularly from primary cancer of the spleen, pancreas, and GI tract.[353,354] Primary hepatobiliary tumors are more common than metastatic disease in cats.[356] The liver can also be involved in other malignant processes, such as lymphoma, malignant histiocytosis, and systemic mastocytosis.[354,355] Nodular hyperplasia is a relatively common diagnosis in older dogs but is benign and probably does not represent a preneoplastic lesion.[356]

There are four basic categories of primary malignant hepatobiliary tumors in cats and dogs: hepatocellular, bile duct, neuroendocrine (or carcinoid), and mesenchymal.[356] Malignant tumors are more common in dogs, whereas benign tumors occur more frequently in cats.[354–360] There are three morphologic types of these primary hepatic tumors: massive, nodular, and diffuse (Table 23.6).[357] Massive liver tumors are defined as a large, solitary mass confined to a single liver lobe (Fig. 23.17); nodular tumors are multifocal and involve several liver lobes (Fig. 23.18); and diffuse involvement may represent the final spectrum of neoplastic disease with multifocal or coalescing nodules in all liver lobes or diffuse effacement of the hepatic parenchyma (Fig. 23.19).[356,357]

The prognosis for cats and dogs with liver tumors is determined by histology and morphology. The prognosis is good for massive hepatocellular carcinomas (HCC) and benign tumors because complete surgical resection is usually achievable and their biologic behavior is relatively nonaggressive with an indolent growth rate.[359–363] In contrast, the prognosis is poor for cats with any type of malignant tumor, dogs with malignant tumors other than massive HCC, and cats and dogs with nodular and diffuse liver tumors because resection is less feasible and/or metastasis is more common.[354–366]

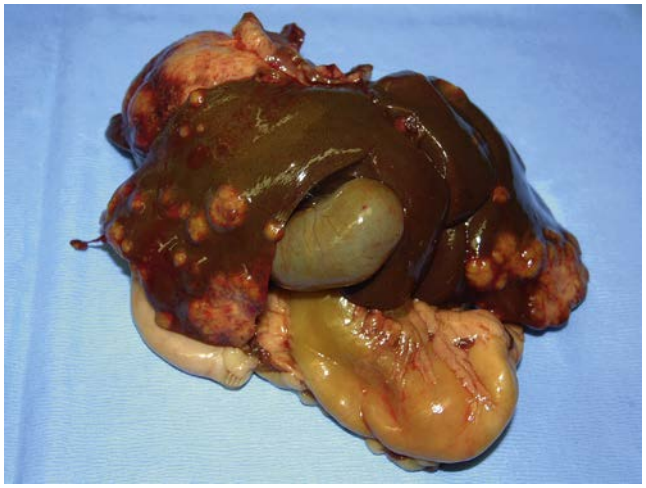


TABLE 23.6 Morphologic Types of Canine Hepatic Tumors

	Massive (%)	Nodular (%)	Diffuse (%)
Hepatocellular carcinoma	53–84	16–25	0–19
Bile duct carcinoma	37–46	0–46	17–54
Neuroendocrine tumor	0	33	67
Sarcoma	36	64	0

In people, primary liver tumors have been reclassified according to the presence of hepatic progenitor cells and immunohistochemical markers to differentiate hepatocytic and cholangiocytic lineages.[367] Liver tumors with hepatic progenitor cell characteristics are typically more poorly differentiated and biologically aggressive, resulting in a poorer prognosis.[367] Primary liver tumors in dogs and cats have also been reclassified according to these criteria.[367,368] Based on histologic findings and the degree of immunoreactivity to keratin 19, hepatocellular tumors were divided into well-differentiated, scirrhous, and poorly differentiated tumors.[367] HCCs expressing less than 5% of keratin 19 were more likely to be derived from mature hepatocytes with minimal evidence of cellular pleomorphism, infiltrative growth, and rare metastasis,[367] and this accounted for 79% of canine HCCs and all feline HCCs.[367,368] In contrast, primary liver tumors with keratin 19 expression, which included poorly differentiated HCCs and cholangiosarcomas, were characterized by a high grade of cellular pleomorphism, infiltrative growth, vascular invasion, and intra- or extrahepatic metastasis.[367,368] These tumors were probably derived from either hepatic progenitor cells or dedifferentiation of mature hepatocytes.[367]

Pathology and Natural Behavior

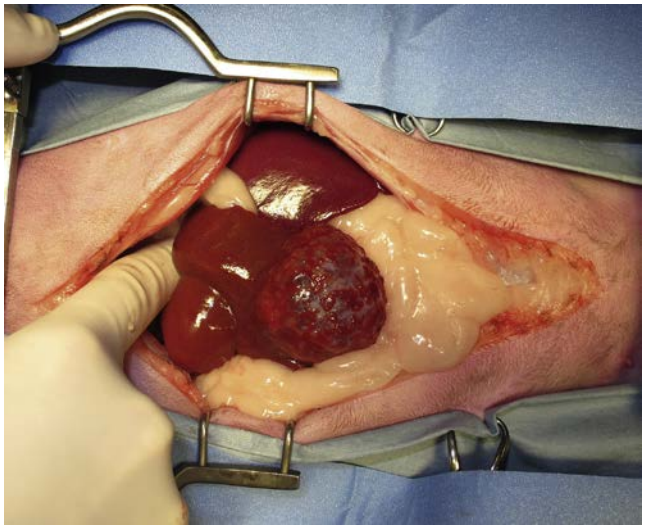
Hepatocellular Tumors

Hepatocellular tumors include HCC, hepatocellular adenoma (or hepatoma), and hepatoblastoma.[356] Hepatoblastoma is a rare tumor of primordial hepatic stem cells and has only been reported in one dog.[369] Hepatocellular adenoma is usually an incidental finding and rarely causes clinical signs.[354] Of the hepatocellular tumors, hepatocellular adenoma is more common in cats and HCC occurs more frequently in dogs.[354,357,358]

HCC is the most common primary liver tumor in dogs, accounting for up to 77% of cases, and the second most common in cats.[354–360,367] Etiologic factors implicated in the development of HCC in humans include infection with hepatitis virus B or C and cirrhosis.[370] A viral etiology has also been demonstrated in woodchucks but not in cats or dogs, and cirrhosis is rare in dogs with HCC.[358–361] A link between progressive vacuolar hepatopathy and HCC has been proposed in Scottish terriers, with HCC diagnosed in 34% of Scottish terriers with progressive vacuolar hepatopathy.[371] In one study, 20% of dogs with HCC were diagnosed with additional tumors although most were benign and endocrine in origin.[357]

A breed and sex predisposition has not been confirmed in dogs with HCC, but miniature schnauzers and male dogs are overrepresented in some studies.[357,361,363,372] Morphologically, 53% to 83% of HCCs are massive (see Fig. 23.17), 16% to 25% are nodular, and up to 19% are diffuse.[354,357] The left liver lobes, which include the left lateral and medial lobes and papillary process of the caudate lobe, are involved in more than two-thirds of dogs with massive HCC,[357,361–363] but tumors are equally distributed between the left and right liver lobes in cats.[373] Metastasis to regional LNs, peritoneum, and lungs is more common in dogs with nodular and diffuse HCC.[354,357,361] Other metastatic sites include the heart, kidneys, adrenal glands, pancreas, intestines, spleen, and urinary bladder.[354,357,361] The metastatic rate varies from 0% to 37% for dogs with massive HCCs and 93% to 100% for dogs with nodular and diffuse HCCs.[354,357–363]

Bile Duct Tumors



Bile Duct Adenoma (Biliary Cystadenoma)

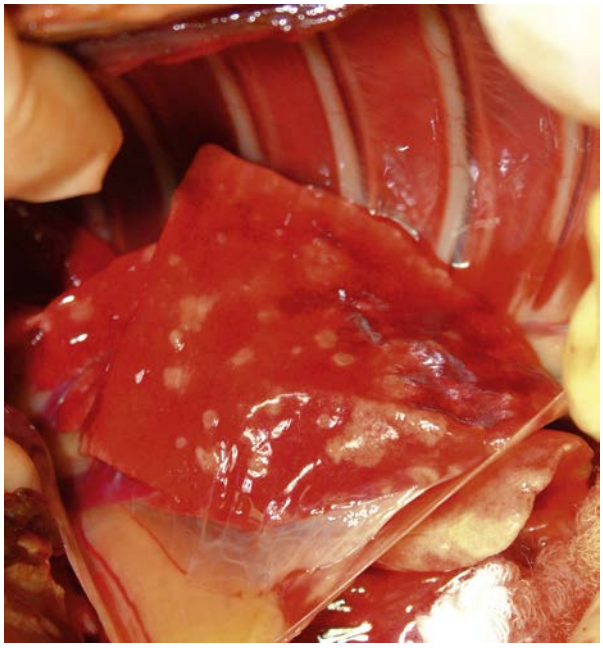
There are two types of bile duct tumors in cats and dogs: bile duct adenoma and carcinoma.[354,357–360,364,365,374–378] Bile duct adenomas are common in cats, accounting for more than 50% of all feline hepatobiliary tumors, and are also known as biliary or hepatobiliary cystadenomas because of their cystic appearance (Fig. 23.20).[358–360,374–376] Male cats may be predisposed.[374,376] Bile duct adenomas usually do not cause clinical signs until they reach a large size and compress adjacent organs.[374–376] There is an even distribution between single and multiple lesions.[358–360,374–376] Malignant transformation has been reported in humans, and anaplastic changes have been observed in some feline adenomas.[358,374]

Bile Duct Carcinoma (Cholangiocarcinoma)

Bile duct carcinoma is the most common malignant hepatobiliary tumor in cats and the second most common in dogs.[354,357–360] Bile duct carcinomas account for 9% to 41% of all malignant liver tumors in dogs.[357,368,379] In humans, trematode infestation, cholelithiasis, and sclerosing cholangitis are known risk factors for bile duct carcinoma.[380] Trematodes may also be involved in the etiology of bile duct carcinoma in cats and dogs, but they are

VetBooks.ir

• **Fig. 23.20** Intraoperative image of a bile duct cystadenoma in a cat. Surgical resection was curative in this cat.



unlikely to be a major contributor because bile duct carcinomas also occur in geographic regions outside the normal distribution of trematodes.[356,360,365]

A predilection for Labrador retrievers has been proposed.[365] A sex predisposition has been reported for female dogs.[357,364,372] In cats, however, the sex predisposition is conflicting.[358–360] The distribution of morphologic types of bile duct carcinoma is similar to HCC, with 37% to 46% massive, up to 54% nodular (see Fig. 23.18), and 17% to 54% diffuse.[354,357,364,365] Bile duct carcinomas can be intrahepatic, extrahepatic, or within the gall bladder.[354,357–360,364,365] Intrahepatic carcinomas are more common in dogs,[357,364,365] whereas an equal distribution of intrahepatic and extrahepatic tumors to extrahepatic predominance has been reported in cats.[358–360] Solid and cystic (or cystadenocarcinoma) bile duct carcinomas have been reported, but this distinction does not influence either treatment or prognosis.[364] Bile duct carcinoma of the gall bladder is rare in both species.[354,357–360,364,365]

Bile duct carcinomas have an aggressive biologic behavior. Metastasis is common in dogs, with up to 88% metastasizing to the regional LNs and lungs (Fig. 23.21); other sites include the heart, spleen, adrenal glands, pancreas, kidneys, and spinal cord.[354,357,364,365] In cats, diffuse intraperitoneal metastasis and carcinomatosis occur in 67% to 80% of cases.[358–360]

Neuroendocrine Tumors

Neuroendocrine tumors, also known as carcinoids, are rare in cats and dogs.[354,357–360,367,368] These tumors arise from neuroectodermal cells and are histologically differentiated from carcinomas with the use of silver stains.[355,366] Neuroendocrine hepatobiliary tumors are usually intrahepatic, although extrahepatic tumors have been reported in the gall bladder.[366,377,378,381] Carcinoids tend to occur at a younger age than other primary hepatobiliary tumors.[357,366] Morphologically, carcinoids are nodular in 33% and diffuse in the remaining 67% of cases.[357,366] Primary hepatic neuroendocrine tumors have an aggressive biologic behavior with frequent involvement of more than one liver lobe and metastasis to the regional LNs, peritoneum, and lungs in cats and dogs.[357,366,381] Other metastatic sites include the heart, spleen, kidneys, adrenal glands, and pancreas.[366]

• **Fig. 23.21** Lung metastasis in the cat with bile duct carcinoma depicted in Fig. 23.18. This cat also had diffuse peritoneal metastasis.

Sarcomas

Primary and nonhematopoietic hepatic sarcomas are rare in cats and dogs.[354,357–360,380] The most common primary hepatic sarcomas are hemangiosarcoma (HSA), leiomyosarcoma, and fibrosarcoma, with HSA the most frequently diagnosed primary hepatic sarcoma in cats and leiomyosarcoma the most common in dogs.[354,357–360,380,382–385] The liver is a common site for metastatic HSA in dogs, whereas only 4% to 6% of HSA occur primarily in the liver.[384,385] Other primary hepatic sarcomas include rhabdomyosarcoma, liposarcoma, OSA, and malignant mesenchymoma.[354–360] The liver, with lungs, LNs, spleen, and bone marrow, is commonly involved in dogs with disseminated histiocytic sarcoma (HS).[386,387] Benign mesenchymal tumors such as hemangiomas are rare.[354–360] There are no known breed predispositions, although a male predilection has been reported.[357] Diffuse morphology has not been reported, with massive and nodular types accounting for 36% and 64% of sarcomas, respectively.[357,380] Hepatic sarcomas have an aggressive biologic behavior, with metastasis to the spleen and lungs reported in 86% to 100% of dogs.[357,380]

Other Primary Hepatic Tumors

Myelolipoma is a benign hepatobiliary tumor in cats.[355,356] Histologically, myelolipomas are composed of well-differentiated adipose tissue intermixed with normal hematopoietic elements.[356] Chronic hypoxia has been proposed as an etiologic factor because myelolipomas have been reported in liver lobes entrapped in diaphragmatic herniae.[356] Myelolipomas can be either single or multifocal.[356]

History and Clinical Signs

Hepatobiliary tumors are symptomatic in approximately 50% of cats and 75% of dogs, especially in animals with malignant

tumors.[353–366,373] With respect to the massive form of HCC, most clinical signs are related to the mechanical mass effect of the tumor and only rarely to any systemic effects of the tumor or hepatic insufficiency. The most common presenting signs are nonspecific, such as inappetence, weight loss, lethargy, vomiting, polydipsia–polyuria, and ascites.[353–366,373] Weakness, ataxia, and seizures are uncommon and may be caused by hepatic encephalopathy, paraneoplastic hypoglycemia, or central nervous system metastasis.[357,361,388] Icterus is more common in dogs with extrahepatic bile duct carcinomas and diffuse neuroendocrine tumors.[354,357,364] Hemoperitoneum secondary to rupture of massive HCC has been reported in two dogs.[389] Physical examination findings are often unrewarding. A cranial abdominal mass is palpable in up to 75% of cats and dogs with liver tumors, although palpation can be misleading because hepatic enlargement may be either absent in nodular and diffuse forms of liver tumors or missed because of the location of the liver in the cranial abdominal cavity deep to the costal arch.[353–366]

Diagnostic Techniques and Workup

Laboratory Tests

Hematologic and serum biochemical abnormalities are usually nonspecific. Leukocytosis, anemia, and thrombocytosis are common in dogs with liver tumors.[353–366] Anemia is usually mild and nonregenerative.[357,363] Thrombocytosis is seen in approximately 50% of dogs with massive HCC.[363]Anemia and thrombocytopenia are relatively common in dogs with primary and metastatic hepatic HSAs.[355] Prolonged coagulation times (e.g., increased prothrombin time, thrombin time, and activated partial thromboplastin time) and specific clotting factor abnormalities (e.g., decreased factor VIII:C and increased factor VIII:RA and fibrinogen degradation products) have been identified in dogs with hepatobiliary tumors, although these are rarely clinically relevant.[390]

Liver enzymes are commonly elevated in dogs with hepatobiliary tumors (Table 23.7). Increased activity of liver enzymes probably reflects hepatocellular damage or biliary stasis and is not specific for hepatic neoplasia.[356] There is also no correlation between the degree of hepatic involvement and magnitude of liver enzyme alterations.[356,363] The type of liver enzyme abnormalities may provide an indication of the type of tumor and differentiate primary and metastatic liver tumors.[391] Alkaline phosphatase (ALP) and alanine transferase (ALT) are commonly increased in dogs with primary hepatic tumors, whereas aspartate aminotransferase (AST) and bilirubin are more consistently elevated in dogs with metastatic liver tumors.[353,391] Furthermore, an AST-to-ALT ratio less than one is consistent with HCC or bile duct carcinoma, whereas a neuroendocrine tumor or sarcoma is more likely when the ratio is greater than one.[357] In general, however, liver enzyme elevations are not specific for the diagnosis of hepatobiliary diseases.[392] Other changes in the serum biochemical profile in dogs with hepatic tumors may include hypoglycemia, hypoalbuminemia, hyperglobulinemia, and increased preprandial and postprandial bile acids.[353,354,357,361–366] Hypoglycemia is a paraneoplastic syndrome reported secondary to hepatic adenoma and management is described in more detail in Chapter 5. In contrast to dogs, azotemia is often present in cats with hepatobiliary tumors and may be the only biochemical abnormality, although liver enzyme abnormalities, especially ALT, AST, and total bilirubin, are also common and are significantly higher in cats with malignant tumors.[358–360]

TABLE 23.7 Common Clinicopathologic Abnormalities in Cats and Dogs with Hepatobiliary Tumors

Parameter	Cat (%)	Dog (%)
Leukocytosis		54–73
Anemia		27–51
Hypoalbuminemia		52–83
Increased ALP	10–64	61–100
Increased ALT	10–78	44–75
Increased AST	15–78	56–100
Increased GGT	78	39
Increased total bilirubin	33–78	18–33
Increased serum bile acids	67	50–75

ALP, Alkaline phosphatase; *ALT*, alanine transferase; *AST*, aspartate aminotransferase; *GGT*, γ-glutamyltransferase.

α-Fetoprotein, an oncofetal glycoprotein, is used in the diagnosis, monitoring response to treatment, and prognostication of HCC in humans.[370] In dogs, serum levels of α-fetoprotein are increased in 75% of HCC and 55% of bile duct carcinomas.[393,394] However, α-fetoprotein has limited value in the diagnosis and treatment monitoring of canine HCC, as serum levels of α-fetoprotein are also increased in other types of liver tumors, such as bile duct carcinoma and lymphoma, and nonneoplastic hepatic disease.[394,395] Hyperferritinemia is common in dogs with HS and immune-mediated hemolytic anemia (IMHA); thus, once IMHA has been excluded, serum ferritin levels may be useful in differentiating HS from other causes of liver disease.[396]

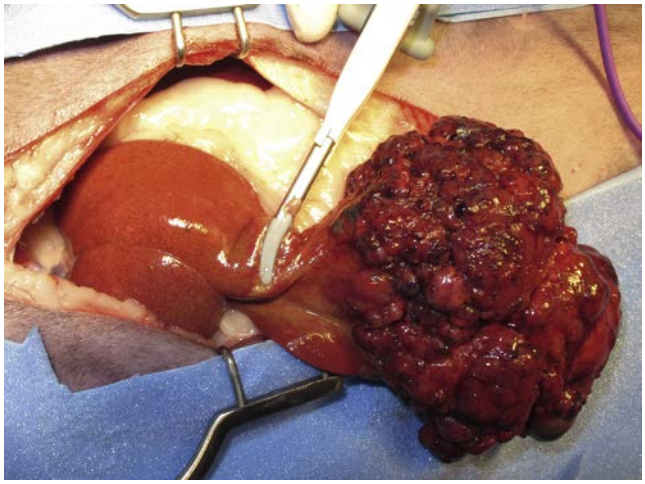
Imaging

Radiographs, ultrasonography (US), and advanced imaging can be used for the diagnosis, staging, and surgical planning of cats and dogs with hepatobiliary tumors. A cranial abdominal mass, with caudal and lateral displacement of the stomach, is frequently noted on abdominal radiographs of cats and dogs with massive liver tumors.[362,363,372] Mineralization of the biliary tree is a rare finding in dogs with bile duct carcinoma.[356] Sonographic or CT examination is recommended because these radiographic findings are not specific for the diagnosis of a hepatic mass and do not provide information on the relationship of the hepatic mass with regional anatomic structures.

Abdominal US or triphasic (arterial, venous, and delayed contrast phases) CT are preferred for identifying and characterizing hepatobiliary tumors in cats and dogs.[397] US examination is useful in determining the presence of a hepatic mass and defining the tumor as massive, nodular, or diffuse[398–402] and, in the case of cats, whether the tumor is cystic or not.[372] If focal, the size and location of the mass and its relationship with adjacent anatomic structures, such as the gall bladder or caudal vena cava, can be assessed.[376,398–402] Tumor vascularization can be determined using Doppler imaging techniques or triphasic CT, although the latter is superior.[356,402] The US appearance of hepatobiliary tumors varies and does not correlate with histologic tumor type.[376,397–406] However, US-guided FNA or needle-core biopsy of hepatic masses is

VetBooks.ir

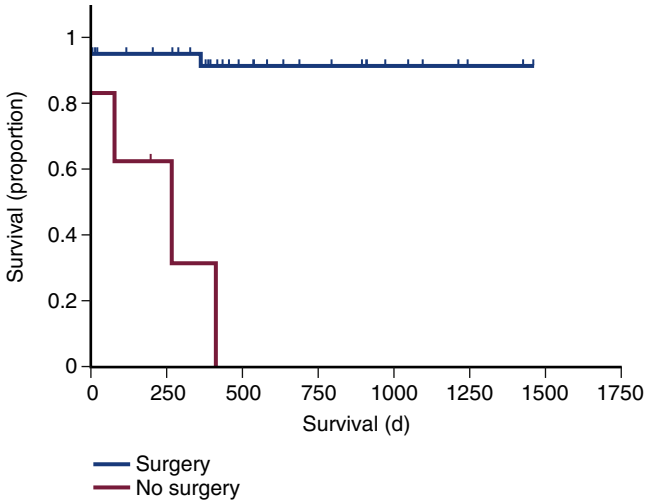
a useful, minimally invasive technique to obtain cellular or tissue samples for diagnostic purposes.[398–401] A coagulation profile is recommended before hepatic biopsy because mild-to-moderate hemorrhage is the most frequent complication, occurring in approximately 5% of cases.[398–401] A correct diagnosis is obtained in up to 60% of hepatic aspirates and 90% of needle-core biopsies.[398–401,407] The most useful cytologic features for the diagnosis of well-differentiated HCCs include dissociation of hepatocytes, acinar or palisading arrangement of neoplastic cells, and the presence of naked nuclei and capillaries, together with mild anisocytosis, anisokaryosis, multinuclearity, and increased N:C ratios.[408,409] More invasive techniques, such as laparoscopy and open keyhole approaches, can also be used for the biopsy and staging of cats and dogs with suspected liver tumors. In humans, laparoscopy is recommended for local staging, as up to 20% of cases do not proceed with open surgery because of either nodular or diffuse tumors or unresectable disease.[410] However, for solitary and massive hepatic masses, surgical resection can be performed without a preoperative biopsy because both diagnosis and treatment can be achieved in a single procedure.



Advanced imaging techniques, such as triphasic CT and MRI, are preferred in humans for the diagnosis and staging of liver tumors and many veterinary centers also use this methodology.[370,397] Unlike US, imaging appearance may provide an indication of tumor type.[370] Furthermore, CT and MRI are more sensitive for the detection of small hepatic lesions and determining the relationship of liver masses with adjacent vascular and soft tissue structures.[370] In dogs, there are CT features that can be used to differentiate nodular hyperplasia, hepatic adenomas, and HCCs based on enhancement patterns during arterial and portal venous phases.[411,412] However, in another study, there were no features on dual-phase CT scans that differentiated benign and malignant hepatic lesions.[413] Triphasic CT was reported to be more than 90% accurate in differentiating benign from malignant masses in 44 dogs and was superior to color-flow, power, and pulse-wave Doppler US, but could not differentiate the histologic type of malignant tumor.[397] MRI with a liver-specific contrast agent, gadoxetate disodium, has been described in seven dogs with HCC, but imaging findings were variable.[414]

Imaging is also important for the staging of cats and dogs with liver tumors. Local extension and regional metastasis can be assessed with abdominal US, CT, MRI, or laparoscopy. The sonographic and sometimes gross appearance of nodular hyperplasia and metastatic disease is similar. In two studies, 25% to 36% of dogs with ultrasonographically detectable focal hepatic lesions were diagnosed with nodular hyperplasia.[415,416] Biopsy of such lesions is recommended before definitively diagnosing metastatic disease and excluding animals from curative-intent surgery.[417] Although rare at the time of diagnosis, three-view thoracic radiographs or advanced imaging techniques should be assessed for evidence of lung metastasis before treatment.

Therapy and Prognosis



Hepatocellular Tumors

Liver lobectomy is recommended for cats and dogs with any hepatic tumor that has a massive morphologic appearance, particularly HCC. Surgical techniques for liver lobectomy include finger fracture, mass ligation, mattress sutures, bipolar vessel sealant devices, and surgical stapling.[417] Mass ligation is not recommended for large dogs, tumors involving either the central or right liver divisions, or tumors with a wide base.[417] The finger-fracture technique, involving blunt dissection through hepatic parenchyma and individual ligation of bile ducts and vessels, is acceptable for smaller lesions. Surgical staplers or bipolar vessel sealant devices are preferred for liver lobectomy because operative time is shorter with fewer complications (see Fig. 23.17; and 23.22).[363,417] A hilar dissection technique may be required for larger tumors extending to the hilus of the liver lobe because adequate margins may not be achievable with a surgical stapler.[418] Complete histologic excision of massive HCCs is associated with significantly better local tumor control and survival times,[419] and the use of real-time fluorescent imaging has been described to assess the completeness of excision intraoperatively in dogs with massive HCCs.[420] Advanced imaging and intraoperative US may provide information on the relationship of right-sided and central liver tumors with the caudal vena cava before liver lobectomy. Right-sided liver tumors can be excised even if intimately associated with the caudal vena cava, with or without an ultrasonic aspirator, but the surgeon should be familiar with the course of the caudal vena cava through the hepatic parenchyma. En bloc resection of the caudal vena cava with a right-sided HCC has been reported.[421] In one report of 42 dogs with massive HCC treated with liver lobectomy, the intraoperative mortality rate was 4.8% and the complication rate was 28.6%.[363] Complications include hemorrhage, vascular compromise to adjacent liver lobes, and transient hypoglycemia and reduced hepatic function.[356,363,417] In one single institution study, blood transfusions were required in 17% of dogs and 44% of cats treated with liver lobectomy for various hepatic conditions,[422] which highlights the importance of preoperative cross-matching or blood typing before liver lobectomy to be more adequately prepared to manage intraoperative bleeding.

• **Fig. 23.22** Liver lobectomy using a bipolar vessel sealing device.

The prognosis for dogs and cats with massive HCC is good (Fig. 23.23). Local tumor recurrence is reported in 0% to 13% of dogs with massive HCC after liver lobectomy.[362,363] In a recent study investigating the effect of the completeness of histologic excision in 37 dogs with massive HCC, local tumor recurrence was reported in 12% of dogs with complete histologic excision and 58% of dogs with incomplete histologic excision.[419] The median progression-free and overall survival times were significantly longer in dogs with complete histologic excision (1000 days and greater than 1836 days, respectively) than incomplete histologic excision (521 days and 765 days, respectively) although both groups enjoyed durable postsurgical

• **Fig. 23.23** Kaplan–Meier survival curve for dogs with massive hepatocellular carcinoma. The median survival time for dogs with surgically resected tumors is significantly better than dogs not treated with curative-intent liver lobectomy. (Reprinted with permission from Liptak JM, Dernell WS, Monnet E, et al. Massive hepatocellular carcinoma in dogs: 48 cases (1992–2002). *J Am Vet Med Assoc*. 2004;225:1225–1230.)

survival.[419] Metastasis to other regions of the liver and lungs has been documented in 0% to 37% of dogs, but metastasis is rare in recent clinical reports and most deaths are unrelated to HCC.[357,362,363,419] The MST for dogs with massive HCC after liver lobectomy are greater than 1460 to 1836 days,[363,419] and the MST was 2.4 years for six cats with HCC treated with liver lobectomy.[373] In comparison, the MST of 270 days was significantly decreased for six dogs managed conservatively, and these dogs were 15.4 times more likely to die of tumor-related causes than dogs treated surgically.[363] Prognostic factors in dogs with massive HCC include surgical treatment, side of liver involvement, ALT and AST activity, ratios of ALP-to-AST and ALT-to-AST, and completeness of histologic excision.[363,419] Right-sided liver tumors, involving either the right lateral lobe or caudate process of the caudate lobe, had a poorer prognosis because intraoperative death was more likely due to caudal vena cava trauma during surgical dissection.[363] There was no difference in survival time if dogs with right-sided massive HCC survived surgery.[363] Increased ALT and AST were associated with a poor prognosis in one study, which may reflect more severe hepatocellular injury secondary to either large tumor size or more aggressive biologic behavior.[363]

In contrast, the prognosis for dogs with nodular and diffuse HCC is poor. Surgical resection is usually not possible because of involvement of multiple liver lobes. Treatment options for nodular and diffuse HCC in humans include liver transplantation or minimally invasive procedures for regional control, such as ablation or embolization.[370] Bland embolization and chemoembolization have been reported with moderate success in the palliation of four dogs and one cat with HCC,[423–425] and microwave ablation has been described in five dogs with diffuse hepatic neoplasia, including one dog with HCC.[426] The role of RT and chemotherapy in the management of HCC is largely unknown.

Traditional RT is ineffective in the management of liver tumors, as the canine liver cannot tolerate cumulative doses greater than 30 Gy[356,370]; however, three-dimensional (3-D) conformal RT, which enables targeted high-dose RT to the tumor while sparing adjacent normal hepatic tissue, has been described in 6 dogs with nonresectable HCC.[427] In this study, 3-D conformal RT was delivered at 6 to 10 Gy per fraction to a total dose of 18 to 42 Gy with 1 to 2 fractions per week for a total of 3 to 7 fractions.[427] This RT protocol resulted in partial responses in five of the six dogs, and an MST of 567 days.[427]

HCC is considered chemoresistant in humans because response rates are usually less than 20%.[356,370] The poor response to systemic chemotherapy is probably a result of rapid development of drug resistance due to either the role of hepatocytes in detoxification or expression of P-glycoprotein, a cell membrane efflux pump associated with multidrug resistance.[356] However, single-agent gemcitabine has been investigated in dogs with unresectable HCC with encouraging results.[428] In one this study, 18 dogs with mostly nodular and diffuse well-differentiated HCCs were treated with gemcitabine for 5 weeks.[428] The overall MST was 983 days, but depended on the morphology and resectability of the tumor.[428] The MSTs were 1339 days for dogs with massive HCC, 983 days for dogs with nodular HCC, and 113 days for dogs with diffuse HCC; and the MSTs were 1339 days for dogs with incompletely excised HCC, which included all four dogs with massive HCC and 9 of 10 dogs with nodular HCC, and 197 days for dogs with nonresectable HCC, including all four dogs with diffuse HCC.[428] Novel treatment options currently being investigated in human medicine include immunotherapy, hormonal therapy with tamoxifen, and antiangiogenic agents.[370]

Bile Duct Tumors

Bile duct adenomas can present as either single (e.g., massive) or multifocal lesions. Liver lobectomy is recommended for cats with single bile duct adenoma (cystadenoma) or multifocal lesions confined to one to two lobes.[358–360,374–376] The prognosis is very good after surgical resection with resolution of clinical signs and no reports of local recurrence or malignant transformation.[360,374,375]

Liver lobectomy is also recommended for cats and dogs with massive bile duct carcinoma. However, survival time has been poor in cats and dogs treated with liver lobectomy because the majority have died within 6 months as a result of local recurrence and metastatic disease.[360,429] There is no known effective treatment for cats and dogs with nodular or diffuse bile duct carcinomas because these lesions are not amenable to surgical resection and other treatments are often not successful.

Neuroendocrine Tumors

Carcinoids have an aggressive biologic behavior and are usually not amenable to surgical resection because solitary lesions and massive morphology are rare.[357,366] The efficacy of RT and chemotherapy is unknown. Prognosis is poor because metastasis to the regional LNs, peritoneum, and lungs occurs in 93% of dogs and usually early in the course of disease.[357,366]

Sarcomas

Liver lobectomy can be attempted for solitary and massive sarcomas. However, the prognosis is poor because metastatic disease is often present at the time of surgery.[357,380] Chemotherapy has not been investigated in the treatment of primary hepatic sarcomas, although, similar to other solid sarcomas, response rates are likely to be poor. Doxorubicin-based protocols and ifosfamide

have shown some promise with sarcomas in other locations and warrant consideration for cats and dogs with primary hepatic sarcomas.[430,431]

Other Primary Hepatic Tumors

Surgical resection with liver lobectomy is recommended for cats with primary hepatic myelolipoma, and the prognosis is excellent with prolonged survival time and no reports of local recurrence.[356]

Comparative Aspects

HCC is one of the most common malignancies in humans as a result of viral infections with hepatitis viruses B and C and cirrhosis induced by alcohol consumption and other disease.[370] A number of paraneoplastic syndromes have been described including hypoglycemia, erythrocytosis, and hypercalcemia.[368] US is considered a good screening imaging modality, but advanced imaging with contrast-enhanced CT or MRI is preferred to determine the location, size, and extent of hepatic lesions.[368] Other tests include serum α-fetoprotein, serologic tests for hepatitis B and C viruses, and histologic confirmation with core liver biopsies.[368] Unlike HCC in dogs, the morphology of HCC in humans is often nodular or diffuse, which makes definitive treatment more problematic. Treatment options depend on the stage of disease and include surgery (e.g., liver lobectomy and liver transplantation), local ablative therapies (e.g., cryosurgery, ethanol or acetic acid injection, and microwave or radiofrequency ablation), regional therapies (e.g., transarterial chemotherapy, embolization, chemoembolization, or RT), and systemic treatment with chemotherapy or immunotherapy.[368] Response rates to single- and multiple-agent chemotherapy protocols are less than 25%, and chemotherapy is no longer recommended for human patients with HCC.[370]

Bile duct carcinomas are rare and, similar to those in cats and dogs, often associated with a poor prognosis.[382] Risk factors include primary sclerosing cholangitis, the liver flukes *Opisthorchis viverrini* and *Clonorchis sinensis* in endemic areas of Southeast Asia and China, and cholelithiasis.[382] Surgical resection is preferred but, because of the high rate of local or regional recurrence, adjuvant treatment with RT or chemotherapy is recommended.[382] However, because of the rarity of this tumor, studies supporting the efficacy of these adjuvant treatments are lacking. Papillary histology, extrahepatic location, and complete resection are favorable prognostic factors in humans with bile duct carcinomas.[432]

SECTION G: INTESTINAL TUMORS

LAURA E. SELMIC, KIM A. SELTING AND JENNIFER K. REAGAN

Incidence and Risk Factors

Intestinal tumors are rare in dogs and cats.[433–435] In a survey of insured dogs in the United Kingdom, a standardized incidence rate of 210/100,000 dogs was reported for alimentary tumors and this accounted for 8% of all tumor submissions.[436] Incidence of feline digestive neoplasia in a South African survey comprised 13.5% of all tumors, which likely included oral tumors.[437] In the United States, a query of more than 300,000 cat submissions to the Veterinary Medical Database found 8% to relate to cancer and less than 1% (13% of the cancer cases) to be intestinal neoplasia.[438] Regarding specific tumor types, lymphoma comprises nearly 30% of all feline tumors and 6% of all canine tumors and is the most common intestinal tumor in most reports.[434,439–441] In 163 cases of feline lymphoma, the intestine was the most commonly affected site.[442] Adenocarcinoma is the second most frequent tumor in both species, with mast cell tumors (MCTs) in cats and leiomyosarcomas or gastrointestinal stromal tumors (GISTs) in dogs the third most common tumors.

As with many cancers, the incidence of intestinal neoplasia increases in older dogs and cats. Mean ages of affected cats for small and large intestinal neoplasia generally range between 10 and 12 years, and increasing risk after 7 years of age has been reported.[434,438,442–448] Dogs are also usually middle aged or older, with mean ages most often between 6 and 9 years and possibly older (12 years) for dogs with leiomyosarcoma.[443,448–452]

Overall, there may be a slight sex predilection for males to develop intestinal tumors. Many studies report a near equal incidence among male and female dogs,[452–455] although one study did find 76% of dogs with intestinal adenocarcinoma to be male.[456] Males also appear overrepresented for smooth muscle tumors,[448] comprising 82% of gastrointestinal (GI) leiomyomas[457] and 76% of dogs with leiomyosarcoma.[451] In addition, 90% of dogs with GI lymphoma were male[448] and there was a slight male predominance in nonlymphomatous tumors.[441,458,459] In cats, males have greater representation in some studies,[446,460] while only slightly exceeding or equaling females in other studies.[445,446,460–462]

Siamese cats are 1.8 times more likely to develop intestinal neoplasia[438] and are overrepresented in studies of intestinal adenocarcinoma, up to eight times greater than other breeds.[434,438,444,458,461] Although small numbers of Siamese cats are included in many series of feline intestinal lymphoma, one study did show a significant overrepresentation.[443] Otherwise, there is no breed predilection for intestinal lymphoma in cats. In dogs, few studies of intestinal neoplasia report an overrepresentation of specific breeds. Large-breed dogs in general constituted most cases in a series of smooth muscle tumors.[454] Collies and German shepherd dogs are overrepresented in some reports for intestinal tumors, especially adenocarcinoma, rectal carcinoma, and rectal polyps.[449,463] In a recent Czech necropsy study, breed predispositions were identified in the pug, Leonberger, and English setter for intestinal adenoma; in the English setter and Hovawart for intestinal adenocarcinoma; and the Doberman and Hovawart for intestinal lymphoma.[448] MCTs have been reported primarily in Maltese. Although these reports came from Japan, where small breeds are popular, more than 50% of reported cases in two series were in Maltese dogs with a male predominance.[464,465]

With the exception of retroviral influence on the development of feline lymphoma, there are no known etiologic organisms or chemical agents that reliably contribute to the development of spontaneously occurring intestinal neoplasia in dogs and cats. A recent retrospective study in 55 cats with intestinal carcinoma showed significant association between the presence of *Helicobacter* species and development of poorly differentiated large intestinal mucinous adenocarcinoma.[466] The findings of this study suggest *Helicobacter* spp. may play a possible role in intestinal carcinoma formation and determining site of development in cats.[466] However, it has also been suggested *Helicobacter* species in the feces may represent normal flora rather than pathogens.[467]

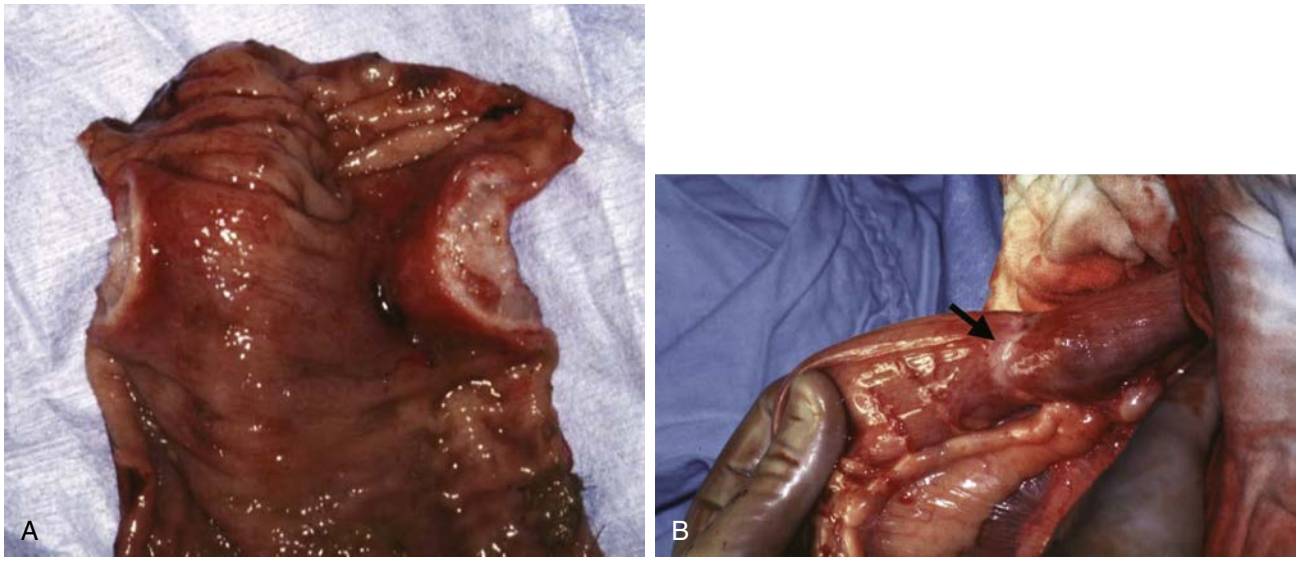
VetBooks.ir

Pathology and Natural Behavior

Epithelial, mesenchymal, neuroendocrine, and discrete/round cell neoplasias can all be found in the intestinal tract. Although most small intestinal tumors are malignant in dogs, most rectal tumors are benign polyps, adenomas, or carcinomas in situ (Fig. 23.24).[455,468]

When tumors of the GI system metastasize, sites of predilection in decreasing frequency include mesenteric LNs (especially adenocarcinoma), liver (especially leiomyosarcoma), mesentery, omentum, spleen, kidney, bone, peritoneum (e.g., carcinomatosis), and lung.[441,458,462,469] Interestingly, metastasis from intestinal adenocarcinoma was discovered in three dogs initially presented for testicular masses.[470] One dog was presented for multiple cutaneous masses that IHC confirmed were epithelial in origin and a primary small intestinal adenocarcinoma with additional visceral metastasis was diagnosed at necropsy.[471] GI lymphoma is often a systemic disease; 25% of dogs and 80% of cats will have concurrent involvement of other organs.[443,450]

• **Fig. 23.24** Cobblestone appearance to a rectal adenocarcinoma. Dogs with this tumor type live an average of 12 months after surgical excision. (Courtesy Dr. Eric Pope, Ross University, College of Veterinary Medicine.)



Lymphoma

Lymphoma is the most common type of small intestinal neoplasia in cats and dogs. For feline intestinal lymphoma, subtypes include lymphocytic, lymphoblastic, epitheliotropic, and large granular lymphocyte (LGL) types. Intestinal lymphoma in dogs occurs in the stomach and small intestine equally and more often in both of these sites than in the large intestine. For additional information regarding canine and feline lymphoma the reader is referred to Chapter 33, Sections A and B.

Adenomatous Polyps and Adenocarcinoma

Most alimentary adenocarcinoma in cats is found in the small intestine[433,456,462]; however, the colon and rectum are more common sites in dogs.[472,473] For colorectal adenocarcinomas, the rectum is a more common site than the colon.[474] The cecum is more likely to develop leiomyosarcomas or GISTs than adenocarcinoma.[451,473] Histologic descriptors for carcinoma of the intestine include adeno- (forming glands), mucinous (>50% mucin), signet ring (>50% of cells have intracellular mucin), and undifferentiated or solid (no evidence of gland formation).[472] Grossly, colorectal adenocarcinomas may demonstrate a pedunculated (especially in the distal rectum), cobblestone (middle rectum), or annular (middle rectum) appearance, which may relate to behavior and prognosis (Fig. 23.25).[469,473,474]

Adenomatous polyps are found in the rectum of dogs and carcinomas in situ are found in both the colon and rectum. Most lesions are solitary, although multiple and diffuse lesions can be seen and are associated with increased recurrence rates.[455] A case series of 31 dogs with colorectal carcinoma found that most were B-cell, high-grade, and caused hematochezia.[475] Miniature dachshunds are overrepresented for inflammatory colorectal polyps, suggesting a breed predisposition in multiple case series from Japan.[476,477] The

VetBooks.ir

inflammatory polyps presented as multiple small polyps, whereas other colorectal polyps generally presented as either solitary or multiple lesions.[476,477] In cats, polyps are more common in the duodenum and intestinal obstruction resulting from a duodenal Brunner's gland adenoma has been reported in a dog.[478]

Leiomyomas, Leiomyosarcomas, and GISTs

Leiomyomas occur more commonly in the stomach, but have also been reported in the esophagus, small intestine, and colorectum.[457] GISTs are well documented in humans and have been reported in dogs and cats.[479–481] These nonlymphoid tumors of mesenchymal origin were originally diagnosed as leiomyosarcomas and some, but not all, were leiomyomas. Histologically, GISTs are highly cellular mesenchymal tumors that do *not* show ultrastructural characteristics consistent with smooth muscle differentiation. GISTs are thought to arise from multipotential stem cells phenotypically similar to interstitial cells of Cajal, driven by activating mutations of c-*Kit* (a proto-oncogene). Although these cells can differentiate into smooth muscle cells if deprived of KIT (a receptor tyrosine kinase), GISTs are a discrete clinical entity from leiomyosarcoma.[482] Leiomyosarcomas are positive for smooth muscle actin and desmin and negative for KIT. GISTs are distinguished by high vimentin immunoreactivity, low alpha smooth muscle actin reactivity, and CD117 (KIT) reactivity, and arise primarily in the small and large intestine.[457,483,484] c-*Kit* exon 11 mutations have been found to occur frequently in canine GISTs, which is similar to human GISTs, where exon 11 mutations occur in 60% to 70% of cases and mutations in exon 9 occur in 5% to 10% of cases.[457,485] To date, only one dog with an exon 9 mutation has been reported.[486] CD117 (KIT) reactivity is considered a major diagnostic criterion and is used to distinguish GISTs from leiomyosarcomas in many studies.[487,488] When stratified as such, 28 of 42 leiomyosarcomas in dogs were reclassified as GISTs and only 2 of the 28 cases of GIST metastasized (7%), with those dogs living longer than dogs with leiomyosarcoma.[487] These investigators also found that GISTs were significantly more likely to occur in the large intestine, specifically the cecum, and leiomyosarcomas in the stomach and small intestine,[487] yet a recent study contradicted this finding with GISTs occurring primarily in the small intestine.[484] Considering these findings, the incidence of true leiomyosarcoma is likely low because many previously reported cases may have actually been GISTs. The inclusion of GISTs as leiomyosarcomas will also have caused confounding of clinical behavior in these studies. In addition to the effect on incidence, conflicting reports of biologic behavior are problematic. Although the study cited earlier found a 7% rate of metastasis for dogs with GISTs and a worse prognosis for dogs with leiomyosarcoma, a recent study reported a higher rate of metastasis (27%) in GISTs and no metastasis in dogs with leiomyosarcomas.[484]

Mast Cell Tumors

Intestinal MCTs are the third most common tumor after lymphoma and adenocarcinoma in cats, but their incidence and behavior are poorly reported. For further details, the reader is referred to Chapter 21.

Other Tumor Types

The term *carcinoid* refers to tumors that arise from the diffuse endocrine system rather than the intestinal epithelium, despite histologic similarity to carcinomas. Carcinoid cells arise from enterochromaffin cells of the intestinal mucosa and contain secretory granules that may contain substances such as 5-hydroxytryptamine (serotonin), secretin, somatostatin, and gastrin, among others.[472] IHC for cytokeratin and for secretory substances, such as serotonin, may be positive, and serum concentration of serotonin has been documented at 10 times the normal range in one dog with a carcinoid.[489] Carcinoids have been described in many species and may occur in both the large and the small intestines and frequently metastasize to the liver.[434,473,489] Carcinoids may follow an aggressive and debilitating clinical course.[489]

Extramedullary plasmacytomas (EMPs) are solitary tumors with no evidence of systemic multiple myeloma and the reader is referred to Chapter 33, Section D , where they are covered in detail. Another uncommon tumor type is extraskeletal OSA, which has been reported in the duodenum of a cat.[490] This cat had no evidence of metastasis at diagnosis and did well for 4 months after surgery when clinical signs recurred and the cat died.[490] Three of 55 extraskeletal and 145 total cases of feline OSA were of intestinal origin.[491] A series of four cats was reported with intestinal hemangiosarcoma arising from four different locations within the intestines; no cat survived greater than 1 week.[492] Finally, one dog was diagnosed with ganglioneuroma of the rectum and experienced long-term survival after surgical resection.[493] Small intestinal ganglioneuromatosis has also been reported in a dog with a similar good outcome after surgical resection.[494]

Molecular Aspects

With an increasing armamentarium of molecular diagnostics, insights into the pathogenesis, progression, and prognosis of tumors are constantly emerging. Cellular adhesion and invasion (e.g., Tenascin-C,[463,495] versica, hyaluronan,[496] β-catenin, and E-cadherin[497–499]), stromal remodeling, and alterations in tumor suppressor genes (e.g., *p53*[497,499–501]) may play a role in the development and progression of intestinal neoplasia. The importance of the relationship between a tumor cell and its stroma should not be underestimated. Although molecular markers/targets likely play an important role in intestinal tumors, the utility of these in diagnostics, prognostication, and therapy in companion animal species, with the exception of GIST and CD117 expression, is limited.[481]

COX enzymes are responsible for prostaglandin synthesis and COX-2 is overexpressed in many head/neck and genitourinary tumors, creating a possible therapeutic target. COX-2 has been identified in both benign and malignant small intestinal and colorectal epithelial tumors in dogs, although the number of positive cells varies and was very low in some studies.[502,503] In addition, one study found no COX-2 staining in 13 intestinal tumors in cats.[504] COX inhibitors are thus of questionable value in treating intestinal tumors.

History and Clinical Signs

The duration of clinical signs before presentation typically averages 6 to 8 weeks, but can range from less than 1 day to several months.[441,450,451] Clinical signs include (in varying order of frequency): weight loss, diarrhea, vomiting, and anorexia, and, less frequently, melena, anemia, and hypoglycemia (with smooth muscle tumors).[434,441,444,453,460,461,505–508] Clinical signs often relate to location of the tumor within the GI tract. Proximal lesions more commonly result in vomiting;

small intestinal lesions in weight loss; and large bowel lesions in hematochezia and tenesmus.[456,458] Although carcinoids may secrete endocrine substances, clinical signs do not always reflect hypersecretion.[472] Dogs and cats may present with clinical signs relating to intestinal obstruction, such as anorexia, weight loss, and vomiting. In dogs with cecal GISTs, 25% to 32% cause perforation which results in a localized peritonitis and clinical signs of an acute abdomen.[487,488] Smooth muscle tumors are located within the muscular layer of the intestines and not within the lumen and evidence of GI bleeding is often absent, but anemia and melena have been reported.[451,452] Clinical signs of chronic small bowel disease should not be ignored in cats, as 96% to 99% had abnormalities on biopsy consistent with inflammatory bowel disease (IBS) or neoplasia (lymphoma, MCT, adenocarcinoma).[507,508]

Paraneoplastic Syndromes

One dog was presented for alopecia and *Cheyletiella* infection within 2 months of euthanasia for abdominal carcinomatosis from intestinal carcinoma. The neoplasia was not identified with abdominal US at the original workup, but immunosuppression resulting from an underlying neoplasia was thought to lead to opportunistic *Cheyletiella* infection. Although pruritus resolved with ivermectin therapy, alopecia persisted, suggesting a paraneoplastic origin.[509] Alopecia has also been reported as a paraneoplastic syndrome secondary to a metastasizing colonic carcinoma in a cat.[510] Neutrophilic leukocytosis (in one dog associated with monocytosis and eosinophilia) has been reported in dogs with rectal tumors. Resolution or improvement of hematologic abnormalities occurred after treatment for adenomatous rectal polyps.[502,511] Hypereosinophilia and eosinophilic tumor infiltrates have been reported in a cat and several dogs with intestinal T-cell lymphoma; the suggested cause was IL-5 secretion by the neoplastic lymphocytes.[512–514] EMP may lead to a hyperviscosity syndrome resulting from overproduction of immunoglobulin.[515] Erythrocytosis managed with periodic phlebotomy was related to a cecal leiomyosarcoma in a 14-year-old dog. The diagnosis was made at postmortem 2 years later; erythropoietin mRNA and protein were isolated from tumor cells, suggesting ectopic erythropoietin production as the cause of the erythrocytosis.[516] Hypoglycemia has also reported with intestinal smooth muscle tumors as a paraneoplastic syndrome.[517] Nephrogenic diabetes insipidus has also been documented in one dog with intestinal leiomyosarcoma.[518]

Diagnostic Techniques and Workup

Physical Examination

An abdominal mass may be palpated on initial examination in approximately 20% to 40% of dogs with lymphoma[450,453] and 20% to 50% of dogs with nonlymphomatous solid intestinal tumors.[441,456,458] Pain and fever were reported in 20% of dogs with lymphoma in one report.[450] Digital rectal examination may identify masses or annular strictures due to rectal tumors or polyps in as high as 63% of dogs.[456,474] Abdominal masses are also often readily palpated in cats with both lymphoma and adenocarcinoma.[444,445,458,460] Dehydration is also common and occurs in 30% to 60% of cats with nonlymphomatous tumors.[444,458]

Clinical Pathology

Complete Blood Count

Anemia is common in dogs and cats with intestinal tumors and is often not characterized, but may occur in conjunction with melena and elevated blood urea nitrogen (BUN). Anemia affects nearly 40% of dogs in most studies and as low as 15% but up to 70% of cats.[441,445,451,452,456,458,460] Leukogram changes are also common including leukocytosis in 25% to 70% of dogs and 40% of cats.[441,444,452,458] A left shift may be seen as well as monocytosis in some patients.[458,460]

Chemistry Profile

Biochemical abnormalities are similar between dogs and cats with intestinal tumors. As a result of malabsorption, hypoproteinemia may be present in one-fourth to one-third of patients.[441,444,445,452,453,456] Other common abnormalities include elevated liver enzymes, specifically alkaline phosphatase in 15% to 33% of dogs and up to 85% of cats with nonlymphomatous neoplasia.[441,452,456,458,460] In one series, high cholesterol was seen in 41% of cats with nonlymphomatous tumors.[458] An elevated BUN has been reported in 13% of dogs and 30% of cats with intestinal adenocarcinoma.[441,444] This may be a result of concurrent renal insufficiency, intestinal bleeding due to the tumor, or dehydration. Although some cats may have hyperglycemia,[458] smooth muscle tumors can cause up to 55% of patients to be hypoglycemic as a result of insulin-like growth factor secretion.[451] Dogs may also have increased amylase and electrolyte disturbances,[456] and patients with lymphoma may be hypercalcemic.[445] Serum alpha 1-acid glycoprotein, an acute-phase reactant protein, may be increased in cats with cancer, but this lacks specificity and prognostic relevance.[519,520]

Cytology and Histopathology

As with other anatomic sites, cytology of the intestinal tract can help differentiate major tumor types. In addition, lymphocyte accumulations can be tested using polymerase chain reaction (PCR) for antigen receptor rearrangement (PARR) for clonality (see Chapter 33, Section A and B for further details). In cats, mucosal biopsies of the upper GI tract are commonly obtained in a minimally invasive fashion using endoscopy. Despite the superiority of full thickness biopsies (because submucosal and muscularis infiltration can be characterized), the ease of endoscopic biopsy has resulted in rigorous evaluation of ancillary diagnostics to improve accuracy on these samples. Because of reported eosinophilia with intestinal lymphoma and reports of MCT with concurrent small T-cell lymphoma in cats, it may be challenging to distinguish between the two tumor types.[512,521,522]

Imaging

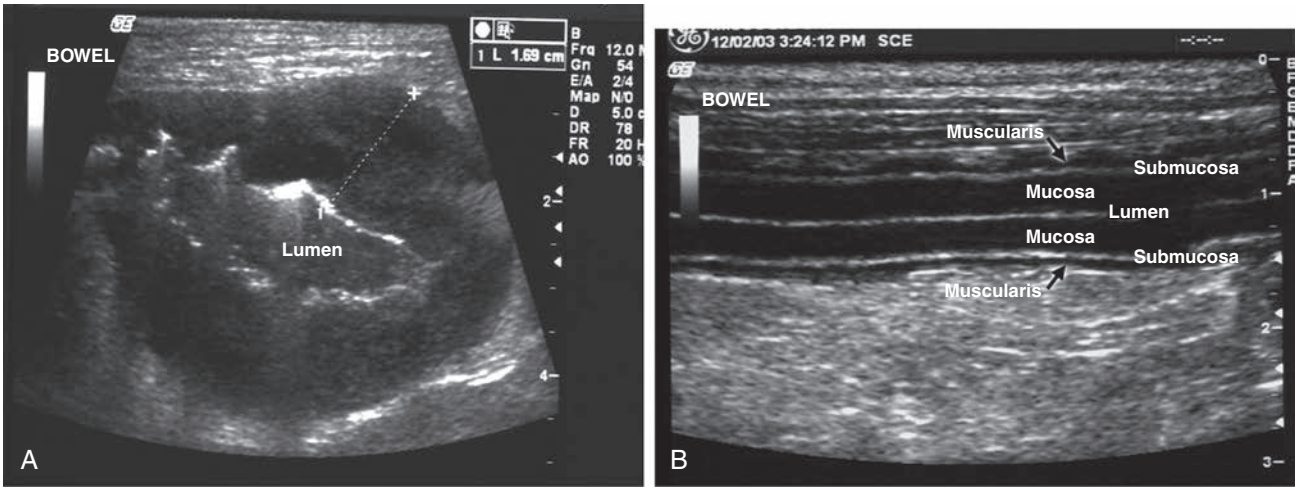
Abdominal Radiographs and Ultrasound

In dogs and cats with intestinal lymphoma, concurrent enlargement of liver, spleen, and/or mesenteric LNs may be seen.[450] Plain abdominal radiographs may reveal an abdominal mass in approximately 40% of both dogs and cats, although some reports are higher for solid tumor types and lower for lymphoma.[441,444,445,450,452,458] An obstructive pattern may also be seen on plain radiographs in 10% to 75% of cats and dogs.[441,452,456,458] Other abnormalities may include poor serosal detail and thickened stomach wall.[445]

VetBooks.ir

Contrast radiography, although used less after advances in US, has often been used to evaluate patients with signs of primary GI disease. US can help facilitate noninvasive localization of the tumor and identification of other sites of metastasis or involvement. It also can guide needle aspiration or needle biopsy or assist in treatment planning. US is a more sensitive diagnostic test than radiographs for identifying a mass.[441,451,454,523] US is also less time consuming than contrast radiography, and the increased use, availability, and operator skill for the former has diminished the need for the latter.

US findings in dogs and cats with intestinal neoplasia most consistently include bowel wall thickening and loss of normal wall layering.[456,523,524] Intestinal lymphoma in dogs more often results in long segments of involved bowel and either a solitary mass or diffusely thickened bowel loops with thickening of the muscularis propria in cats.[506,524,525] However, the normal appearance of intestine does not rule out the presence of lymphoma, as one study showed 26% of dogs diagnosed with GI lymphoma did not have sonographic abnormalities.[526] Adenocarcinoma in cats has been described as having mixed echogenicity and was asymmetric in three of five cats.[523] In one study, two-thirds of dogs with intestinal adenocarcinoma had hypoechoic tumors and most had decreased motility.[456] These masses averaged 4 cm long with a median wall thickness of 1.2 cm.[456,473] MCTs have an eccentric appearance with alteration, but not loss of wall layering, commonly involving the muscularis propria.[522] Smooth muscle tumors are characteristically large (median diameter 4.8 cm) and anechoic/hypoechoic, and a muscular layer origin may be identified. Leiomyomas may have a smooth contour.[454] One report of metastatic mammary carcinoma to the small intestine described the appearance as multiple, hypoechoic, well-defined or marginated nodules within the muscularis layer of the jejunum that did not disrupt the intestinal layering.[527]



Degree of thickening, distribution of lesion(s), and symmetry are used to help differentiate neoplastic from nonneoplastic disease.[528] In one study, 99% of dogs with neoplasia had a loss of wall layering and this was associated with a 50 times greater likelihood of neoplasia than enteritis (Fig. 23.26).[524] In addition, dogs with walls thicker than 1 cm are nearly four times as likely to have a tumor and those with focal lesions are nearly 20 times as likely to have a tumor.[524] Nevertheless, possible differential diagnoses include fungal (pythiosis and histoplasmosis) masses, as these can mimic neoplasia.[528] In general, neoplasia exhibits more dramatic thickening with loss of wall layering and greater LN enlargement, as well as more frequent focal lesions than nonneoplastic intestinal disease.[528] Similar changes (thickened muscularis propria, and ratio of muscularis to mucosa >1) can be seen in cats with intestinal lymphoma, but do not reliably distinguish neoplasia from IBD.[529] In a series of 14 cats with carcinomatosis, three of which were a result of small intestinal tumors (two carcinomas and one lymphoma), the hallmark ultrasonographic finding was the presence of masses in the double sheet portion of peritoneum that connects the visceral and parietal portions (100% of cats); all cats also had free peritoneal fluid.[530]

Thoracic Radiographs

Thoracic radiographs are critical to the complete evaluation of the cancer patient. For dogs with nonlymphomatous intestinal tumors, yield is low, with very few patients presenting with pulmonary metastasis.[441] This may be due to a bias in reporting because many reports detail outcome of treatment and patients with metastatic disease may not receive treatment. In fact, many case series report no evidence of metastasis on initial evaluation for solid tumors of the intestine in dogs.[441,451,452,456,458] Two of 14 cats in one series and no cats in another series had pulmonary nodules at initial evaluation.[444,458] For cats and dogs with lymphoma, enlarged sternal or perihilar LNs, pleural effusion, or diffuse interstitial changes may be seen.[445,450]

Endoscopy, Colonoscopy, and Laparoscopy

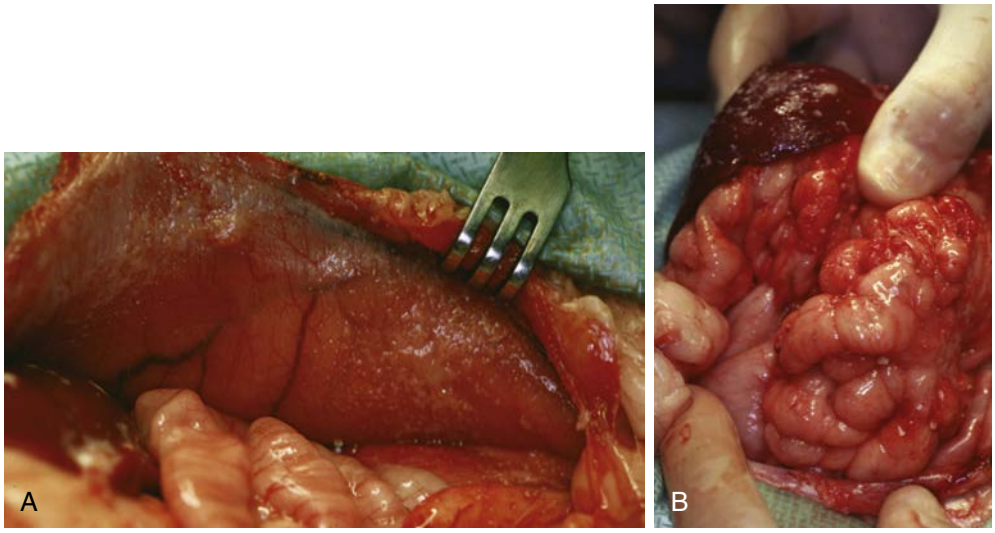
Minimally invasive methods of collecting tissues to aid in diagnosis are increasingly used. Endoscopic findings in dogs with intestinal lymphoma include an irregular cobblestone or patchy erythematous appearance to the duodenal mucosa and poor distensibility and elasticity of the duodenal wall.[453] Colonoscopy can be considered to evaluate for multiple colorectal masses as well as

• **Fig. 23.26** A cross-sectional ultrasound image of a segment of small intestine with lymphoma (A) is compared with a longitudinal view of a segment of normal small intestine (B). Note that the clearly defined intestinal layers in the normal tissue are completely effaced in the tumor tissue. A loss of layering is strongly supportive of neoplasia. The diseased bowel is also markedly thickened, suggesting neoplasia. (Courtesy Dr. Stephanie Essman, University of Missouri, College of Veterinary Medicine.)

obtain biopsy samples; however, single rectal masses appear to be more common in dogs and these masses were not present beyond the colorectal border.[531] Therefore proctoscopy or transanal single laparoscopic port evaluation may provide information regarding mass number and characteristics without the need for extensive bowl preparation and surgical delay.[531] Of note, 5 of 16 dogs (31%) had different colonoscopy biopsy results compared with the final histopathology results with a tendency to underdiagnose malignancy.[531] Interobserver variation is likely to be more pronounced with small tissue samples and this is a limitation of these less invasive approaches.

Exploratory Laparotomy

When noninvasive or minimally invasive diagnostics fail to confirm a diagnosis, an exploratory laparotomy may be indicated for dogs and cats with persistent signs of GI disease. Benefits include direct visualization of all abdominal viscera and the ability to collect full-thickness biopsies of all segments of intestines and other viscera. Patients with resectable solid tumors may be both diagnosed and treated in a single procedure with intestinal resection and anastomosis. In a series of dogs with GI lymphoma, endoscopic biopsies were sometimes difficult to interpret because of lymphoplasmacytic infiltrate, but surgical biopsies obtained by laparotomy confirmed the diagnosis in all cases.[450] In a study evaluating 367 dogs and cats undergoing GI biopsies, the risk of GI dehiscence was found to be very low (1% dogs, <3% cats) with possible risk factors in cats being neoplasia and hypoalbumenia, although these had wide confidence intervals.[532] It should be noted that carcinomatosis should not always be seen as an indication for euthanasia (Fig. 23.27). After removal of the primary intestinal adenocarcinoma, two cats with malignant effusion lived 4.5 and 28 months after surgery.[444]

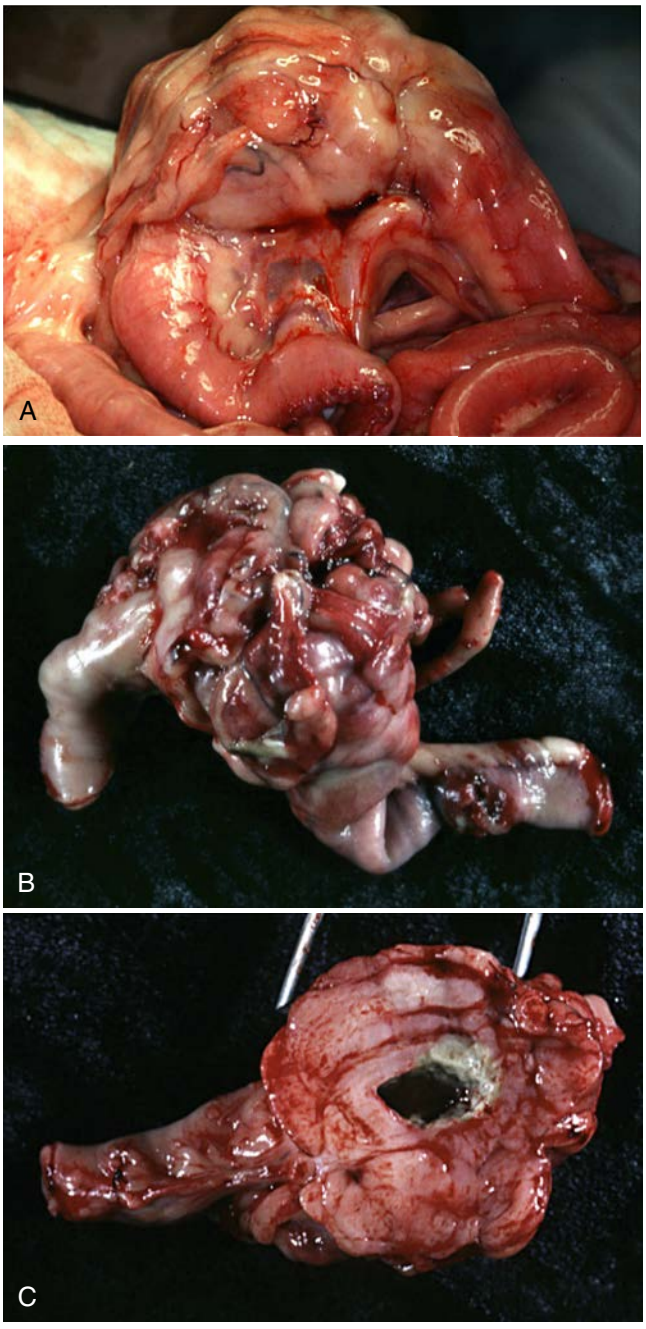


Therapy and Prognosis

Surgery

With the exception of lymphoma, surgical resection is the primary treatment for intestinal tumors. Lymphoma is treated primarily with chemotherapy except when intestinal perforation or the need for a biopsy necessitates surgery (Fig. 23.28). As long as severe extraserosal invasion and/or adhesions do not complicate the surgical approach, complete excision of intestinal tumors is often possible. For dogs and cats without evidence of local or distant metastasis, long-term survival is possible, although some tumors may later metastasize. Overall, the 1-year survival rate is approximately 40% for dogs with solid small intestinal tumors.[441] For cats with adenocarcinoma, approximately 50% will metastasize to the local LNs, 30% to the peritoneal cavity (carcinomatosis), and 20% or less to the lungs.[434,458,462] Dogs have similar rates of metastasis to LNs for both adenocarcinoma and leiomyosarcoma, although the liver is usually the second most frequent site.[441,458,473] Perioperative mortality can approach 30% to 50% as a result of sepsis, peritonitis, or owner decision for euthanasia when nonresectable tumors are present.[441,451]

Small Intestine



Intestinal resection and anastomosis is the most common surgical technique for tumors of the small intestine. Stapling techniques have been shown to be equivalent to hand suturing in both the large and small intestine.[533,534] Canine small intestinal adenocarcinoma has a guarded prognosis with a mean survival time (ST) of only 12 days without treatment and a mean ST of 114 days after surgical resection, though others report median STs (MSTs) of 7 and 10 months.[441,456,458] Dogs with leiomyosarcoma who survive the perioperative period have MSTs of 1.1 to almost 2 years.[451,452] One case series found the MST for 28 dogs with GIST to be approximately 38 months (1 year if postoperative deaths were included) versus an MST of 8 months for 10 dogs with leiomyosarcoma, although this difference was not statistically significant.[487] Another study found no difference in survival between dogs with GIST and leiomyosarcoma with 1-year survival rates of approximately 80% for both tumor types (Fig. 23.29).[488] The benefit of surgery is questionable for dogs with intestinal MCTs. In two case series, most dogs died within the first month. Only 2 of 49 dogs (combined total for two series with almost all being GI MCTs) lived past 180 days and prednisone was not helpful in most cases.[465,466]

VetBooks.ir

In cats with small intestinal adenocarcinoma, there is significant perioperative risk, but cats that live beyond 2 weeks may experience long-term control with surgery alone (Fig. 23.30). In two series, all cats that did not have their tumors resected were euthanized or died within 2 weeks of surgery.[444,458] After surgical resection, one-half of cats in one report and all cats in another study died within 2 weeks of surgery, and 4 of 11 cats surviving beyond 2 weeks died within 2 months of complications or other nontumor causes.[444,458,462] For eleven of the 12 cats that survived 2 weeks beyond surgery, mean ST was 15 months, although in another report the MST was 2.5 months.[444,461] For details about outcome after treatment for alimentary lymphoma see Chapter 33, Sections A and B.

Large Intestine

There are various approaches for removal of tumors from the large intestine based on the size, location, and depth of penetration of the mass. Generally, for rectal mucosal masses suspected to be benign polyps, the masses can be removed via mucosal eversion and submucosal resection.[535] Transrectal endoscopic removal of benign canine rectal tumors can be considered if more extensive surgery is required because of the location of the tumor. Using this technique, five of six dogs showed significant improvement in quality of life and three dogs were cured; however, one dog died due to rectal perforation, which is a known complication of this procedure.[536] The other disadvantage of this technique is there is often incomplete removal of the mass, as it is usually removed piecemeal. In a recent case report, this technique was modified to inject saline to separate the mucosa from the submucosa to improve visibility and the ability to completely remove

VetBooks.ir

the mass.[537] For malignant rectal tumors, full-thickness removal of the rectum is generally indicated. Rectal-pull through is commonly performed for rectal adenocarcinomas. This can be performed through either a perineal or combined perineal-abdominal approach.[538,539] Complications are relatively common, including fecal incontinence (57% total with 40% permanent fecal incontinence), diarrhea (43%), tenesmus (31%), stricture formation (21%), rectal bleeding (11%), dehiscence (8%), and infection (5%).[538] Colostomy use has been reported to aid in management of dogs with nonresectable rectal tumors. In one report, skin excoriation was the most common complication, but colostomy bags were managed for up to 7 months.[540]

For rectal polyps and carcinomas in situ, depending on the surgical technique used for resection, local recurrence of clinical signs is reported in up to 41% of dogs and 18% of dogs had malignant transformation associated with tumor recurrence.[455] Surgical removal of duodenal polyps in cats is typically curative.[446] For dogs with colorectal adenocarcinoma, local excision results in MSTs of 2 to more than 4 years compared with 15 months for stool softeners alone;[474,475,539,541] colorectal EMPs and polyps also fare well with MSTs of 15 months and 2 years or more, respectively, after surgical excision.[464,542]

In cats with large intestinal neoplasia, STs after surgery alone are approximately 3.5 months for lymphoma, 4.5 months for adenocarcinoma, and 6.5 months for MCT. Subtotal colectomy has been recommended for cats with colonic adenocarcinoma.[447,543] Adjuvant chemotherapy has improved STs for cats with adenocarcinoma, but not for lymphoma.[447]

Chemotherapy

No randomized studies exist to investigate the efficacy of adjuvant chemotherapy after resection of epithelial intestinal tumors in dogs and cats. The benefit of adjuvant chemotherapy in humans is questionable, although current fluorouracil-based regimens are often considered to be the standard of care. When attempted, adjuvant chemotherapy typically includes doxorubicin in veterinary medicine. One retrospective study in cats with colonic adenocarcinoma treated with subtotal colectomy did show a significant survival advantage for cats receiving adjuvant doxorubicin; MSTs were 280 days with and 56 days without chemotherapy.[447] In another retrospective study using adjuvant carboplatin, the MST was 269 days, but no controls were included to evaluate treatment without chemotherapy.[543] Distant and nodal metastases were found to be negative prognostic indicators, with an MST of 200 days versus 340 days and 178 days versus 328 days, respectively.[543] For carcinomatosis, intracavitary therapy may be helpful with carboplatin for cats or cisplatin or 5-fluorouracil (5-FU) for dogs.[544] For further details about treatment of alimentary lymphoma please see Chapter 33, Sections A and B.

Individual case reports in dogs using receptor tyrosine kinase inhibitors (TKIs, imatinib and toceranib phosphate) to treat GISTs in the setting of metastatic disease, nonresectable disease, or recurrent disease have shown good responses with partial (PR, n = 1) or complete responses (n = 2) for greater than 140 days, greater than 9 months, and greater than 4 years, respectively.[486,545,546] The only toxicity seen was in one dog, and this manifested as an increase in ALT resulting in dose reduction of imatinib.[546] After this dose decrease, the PR ceased, which could have been due to the lower dose or emergence of resistance as has been documented in human GISTs due to a second site mutation in c-*kit*.[546] Imatinib has also been reported in the treatment of canine intestinal MCT with metastasis to the spleen. A strong PR was seen but was brief in duration.[547]

A reduction in the size and clinical signs of rectal polyps in 8 dogs was noted after piroxicam therapy, either orally or in suppository form. Clinical response did not relate to whether there was inflammation associated with the tumor.[502]

Radiation Therapy

RT is seldom used in the treatment of intestinal tumors because of the concern regarding toxicity to surrounding abdominal viscera, the ability to often obtain adequate local control via surgery, and the inability to reliably irradiate the same tissue each day because of the mobility of the intestine.

Prognostic Factors

Intestinal perforation does not appear to be a negative prognostic factor for leiomyosarcoma because dogs surviving the perioperative period had prolonged STs in one series.[451] For colorectal tumors, treatment is prognostic, with local excision resulting in significantly better outcomes than palliative care. Gross appearance, although not statistically examined, may determine outcome because dogs with annular, obstructing masses survived a mean ST of 1.6 months whereas dogs nodular/cobblestone masses or single pedunculated masses had mean STs of 12 and 32 months, respectively.[474]

For nonlymphomatous small intestinal tumors in dogs, metastasis at the time of surgery resulted in significantly shorter STs (3 months vs. 15 months). The 1-year survival rates for dogs with and without LN metastasis were 20% and 67%, respectively.[441] In another study, however, dogs with and without visceral metastasis from leiomyosarcoma survived equally as long after surgical resection (21 months).[451] Male dogs with small intestinal adenocarcinoma had a significantly better outcome; however, the number of female dogs in that study was low.[456] Cats with adenocarcinoma, however, survived significantly longer if they were treated with subtotal colectomy (138 days vs. 68 days with mass excision), received postoperative doxorubicin (280 days with vs. 56 days without doxorubicin), and had no LN metastasis at surgery (259 days for no LN metastasis vs. 49 days with LN metastasis).[447] For further details about prognosis for dogs and cats with intestinal MCT see Chapter 21. For prognostic factors for canine and feline alimentary lymphoma see Chapter 33, Sections A and B.

Comparative Aspects

Although cancer of the large intestine and rectum is well characterized in humans, small intestinal neoplasia is rare. Theories for this discrepancy include more rapid small intestinal transit time compared with the large intestine (creating less contact time for carcinogens), dilution of carcinogens with fluid compared with solid stool, differences in pH, relative lack of bacteria to allow transformation of procarcinogens, presence of detoxifying enzymes, and increased presence of immunoglobulin A promoting local immunosurveillance of damaged cells as a result of increased lymphocytes in the small intestine. This is in contrast to veterinary medicine where in cats and sometimes dogs, malignant neoplasia is more common in the small intestine than the large intestine. This may reflect differences in physiology, diet, or genetics. As in animals, tumors of the small intestine of humans are usually malignant. Diagnostic evaluation is similar to that described in

VetBooks.ir

animals, although advanced imaging modalities, such as CT, are more often used. Most diagnoses are made at surgery and 5-year survival rates average approximately 20%.[548]

Large bowel/colorectal cancer is one of the most frequently diagnosed cancers in both men and women. Risk factors include genetic predisposition/familial history, tobacco and alcohol intake, advanced age, and predisposing medical conditions, among others. Colorectal cancer development may further be influenced by intake of red meat (especially fried), low-fiber and/or high-fat diets, obesity, fecal pH, and fecal mutagens. Among genetic risk factors, polymorphism in colonic enzymes and mutations leading to familial adenomatous syndromes are uncommon but are important as models of carcinogenesis. In most familial polyposis syndromes, the adenomatous polyposis coli (APC) gene is mutated. The multistage progression from benign polyp to carcinoma is well understood and underscores the importance of early detection.[549] Recently, the APC gene was found to be altered in about 70% of tested canine colorectal tumor samples, suggesting a similar molecular pathogenesis.[550] In contrast, hereditary nonpolyposis colon cancer develops without known premalignant polyps; this is inherited via autosomal dominance with high penetration and is characterized by microsatellite instability.[551]

In human medicine, GISTs are also subcategorized by the histopathologic morphology, a recent publication on canine intestinal tumor classification divided canine GISTs into 2 morphologic groups: spindlyloid/storiform and epitheloid, with the majority of GISTs in this study being spindlyloid.[484] In addition, it has been suggested in humans there may be a subset of GISTs that are KIT negative.[484] A recent study evaluated the use of protein 1 (DOG1) IHC marker to identify GISTs and it was found to have an increased specificity and sensitivity compared with KIT IHC.[552] In this study, 2 tumors were negative for KIT and positive for DOG1. This may indicate there is a subpopulation of GISTs in dogs that are also KIT negative. The authors concluded that utilizing diagnostic panels with KIT and DOG1 markers would improve the accuracy of diagnosis.[552]

The most clinically important aspects of comparative oncology when considering intestinal neoplasia in humans are the use of COX inhibitors in the treatment and prevention of colorectal neoplasia, and the use of TKIs. In people, KIT mutations in GISTs have led to the use of imatinib mesylate, a TKI that inhibits KIT.[553] This illustrates the notion of therapy directed at the molecular defect rather than the histologic diagnosis. KIT is mutated in some canine GISTs and thus TKIs may benefit this population as well. COX inhibition byNSAIDs decrease the incidence of colorectal cancer and mortality by 40% to 50%.[554] Among the proposed mechanisms of action, prostaglandin production may be related to tumor progression and therefore inhibition leads to cancer prevention. In addition, non-COX pathways include inhibition of transcription factors and induction of nuclear hormone receptors that lead to cellular differentiation.[554] Interestingly, a retrospective study found a significantly reduced incidence of cancer in dogs with a history of NSAID use (71% reduced risk).[555]

Therapy in humans is similar to that in companion animals. Surgical resection is the primary mode of therapy with adjuvant targeted or traditional chemotherapy in many cases, especially if patients present with LN metastasis or unresectable disease. TKIs may improve prognosis for unresectable and metastatic GISTs.[556] Adjuvant chemotherapy is used in colon cancer, with oxaliplatin in combination with capecitabine or with leukovorin and 5-FU, but without a convincing increase in overall STs.[557] RT is used primarily for areas of the GI tract that are not very mobile, such as the stomach and rectum.

SECTION H: PERIANAL TUMORS

JULIUS M. LIPTAK AND
MICHELLE M. TUREK

The perianal area of dogs contains several glands and structures from which tumors may develop. Perianal, or circumanal, glands are located in the dermis in a circular fashion around the anus and are also scattered in areas on the prepuce, tail, pelvic limbs, and trunk.[558] These are commonly referred to as hepatoid glands as a result of their cellular morphologic resemblance to hepatocytes and are considered nonsecretory sebaceous glands in the adult dog.[558,559]The anal sacs represent blind cutaneous diverticula that are located on each side of the anus at the 4 o'clock and 8 o'clock positions. Located in the connective tissue surrounding these diverticula are distinct apocrine sweat glands that empty their secretions into the lumen of the anal sacs. The most frequently observed tumors of this region in dogs include perianal sebaceous adenoma, perianal sebaceous adenocarcinoma, and apocrine gland anal sac adenocarcinoma (AGASAC). Other tumors arising from the anal sacs include squamous cell carcinoma (SCC) and malignant melanoma,[560–563] but benign tumors of the anal sac are rare.[564] Any cutaneous or subcutaneous tumor can affect the perianal region, including mast cell tumor, soft tissue sarcoma, squamous cell carcinoma, hemangiosarcoma, lymphoma, melanoma, leiomyoma, and transmissible venereal tumor.

Because cats do not have glands analogous to the perianal sebaceous glands in the dog, perianal adenoma and perianal adenocarcinoma are uncommonly recognized in this species. Apocrine gland adenocarcinoma of the anal sac occurs rarely in the cat.[565–567]

Perianal Adenoma and Adenocarcinoma

Incidence and Risk Factors

Perianal adenomas (circumanal, hepatoid tumors) represent the majority of canine perianal tumors (58%–96%).[558,568] Development and progression of these benign tumors appear to be sex hormone–dependent, with growth stimulated by androgenic hormones and supressed by estrogenic hormones.[558,569,570] Older, intact male dogs are at higher risk.[558,568,569] The mean reported age is 10 years.[568] A high incidence of associated testicular interstitial cell tumors has been reported for males with perianal adenomas, supporting testosterone production as a cause[569]; however, a true cause-and-effect relationship has not been clarified because interstitial cell tumors are also a common incidental finding in non–adenoma-bearing, older intact males. Perianal adenomas in the female occur almost exclusively in ovariohysterectomized animals in which low levels of estrogen do not suppress tumor growth. Rarely, androgenic steroid secretion from the adrenal glands, occasionally accompanied by signs of hyperadrenocorticism, may stimulate perianal adenoma formation in female dogs.[571,572] Cocker spaniels, beagles, bulldogs, and Samoyeds may be predisposed.[558,569] Some authors have proposed the term epithelioma to describe a subset of perianal sebaceous gland tumors.[573] Epitheliomas are considered low-grade malignancies with a greater

VetBooks.ir

tendency to be locally invasive and to recur after surgical excision.[574,575] To date, there is little clinical information to support a distinction between adenoma and epithelioma.

Perianal adenocarcinoma, a malignant tumor of the perianal glands, occurs much less frequently than its benign counterpart, representing only 3% to 21% of all tumors in this region.[558,568] The mean age of affected dogs is 11 years.[568,576] Tumors occur in castrated or intact males, as well as in females, implying no hormonal dependency; however, this does not preclude earlier hormonal initiation.[569,576] Large-breed male dogs appear to be overrepresented.[576]

Pathology and Natural Behavior

Perianal adenoma is benign. These are slow-growing tumors and, although local disease may be extensive, metastasis does not occur.[558,576]

Perianal adenocarcinoma is generally associated with a low rate of metastasis (<15%) at the time of diagnosis.[576] Metastasis may be more likely to develop later in the course of disease as the primary tumor becomes larger and more invasive.[576] The most frequent site of metastasis is the regional LNs.[558,576] Distant metastasis is rare, but has been reported in the lungs, liver, kidney, and bone.[569,576] This tumor tends to be more rapidly growing, fixed, and firmer than the more common benign perianal adenoma.

The pathogenesis of canine perianal tumors is not known. In a large study evaluating tumor growth characteristics of 240 perianal gland tumors, cell proliferation and apoptosis were quantified by proliferating cell nuclear antigen (PCNA) IHC and microscopic detection of apoptotic corpuscles.[577] Increases in both parameters were observed in perianal adenocarcinomas compared with perianal adenomas.[577] Ki67 immunoreactivity has also been evaluated and was found to increase from benign to malignant lesions, being highest in perianal adenocarcinomas and recurrent tumors.[574,575,578] Collectively, these results suggest that a high proliferative index may be related to tumor aggressiveness. Other IHC studies have attempted to elucidate possible molecular mechanisms involved in canine perianal gland tumorigenesis. Nuclear *p53* accumulation was detected in 50% of perianal sebaceous gland adenocarcinomas in one study, suggesting that expression of a mutated *p53* tumor suppressor protein may play a role.[579] Discordant results were reported in another study in which *p53* reactivity was found in none of 11 perianal gland adenocarcinomas and in only a small percentage of adenomas.[580] In the same tumor samples, *Mdm2* expression was observed in both adenomas and adenocarcinomas.[580] A study that evaluated androgen receptor expression found no difference between perianal adenomas and adenocarcinomas; the authors concluded that the mechanism by which androgens influence carcinogenesis is still unknown.[581] Vascular endothelial growth factor (VEGF) may also be involved in tumorigenesis. Serum VEGF levels corresponded with tumor aggressiveness and tumor burden in one study.[575] The same study suggested a correlation between serum 17-β-estradiol and VEGF levels, supporting the role of hormones in carcinogenesis in some perianal tumors.[575] Another proposed mediator of tumor development is growth hormone. Growth hormone was detected with IHC in 96% of perianal adenomas and 100% of perianal sebaceous gland adenocarcinomas.[582] Finally, serum magnesium levels were found to be higher in dogs with malignant perianal tumors than in those with benign tumors.[583]

History and Clinical Signs

Benign perianal adenomas tend to be slow-growing (over months to years) masses that are nonpainful and usually asymptomatic. They may be single, multiple, or diffuse (similar to generalized hyperplasia or hypertrophy of the perianal tissue).[558] Most occur on the hairless skin around the anus, although they may extend to haired regions and can develop on the prepuce, scrotum, or tail head (stud tail or "caudal tail gland").[558] Benign lesions may ulcerate and become infected but are rarely adherent or fixed to deeper structures.[558] They are usually fairly well circumscribed, on average 0.5 to 3 cm in diameter, and elevated from the perineum.[558]

Perianal adenocarcinoma may have a similar gross appearance to perianal adenoma; however, they tend to have a faster growth rate, present more commonly as a larger and firmer mass with some degree of ulceration and fixation to deeper tissues, and they are more likely to recur after conservative surgical resection.[576] Perianal adenocarcinomas can be multiple.[573] Obstipation, dyschezia, or perianal pain or irritation can be seen with larger masses.[576] Rarely, clinical signs are related to obstruction of the pelvic canal by LN metastasis. Castrated male dogs with a new or recurrent perianal tumor may have an increased risk for malignant rather than benign disease because, unlike perianal adenoma, perianal adenocarcinomas are not hormonally dependent.

Diagnostic Techniques and Workup

Signalment, history, and physical examination findings will assist in developing a preliminary suspicion of tumor type as well as treatment planning. The mass should be palpated and a rectal examination performed to assess the degree of fixation and extent of the mass as well as the presence of enlarged LNs. Physical examination findings may provide some indication of whether a perianal mass is benign or malignant; however, there is a degree of overlap in the gross appearance of perianal adenoma and adenocarcinoma. FNA cytology to differentiate benign from malignant tumors can be unrewarding, although it is helpful in ruling out other tumor types. Incisional biopsy is recommended for definitive diagnosis and to better direct clinical staging tests and treatment options.[584] Malignant disease is more likely in tumors showing invasiveness into surrounding tissue, disorderly arrangement of cells, increased nuclear pleomorphism, and increased numbers of mitotic figures.[584] In some cases, a definitive diagnosis may not be possible histologically, and IHC with monoclonal antibodies against carcinoma-associated antigens 4A9, 1A10, as well as PCNA, and Ki67 may assist in differentiating perianal adenoma from adenocarcinoma.[573–578,585] In the rare event that differentiation from AGASAC is needed, cytokeratin expression patterns may be helpful.[586] Clinical validation is needed to confirm the utility of these IHC approaches.

For dogs with perianal adenocarcinoma, abdominal and thoracic imaging is recommended to investigate for the presence of metastatic disease. Up to 15% of dogs with perianal adenocarcinoma have evidence of metastatic disease at the time of diagnosis, and the regional LNs and lungs are the most common sites of metastasis.[558,569,576] Based on studies of canine AGASAC, advanced imaging modalities, such as CT andMRI, are superior to abdominal ultrasonography for the detection of enlarged LNs, particularly those within the pelvic canal. Although distant metastasis is uncommon, three-view thoracic radiographs or thoracic CT is recommended for the detection of pulmonary metastasis.

Treatment

Surgical resection is the recommended treatment for dogs with perianal adenomas and adenocarcinomas. Perianal adenomas can be excised with minimal margins of less than 1 cm, whereas larger

margins are recommended for perianal adenocarcinomas because of their propensity for local recurrence after more conservative resections.[574] Castration is also recommended in intact male dogs with perianal adenomas because of the role of testosterone in the tumorigenesis of these tumors.[569,587] For diffuse or large perianal adenomas located on or in the anal sphincter, staged surgery may be preferable with castration initially to decrease tumor volume followed by surgical resection when the perianal adenoma is small enough that it can be more easily and safely resected. More than 90% of male dogs will be cured with castration and local resection of the perianal adenoma.[558,569]

Cryosurgery and carbon dioxide laser ablation are possible alternative treatment options for perianal adenomas, especially if small,[588,589] but the major limitation of these techniques is an inability to assess the surgical margins for the completeness of excision. Hyperthermia and RT have also been used successfully.[590,591] The cost, added morbidity, and limited availability of these modalities make them a poor alternative to standard surgical resection.

Electrochemotherapy has been described in dogs with perianal adenoma and consists of intratumoral injections of chemotherapy followed by local delivery of electric pulses to potentiate drug uptake by tumor cells.[587,592] Treatments are delivered in 1 or 2 weekly sessions. Based on limited studies, the reported overall response rate is greater than 90%, with 65% complete responses.[587,592] Smaller tumors (<5 cm) generally respond better than larger tumors.[587,592] Larger tumors are more likely to develop local complications, including focal necrosis, erythema, and inflammation.[587,592] Systemic effects are not reported.[587,592] Perianal adenoma may also regress after estrogen therapy[575]; however, its use is associated with a risk of myelosuppression. Cyclosporin is reported to have had a palliative effect in one dog with multiple ulcerated perianal adenomas and a measurable reduction in tumor size was observed.[593]

Perianal sebaceous gland adenocarcinoma is more locally invasive and generally does not respond to castration.[569] Aggressive surgical resection with a minimum of 1-cm lateral margins is recommended. Removal of one-half or more of the anal sphincter is possible with only rare transient loss of fecal continence. Preoperative incisional biopsy is recommended to differentiate perianal adenoma from adenocarcinoma because this differentiation may not be possible based on history, gross tumor characteristics, or cytology. If an excisional biopsy is performed, then there is a risk of incomplete histologic excision and local tumor recurrence. The rate of local tumor recurrence is unknown after incomplete histologic excision, but further surgery is complicated by the regional anatomy with a greater risk of treatment-associated morbidity. Adjuvant RT may improve local tumor control after incomplete excision; however, data for this approach are lacking. The use of electrochemotherapy has been reported in a small series of dogs.[587,592] Favorable outcomes have been reported, but additional clinical studies are needed to validate the efficacy of electrochemotherapy.[587,592]

Prognosis

The vast majority of dogs with perianal adenoma are cured with surgical resection and, if indicated, castration.[558,561] Serum VEGF levels may correlate with biologic behavior of this tumor type.[576]

In a series of 41 dogs with perianal adenocarcinoma, stage of tumor had a significant influence on DFI and overall survival times (OSTs).[576] Tumors less than 5 cm in diameter (T2) were associated with 2-year tumor control rates in excess of 60%,[576] suggesting that surgical removal of these masses at an early stage is relatively successful with respect to disease control. The rate of metastasis at diagnosis is 15% and is a poor prognostic factor for survival.[576] The MST for dogs with LN or distant metastasis was 7 months; however, aggressive treatment was not attempted in five of six dogs.[576] In a smaller study, tumor recurrence occurred in 75% of dogs; however, tumor size, surgical approach, and completeness of excision were not reported.[574]

If present, regional LN metastasis may be resected and this may result in improved ST. The use of RT and/or chemotherapy, including actinomycin D, has been reported anecdotally, but their role in local or distant control is undefined.[576,594,595] Nuclear size, as measured by computer-assisted image analysis in cytologic tumor samples, and Ki67 expression may correlate with biologic behavior of perianal adenocarcinoma.[574,596]

Apocrine Gland Anal Sac Adenocarcinoma and Other Tumors of the Anal Sac

Incidence and Risk Factors

AGASAC accounts for 17% of perianal malignancies and 2% of all skin and subcutaneous tumors.[568,597] Spaniels, particularly English cocker spaniels, German shepherds, Alaskan malamutes, and dachshunds have been reported to have an increased risk of AGASAC.[598–601] A female predilection was reported in earlier studies[601–604]; however, an approximately equal sex distribution has been shown in multiple larger series.[598–601,605] Neutering may be associated with increased incidence of AGASAC in male dogs.[598] The mean age of dogs at diagnosis of AGASAC is 9 to 11 years.[568,599–606] Tumors in dogs as young as 5 years have been reported, suggesting that evaluation of the perineum and palpation of the anal sacs should be a routine part of the physical examination of every adult dog.

AGASAC is a rare tumor in the cat, representing 0.5% of all feline skin and subcutaneous neoplasms.[565] The median age of affected cats is 13 years, although animals as young as 6 years have been reported.[565,566] Siamese cats may be at higher risk.[565,566]

Pathology and Natural Behavior

AGASACs are distinct from perianal gland adenocarcinomas histologically and clinically. Histologic patterns of tumor cell arrangement in AGASAC have been classified as solid (closely packed neoplastic cells in lobules or nests with minimal stroma), tubules/rosettes/pseudorosettes (cells are radially arranged around a central tubule or a collection of cytoplastic processes or a small blood vessel), and papillary (elongated tree-like projections with a fibrovascular stalk).[607,608] The solid and tubules/rosettes/pseudorosettes patterns occur in about 95% of cases.[607,608]

AGASACs are usually unilateral, although bilateral AGASACs have been reported.[564,603–606,609–611] The overall incidence of bilateral AGASACs, either simultaneously or temporally separated, is up to 14%.[603,604,606,611,612]

Paraneoplastic hypercalcemia is reported in 16% to 53% of dogs with AGASAC.[564,581–602,605–607,609,613–617] Hypercalcemia is caused by the synthesis and secretion of parathyroid hormone–related peptide from neoplastic tissue.[618–620] Hypertrophic osteopathy in association with pulmonary involvement has been reported in two dogs.[621,622] Metastasis is common in dogs with AGASAC. Overall, metastasis is reported in 26% to 96% of dogs at the time of diagnosis, with 26% to 89% of dogs having metastasis to the regional LNs and 0% to 42% with metastasis to distant

VetBooks.ir

sites.[564,568,599–602,605,606,610,616] Metastasis can be present even when the primary tumor is small (<1 cm).[607] The medial iliac and internal iliac LNs (collectively called sublumbar LNs) and sacral LNs are the most common sites of metastasis,[564,599–601,605,606,609] whereas distant sites include lungs, liver, spleen, bone, and, less commonly, heart, adrenal glands, stomach, omentum, pancreas, kidneys, urinary bladder, and the mediastinum.[564,568,599–604] AGASAC micrometastases were detected incidentally in the bone marrow in one of four dogs in one study.[623] Tumor behavior can vary, because some dogs with large primary tumors may present without metastatic disease, whereas others may have a small primary tumor that has already metastasized.[607] In one study, dogs with clinical signs were more likely to have LN metastasis at diagnosis compared with dogs whose tumors were detected incidentally.[607] Histologic features including marked peripheral infiltration into surrounding tissue (neoplastic aggregates separated from the main tumor nodule), lymphovascular invasion, and solid pattern of cell arrangement were also associated with nodal metastasis at diagnosis, whereas mitotic index and presence of necrosis were not.[607] In another study, E-cadherin, a protein that mediates adhesion and communication between cells and the extracellular matrix, was evaluated as a prognostic marker in dogs with AGASAC.[624] A positive relationship between survival and the proportion of cells expressing E-cadherin immunoreactivity was observed, suggesting that loss of E-cadherin expression may play a role in tumor progression.[624] *p53* expression has been detected via IHC in a low-to-moderate proportion of AGASAC samples; however, no clinical implications have come from these findings.[579] A genetic analysis study in English cocker spaniels showed a higher frequency of AGASAC in dogs with the major histocompatibility complex DLA–DBQ1 allele, suggesting that a genetic factor may play a role in tumor development in this breed.[625] COX-2 expression also has been evaluated in AGASAC.[626] All tumor samples evaluated in one study showed positive immunoreactivity, as did ductal cells in normal anal sacs.[626] Neuroendocrine differentiation, suggested by expression of markers including synaptophysin, chromogranin A, and neuron-specific enolase, was detected via IHC in 30% of AGASAC.[608,627]

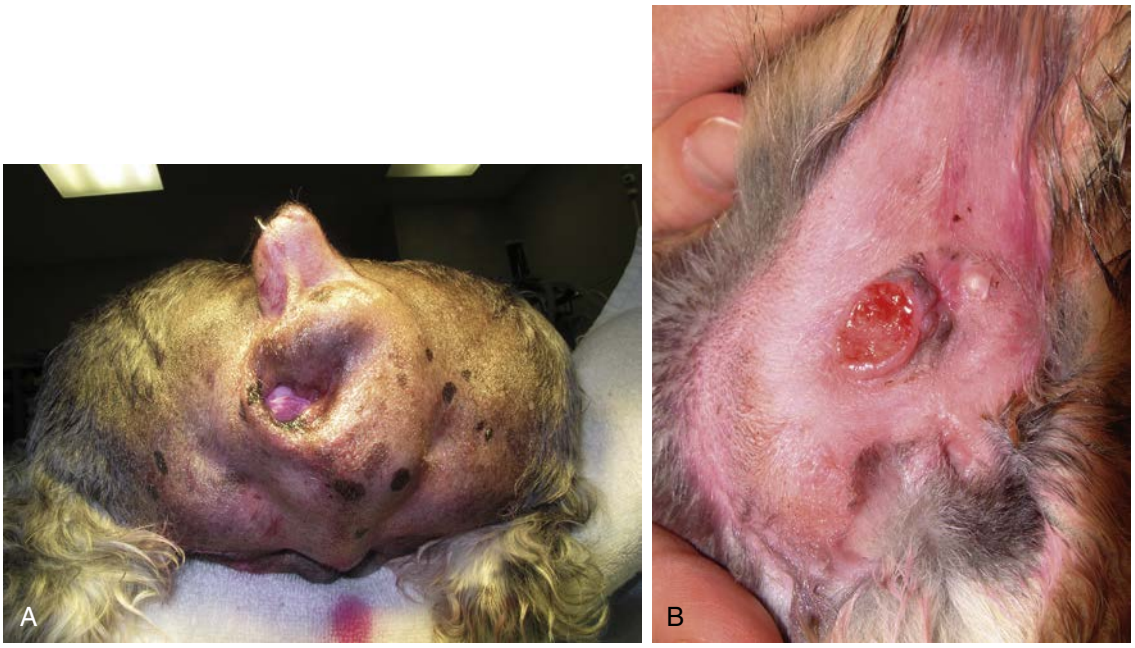
To further dissect the molecular basis of AGASAC and its reported sensitivity to the tyrosine kinase inhibitor toceranib phosphate (Palladia), expression of key toceranib targets has been evaluated.[628,629] In one study, mRNA for vascular endothelial growth factor receptor (VEGFR)-2, platelet-derived growth factor receptor (PDGFR)-α and -ß, and KIT was detected in all 24 tumors evaluated, but protein expression assessed by IHC was less consistent.[629] Protein expression of VEGFR-2 and PDGFR-α was present in most tumors; however, only one third expressed KIT. PDGFR-ß was strongly expressed in stroma.[629] Interestingly, RET expression was observed at both the mRNA and phosphorylated protein levels.[629] Phosphorylation of other receptor tyrosine kinases, including EGFR, Dtk/TYRO3, ROR-1, ROR-2, Tie-1, insulin-R, and RON, was observed in more than half of the tumors, suggesting that these may also have a role in AGASAC tumorigenesis.[629]

A case series of 11 dogs with anal sac melanoma suggests a moderate to aggressive biologic behavior.[560] Primary tumors were unilateral in all cases with a mean diameter of 3.4 cm. At the time of diagnosis, four of eight dogs had confirmed or suspected sublumbar LN metastasis, and 1 of 11 dogs had pulmonary metastasis.[560] The median mitotic index of the primary tumors was 50 per 10 high-power fields. Ten of 11 dogs died due to tumor progression.[560] Squamous cell carcinoma has also been reported arising from the anal sac in nine dogs, all with unilateral disease.[561–563] Four of these dogs were clinically staged and none had evidence of regional LN or distant metastasis. Tumors recurred in four of five dogs after surgical excision.[561–563]

The biologic behavior of feline AGASAC has not been clearly defined. Most reports suggest that it is a locally invasive disease associated with a moderate-to-high risk of tumor recurrence after surgery.[565–567] The rate of metastasis is variable between studies.[565–567] Metastasis to the regional LNs was suspected at the time of diagnosis in 20% of surgically treated cats with AGASAC.[566] Metastatic sites include regional LNs, liver, diaphragm, and lungs.[565,567] Paraneoplastic hypercalcemia is relatively rare in cats with AGASAC, being reported in 11% of cats in one series.[565,566] Bilateral tumors have not been reported.

History and Clinical Signs

Clinical signs in dogs with AGASAC are often referable to either the presence of the primary mass (perianal discomfort, swelling [Fig. 23.31A], discharge, bleeding, scooting, perianal licking), obstruction of the pelvic canal by LN metastasis (tenesmus, abnormal stool shape, constipation, lethargy, anorexia), or to hypercalcemia (polyuria, polydipsia, hyporexia, lethargy, vomiting).[599,600,607] The primary tumor is an incidental finding on physical examination in up to 47% of reported dogs.[600,603] Rarely, dogs present with pain or lameness as a result of bone metastasis or direct extension of metastatic LNs into the lumbar or sacral vertebrae. In one study, presence of clinical signs was associated with the size of the primary tumor.[616]



Dogs with anal sac melanoma or SCC present with clinical signs related to the primary tumor.[561–563] Common signs include hemorrhagic discharge and perineal licking.[561–563] Tenesmus and constipation may be less common than in dogs with AGASAC.[561–563] In one study, all dogs with anal sac melanoma presented with clinical signs; none of the tumors were detected incidentally.[560] Of nine dogs with anal sac SCC, one dog was diagnosed incidentally.[561–563]

In cats with AGASAC, the most common clinical sign is perineal ulceration or discharge and this is present in up to 85% of cats (see Fig. 23.31B).[566] Other clinical signs include tenesmus, constipation, scooting, and excessive grooming of the perineal area.[565–567] Lethargy and/or hyporexia may be secondary to severe constipation. Not all cats present with clinical signs, and tumors can be detected incidentally during a routine physical examination, although this is rare.[565] It is not uncommon for an AGASAC to be misdiagnosed as an anal sac abscess based on the presence of ulceration and discharge in the perineal region.[565,566]

Diagnostic Techniques and Workup

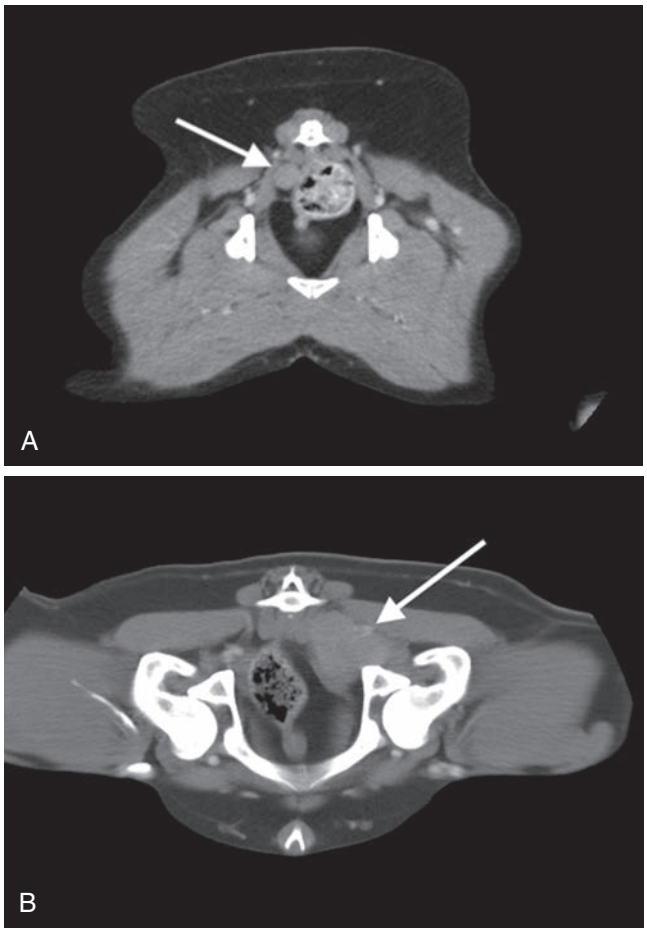
Because dogs with AGASAC may present with signs unrelated to perianal disease (i.e., polyuria and polydipsia due to hypercalcemia), assessment of animals with suspicious clinical signs requires a careful rectal examination, including palpation of both anal sacs and evaluation for possible regional lymphadenomegaly. Although a definitive diagnosis requires either an FNA or biopsy, the likelihood of AGASAC is high in animals with a firm and discrete mass in the anal sac. AGASAC has a characteristic "neuroendocrine" cytologic appearance consisting of polyhedral to roundish epithelial cells with uniform round nuclei and light blue-gray, slightly granular cytoplasm (see Fig. 7.18). Cytologic criteria of malignancy are often subtle or absent. FNA cytology

VetBooks.ir

• **Fig. 23.31** (A) The typical appearance of a large apocrine gland anal sac adenocarcinoma in a dog. (B) The typical appearance of an apocrine gland anal sac adenocarcinoma in a cat. Ulceration with an associated discharge is the most common finding in cats with apocrine gland anal sac adenocarcinomas.

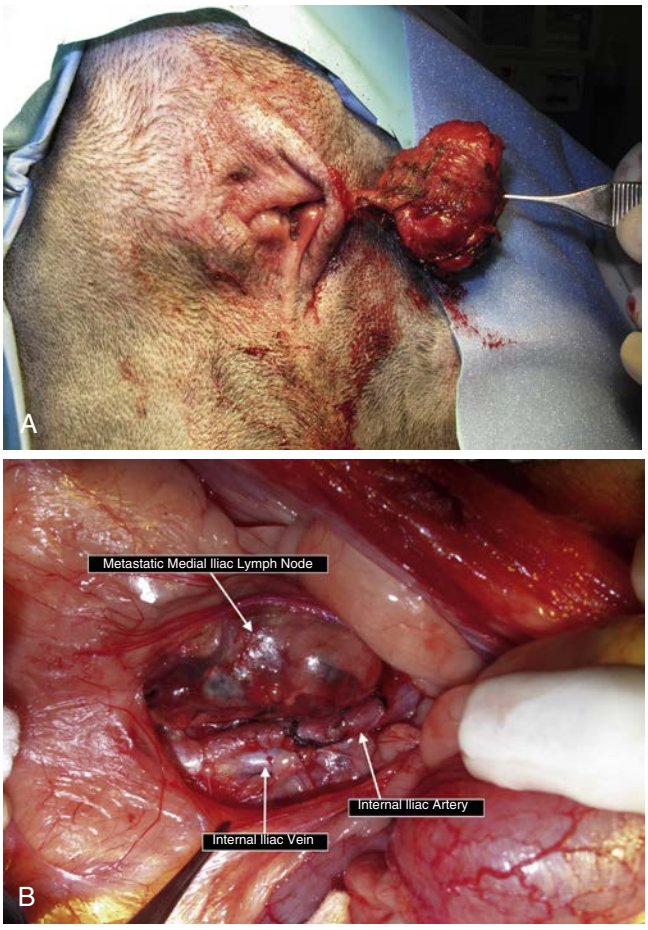
is valuable for ruling out impaction, infection, or inflammatory disease of the anal sac, although AGASAC can become secondarily infected or inflamed. Although special stains are almost never needed to confirm the diagnosis, a small study of cytokeratin immunoreactivity in perianal tumors showed a repeatable pattern of expression (CK7+/CK14–) in AGASAC.[586]

Clinical staging in dogs and cats with AGASAC includes assessing the size of the anal sac mass, evaluating for hypercalcemia, and investigating the abdomen and thorax for metastatic disease. Serum ionized calcium levels are preferred to total calcium concentrations for the assessment of hypercalcemia.



Accurate tumor staging in the abdomen and pelvic canal is important, because presence of metastasis affects prognosis and treatment decisions. Abdominal radiographs may reveal regional lymphadenomegaly in advanced cases, but are inadequate for the assessment of smaller metastatic LNs and metastasis to other abdominal organs such as the liver and spleen. Abdominal ultrasonography is commonly used to evaluate the abdomen and is more sensitive than radiography.[630] Despite its superiority to radiography, ultrasound has limitations. In one study, the only sonographic feature that separated benign from malignant LNs was LN size.[631] Changes in shape, contour, cavitation, echogenicity, and parenchymal uniformity did not reliably distinguish metastatic LNs.[631] Identification of nodal metastasis by ultrasound is further limited by anatomy, because the pelvic floor precludes visualization of LNs in the pelvic canal. Advanced imaging, including CT and MRI, allows for evaluation of LNs in the pelvic canal and can detect lymphadenomegaly in dogs deemed normal by ultrasound (Fig. 23.32).[632] Furthermore, studies have shown that advanced imaging detects a greater number of enlarged LNs than ultrasonograpy.[632–634] Sentinel LN mapping, using indirect CT lymphography, has been described in 18 dogs with AGASAC.[635] This study, along with the advanced imaging studies, suggests that patterns of LN metastasis can vary, and do not always follow lymphatic drainage linearly from the perineum.[633–635] Lymphadenopathy related to AGASAC can involve any of the three LN centers (medial iliac, internal iliac, or sacral), and often skips LNs. The sacral LN was deemed the sentinel LN in only 25% of cases.[635] Collectively, these findings suggest that advanced imaging is necessary for optimal treatment planning to thoroughly assess the extent of disease. Importantly, these studies also bring to light that outcomes of treatment studies can be significantly affected by choice of staging tests. Three-view thoracic radiographs or thoracic CT are recommended for detection of pulmonary metastasis or rare mediastinal involvement.

In rare instances, pulmonary metastasis can be present without obvious regional LN disease. Lameness or bone pain should be evaluated with radiography, advanced imaging, and/or nuclear scintigraphy to rule out bone metastasis. Workup should also include complete blood count, serum biochemistry panel, and urinalysis. Hypercalcemia of malignancy can result in renal damage, which may modify prognosis and anesthetic risk. Medical management of hypercalcemia or impaired renal function may be necessary before surgery or for nonresectable disease (see Chapter 5).



Diagnosis of anal sac melanoma or SCC requires a tissue biopsy for histopathologic confirmation; however, cytology can be highly suggestive.[560] Although the biologic behavior of these less common anal sac tumors is not clearly defined, abdominal and thoracic imaging are recommended for complete tumor staging.[561–563] Metastasis appears common in dogs with anal sac melanoma, but not with SCC.[560–563]

Treatment

Surgery is considered the mainstay of treatment for dogs with nonmetastatic AGASAC or AGASAC metastatic to the regional LNs.[564,600,605,606,612] Excision of the primary tumor can be daunting because of the location of the anal sacs relative to the rectum, external anal sphincter, and perineal neurovascular structures;

• **Fig. 23.32** Transverse computed tomography (CT) images at the level of the pelvic canal in two dogs with apocrine gland anal sac adenocarcinoma. Small (A) and large (B) ipsilateral sacral lymphadenomegaly is noted *(arrow)*, and both of these were not detected during abdominal ultrasonography. Three-dimensional advanced imaging, such as CT or magnetic resonance imaging, is preferred for tumor staging because it allows better visualization of the sacral lymph nodes within the pelvic canal.

• **Fig. 23.33** Surgical management of dogs with apocrine gland anal sac adenocarcinoma depends on the stage of disease. (A) Closed anal sacculectomy for excision of an apocrine gland anal sac adenocarcinoma in a dog. (B) View of the dorsal aspect of the caudal abdomen during surgical extirpation of a metastatic sublumbar lymph node. Resection of metastatic lymph nodes can be complicated by regional vasculature *(pictured)*, deep location within the abdominal cavity and pelvic canal, and the nature of the metastatic lymph nodes (such as invasion into regional musculature or being cystic).

however, the majority of AGASACs can be resected with a closed anal sacculectomy and a low risk of postoperative complications (Fig. 23.33A).[605] The complication rate after local AGASAC excision is 5% to 24%, with the most common complications being wound dehiscence, rectal perforation, rectocutaneous fistulation, incisional infection, and transient fecal incontinence.[605,606,610] Risk of complications may be related to tumor size.[610] In an older study, mild to severe fecal incontinence was reported in 19% of dogs, and this incontinence was transient in 40% and permanent in 60%[603]; however, the surgical approach used in this study was more aggressive than what is currently recommended, with resections involving 120° to 270° anoplasties.[603] Local resection of AGASAC is almost always marginal because of the location of these masses within the perineal space.[616] As a result, the completeness of histologic excision is determined by tumor biology rather than the surgical approach; incomplete histologic excisions are expected when tumors have ruptured through their capsule either microscopically or macroscopically.

Lymphadenectomy is recommended for excision of metastatic sublumbar and sacral LNs because STs appear to be significantly improved when metastatic LNs are removed.[601] When nodal enlargement is obstructing the pelvic canal or contributing to hypercalcemia, lymphadenectomy relieves clinical signs and improves quality of life. The sublumbar LNs include the paired medial and internal iliac LNs.[630,631] These LNs are located in close proximity to the terminal branches of the aorta and caudal vena cava in the dorsal aspect of the caudal abdomen (see Fig. 23.33B). The majority of metastatic sublumbar and sacral LNs are solid, although occasionally they can be cystic.[636] Excision can be complicated by their location, regional anatomic structures, invasion into lumbar vertebrae, and if they are cystic. Omentalization of an unresectable cystic nodal metastasis was reported in one dog with good results.[636] Iatrogenic trauma to the terminal branches of the aorta or, more commonly, the thin-walled caudal vena cava, can result in significant intraoperative bleeding and the need for blood products. As a result, cross-matching is recommended before surgery in dogs treated with surgical excision of metastatic LNs. The complication rate after LN extirpation varies from 0% to 12%, with the most commonly reported complications being intraoperative hemorrhage, unresectable metastatic LNs, LN rupture, and abdominal wall dehiscence.[605,606,612] Sacral LNs are more difficult to expose, but can usually by extirpated with careful digital dissection. Pelvic osteotomies are rarely required to provide additional exposure for removal of metastatic sacral LNs. Multiple studies

VetBooks.ir

have shown that there is a survival advantage associated with treatment of progressive disease in dogs with AGASAC.[605,606,612,637] Therefore excision of recurrent tumors or progressive nodal metastasis is recommended, especially when it can be done with low morbidity. Although surgery rarely has a role in the management of distant metastatic disease, particularly at the time of diagnosis, splenectomy may be considered in dogs with splenic metastasis in the context of slowly progressive disease when there is no evidence of metastasis to other distant sites.[607]

The roles for adjuvant chemotherapy and RT are controversial and not fully defined. Chemotherapy has traditionally been recommended for the treatment of canine AGASAC because of the risk of metastasis. Drugs with demonstrated antitumor activity in the gross disease setting include carboplatin, cisplatin, and actinomycin D.[594,598,599] Other drugs reported in the postoperative setting include mitoxantrone and melphalan.[564,609] However, no controlled study has shown a survival advantage with the use of adjuvant chemotherapy in dogs with AGASAC.[600,601,605,606] In one study of 113 dogs with AGASAC, there was no significant difference in outcome between dogs treated with surgery alone and dogs treated with surgery and chemotherapy, with MSTs of 500 days and 540 days, respectively.[600] Similarly, in another study of 74 dogs, there was no significant difference in either MST or time to progression for dogs treated with surgery alone (581 days and 402 days, respectively) and surgery and carboplatin (723 days and 384 days, respectively).[606] In fact, in another study, the use of adjuvant chemotherapy had a negative effect on DFI and no effect on ST.[605] In these retrospective studies, it is possible chemotherapy was more often offered or chosen in patients with more advanced disease, which could have resulted in a bias against chemotherapy effectiveness. Until controlled clinical trials are performed to definitively define the role of chemotherapy in the management of dogs with AGASAC, there is little evidence to support its use in the adjuvant setting.

Toceranib has been associated with modest tumor responses in canine AGASAC.[638] In a retrospective study of 32 dogs with multiple prior failed therapies, use of toceranib resulted in tumor response durations of 10 to 47 weeks.[638] A 25% partial response rate was noted and an additional 63% of dogs maintained stable disease, for a total clinical benefit rate of 88%. Resolution of hypercalcemia has also been reported with toceranib treatment.[638] The antitumor effect of toceranib may be mediated through inhibition of the PDGFR-β or vascular endothelial growth factor receptor 2, both of which are expressed in canine AGASAC.[628,629] Controlled clinical trials are needed to determine the role of toceranib in the treatment of dogs with AGASAC. COX-2 is expressed in the glandular epithelial cells of AGASAC,[626] and this may suggest a potential role for COX-2 inhibitors in the management of dogs with AGASAC. Adjuvant electrochemotherapy using cisplatin has been reported in a single dog after an incomplete primary tumor excision.[639]

RT has been described for both palliation and multimodal, curative-intent treatment of dogs with AGASAC.[600,601,609,611,617] Measurable response rates of 38% to 75% have been observed in dogs with bulky disease treated with hypofractionated or fractionated protocols, suggesting radiosensitivity in the gross disease setting[609,611,617,640]; however, the role of RT for tumor control in the microscopic setting after surgical resection of primary or nodal AGASAC remains poorly defined. In a study of 113 variably treated dogs, the use of adjuvant RT did not result in a significant improvement in STs in 15 dogs.[600] This may have been due to low statistical power, as the MST of these dogs was longest among the treatment groups at 742 days.[600] Radiation protocols, treatment intent, and tumor stage were not described.[600] In the only report of standardized curative-intent adjuvant RT, the MST of 15 dogs was 956 days.[609] Dogs received 15 daily fractions of 3.2 Gy (total dose of 48 Gy) to the primary site and regional LN beds using a nonconformal technique in combination with mitoxantrone chemotherapy. Although STs were favorable, late complications developed in half of the dogs.[609] Subsequent radiation toxicity studies showed that late radiation effects such as rectal stricture, rectal perforation, and chronic colitis are more likely to occur when radiation doses per fraction of 3 Gy or greater are used.[641,642] Therefore future curative-intent protocols should include pelvic irradiation at doses less than 3 Gy per fraction.[641,642] Use of conformal radiation technology, such as intensity-modulated RT, should further reduce the risk of toxicity by optimizing avoidance of critical structures. Dose-dependent, self-limiting acute effects reported in the study of nonconformal curative-intent irradiation of this region included mild to severe moist desquamation of the perianal area and colitis resulting in perianal discomfort lasting 1 to 4 weeks.[609,642]

The role of palliative-intent RT for relief of clinical signs associated with bulky AGASAC is better defined. Various hypofractionated protocols have been described including 5 daily fractions of 4 Gy, 3 to 4 weekly fractions of 6 to 9 Gy, 8 fractions of 3.8 Gy on a Monday–Wednesday–Friday schedule, and 5 biweekly fractions of 5 Gy.[601,611,617,640] These palliative RT protocols resulted in an improvement in clinical signs in up to 63% of dogs, including resolution of obstipation in some dogs.[611,617,640] Hypercalcemia resolved with RT alone in 31% of dogs and in an additional 46% of dogs when RT was combined with prednisone and a bisphosphonate.[617,640] The reported median progression-free intervals (PFIs) for dogs treated with palliative-intent hypofractionated protocols were 10 to 11 months, and MSTs ranged from 8 to 15 months.[601,611,617,640] Acute effects were mild and infrequent with grade I–II acute colitis in 8% to 27% of dogs, and grade I–II acute skin effects in 17% to 21% of dogs.[611,617] Late effects were rare in one study and included suspected rectal stricture in 3% of dogs and grade I late skin effects in 6% of dogs; these occurred in dogs treated with fractions of 5 Gy or greater.[617] In contrast, late effects were not observed in dogs treated with 8 fractions of 3.8 Gy delivered on a Monday–Wednesday–Friday schedule.[611] Severely hypofractionated RT should be used cautiously because late effects, such as rectal stricture, rectal perforation and chronic colitis, are related to dose per fraction.[611,617,641,642]

When interpreting the results of RT studies, it is important to consider that tumor control probability and risk of RT complications are affected by radiation dose distributions in the patient. A radiation treatment planning study showed that computerized, CT-based, 3-D conformal RT planning results in improved radiation dose distributions, with greater dose homogeneity in neoplastic tissues and better control of exposure of critical normal structures compared with nongraphic manual RT planning.[643] This has important implications for the interpretation of tumor control and toxicity profiles of older studies in which manual treatment planning was used.[643] It is possible that contemporary and future studies that take advantage of sophisticated treatment planning systems and conformal radiation delivery techniques may achieve different tumor control rates and complication risks than those described in older reports. Radiation studies should also be evaluated in the context of the regions that are irradiated, with reported radiation fields including the perianal region alone, perianal region and

VetBooks.ir

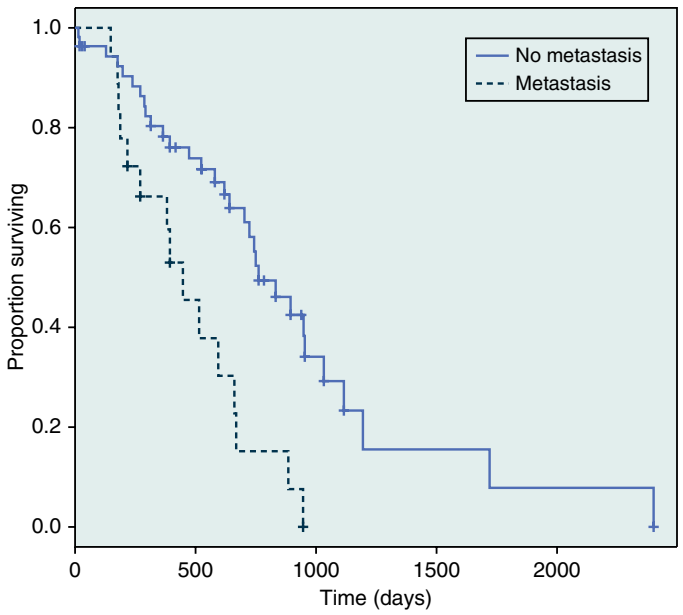
enlarged LNs,[611,617] or perianal region and regional lymphatic chain regardless of the size of the regional LNs.[609,617] These differences could affect clinical outcomes and should be considered when studies are compared. There may be a role for RT in the curative-intent management of dogs with incompletely excised AGASAC or dogs with surgically excised regional LN metastasis, or in the palliative management of dogs with measureable disease[600,601,609,619]; however, further studies are required to determine how RT should be optimized.

The majority of published studies have not standardized therapy for AGASAC according to clinical stage, and there is some evidence that the treatment approach may be stage dependent.[601] In one study, a clinical stage system and treatment algorithm were developed on the basis of a retrospective analysis of 80 dogs, and then these were evaluated in a prospective cohort of 50 dogs.[601] The proposed treatment algorithm included various combinations of surgery, carboplatin chemotherapy, and hypofractionated RT. However, this staging system has not been widely accepted, likely because it does not prioritize surgical excision on the basis of resectability. Surgery, according to the algorithm, is recommended only for primary tumors smaller than 2.5 cm and for metastatic LNs smaller than 4.5 cm when the primary tumor is smaller than 2.5 cm. In light of the increasing evidence of the importance of surgery in the treatment of AGASAC and its positive effect on survival,[600,601,605–607,612,637] surgical excision, including resection of recurrent disease, has become the mainstay of treatment for resectable AGASAC irrespective of size. Further studies are required to investigate the optimal combinations of surgery, chemotherapy, and RT in the management of dogs with various clinical stages of AGASAC.

Prognosis

Although dogs with metastatic AGASAC are rarely cured, long-term survival may be achieved in many cases after surgery-based treatments of the primary tumor and metastatic LNs both at presentation and in the face of recurrence. The reported DFIs for dogs treated surgically, with or without adjuvant therapy, range from 262 to 443 days.[605–607] Local recurrence rates vary widely from 5% to 44%.[603,605–607,612] Local recurrence is not associated with completeness of excision,[603,607] and this highlights the difficulty in using the completeness of excision to determine whether adjuvant therapies, such as RT or revision surgery, are required after incomplete histologic excision. Metastasis to regional LNs and to distant sites after surgery has been reported in 31% to 69% and 14% to 18% of dogs, respectively.[603,606,607,612] Multiple studies have reported shorter median DFIs in dogs with LN metastasis at diagnosis (134–197 days) compared with dogs without LN metastasis (529–760 days).[603,606,607] Dogs with LN metastasis at the time of surgery have a 2.5-fold hazard of disease progression compared with dogs without LN metastasis.[603]

For dogs with either local recurrence or postoperative LN metastasis, further treatment can improve STs.[606,610,637] In one study of 74 dogs with AGASAC treated surgically, with or without adjuvant chemotherapy, 55% developed either local recurrence and/or LN metastasis.[606] Of these dogs, 68% were treated with additional surgery, RT, and/or chemotherapy. The MST for dogs in which recurrent or metastatic disease was treated was 374 days after treatment for progressive disease, compared with 47 days for dogs in which the recurrent or metastatic disease was not treated.[606] In another study, the additional MST associated with a second surgical intervention was 283 days.[612]



Overall, the reported MSTs for dogs with AGASAC range from 386 to 960 days,[564,599–603,605–607,609–611,615,616] with estimated 1- and 2-year survival rates of 65% and 29%, respectively.[600] Tumor-related deaths vary widely between studies, with 41% to 81% of dogs dying as a result of AGASAC.[600,601,605,606]

The prognosis for dogs with AGASAC is dependent on a number of factors, especially clinical stage. In one study, dogs with no metastasis and primary tumor size less than 2.5 cm treated with surgery alone had overall favorable outcomes with the MST not reached and with only 9% of dogs experiencing tumor-related deaths.[601] In other studies, dogs with LN metastasis treated surgically, with or without adjuvant chemotherapy, had significantly shorter OSTs compared with dogs without metastasis.[605–607] OST was 293 to 448 days in dogs with LN metastasis and 529 to 925 days in dogs without metastasis.[605–607] In a study of 28 dogs with advanced LN metastasis (larger than 4.5 cm), treatment with hypofractionated RT resulted in a better median PFI and MST (347 days and 447 days, respectively) than did surgery with extirpation of metastatic LNs (159 days and 182 days, respectively).[611] Based on these collective findings, the role of a stage-dependent treatment algorithm is attractive and may become a future direction in the treatment of dogs with AGASAC.

Poor prognostic factors reported in various studies include primary tumor size,[600,601,607,617] presence of clinical signs,[607] presence of LN metastasis,[601,605–607] size of LN metastasis,[601] presence of distant metastasis,[600,601,624] nonpursuit of surgery,[600,601] treatment with chemotherapy alone,[600] lack of any therapy at all,[601] histologic features of the primary tumor,[607,608] E-cadherin immunoreactivity,[624] and, in some studies, hypercalcemia.[600,602,607]

Tumor size is prognostic for survival in a number of studies, but the threshold varies.[600,601,606,615,616] In one study of 113 dogs, dogs with tumors less than 10 cm^2 had a better MST (584 days) than dogs with AGASAC greater than 10 cm^2 (292 days).[600] In another study, a maximal tumor dimension of 2.5 cm was found to be prognostic.[601] In the retrospective arm of this study, the MSTs were 1205 and 722 days for dogs with nonmetastatic AGASAC less and greater than 2.5 cm, respectively.[601] In a study of 77 dogs treated with palliative-intent hypofractionated RT, the only negative predictor for survival was tumor size greater than 2.5 cm.[617] In another study, a tumor size of 2.5 cm was not predictive of survival in 39 dogs, but a 4-cm cutoff was prognostic.[607] Dogs with AGASAC smaller than 4 cm had a longer PFI and MST (518 and 773 days, respectively) than dogs whose tumors were greater than 4 cm (251 and 433 days, respectively). These discrepancies in prognostic tumor size could reflect differences in how tumors are measured, the difficulty in using an absolute metric measurement across a wide range of dog sizes and body weights, and/or the inherent difficulty in identifying consistent prognostic factors using nonstandardized cohorts. Tumor size was associated with the presence of clinical signs in one study.[607] Dogs with clinical signs were more likely to have local recurrence after surgery and shorter OSTs compared with dogs diagnosed incidentally.[607] Compared with asymptomatic dogs or dogs with local signs, dogs with systemic clinical signs (e.g., anorexia, polyuria/polydipsia, abnormal stool shape, tenesmus, constipation, and/or lethargy) had significantly shorter PFIs and OSTs.[607]

Metastatic disease, both to the regional LNs and distant sites, is associated with a worse prognosis in dogs with AGASAC (Fig. 23.34).[600,601,605–607,624] The reported MSTs for dogs with LN metastasis at diagnosis treated with various modalities

• **Fig. 23.34** Estimated Kaplan–Meier survival curves for overall survival times in dogs with apocrine gland anal sac adenocarcinoma with *(dashed)* and without *(solid)* metastasis at the time of diagnosis. The median overall survival times for dogs with metastasis (448 days) was significantly shorter than for dogs without metastasis (761 days, $p = 0.042$). (Reprinted with permission from Wouda RM, Borrego J, Keuler NS, et al. Evaluation of adjuvant carboplatin chemotherapy in the management of surgically excised anal sac apocrine gland adenocarcinoma in dogs. *Vet Comp Oncol*. 2016;14:67–80.)

range from 293 to 448 days and this is significantly worse than the MSTs of 529 to 1205 days for dogs without LN metastasis.[601,605,606] Dogs with LN metastasis at the time of diagnosis have a 2.3-fold increased risk of tumor-related death.[605] Although the prognosis is worse for dogs with LN metastasis,[601] MSTs improve after excision of the metastatic LNs.[601] The role of chemotherapy in dogs with LN metastasis disease remains undefined. The MST for dogs with distant metastasis ranges from 71 to 82 days in one study to 219 days in another study, and this is significantly worse than the MST in dogs without distant metastasis.[600,601]

Treatment also has an effect on STs in dogs with AGASAC. Overall, when considering all dogs with AGASAC, those treated with surgery have a significantly better outcome (MST 548 days) than those treated with either chemotherapy (MST 202 days) or those for which surgery was not part of the treatment protocol (MST 402 days).[600] However, when dogs with advanced LN metastasis (>4.5 cm) were expressly evaluated, treatment with hypofractionated RT resulted in significantly better outcomes compared with surgical extirpation.[611]

AGASAC has been classified histologically according to its tumor cell arrangement, including solid, rosette, tubular, papillary, and mixed patterns.[607,608] In one study of 39 dogs, dogs with a predominantly solid pattern had shorter PFIs and OSTs compared with dogs with other histologic patterns, corroborating a prior study that also associated tumor-related death with solid histologic pattern.[607,608] Other histologic features of the primary tumor that have been associated with shorter PFIs and OSTs include increased peripheral infiltration into surrounding tissue, presence of necrosis, and lymphovascular invasion.[607] In an IHC study, the expression of E-cadherin in greater than 75% of AGASAC cells was associated with a longer MST (1168 days) than in dogs whose AGASAC expressed E-cadherin in fewer than 75% of cells (448 days).[624]

In a study of 113 dogs with AGASAC, MSTs for dogs with and without hypercalcemia were 256 days and 584 days, respectively.[600] Although hypercalcemia is a poor prognostic factor in some studies,[600,602,607] other studies have found no difference in survival between hypercalcemic and normocalcemic dogs.[599,605,606,609] Dogs with hypercalcemia require complete or near-complete removal of the tumor burden, including metastatic disease, to resolve the hypercalcemia.[603,613,637] Tumor responses to hypofractionated RT and toceranib have resulted in resolution of hypercalcemia in some dogs.[611,617,640] Medical management with corticosteroids and/or bisphosphonates may be needed to improve control of hypercalcemia. Recurrence of hypercalcemia after tumor-ablating treatment is typically associated with recurrent or metastatic disease.[600,603,614]

In 11 dogs with anal sac melanoma treated with various combinations of surgery, RT, chemotherapy, immunotherapy, and supportive medical management, the median PFI and OST were only 3 months and 3.5 months, respectively.[560] Ten of 11 dogs died due to local or distant tumor progression.[560] One dog with a small, 1.5 cm primary tumor survived at least 58 months after surgery and adjuvant chemotherapy.[560] Six of nine dogs with anal SCC survived 0 to 7 months after diagnosis.[561–563] Two dogs were lost to follow-up 7 months after diagnosis and one dog was disease-free 1 year after treatment with hypofractionated RT and carboplatin for a recurrent SCC.[561–563] Of five dogs that underwent surgical resection of the primary tumor, four dogs had recurrence within 1 to 5 months of surgery.[561,563]

The MST for 30 cats treated surgically, with or without adjunctive chemotherapy and/or RT, is 260 days.[566] The 1-, 2-, and 3-year survival rates were 42%, 27%, and 18%, respectively, with a tumor-related mortality rate of 53%.[566] Poor prognostic factors for survival in treated cats with AGASAC include local tumor recurrence and increased nuclear pleomorphic score. The risk of tumor-related death increased by 8 times for cats with local tumor recurrence and 10 times for cats with increased nuclear pleomorphic score.[566] The MSTs for cats with a nuclear pleomorphic score of 2 and 3 were 909 days and 187 days, respectively, and this was significantly different.[566] The role of chemotherapy and RT are unknown, but RT would theoretically be indicated because of the high rate of local tumor recurrence, especially after incomplete histologic excision. A short-lived partial response to carboplatin was reported in one cat with recurrent AGASAC.[644] In another report, adjuvant curative-intent RT (48 Gy) and carboplatin resulted in local recurrence and/or metastasis within 6 months of treatment in two cats.[567] In both cats, RT was well tolerated with minimal acute effects.[567]

Comparative Aspects[645–648]

No similar hormonally dependent perianal disease state exists in humans. The most common cancer of the anal margin is squamous cell (epidermoid) carcinoma. These tumors arise from the junction of haired skin and mucous membrane of the anal canal. Risk of developing cancer in this location is positively correlated with sexual activity, and most tumors are associated with human papillomavirus infection. Precancerous changes (dysplasia) in the epithelium of the anal canal may precede tumor development. Regional LNs are the most common site of metastasis. Previously considered a surgical disease requiring a permanent

colostomy, improved outcomes have been achieved with definitive chemoradiation. The standard approach to therapy is concomitant RT and chemotherapy using 5-FU and mitomycin C. Surgery is reserved for locally recurrent or persistent disease. The mean 5-year disease-free survival and overall survival rates are 60% and 75%, respectively. Size and degree of invasion of the primary tumor, regional LN involvement, and presence of distant metastases are important prognostic factors. Identification of biomarkers that may serve as predictors of outcome or targets for therapy is being explored.

Tumors of the Respiratory System

SECTION A: CANCER OF THE NASAL PLANUM

WILLIAM T.N. CULP

Anatomy

The nasal planum is considered the apical portion of the external nose. This region is flattened, generally hairless, and includes the nares and philtrum.[1] The nasal planum is located rostrally to the nasal cartilages, which is a mobile group of seven cartilages attached to the bony part of the nose via three ligaments (paired lateral nasal ligaments and a dorsal nasal ligament).[1]

Pathology, Behavior, and History

The vast majority of the literature dedicated to nasal planum neoplasia has focused on squamous cell carcinoma (SCC). Other reported tumors of the nasal planum include fibrosarcoma, melanoma, mast cell tumor (MCT), osteosarcoma, and desmoplastic ameloblastoma.[2] The biologic behavior of SCC of the nasal planum is similar to other locations in dogs and cats; these tumors rarely metastasize, but have the potential to be aggressive locally in some species.[3,4]

In general, SCC is a relatively common tumor in cats, but rare in dogs.[5] These tumors are thought to be sunlight-induced and may represent a malignant transformation from keratosis or carcinoma in situ to SCC;[6] many cats (95% in one study[3]) are white or partially white in color.[7] Labrador retrievers and golden retrievers may be overrepresented, accounting for 50% to 76% of cases in two studies.[4,8] These tumors occur in older dogs or cats, with ages at presentation generally greater than 10 years.[3,4]

Diagnostic Evaluation

Pretherapeutic evaluation of nasal planum tumors is important to direct diagnostics and eventual treatment. Although nasal planum SCC has a characteristic gross appearance, fine-needle aspiration (FNA) cytology and/or incisional biopsy should be considered to obtain a definitive diagnosis.

The nasal planum should be imaged to determine the extent of disease, especially in dogs. Radiographs, ultrasound, and rhinoscopy are of limited value; however, swelling of the nasal planum, occlusion of nasal passages, and increased opacity within the rostral portion of the nasal cavity has been noted on radiographs.[8] Advanced imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is preferred, especially when tumors of the nasal planum are suspected to extend into the nasal cavity.[8] These diagnostics are also useful in determining the presence of bony invasion.[8]

Treatment

Surgery

Nasal planum resection is the most commonly described and performed technique for the management of dogs and cats with nasal planum SCC. The nasal planum can be removed alone (Fig. 24.1) or in combination with the incisive[9] or maxillary bones.[10] The latter is indicated for tumor types where larger surgical margins are required for complete histologic excision, such as MCTs or soft tissue sarcomas, or for tumors extending caudally beyond the nasal planum.

The postoperative appearance after nasal planum resection can be challenging, especially for owners. A thorough discussion with an owner regarding the treatment options, postoperative function, and postoperative cosmetic appearance is imperative to adequately prepare them for nasal planum resection, including the provision of images of the postoperative appearance of dogs postnasal planum resection.

The prognosis after nasal planum resection is generally good in dogs. Local recurrence was reported in two of six dogs treated with surgery alone in one study, both with incomplete histologic excision.[4] Seven dogs with more advanced tumors were treated with a combination of surgery and adjuvant radiation therapy (RT), and all seven dogs had local tumor recurrence with a median time to recurrence of 9 weeks.[4] Local recurrence was not reported in three dogs treated with combined nasal planum resection-incisivectomy[9] and five of six dogs treated with combined nasal planum resection-bilateral maxillectomy.[10]

The prognosis is very good in cats after surgery. In one study of 61 cats with SCC, local tumor recurrence (Fig. 24.2) was reported in less than 10% of cats, with median disease-free intervals (DFIs) of 594 days and 426 days for cats with isolated nasal planum SCC and SCC in multiple locations, respectively, when treated with

• **Fig. 24.1** (A) Preoperative image of nasal planum squamous cell carcinoma in a 10-year-old Labrador retriever. (B) Immediately after nasal planectomy; (C) 9 days postoperatively; and (D) 6 weeks postoperatively.

• **Fig. 24.2** Recurrence of a nasal planum squamous cell carcinoma (SCC) in a 13-year-old domestic shorthair cat 3 months after nasal planum resection. Recurrence of the tumor can be seen in the ventral aspect of the left neo-nare *(arrow)*.

surgery alone.[3] The median survival times (MSTs) for surgically treated cats in this study were 673 days and 530 days for cats with isolated nasal planum SCC and SCC in multiple locations, respectively.[3]

Conservative surgical approaches are not typically recommended as most nasal planum tumors are invasive and recurrence rates are high when an aggressive surgical approach is not utilized. However, surgical curettage and diathermy has been described in 34 cats with nasal planum tumors, including nine cats with carcinoma in situ and seven cats with SCC.[11] This technique resulted in better cosmesis and good local tumor control with a local tumor recurrence rate of 6% after a median follow-up time of 18 months.[11]

External Beam Radiation Therapy

External beam RT has been described for the treatment of nasal planum SCC in both dogs and cats, either for primary treatment or in the adjuvant setting. The results have been discouraging in dogs with local recurrence reported in virtually all patients with median times to recurrence of 2 to 3 months.[4,5]

RT has been described for the treatment of cats using either orthovoltage,[7] megavoltage,[3,12] or an accelerated protocol using protons.[13] For cats treated with orthovoltage, the 1-year progression-free survival (PFS) rate was 60%, and prognostic factors

• **Fig. 24.3** Strontium plesiotherapy treatment of feline squamous cell carcinoma. (Image courtesy Dr. Michael Kent.)

included clinical stage and proliferative fraction.[7] The median DFIs for 55 cats treated with megavoltage in two studies was 361 to 916 days,[3,12] with a MST of 902 days.[12] Cats with larger tumors had 5.4 and 6.3 times greater risk of recurrence and dying, respectively, than cats with smaller tumors.[12] For 15 cats treated with an accelerated RT protocol using protons, the PFS rate was 64% and the MST was 946 days.[13] Side effects were considered minimal.[13]

Strontium Plesiotherapy

Strontium plesiotherapy is the application of a radioactive substance (strontium Sr90 or ^{90}Sr) directly to the nasal planum tumor (Fig. 24.3). When using this technique, less than 10% of the radiation dose penetrates to a depth of 3 mm, and hence this treatment is primarily indicated for cats with superficial and minimally invasive SCCs.[14] Strontium plesiotherapy allows for a large dose of radiation to be delivered to superficial lesions while avoiding radiation dosing of deeper nonneoplastic tissues.[15] In two studies totaling 64 cats treated with ^{90}Sr, the complete response (CR) rate was 88%; local recurrence was reported in 20% of cats, and 33% of cats developed new lesions in different locations.[15,16] The median progression-free interval was 1710 days, with 1- and 3-year disease-free rates of 89% and 82%, respectively.[15] The overall MST was 3076 days, and cats with a CR had significantly longer MSTs.[15]

Chemotherapy

The most common reported use for chemotherapy in cats with nasal planum SCC is intralesional, either alone or with electrochemotherapy. In one study of 23 cats treated with intratumoral administration of carboplatin to treat SCC of the nasal planum, there was no systemic toxicity and local side effects were minimal and self-limiting.[17] A CR was noted in 73% of cats, with a 30% local recurrence rate and a mean PFS time of 16 months.[17] Intralesional carboplatin was combined with superficial orthovoltage RT in six cats; all cats achieved a CR and five of six cats had local tumor control at 6 months posttreatment.[18]

Electrochemotherapy utilizing bleomycin has been described in two case series for a total of 15 cats with nasal planum SCC.[19,20] A CR was noted in 75% to 86% of cats with a DFI between 7 to 36 months.[19,20] No local or systemic side effects were noted.[20]

Photodynamic Therapy

Photodynamic therapy is the use of applied light after the administration of a photosensitizer. The photosensitizer is activated by the light to form free radicals, which results in the induction of cell death.[21] Due to the limited penetration of light into the tissue, the treatment depth is considered 5 mm or less.[21]

Photodynamic therapy has been described for the treatment of nasal planum SCC in cats.[21,22] In a large prospective study of 55 cats treated with photodynamic therapy using 5-aminolevulinic acid (5-ALA) as a photosensitizer,[23] the overall response rate was 96% with 85% of cats having a CR. Fifty-one percent of cats with a CR developed local recurrence with a median time to recurrence of 157 days. At a median follow-up time of 38 months, 45% of cats were alive without recurrence and 33% of cats were euthanatized because of local recurrence.[23] In a study of 61 cats assessing response to photodynamic therapy based on tumor staging, 49%, 12%, and 39% of cats demonstrated complete, partial, and no responses, respectively.[22] The rate of CR was significantly associated with stage; CR was noted in 100% of noninvasive tumors measuring <1.5 cm in diameter, 56% of invasive tumors measuring <1.5 cm in diameter, and 18% of invasive tumors measuring >1.5 cm in diameter.[22]

Other Treatments

Cryosurgery, using liquid nitrogen to freeze SCC lesions, has been described in two studies totaling 101 cats,[3,24] and is primarily indicated for the treatment of small (<5 mm), superficial, and noninvasive SCC lesions.[3] The response rate for cats with nasal planum SCC was 81% after two to three treatments.[24] The local tumor recurrence rates are between 17%[24] and 73%[3] with a median DFI of 184 days[3] to 26.7 months.[24]

SECTION B: NASAL CAVITY AND SINUS TUMORS

SUSAN E. LANA AND MICHELLE M. TUREK

Canine Sinonasal Tumors

Incidence and Risk Factors

Tumors of the nasal cavity and paranasal sinuses account for approximately 1% of all neoplasms in dogs.[25] The average age of dogs with this disease is approximately 10 years, although canine patients as young as 9 months have been reported.[26,27,28] Medium-to-large breeds may be more commonly affected.[26,29] It has been speculated, but is unproved, that dolichocephalic breeds (long-nosed) or dogs living in urban environments, with resultant increased nasal filtering of pollutants, may be at higher risk for developing nasal cancer.[29–31] Exposure to environmental tobacco smoke has been associated with an increased risk of nasal cancer in a group of dogs in one study,[32] but the same was not true in another.[31] Evaluation of DNA damage in biopsy samples of the oropharyngeal region of dogs exposed to cigarette smoke showed higher levels compared with those not exposed, suggesting that dogs could be used as a sentinel for early DNA damage caused by exposure to environmental agents, although the numbers evaluated were small.[33] Indoor exposure to fossil fuel combustion products, such as those produced by coal or kerosene heaters, may contribute to the suggested environmental component of this cancer.[31]

VetBooks.ir

Pathology and Natural Behavior

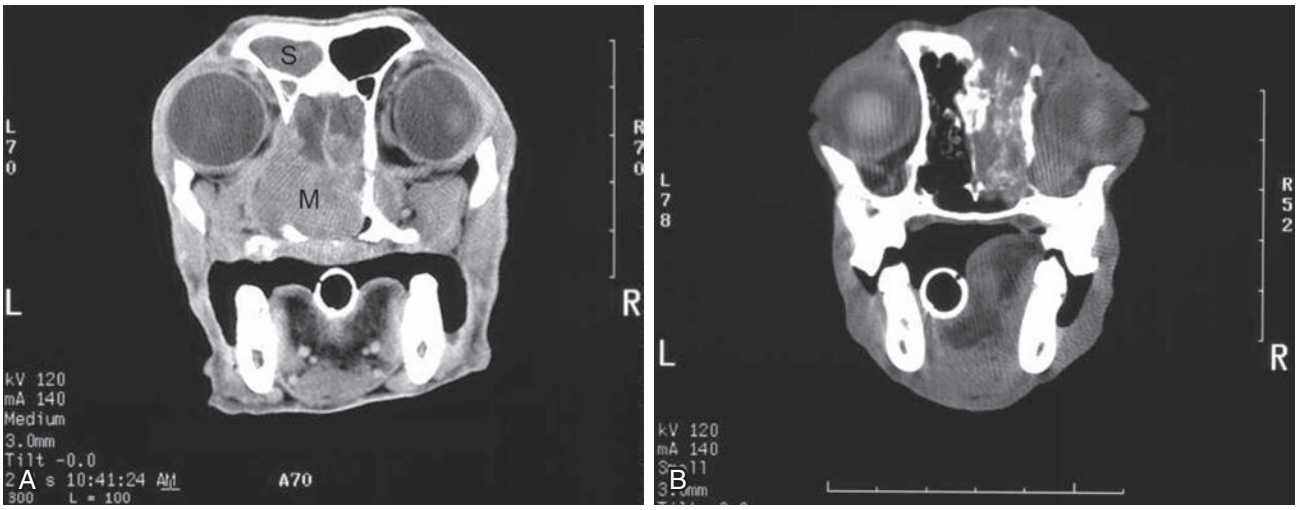
Carcinomas, including adenocarcinoma, SCC, and undifferentiated carcinoma represent nearly two-thirds of canine intranasal tumors.[34] Sarcomas (usually fibrosarcoma, chondrosarcoma, osteosarcoma, and undifferentiated sarcoma) comprise the bulk of the remaining cancers.[35] Both carcinomas and sarcomas are characterized by progressive local invasion. The metastatic rate is generally considered low at the time of diagnosis but may be as high as 40% to 50% at the time of death, which is usually attributable to the primary disease rather than metastatic lesions.[26] The most common sites of metastasis are the regional lymph nodes (LNs) and the lungs.[26,35,36] Less common sites include bones, kidneys, liver, skin, and brain.[37–40]

Rare tumors of the sinonasal region in dogs include round cell tumors (such as lymphoma), mast cell tumor (MCT), and transmissible venereal tumor. Other malignancies include hemangiosarcoma, melanoma, neuroendocrine carcinoma, nerve sheath tumor, neuroblastoma, fibrous histiocytoma, multilobular osteochondrosarcoma, hamartoma, rhabdomyosarcoma, and leiomyosarcoma.[26,41–58] The biologic behavior of these less common malignancies is not well defined, although small retrospective case series have been reported for lymphoma, intranasal MCT, and melanoma.[59–62] Benign, yet often locally invasive lesions such as polyps, fibromas, dermoid cysts, and angiofibroma can also be seen.[63,64]

A number of studies have attempted to elucidate possible molecular mechanisms associated with canine sinonasal tumorigenesis. In one study using a single polyclonal antihuman antibody, nuclear *p53* accumulation was detected in nearly 60% of nasal adenocarcinomas (11 of 19), which suggests that overexpression of a mutated *p53* tumor suppressor protein may play a role.[65] Cyclooxygenase-2 (COX-2) expression has been detected to varying degrees in most sinonasal epithelial tumors sampled[66–69] and in normal paratumoral respiratory epithelium and stromal tissue.[69] In one study, epidermal growth factor receptor (EGFR) expression and vascular endothelial growth factor (VEGF) expression were detected in over 50% and 90% of the 24 nasal carcinomas evaluated, respectively.[70] All tumors expressed either EGFR or VEGF, but there was no association between the immunoreactivity for each protein.[70] To evaluate expression of receptor tyrosine kinases (RTKs) with the intent to establish a rationale for use of TK inhibitors (TKIs), VEGFR2 and platelet derived growth factor receptor (PDGFR) α and β have been evaluated in 187 nasal carcinoma samples.[71] VEGFR was expressed in 84% of the samples and was predominantly cytoplasmic-membranous, similar to what is seen in high grade MCTs. PDGFRα was noted in 71% of cases and PDGFRβ in 40%, both with weak to moderate intensity. Coexpression of RTKs was common. The authors concluded that studies evaluating clinical utility of TKIs are warranted.[71] Expression of peroxisome proliferator-activated receptor γ (PPAR-γ), a nuclear receptor involved in glucose metabolism and fatty acid storage, has also been shown in canine nasal carcinomas.[72] The authors of that study suggested that expression patterns may differ in tumor tissue compared with normal nasal epithelium.[72] The role of these proteins in carcinogenesis is not clear, and further investigation is needed before clinical relevance can be determined. Evaluation of the inflammatory infiltrate in 31 canine nasal carcinomas revealed an abundance of neutrophils and macrophages, which were present in greater numbers than in normal canine mucosa.[73] Plasma cells and T lymphocytes were also detected; however, levels did not correlate with particular tumor subtype.

History and Clinical Signs

Although many intranasal diseases will have overlapping clinical signs, a strong suspicion of cancer is appropriate for older animals with an intermittent and progressive history of unilateral (initially) epistaxis or mucopurulent discharge (or both). The average duration of clinical signs before diagnosis is 2 to 3 months;[25,74] these most commonly include epistaxis, bloody or mucopurulent nasal discharge, facial deformity due to bone erosion and subcutaneous extension of tumor, unwillingness to open the mouth, sneezing, dyspnea or stertorous breathing, exophthalmos, and ocular discharge as a result of mechanical obstruction of the nasolacrimal duct.[25,34,74] Differential diagnoses for animals with these clinical signs include fungal (*Aspergillus* sp.) or bacterial rhinitis, idiopathic nonspecific rhinitis (usually lymphoplasmacytic), rare nasal parasites, bleeding disorders, hypertension, foreign body, trauma, and developmental anomalies (e.g., cystic Rathke's clefts).[75–77] If facial deformity is present, the diagnosis is almost always cancer;[78–79] however, aspergillosis, sporotrichosis, and a rare, benign condition, angiomatous proliferation of the nasal cavity or angiofibroma, also can cause facial deformity. In a retrospective study of 105 cases of dogs with intranasal disease, the characteristics of the nasal discharge were evaluated to determine whether they correlated with diagnosis.[80] In dogs with confirmed neoplasia (n = 23), the median duration of discharge was 60 days. Mucoid discharge in pure or mixed form was seen more frequently in neoplasia compared with fungal, nonspecific rhinitis and foreign body cases. When signs lasted more than 14 days, hemorrhagic discharge was seen more commonly in dogs with neoplasia compared with those with rhinitis or other causes. Nasal stridor was also noted more often in dogs with neoplasia.



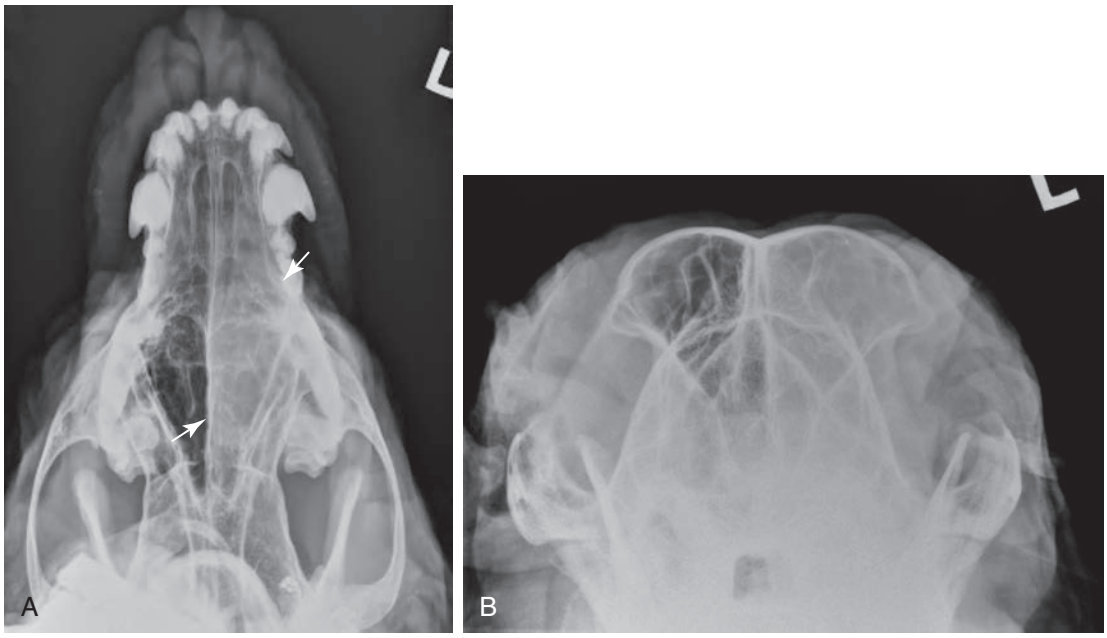
Clinical signs can be temporarily alleviated by a variety of symptomatic treatments, including antibiotics, steroids, and nonsteroidal antiinflammatory drugs (NSAIDs).[74] An initial response to these treatments should not diminish the index of suspicion for neoplasia in older dogs with clinical signs consistent with cancer.[74]

On rare occasions, animals with tumors involving the caudal region of the nasal cavity may have only neurologic signs (e.g., seizures, acute blindness, behavior change, paresis, circling, and obtundation) caused by direct invasion of the cranial vault.[55,56,81] However, absence of neurologic signs does not rule out tumor extension into the cranial vault because most dogs with nasal tumors that extend beyond the cribriform plate do not exhibit neurologic signs.

Diagnosis and Staging

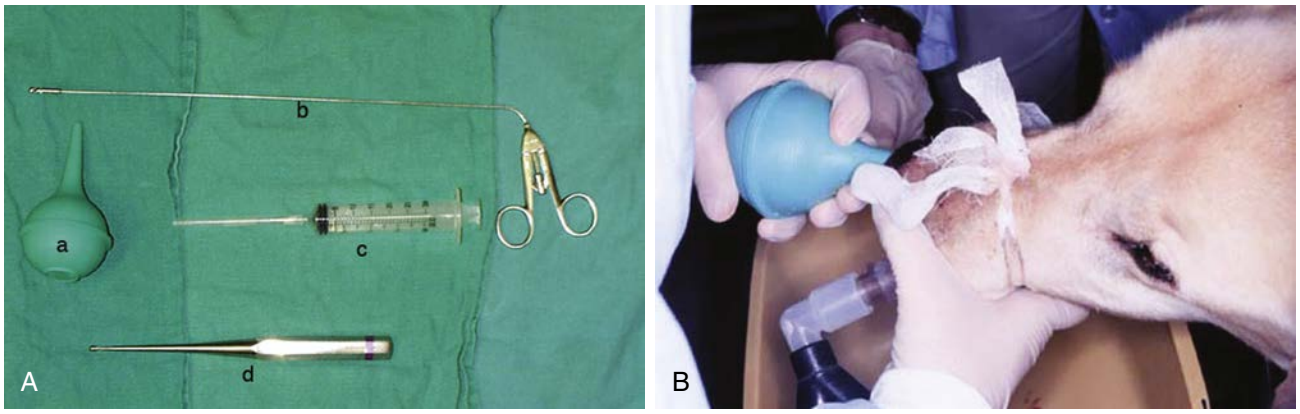
A definitive diagnosis of sinonasal cancer requires a tissue biopsy, even though diagnostic imaging and historic information can be highly suggestive. Coagulation disorders must be ruled out before biopsy because bleeding during the procedure is to be expected.

The superior imaging value of CT and MRI over conventional radiographs for canine nasal disease, including neoplasia, is well documented.[27,49,75,82–88] Cross-sectional imaging provides improved anatomic detail, which allows accurate determination of the extent of tumor (staging) and localization of nasal cavity abnormalities (Fig. 24.4).[27,49,75,82–88] It also facilitates evaluation of the integrity of the cribriform plate and identification of potential tumor extension into the cranial vault. Although, in general, MRI allows for better resolution of soft tissue structures, one report showed no clinically relevant benefit to using MRI over CT to evaluate nasal tumors that do not extend into the cranial



• **Fig. 24.4** (A) Contrast-enhanced computed tomography (CT) images of a dog with sinonasal cancer taken in the transverse plane at the level of the orbit and the olfactory bulb of the brain. Note the contrast-enhancing mass *(M)* in the nasopharynx, which is causing erosion of the frontal and palatine bones. The tumor has invaded the left retroorbital space and the cranial vault, resulting in deviation of the falx cerebri. Noncontrast-enhancing material in the left frontal sinus *(S)* suggests accumulation of the nasal exudates. (B) Noncontrast-enhanced CT images of a dog with sinonasal cancer taken in the transverse plane at the level of the orbit. Note the soft tissue attenuating mass in the right nasal cavity. Erosion of the frontal bone has allowed the tumor to extend into the subcutaneous tissues on the dorsum of the head; erosion of the palatine bone has allowed invasion of the right retroorbital space.

vault.[85] CT enables better visualization of lysis of bones bordering the nasal cavity, which is important for accurate RT planning. It has been proposed that tumor signal intensity on MRI may help distinguish sarcomas from carcinomas,[86] although this application requires further validation before it can be used clinically. Both modalities are useful for imaging nasal tumors, although CT is used more commonly than MRI due to its lower cost in most facilities, wider availability, and usefulness for computer planning of RT. A pilot study has evaluated tumor volume using bidimensional measurements and staging, comparing CT and MRI in six dogs with nasal tumors.[90] The authors concluded that determining extent of tumor margins on MRI resulted in a higher tumor volume (18%) in 5/6 dogs and greater likelihood of detecting meningeal involvement. However, 5/6 dogs were classified as the same stage whether determined by CT or MRI. Further research is needed to determine whether MRI will affect RT volumes, and ultimately total tumor dose and patient outcome.



Certain CT or MRI findings have been correlated with a diagnosis of cancer in dogs with nasal disease.[49,75,89] None of these, alone or in combination, is definitive for neoplasia.[49,75,89] These findings include bony destruction (e.g., ethmoid bones, cribriform plate, and the bones surrounding the nasal cavities), destruction of the sphenoid sinus, abnormal soft tissue in the retrobulbar space, nasopharyngeal invasion, hyperostosis of the lateral maxilla, and patchy areas of increased density within abnormal soft tissue opacity.[49,89] It is important to recognize that detection of a mass in the nasal cavity of a dog is not specific for a diagnosis of neoplasia.[49] Idiopathic inflammatory disease, polyps, and fungal infections can present in this manner.[49,64]

Conventional radiography can still have a place in the diagnostic workup of dogs suspected of having nasal tumors. Despite the inherent limitation of tissue superimposition, the sensitivity of radiography in detecting major nasal cavity abnormalities in dogs with nasal tumors is comparable to that of CT or MRI when tumors are sufficiently advanced to cause clinical signs.[88,91] Certain radiographic signs have been correlated with a positive predictive value for neoplasia.[92] These include the presence of a soft tissue opacity, loss of turbinate detail affecting the entire ipsilateral nasal cavity, invasion of bones surrounding the nasal cavity, and soft tissue/fluid opacities within the ipsilateral frontal sinus (Fig. 24.5).[92] As is true for CT and MRI changes, no radiographic sign is definitively diagnostic for neoplasia.[88,92] PET/CT using ^{18}F-FDG as well as biomarkers of resistance to radiation, including ^{18}F-FLT for proliferation and ^{61}Cu-ATSM for hypoxia, has been used in a research setting for canine nasal carcinoma and sarcoma.[93–97] Changes in tracer uptake as a result of RT were observed; however, pretreatment PET/CT failed to reliably predict areas of residual tumor or recurrence that could be targeted with a boost dose of radiation to improve tumor control.[97] Relationships of glucose metabolism, proliferation, and hypoxia were heterogeneous across different tumor types.[94] Tumor volume measured by PET-CT and radiation-induced changes in tumor proliferation as shown by FLT uptake may be predictive of tumor behavior and clinical outcome.[96] Further validation of molecular imaging is needed before it can be used for treatment planning or prognostication. A tissue biopsy should be obtained while the patient is under anesthesia for diagnostic imaging. Suitable samples can be acquired by a variety of techniques.[98–100] These include vigorous nasal flushing to dislodge mass lesions, transnostril blind biopsy using cup forceps or a bone curette, rhinoscopic-guided biopsy, FNA or punch biopsy of facial deformities, transnostril core biopsy, CT-guided stereotactic biopsy, and surgical biopsy via rhinotomy (Fig. 24.6). Rhinoscopy can be used to visualize the nasal cavity and to guide biopsy, although this is often not necessary and samples collected in this manner risk being small and superficial.[101] With any nonimage guided transnostril technique, it is important to avoid penetrating the cribriform plate. The biopsy instrument should be marked with tape or cut off at a length that ensures that the instrument does not penetrate farther than the distance from the tip of the nares

to the medial canthus of the eye (Fig. 24.7). Mild-to-moderate hemorrhage is to be expected and generally subsides within several minutes. Inadequate biopsy size or sampling outside the region of the tumor may preclude an accurate diagnosis. Further testing may be necessary when clinical and histologic findings are incongruent. In cases in which imaging results are suggestive of an aggressive process, yet histopathologic changes are consistent with nonspecific inflammatory disease, repeat biopsy may be needed for definitive diagnosis.[27,49] One study evaluated the diagnostic accuracy of three different biopsy techniques in 117 dogs with confirmed nasal neoplasia.[102] Techniques included blind biopsy, advanced image-guided biopsy to direct location of a blind biopsy, or rhinoscopy guided. For all patients, a diagnosis of neoplasia was made in only 56% of the samples on the first attempt in spite of the presence of a mass lesion seen either on imaging or rhinoscopy. The proportion of first biopsies yielding accurate results did not differ between the techniques, indicating that blind biopsy may be as diagnostic as rhinoscopy guided. This study also found that in cases that had both advanced imaging and rhinoscopy (n = 54), imaging detected a mass in all cases compared with rhinoscopy, which identified a mass in 41% of the cases.[102]

Attempts at nasal washing and fluid retrieval for cytologic examination generally have been unrewarding and are not recommended as the sole means of diagnosis.[25] Brush cytology also has been described, but it often is not diagnostic.[103]

• **Fig. 24.7** Regardless of the biopsy technique chosen, any instrument that is passed through the naris must be measured; it also should be marked with tape or cut off at a length that ensures that the instrument does not penetrate farther than the distance from the tip of the naris to the medial canthus of the eye. This ensures that the instrument does not pass through a potentially compromised cribriform plate.

Multiple staging systems for canine sinonasal neoplasia have been proposed on the basis of local tumor extent and bony erosion.[29,104–107] The most clinically relevant and commonly used system is the CT-based, modified Adams clinical staging method, which describes four clinical stages of local tumor extension (Table 24.1).[106] This staging system is based on a review of 94 dogs with nasal carcinoma or sarcoma treated with definitive-intent, nonconformal computer planned RT, which showed that CT evidence of cribriform plate involvement (stage 4) was associated with the shortest median survival time (MST, 6.7 months) and unilateral intranasal involvement without bone destruction beyond the turbinates (stage 1) had the longest MST (23.4 months).[106] Prognostic significance improved when CT findings were combined with histologic category.[106]

Regional LN cytology is positive for metastasis in as many as 10% to 24% of cases and is most commonly associated with carcinoma.[36,74,108–110] Enlarged regional (mandibular and retropharyngeal) LNs should be sampled for cytology to differentiate between a reactive process and metastasis. Thoracic imaging by radiography or CT should be performed but is usually negative for metastasis at initial presentation.[25,26,36,74,110] The reported risk of pulmonary metastasis at the time of diagnosis is 2% to 10%.[34,74,110] In a study evaluating the detection of comorbidities in a large cohort of dogs, 25 had a primary diagnosis of nasal tumor.[111] All dogs had thoracic radiographs and abdominal ultrasound done as part of routine staging. Two of 25 (8%) dogs had an unrelated intrathoracic abnormality detected, including thymoma in one and cardiac changes in the other. Twenty of 25 nasal tumor patients had abnormalities seen on abdominal ultrasound; however, all were considered clinically insignificant with the exception of two cases (8%): one dog had an intestinal foreign body and another had a bladder mass. Overall, 4 of the 25 dogs had treatment altered due to potentially serious comorbidities. Although it is a small number, the typical patient population with nasal tumors is older, and more thorough screening if treatment is being considered may be warranted.

TABLE 24.1 Modified Adams Clinical Staging Method for Nasosinal Tumors[106]

Stage 1	Confined to one nasal passage, paranasal sinus or frontal sinus, with no bone involvement beyond turbinates
Stage 2	Any bone involvement (beyond turbinates), but with no evidence of orbit/subcutaneous/submucosal mass
Stage 3	Orbit involved, or nasopharyngeal, or subcutaneous, or submucosal mass
Stage 4	Tumor-causing lysis of the cribriform plate

Hematologic and biochemical findings generally are noncontributory in dogs with sinonasal tumors. In rare cases, paraneoplastic erythrocytosis and hypercalcemia have been documented.[112–114]

Treatment and Prognosis

Therapy for sinonasal carcinoma and sarcoma is directed primarily at control of local disease, which usually manifests in a relatively advanced stage in a critical location near the brain and eyes. Without treatment, the MST of dogs with nasal carcinoma is 95 days as reported in a retrospective case series of 139 dogs.[74] Prognosis of dogs with epistaxis appears worse than for dogs without epistaxis (MST 88 days vs. 224 days).[74] Bone invasion occurs early, and curative surgery is virtually impossible. Surgical removal by means of rhinotomy has been associated with a high rate of morbidity without significant extension of life, limiting the utility of this procedure as a sole form of treatment.[25,34,36,115,116] The MST after surgery alone is approximately 3 to 6 months, similar to that reported for no treatment.[25,36,115,116]

RT using high-energy megavoltage (MV) equipment as the sole treatment modality has become the therapy of choice for canine sinonasal tumors. It has the advantage of treating the entire nasal cavity, including bone, and its use has been associated with the greatest improvement in survival. Although surgical removal of the tumor before MV irradiation has not been shown to improve clinical outcome,[36,117,118] controlled studies have not been done for this combination. MSTs after standardly fractionated, definitive-intent MV irradiation alone range from 8 to 19.7 months.[104–106,110,118–125] The reported 1- and 2-year survival rates range from 43% to 68% (1 year) and 11% to 44% (2 years).[104,105,119–121,125] Doses of 42 to 54 Gy are usually delivered in 10 to 18 treatments of 3- to 4.2-Gy fractions over 2 to 4 weeks to the nasal cavity and frontal sinuses as dictated by imaging.[104–106,117,120–122] True statistical comparisons between reports are not possible because of inconsistencies in methodology (including within individual reports) with respect to total dose, fraction number, dose per fraction, treatment schedules, use of CT staging, use of computerized treatment planning, radiation dose distributions, response monitoring, and statistical assessment. Furthermore, differences in tumor type and tumor stage also affect patient outcome.[106] CT-based computerized RT planning greatly enhances normal tissue sparing while ensuring optimized dose distribution within the tumor.

RT can induce normal tissue complications in the radiation treatment field (see Chapter 13). Acute and late toxicities affect

rapidly and slowly renewing tissues, respectively, and depend on daily dose to the tissue, total dose, overall treatment time, and volume of tissue treated.[126] The severity of side effects can therefore vary among protocols and also between individuals on the same treatment schedule, depending on the tissues included in the radiation field. Acute toxicities associated with irradiation of sinonasal tumors are dose- and schedule-dependent and can involve the oral cavity (oral mucositis), eye (keratoconjunctivitis and blepharitis), nasal cavity (rhinitis), and skin (desquamation) (Fig. 24.8).[104,105,119,122,127] Acute effects develop during the course of RT and resolve within 2 to 8 weeks after treatment.[104,105,119,127] Oral antibiotics, pain medications, and/or ocular medications including artificial tears may be needed to support the patient during this period. Rarely, temporary esophagostomy or gastrostomy tube feedings may be indicated if oral mucositis is severe to maintain adequate nutritional intake.

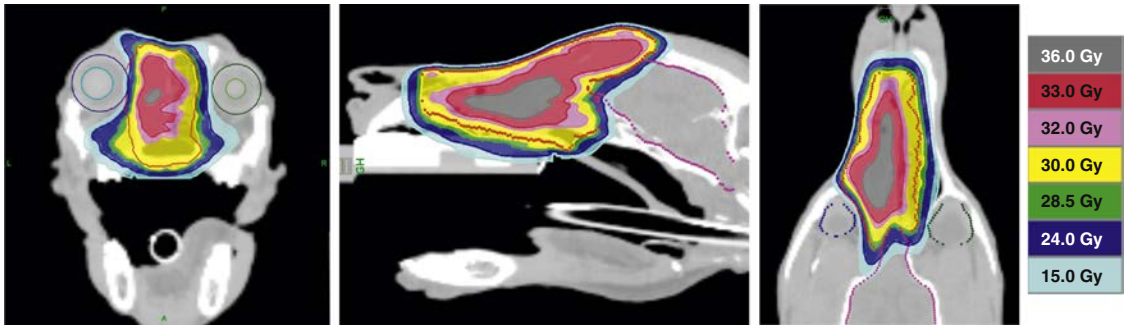
Late radiation effects, although less common than acute effects, are more detrimental and long lasting. Their development is also dose-dependent and should be prevented with thoughtful RT planning. Tissues that may be affected include the ocular lens (cataracts), cornea (keratitis, atrophy, keratoconjunctivitis sicca), anterior uvea (uveitis), retina (hemorrhage and degeneration), neuronal tissue (brain necrosis, causing neurologic changes and/or seizures, and optic nerve degeneration), bone (osteonecrosis), and skin (fibrosis).[104,105,119,122,127–130] Late complications develop months to years after therapy and are generally irreversible. The most commonly observed clinically relevant late effects in dogs treated with definitive RT for sinonasal tumors are those affecting ocular structures when it is not possible to spare the eyes using conformal radiation delivery.[104,119] Late ocular changes in the dog typically occur 6 to 9 months after RT and most often include keratoconjunctivitis sicca, cataract formation, and blindness in the irradiated eye if radiation doses are not limited.[122] The lens is particularly sensitive to radiation damage, with cataracts forming in people at doses as low as 2 to 5 Gy.[131] Other late effects are rare when standard radiation doses per fraction are used. In general, the risk of late effects increases when doses per fraction are increased. The use of highly conformal RT delivery techniques allows for avoidance of critical structures including the eyes and brain.[122]

• **Fig. 24.8** Potential acute effects of radiation therapy (RT) in dogs. (A) Resolving desquamation 1 month after definitive RT for a nasal tumor. Note the hair loss in the radiation field. (B) Oral mucositis on the last day of a definitive radiation protocol. Note the yellowish material on the inner aspect of the upper lip. This represents dead epithelium that is being shed from the mucosa.

Overall, although the majority dogs with sinonasal neoplasia experience a favorable tumor response to RT with resolution of clinical signs, the long-term prognosis is poor. Even when treated with a definitive RT protocol, most dogs die or are euthanized as a result of local disease progression. An investigation of treatment failure patterns after full-course MV irradiation showed that the median duration of local control in 24 dogs was 312 days.[132] Marked tumor regression (90% reduction in size) was observed using CT in 46% of cases and was associated with a longer duration of local control than that seen in dogs in which tumor response to radiation was less favorable (389 vs. 161 days).[132] Most of the dogs in that series experienced local progressive disease, which affirms the need for more effective treatment strategies.

The following approaches have been investigated to improve local control using conventionally fractionated RT.

1. Definitive-intent RT (4.2 Gy × 10 daily fractions) *followed* by surgical exenteration of residual or recurrent disease showed promise in a small series of dogs (n = 13), with a MST of 47 months, compared with 19 months for dogs treated with radiation alone.[121] In this study, complete exenteration of the nasal cavity involving removal of all turbinates and periosteal lining in the nasal cavity was performed. The combination treatment was associated with an increased incidence of late effects, including rhinitis (bacterial and fungal), osteomyelitis, and fistula formation, but MST was the longest reported for dogs with nonlymphomatous sinonasal tumors.[121] The risk of these complications may be reduced with a more limited and focused extirpation of intranasal tissue in the region of the tumor and with the use of highly conformal radiation delivery techniques that minimize dose to normal tissues. A larger group of dogs must be treated in this manner to confirm the safety and efficacy of this modified surgical approach. Another study (n = 16) evaluating exenteration after definitive-intent preoperative RT (median 3 Gy × 18 daily fractions) resulted in a MST of 457 days (15 months) with no long-term side effects observed.[133] The surgical approach used in these cases was not described and some dogs had advanced metastatic disease at the time of surgery, potentially contributing to the less favorable MST.
2. A logical and intuitive approach to improve local control is to increase radiation dose. This was investigated in an older study using a boost technique in which the total radiation dose was escalated to 57 Gy without an increase in overall treatment time. The treatment, delivered using nonconformal radiation and without the benefit of computerized treatment planning in most dogs, proved too toxic with respect to acute effects and



VetBooks.ir

resulted in radiation-related deaths in one-third of evaluated dogs.[127] A recent investigation of a similar approach evaluated a simultaneously integrated boost using highly conformal intensity-modulated RT and led to clinically acceptable side effects in a small pilot study of nine dogs in which a 20% dose increase was delivered to gross disease.[134] These preliminary results suggest that modern conformal techniques may make dose escalation a feasible treatment strategy. Further evaluation is needed to confirm these findings and to assess effectiveness with respect to tumor control.

3. The use of radiosensitizers in conjunction with ionizing radiation has been reported. A Veterinary Radiation Therapy Oncology Group (VRTOG) pilot study described the use of gemcitabine as a radiosensitizer for sinonasal carcinoma.[135] Gemcitabine was given intravenously at a dosage of 50 mg/m^2 twice weekly before daily RT. The authors reported significant hematologic toxicity (neutropenia) and local acute tissue complications associated with this dose and schedule. In another report, low-dose cisplatin (7.5 mg/m^2 given intravenously every other day) administered in conjunction with definitive RT was well tolerated and did not appear to cause an increase in acute or late radiation effects.[123] The efficacy of this approach with respect to improvement of clinical outcome is not known. A combination of RT and cisplatin, administered intramuscularly throughout therapy using a slow-release polymer system (open cell polylactic acid polymer impregnated with platinum [OPLA-Pt]), was well tolerated; however, survival times were similar to those in other studies that used RT alone (MST: 474 days).[120] Use of firocoxib, a COX-2 inhibitor, was evaluated in combination with RT in a small, underpowered study. Quality of life was improved in the dogs receiving the nonsteroidal antiinflammatory drug, but there was no difference in progression-free interval or overall survival compared with RT alone.[136]

An important advancement in the treatment of sinonasal tumors has been the advent of intensity-modulated RT (IMRT), which is now widely available in veterinary medicine. IMRT achieves highly conformal distribution of radiation dose to the tumor while sparing sensitive normal tissues.[122,137–140] Multiple radiation fields of nonuniform beam intensity are delivered with the goal of distributing the radiation dose among larger volumes of normal tissue. The complex shape of sinonasal tumors and the surrounding critical structures, including eyes and brain, provide a strong rationale for application of IMRT with this tumor type. RT-related morbidity can be significantly reduced in dogs with sinonasal tumors when IMRT is used.[122,138] A clinical study compared radiation-induced ocular toxicity in dogs with nasal tumors treated with IMRT to that of historical controls treated with conventional 2D RT.[122] IMRT reduced the radiation dose delivered to the eyes and resulted in bilateral ocular sparing. This was in contrast to profound ocular morbidity observed in the historical control group. MSTs for both groups were similar. Paramount to the success of highly conformal RT is precise daily patient positioning.[137] Millimeter variation in patient setup can result in underdosing of the tumor and unintended irradiation of normal tissues. Daily setup inaccuracies associated with conventional (nonrigid) immobilization techniques used in veterinary RT reduce precision of IMRT delivery over a multiple-week course of treatment for nasal tumors.[140] Daily image guidance is often necessary to ensure daily setup precision.[140] This is referred to as image-guided IMRT (IGRT). Rigid immobilization techniques (head and cranial body fixation devices) have been developed for veterinary patients,[141–144,145] and, in conjunction with daily "on-board" image guidance, permit successful implementation of highly conformal therapy.[140,141,145,146] Also critical to the success of IMRT is the accuracy of radiation target and normal tissue delineation in the treatment planning process, as well as the choice of dose calculation algorithm in the treatment planning system.[147–149]

A newly emerging application of IMRT/IGRT is stereotactic RT (SRT). SRT refers to the delivery of high-dose (ablative) radiation in a single dose or a few fractions.[150] The treatment is delivered with extreme accuracy, and the dose is pinpointed to the tumor, minimizing the effect on nearby organs. The high degree of precision and sharp dose fall-off at the edge of the tumor target is achieved by delivering many (up to hundreds) irregular subfields. This is done using specialized software and sophisticated multileaf collimation to create a complex intensity pattern.[150] To achieve rapid dose fall off outside of the tumor target, dose heterogeneity in the tumor is allowed with the tumor target receiving as much as 30% to 40% above the prescribed dose (Fig. 24.9). SRT fractionation schedules usually involve a daily treatment for 1 to 3 days, which has obvious practical advantages compared with conventionally fractionated schedules that take weeks to complete. SRT requires precision throughout the treatment process: optimized imaging for treatment planning, thoughtful and accurate target and normal tissue delineation, highly reproducible patient immobilization, high-fidelity image guidance, and

• **Fig. 24.9** Stereotactic radiation therapy radiation dose distribution for a stereotactic treatment plan created for a dog with nasal carcinoma. The radiation prescription to the planning target volume (PTV, *red line*) is three daily fractions of 10 Gy for a total dose of 30 Gy. The various color wash regions show heterogeneity of dose within the PTV and rapid dose fall off outside the PTV. The eyes and brain receive minimal dose due to the conformity of the treatment plan.

VetBooks.ir

an intensity modulated radiation beam to achieve extreme precision.[128] Initial SRT experiences in dogs with nasal tumors have been variable.[151–153] Published reports include radiation prescriptions with median doses ranging from 24 to 36 Gy delivered in three fractions (3 daily or every-other-day fractions of 10 Gy, or 3 daily treatments of 8–12 Gy)[152,153] or as a single fraction of up to 33 Gy.[151] In all of these studies, SRT improved clinical signs associated with sinonasal tumors. MST varied, however, ranging from 8.5 months to 19.5 months. Tumor control is dose-dependent, and thus will be contingent on the dose prescription, number of fractions, accuracy of target delineation in the treatment planning process, dose heterogeneity across the tumor, and accuracy of treatment delivery. Variation between studies in any of the factors can dramatically affect clinical outcome. Interestingly, tumor stage was not prognostic in any of these SRT studies,[151–153] which may reflect the ability of modern conformal RT techniques to deliver adequate radiation doses to regions of tumor that abut critical structures such as the brain. Acute effects associated with SRT at the doses delivered are reportedly rare and mild, although it is possible they were underreported.[151–153] Given the high dose per fraction used with SRT, the risk of late effects is higher than for conventionally fractionated protocols. With thoughtful treatment planning and use of normal tissue dose constraints during the treatment planning process, late effects can be minimized.[153] Severe late complications can include oronasal fistula formation, seizures, ocular changes, skin necrosis, and osteonecrosis.[151–153] Late effects are reported in 3% to 40% of dogs and depend on the degree of dose conformality achieved during the treatment process and the dose delivered to normal tissues.[151–153] The most favorable outcome reported to date both in terms of tumor control and toxicity is reported by Gieger et al. who prescribed three daily fractions of 10 Gy planned with well-defined and standardized contouring practices and normal tissue constraints.[153] In that study of 29 dogs, three developed fistulas within the radiation field 4 to 12 months after RT, two of which may have been related to tumor response or progression as opposed to radiation. Two dogs developed fungal rhinitis 1 year after RT. No information about ocular toxicity was provided. The MST was 586 days. Despite the multiple apparent advantages of SRT, the challenges associated with optimal use of this technology must be considered and treatment plan evaluation must be optimized. Controlled clinical trials that rigorously examine normal tissue effects and tumor responses are still needed to validate use of SRT over standardly fractionated conventional RT or IMRT/IGRT in veterinary medicine.

In contrast to curative-intent RT protocols, treatment schedules that are less intensive can be used to palliate tumor-related clinical signs. The goal of palliative RT is to improve quality of life without aiming to maximize tumor sterilization. Palliative protocols involve coarsely fractionated treatments (5–9 Gy per fraction) delivered weekly or biweekly, or daily treatments (4 Gy) for 5 days, or daily treatments (3 Gy) for 10 days.[69,109,110,136,154–158] The result of this approach is temporary improvement of clinical signs in 66% to 100% of dogs and limited morbidity associated with acute side effects.[109,136,154–158] The reported median duration of control of clinical signs ranges from 120 to 308 days.[109,155,157,158] Acute toxicities affecting the oral mucosa and skin are generally mild and short-lived.[109,154–158] Acute and chronic ocular toxicities can develop if the eye is not spared.[155,157,158] Reported MSTs range from 146 days to 512 days.[69,109,154–158] Tumor stage (stage 1) and duration of clinical signs (>90 days) have been correlated with longer survival in cases receiving this type of radiation.[109,155] Although true statistical comparisons between studies are not possible because of inconsistencies in methodology, the best clinical outcomes in terms of survival (approximately 300–500 days) are reported in three studies in which RT planning was performed using CT and 3D-conformal computerized treatment planning software in most dogs.[109,133,158] Modernized RT planning in canine nasal tumor patients treated palliatively may result in more favorable clinical outcomes than for previously reported, less sophisticated approaches.[109,157,158] When lower doses per fraction are used, such as the five daily treatments of 4 Gy protocol described by Tan-Coleman, the radiation treatment course can be repeated upon return of clinical signs to prolong palliation.[157] The use of a nonsteroidal antiinflammatory drug can also help improve overall quality of life.[136]

A number of reports suggest that some dogs with recurrent nasal tumors can experience a second clinical remission after reirradiation.[157,159,160] One study evaluated a selected cohort of nine dogs in which the median time to tumor progression after a first definitive course of RT was 513 days. The first course of radiation delivered a median of 50 Gy in a median of 18 fractions. The median total dose used in the second protocol was 36 Gy, delivered in approximately 2-Gy fractions. The overall MST for this small, selection-biased cohort of dogs was 927 days (95% confidence interval [CI] 423 days to 1767 days). All dogs developed one or more late effects involving the skin, eyes, and nasal cavity. Late effects in seven of the nine dogs were considered mild and did not affect quality of life. Severe late effects were reported in two dogs, and both had sudden blindness that led to euthanasia. A second study reports a MST of 453 days in 37 dogs that were reirradiated after a coarsely fractionated radiation protocol.[159] The median dose for the first course of RT was 24 Gy (median dose per fraction, 7 Gy), and then 20 Gy for the second course (median dose per fraction, 8 Gy). The second course was initiated a median of 150 days after the first. All dogs responded clinically after the first course for a median of 114 days, and 70% responded after the second course for a median of 80 days. Acute toxicities were generally mild and included the skin, oral mucosa, and eye, although normal tissue doses are not described. Based on these reports, reirradiation for recurrent nasal tumors can result in improvement in clinical signs and potentially extend survival time. In a third study of dogs with sinonasal sarcoma, eight dogs that underwent reirradiation had a longer MST (654 days) than those that had a single course of RT (356 days).[28] Further work is needed to refine time-dose prescriptions to minimize radiation-induced late effects.[159,161] Conformal techniques such as IMRT could play a role in this setting to limit morbidity.[161]

Chemotherapy is used rarely as a sole therapy for canine sinonasal tumors. Treatment with cisplatin alone has been shown to benefit some dogs.[162] A clinical response rate of 27%, including one radiographically-confirmed complete remission, was reported in a small series of 11 dogs.[162] All of the dogs experienced alleviation of clinical signs, and the MST was 5 months. Another report evaluated a combination chemotherapy protocol of doxorubicin, carboplatin, and oral piroxicam in eight dogs with advanced nasal tumors.[163] A clinical response rate of 75% was observed, including 4 CRs confirmed by CT imaging. All dogs experienced resolution of clinical signs, and the protocol was well tolerated. The MST in these eight dogs was 210 days (range 150–960 days). These preliminary results are favorable, but the case number is small, and more dogs need to be treated in this manner to confirm these findings. Toceranib phosphate, a TKI, was associated with a clinical benefit in five of seven dogs (71%) with nasal carcinoma,

VetBooks.ir

including one complete tumor response and improvement of clinical signs in five dogs.[164] The median duration of treatment was 18 weeks. Use of toceranib in combination with RT has not yet been reported. In three dogs with SCC limited to the frontal sinus, tumor responses including two complete responses were observed with piroxicam and carboplatin. The third dog had a marked tumor response when toceranib was substituted for carboplatin.[165]

Electrochemotherapy has been described in dogs with nasal cavity tumors, consisting of an intravenous injection of bleomycin followed by local delivery of electric pulses using a custom single needle electrode to potentiate drug uptake.[166] The overall response rate in 11 dogs treated with electrochemotherapy alone was 90% with a MST of 16.9 months, compared with 5.3 months in 10 dogs treated with surgery followed by adjuvant carboplatin chemotherapy. Systemic effects were not reported. Adjuvant electrochemotherapy using a topical application of bleomycin in the nasal cavity is reported in a single dog after surgical extirpation of the tumor.[167]

Other therapeutic approaches to nasal tumors that have been investigated include proton-beam therapy, brachytherapy, immunotherapy, cryotherapy, and photodynamic therapy (PDT). Charged particles like protons have a well-defined tissue range and sharp dose fall off, which could potentially be exploited for conformal tumor targeting and normal tissue sparing.[168] A small clinical trial involving nine dogs with nasal tumors treated with proton-beam therapy resulted in tumor responses and survival times similar to those reported for MV irradiation.[168] Acute effects to the skin and eyes were pronounced in some dogs, and 50% of dogs developed radiation-induced cataracts. Due to limited availability of proton irradiators, this technology is unlikely to be optimized for use in dogs. Intracavitary RT using radioactive isotopes (brachytherapy) has been evaluated after surgical removal of sinonasal tumors in dogs.[169–170] Potential problems associated with this type of radiation include dose distribution and radiation exposure to personnel. The question of whether brachytherapy improves survival over traditional external-beam RT has not been answered. Immunotherapy and cryosurgery have not improved survival times.[25,171] A recent case report described the use of image-guided cryotherapy in the treatment of a rapidly recurrent nasal carcinoma that resulted in long-term tumor control and survival.[172] The authors suggested that further investigation of this technique may be warranted for the management of focal residual or recurrent nasal tumors. Reports evaluating PDT have been published, including in combination with surgery and RT; however, results are too preliminary to draw any conclusions.[173–175]

When all treatments fail to control epistaxis, unilateral or bilateral carotid artery ligation can palliate symptoms in dogs for up to 3 months or longer without damage to the brain.[99]

The importance of prognostic factors in the treatment of canine sinonasal tumors remains controversial. Negative predictors of survival from various studies include age (>10 years),[108] epistaxis,[74] duration of clinical signs,[155] advanced local tumor stage,[104–106,108,109] metastatic disease,[36,108,136] histologic subtype (carcinoma, particularly SCC or undifferentiated),[104,106,98] tumor expression of survivin,[176] and failure to achieve resolution of clinical signs.[155] An analysis of 94 dogs with varying subtypes of nasal carcinoma or sarcoma treated with curative-intent RT at three veterinary facilities was performed.[106] A correlation was demonstrated between clinical outcome and the original Adams tumor staging scheme,[105] as well as the modified Adams tumor staging method.[105] Based on these findings, dogs with cribriform plate involvement as determined by CT imaging (stage 4) have the shortest disease-free survival (DFS) and overall survival time (OST). This subset of dogs had a median DFS of 3.8 months and a median OST of almost 7 months, compared with dogs with unilateral tumors without bone involvement (stage 1) in which DFS and OST were 6.5 and 23 months, respectively. In a recent study of 29 dogs with cribriform involvement (stage 4) treated with definitive-intent IMRT, the MST was 305 days.[177] Compared with the earlier studies that used nonconformal delivery techniques,[105–106] these favorable results suggest that IMRT, with its greater conformality and tumor dose homogeneity, may improve outcomes in dogs with stage 4 disease. Interestingly, intracranial tumor extension past the cribriform plate was not prognostic for survival.[177] This highlights the fact that prognostic indicators may change as technical advances in treatment develop. In most studies, sinonasal carcinomas and sarcomas are grouped together because of a similar biological behavior and clinical response to RT. In the multiinstitutional study of 94 dogs mentioned above,[106] there was no effect on clinical outcome when all carcinomas were compared with all sarcomas; however, when dogs with anaplastic carcinoma, undifferentiated carcinoma, and SCC were grouped together, they had a shorter DFS than dogs with other tumor types. A recent retrospective study limited to dogs with sinonasal sarcoma treated with RT (n = 86), the overall MST was 444 days (15 months), which is in line with previous studies.[28] Radiation protocols were not standardized, but dogs with sarcoma treated with definitive RT had more favorable outcomes compared with those treated in the palliative setting (MST 523 days vs. 305 days). Also, dogs treated daily Monday to Friday had an improved MST compared with dogs treated on a Monday, Wednesday, Friday schedule. Six dogs diagnosed with intracavitary nasal osteosarcoma had a significantly better MST at 624 days than dogs with other mesenchymal tumors. Interestingly, this is in contrast to seven dogs with nasal osteosarcoma treated with SRT that had a shorter OST than dogs with other carcinoma or sarcoma tumor types (MST 3 months vs. 10 months).[151] This difference may be due to chance, or variations in tumor stage, or tumor location, or treatment approaches in these small groups of dogs. The true prognosis of sinonasal osteosarcoma treated with RT is not clear. In a multiinstitutional study of 24 dogs with intranasal lymphoma treated with various RT protocols +/– adjuvant chemotherapy, the overall MST was 375 days for intermediate/large cell and 823 days for the small cell group.[59] There was no difference in MST for dogs treated with RT and chemotherapy versus chemotherapy alone. Eighty-five percent to 90% of dogs treated with RT improved clinically, suggesting that this is a radioresponsive tumor and that RT may play a role in its management. Angiofibroma is a histologically benign but locally aggressive vascular nasopharyngeal tumor characterized by a proliferation of irregular appearing blood vessels that are surrounded by a connective tissue stroma.[63] None of the 13 dogs reviewed retrospectively had metastasis. Prolonged survival of up to 4 years was reported in four dogs after surgical excision. Survival of 1 to 2 years was observed in some dogs with no treatment. A small series of four dogs with intranasal MCT receiving various chemotherapy agents has been reported.[60] Tumor response information was not provided. The survival times ranged from 27 to 134 days. Based on a case report of three dogs treated with RT, intranasal melanoma appears to be a radioresponsive tumor with two dogs experiencing a complete response after RT.[61] Finally, in a case series of five dogs with nasal polyps treated with surgery or nasal flushing, three dogs were alive without recurrence at 16 to 54 months.[64] Two dogs developed recurrence, one of which had

VetBooks.ir

nasal signs controlled for 10 months after definitive RT for polyp recurrence. The role of RT in the management of nasal polyps is not clear.

A major pitfall of many veterinary studies with respect to assessment of treatment efficacy in canine sinonasal cancer is the need for advanced imaging to assess tumor response. Tumor response and TTP are the most representative measures of treatment efficacy. Regular diagnostic imaging, ideally CT or MRI, is necessary for accurate determination of these endpoints. Due to high costs and the need for anesthesia, follow-up is rarely done in this manner. Analyzing the return of clinical signs as an indication of tumor recurrence is problematic because similar signs can result from rhinitis secondary to therapy (RT and/or surgery) or residual tumor.[178] Assessment of survival time may be biased by the use of additional treatments on suspicion of progressive disease and by the decision for euthanasia, which can vary greatly from one pet owner to another. Furthermore, inconsistencies in methodology between studies and even within individual reports, as well as a lack of controlled studies, have limited the informed development of the optimal treatment approach for sinonasal tumors in dogs.

Feline Sinonasal Tumors

Nasal and sinus cavity tumors in the cat are malignant in more than 90% of the histologically diagnosed cases. They occur in an older population of cats with a mean age reported between 9 and 10 years.[179–181] In general, these tumors are locally invasive and associated with a low metastatic rate at the time of diagnosis.[180,182]

Clinical signs related to sinonasal tumors in cats overlap with those of other causes of chronic nasal disease.[179,181] These include nasal discharge, upper respiratory tract dyspnea, sneezing, epistaxis, facial swelling, ocular discharge, and weight loss.[179–181,183–185] Although each of these signs can occur with both neoplasia and rhinitis, in some reports, certain signs are more commonly associated with neoplasia such as unilateral discharge or epistaxis,[179] whereas in others, the character of the clinical signs does not distinguish the underlying cause.[181] The median duration of clinical signs before diagnosis is several months, and many cats will experience temporary alleviation of clinical signs with use of antibiotics and or corticosteroids.[179–181] Differential diagnoses for chronic nasal signs include chronic rhinitis, infectious rhinitis, foreign body, nasal polyp, nasopharyngeal stenosis, and trauma.

Lymphoma is the most commonly diagnosed tumor type in the feline nasal cavity and sinuses, followed by epithelial neoplasms (carcinoma, adenocarcinoma, SCC). Less frequently reported tumor types include sarcomas (fibrosarcoma, osteosarcoma, chondrosarcoma), MCT, melanoma, plasmacytoma, olfactory neuroblastoma, and benign lesions such as nasal hamartoma, chondroma, and neurofibroma.[179–181,186,187]

Diagnostic principles are similar to those in the dog. A tissue sample is required to make a definitive diagnosis of cancer in most cases. DeLorenzi et al evaluated cytology from squash preparations obtained from endoscopic biopsies of nasopharyngeal masses in cats and found that cytologic results were in good agreement with histopathology with an overall accuracy of 90%.[188] However, distinguishing lymphoma from lymphoid inflammatory disease was not as accurate, and histopathologic confirmation was recommended.[188] Another study evaluated the histopathologic and cytologic features of nasal lymphoma in 50 cases. Ninety-one percent of cases were classified as immunoblastic lymphoma according to the National Institutes of Health Working Formulation. The majority of cases were B-cell (68%) and 20% were T-cell, with 12% having a mixed population of B- and T-cells.[186] In another study of 39 cases, 28% were small cell and 87% were B cell.[189] In this study they also evaluated FeLV viral antigens (p27 and gp70) by immunohistochemistry (IHC) and found that 54% of samples were positive, although cases were not serologically tested. The majority of cases in this series did not receive therapy, so the effect of viral positivity on outcome is unknown. Because lymphoma makes up a high percentage of feline nasal tumor cases, special stains may be helpful in obtaining a correct diagnosis. In a retrospective study of 232 feline nasal tumor biopsies reviewed by two pathologists, disagreement in diagnosis was seen in 15 cases, 14 of which were originally diagnosed as carcinoma.[190] IHC with epithelial and lymphoid markers showed that the original diagnosis was incorrect 67% of the time, indicating the usefulness of IHC in establishing a correct diagnosis in feline nasal tumors.

Radiographs of the nasal cavity have been reported as a diagnostic tool in cats with both chronic rhinitis and nasal neoplasia. Although no radiographic sign is entirely specific for neoplasia, findings with the highest predictive value for cancer include displacement of midline structures, unilateral changes such as soft tissue opacity and loss of turbinate detail, and evidence of bone invasion.[191] Similarly, as CT scan becomes a common imaging tool, reports of the characteristic findings of scans from cats with sinonasal disease of all etiologies have been published.[192–194] One retrospective assessment of CT imaging in 62 cats with sinonasal disease showed that, although certain findings such as osteolysis of paranasal bones, extension of disease into the orbit of facial soft tissues, the presence of a space-occupying mass, and turbinate destruction may suggest a CT diagnosis of neoplasia over rhinitis, nasal biopsy is necessary for confirmation.[192] Another study evaluated the clinical characteristics and CT findings in 43 cats and found that those with neoplasia were significantly more likely to have unilateral lysis of the ethmoturbinates as well as dorsal and lateral maxilla, lysis of the vomer bone and ventral maxilla, and unilateral soft tissue or fluid in the sphenoid recess, frontal sinus, or retrobulbar space. Interestingly, in that study population, cribriform plate lysis was not significantly associated with neoplasia.[193] In another report describing CT findings in cats with confirmed fungal rhinitis, they found that some of the features overlap with those seen in neoplasia patients, including older age at the time of diagnosis, soft tissue mass, and osteolysis. Another study sought to determine whether CT characteristics of nasal passages and medial retropharyngeal LNs (MRPLNs) could be used to distinguish neoplasia from rhinitis.[195] Thirty-four cats with rhinitis and 22 cats with neoplasia were evaluated. These authors found that in addition to nasal passage findings typically sited in other studies, the MRPLN characteristics that were significantly associated with neoplasia included abnormal MRPLN hilus, height asymmetry, and decreased MRPLN precontrast heterogeneity. Although these studies confirm the utility of CT scan determining extent of disease, no one group of features replaces histopathology for definitive diagnosis.

Even though the metastatic rate of feline sinonasal cancer at the time of diagnosis is reportedly low, any enlarged regional LNs should be evaluated cytologically to differentiate a reactive process from metastasis. In a recent report of 123 cases of feline sinonasal cancer, 21 cats had regional lymphadenopathy. None showed cytologic evidence of metastasis.[180]

As in the dog, RT continues to be the predominant local therapy of choice for this disease. Reports of treatment for feline nonlymphoma sinonasal tumors are few, and case numbers are

VetBooks.ir

small.[182,196] In one study, 16 cats with nonlymphoproliferative neoplasms were treated using a definitive course of radiation to a total dose of 48 Gy. The therapy was well tolerated, and MST was 12 months with 44% and 16% of cats alive at 1 and 2 years, respectively.[182] In another report of RT for nonlymphoproliferative tumors, this time treated using a coarse fractionation regime, results showed that the protocol was well tolerated, with a MST of almost 13 months and a 63% 1-year survival rate reported.[196] A report of 65 cats receiving palliative hypofractionated RT also determined acute and late side effects in addition to outcome.[197] There were 29 high-grade lymphoma cases with the rest (n = 36) being a variety of carcinomas. Patients received RT weekly (6–8 Gy) for a median total dose of 32 Gy. Many patients also received chemotherapy. Acute complications occurred in 58% of the cases but were considered acceptable. Late effects, typically ocular, occurred in 20% of the cases. The MST in all 65 cats was 432 days. There was no significant difference in MST between cats with lymphoma versus those with other tumor types.

Recent reports of feline nasal and nasal pharyngeal lymphoma treated with RT and/or chemotherapy indicate the potential for long-term survival.[183–186,198] Although treatment protocols vary between reports, in general, overall response rate for feline nasal lymphoma is high, between 70% and 90%. The inclusion of RT appears to enhance overall survival, with MSTs for combination therapy ranging from 174 to 955 days.[184,185] Interestingly, systemic failure of disease at nonnasal sites is also reported in 13% to 16% of cases, indicating that a combination of RT and chemotherapy may be warranted in some patients. However, the timing of such treatment remains to be determined (concurrent vs. sequential), as does which patients are at highest risk for local failure. In an attempt to predict which feline nasal lymphoma cases would respond better to RT, a study was done evaluating pretreatment biopsies in 30 cats looking at apoptotic index and Ki-67 scores.[199] Cases with high proliferative scores were significantly more likely to have a response to RT and have prolonged survival compared with those with low scores. Furthermore, improved RT planning along with optimized RT schedules and doses may ultimately improve local control rates and reduce the risk of systemic failure without the addition of chemotherapy. Published reports of treatment of feline nasal tumors with SRT or more targeted treatment plans are lacking.

Comparative Aspects[200–205]

In humans, cancer of the nasal cavity and paranasal sinuses is classified with other cancers of the upper aerodigestive tract under the all-encompassing title of tumors of the head and neck. Head and neck cancers arise from a variety of sites within the head and neck region, which is divided into five basic areas: (1) oral cavity, (2) pharynx (oropharynx and nasopharynx), (3) larynx, (4) nasal cavity and paranasal sinuses, and (5) salivary glands. The majority of tumors affecting these sites are SCC (head and neck SCC [HNSCC]); however, a range of other malignancies can develop in the nasal cavity and paranasal sinuses, including adenocarcinoma, neuroblastoma, lymphoma, melanoma, angiosarcoma, and tumors of connective tissues. Benign but potentially invasive papillomas are also reported.

Tumors specifically of the nasal cavity and paranasal sinuses are rare in humans and represent less than 1% of all malignant tumors and only about 3% of head and neck cancers. The maxillary sinus is most commonly affected. Tumors of the ethmoid, sphenoid and frontal sinuses, the nasal vestibule and the nasal cavity are less common. Sinonasal cancers are more frequent in men than in women. Some data indicate that various industrial and environmental exposures may be related to sinonasal cancer, including exposure to wood, textile, and leather dusts, as well as formaldehyde. Air pollution and tobacco smoke are also related. Other factors associated with increased risk for all head and neck cancers include smoking and alcohol use, which may have an additive effect. Importantly, human papillomavirus (HPV), a sexually transmitted infection, may be involved in the pathogenesis of sinonasal cancer. HPV has been identified in 25% to 49% of oropharyngeal head and neck cancers and is associated with a significant survival difference compared with HPV-negative oropharyngeal cancers. There is striking evidence of improved outcomes in patients with HPV-positive oropharyngeal tumors. HPV status is the strongest independent determinant of local and regional control, disease specific survival, and overall survival in this group of head and neck cancers. Despite the dramatic influence of HPV in oropharyngeal cancer, its role in the etiology and prognosis of sinonasal head and neck tumors is less well defined.

Sinonasal head and neck tumors are locally invasive and cure rates are generally poor. They are typically advanced at the time of diagnosis because lesions in this area can go undetected for extended periods of time and clinical signs can mimic those of infectious or inflammatory disease. Nodal involvement and distant metastasis are infrequent at the time of diagnosis—reportedly between 10% and 15%. Locoregional recurrence accounts from the majority of cancer deaths.

Surgery and RT are the mainstay of treatment when considered possible, based on stage and location of disease. Chemotherapy can be useful in an adjuvant setting, but it is not curative when used alone. Both RT and surgery have advantages and disadvantages as primary therapies. The OST at 5 years is approximately 60% and 30% for nasal cavity and parasinal tumors, respectively. More favorable prognoses are associated with smaller lesions in which complete surgical resection is achievable. When adequate margins cannot be obtained, surgery and RT are often combined. Incomplete local control of advanced tumors leads to local tumor recurrence in many cases.

The role of chemotherapy in sinonasal head and neck cancer is not clear because these cases are usually reported in conjunction with other head and neck tumors. Active chemotherapy agents include the taxanes, 5-fluorouracil (5-FU), methotrexate, and the platinum drugs. Several studies have reported improved local control and, in some cases, improved OSTs in treatment protocols that combine traditional fractionated RT and chemotherapy; however, the toxicity may also be increased. The optimal case selection, chemotherapy agents, and radiation schedule has yet to be defined.

Multiple targeted and immunotherapies for head and neck cancer have been investigated in clinical trials, most involving EGFR and PD-1 antagonists. Other targeted therapies with potential benefits include VEGF or VEGFR inhibitors and PI3K/AKT/mTOR pathway inhibitors. The U.S. Food and Drug Administration has granted approval to three monoclonal antibodies for use in certain patients with HNSCC. These include EGFR inhibitor cetuximab (Erbitux), and anti-PD-1 antagonists pembrolizumab (Keytruda) and nivolumab (Opdivo). Because of the rarity of sinonasal head and neck cancers, few molecular studies have been done to evaluate novel therapeutic strategies specifically for tumors in this location. In a study evaluating molecular markers in sinonasal SCC (SNSCC), including EGFR, HER2, p53, KIT, Bax, MMP-2, MMP-9 and VEGFR, only EGFR expression

was associated with significantly worse DFS. If confirmed by further studies, EGFR expression may be a prognostic indicator for SNSCC, and targeted inhibition of EGFR may be a new approach to treatment of patients with this rare cancer.

SECTION C: CANCER OF THE LARYNX AND TRACHEA

NICHOLAS J. BACON

Incidence and Risk Factors

Primary tumors of the larynx and trachea are uncommon in domestic animals. Laryngeal tumors comprise 0.02% of all biopsy and necropsy specimens in dogs[206] and a literature review yielded less than 30 dogs with tumors specifically affecting the cartilaginous component of the larynx and trachea.[207] In a study of 2546 insured animals in the United Kingdom in a 12-month period, there were no reported cases of laryngeal or tracheal neoplasia.[208]

Dogs with tracheal masses are often under 2 years (benign cartilage dysplasias) or over 10 years (malignancies) of age. All sized dogs are susceptible with both males and females affected. Arctic breeds, such as the Alaskan malamute or Siberian husky, account for 27% of canine laryngo-tracheal tumors.[207]

Cats with laryngeal or tracheal masses are typically older with a median age of 12 years. Significant correlations have been found between Siamese and domestic long-haired cats and lymphoma, and domestic long-haired cats and adenocarcinoma.[209]

Pathology and Natural Behavior

The larynx is a musculocartilaginous organ lined internally by stratified squamous mucous epithelium. Nearly half of its length is occupied by the rostral epiglottic cartilage. The trachea runs from the larynx to its bifurcation at the carina, just cranial to the heart base. It is composed of approximately 35 C-shaped hyaline cartilages with the tracheal muscle running dorsally. The rings are interconnected by narrow fibro-elastic annular ligaments. The lumen is lined by epithelium.[210]

Benign lesions of the larynx are rare, and rhabdomyoma and oncocytoma make up the majority of these tumors. There is currently some uncertainty whether rhabdomyoma (striated muscle) and oncocytoma (epithelial origin) are in fact variants of the same tumor in the canine larynx.[211,212] Other benign diseases include chondroma, myxochondroma, congenital cysts in young dogs, and lymphoplasmacytic and eosinophilic masses.[207,213]

Rhabdomyosarcoma, SCC, adenocarcinoma, osteosarcoma (OSA), chondrosarcoma (CSA), fibrosarcoma, mast cell tumor (MCT), solitary extramedullary plasmacytoma, and granular cell tumor have been reported in the canine larynx.[214–217]

Young dogs, often 3 to 4 months of age, with active osteochondral ossification sites, are at a higher risk of benign tracheal chondromas, osteochondromas, and osteochondral dysplasia.[207,218–221] These benign osteocartilaginous tumors grow during development and stop growing at skeletal maturity. Leiomyoma has been infrequently reported in the dog.[222,223] Tracheal malignancies are more commonly located on the ventral wall, and adenocarcinoma, MCTs, extramedullary plasmacytoma, OSA, CSA, and lymphoma have all been reported in the canine trachea.[207,221,224–228]

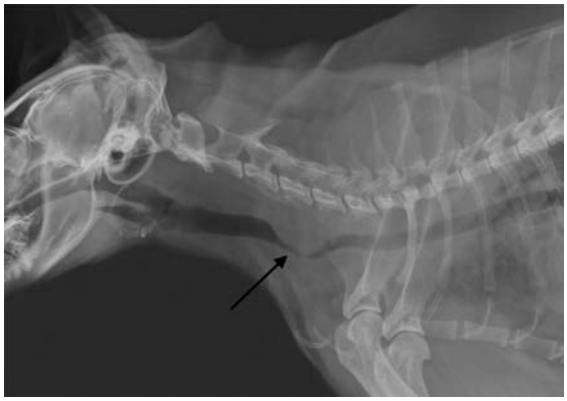
Feline laryngeal tumors include SCC, lymphoma, adenocarcinoma, and poorly differentiated round cell tumors.[209,229–230] Benign laryngeal masses have also been reported, such as lymphoplasmacytic inflammation, lymphoid hyperplasia, and polypoid laryngitis.[209,231]

Primary masses of the trachea in cats include lymphoma, SCC, histiocytic sarcoma, neuroendocrine carcinoma, and adenocarcinoma.[209,232–238] Lymphoplasmacytic inflammation, lymphoid hyperplasia, and epithelial polyp have also been reported.[209,239]

The trachea can be secondarily invaded by adjacent tumors, such as thyroid carcinomas,[240] or the lumen can be narrowed by external compression from lymphomatous nodes.[241]

Distant metastasis from primary laryngo-tracheal tumors is very rare.

History and Clinical Signs



Symptoms may be vague and may include dyspnea, stridor, voice change, exercise intolerance, coughing, gagging, dysphagia, weight loss, wheezing, and anorexia. Some patients may present in acute respiratory distress, including open-mouth breathing in cats. Clinical findings may be unremarkable, although occasionally patients with extratracheal compression may present with a palpable growth in the neck.

Diagnostic Techniques and Workup

Hematology and biochemistry are likely to be unremarkable or show nonspecific changes.

Radiographs of the neck and thorax may identify a solitary soft tissue space-occupying lesion or luminal stenosis within the inherent negative contrast of the airway. Mineralization of tumors is possible for osteochondromas in dogs. Cats with laryngeal and tracheal masses have radiographic abnormalities in 88% of cases (Fig. 24.10).[209] Intraluminal tracheal masses may be able to be detected ultrasonographically.[238] MRI has also been used to identify neoplastic involvement of mucosal or submucosal layers.[216] CT will allow for precise localization of the mass within the lumen and determine whether it has crossed the wall to affect surrounding local tissues.

Direct access to the larynx allows for fine-needle aspirates or grab biopsies to be easily taken under light anesthesia. Superficial biopsies, however, may give a false diagnosis of inflammatory disease and normal squamous epithelium, when inflamed, can have many cytologic characteristics of malignancy. Rigid or flexible endoscopes allow for direct visualization of tracheal

• **Fig. 24.10** Soft tissue mass visible within the air-filled trachea of a cat, later diagnosed as a tracheal carcinoma.

masses, and endoscopic brushings of masses often yield sufficient material for a cytologic diagnosis and immediate treatment (Fig. 24.11). Alternatively, tiny grab biopsies can be obtained through the instrument port for histopathology.[236] Care needs to be taken with larger-bore scopes as extubation must be performed in patients that may already suffer from respiratory compromise.

Excisional biopsy (intralesional or marginal excision, or resection and anastomosis) can be performed to obtain a diagnosis if earlier attempts at diagnosis have been unsuccessful.

Therapy

The relative infrequency and sporadic nature of laryngo-tracheal tumors mean definitive treatment guidelines are lacking. Recommendations are extrapolated from case reports, case series, or oncologic principles of treating similar tumors in other locations.

Larynx

Tube tracheostomy is a short-term measure to provide relief of obstructive symptoms by providing airflow bypass and can be surgically converted to a tracheostomy to allow time for therapies, such as chemotherapy or RT, to have an effect.

Small lesions may be removed by mucosal resection or partial laryngectomy through a transoral, ventral, or lateral laryngeal approach.[213,242,243] Larger lesions may require total laryngectomy incorporating a permanent tracheostomy, but this has been rarely described in dogs.[215,244] External beam RT can be used to treat radiosensitive tumors (e.g., lymphoma), but few reports exist.

Trachea

Surgical removal of the affected tracheal section is most likely to result in the longest disease-free intervals (DFIs) for solid tumors, although tracheal resection and anastomosis is a complex surgical procedure, especially if involving the intrathoracic trachea. Complications include dehiscence, tracheal stenosis, pneumothorax, and laryngeal paralysis.[244]

Endoscopic electrosurgical removal of a bronchial carcinoma in the right mainstem bronchus has been described in a cocker spaniel,[245] and a surgical diode laser has been used to endoscopically debulk an epiglottic CSA and a solid tracheal osteochondroma in dogs.[246,247] Similarly, an endoscopically guided wire snare has been used to debulk tracheal carcinomas in three cats.[248] Surgical debulking followed by cryotherapy has been described to treat an intratracheal adenoma in a cat.[249]

Palliative stenting of malignant tracheal obstructions should result in improvement in clinical signs in both dogs and cats. Endoluminal stents, such as stainless-steel self-expanding metallic stents, are placed minimally invasively under fluoroscopic guidance in anesthetized patients, and the procedure is rapid and low risk. Long sections of trachea that could not be resected surgically can be stented open with a stent greater than 2 cm longer than the tracheal segment affected.[238,250] Potential complications of stenting in dogs and cats include stent migration, fracture, granulation tissue formation, coughing, tumor growing through the stent open-weave, pneumonia, and death.[251]

Chemotherapy and/or RT are primarily reserved for round cell tumors of the trachea, especially lymphoma.

• **Fig. 24.11** Video tracheoscopy has significantly improved the ability to both diagnose and treat luminal masses in dogs and cats. This intraluminal tracheal mass was diagnosed by brush cytology as a poorly differentiated round cell tumor.

Prognosis

Surgical removal of laryngeal cysts should be curative with no reported long-term effect on function.[213] Likewise, benign osteochondromas in young dogs have an excellent prognosis after surgical resection. Intraoral diode laser total epiglottectomy for a laryngeal CSA resulted in a clinically normal dog 12 months postoperatively without any respiratory or digestive problem.[246] Another dog with a low-grade laryngeal CSA was still symptom free 12 months after surgical resection involving ventral laryngotomy and unilateral arytenoidectomy.[243] Three dogs with tracheal CSA underwent surgical excision, with two dogs having no recurrence.[207] One dog had local recurrence at 3 months; the recurrent disease was surgically resected, and the dog survived a further 8 months after the second excision.[207] Endoscopic removal of a bronchial carcinoma in one dog resulted in suspected local recurrence with respiratory difficulties 1 month postoperatively.[245] Macroscopic invasion of the trachea by thyroid carcinoma has been shown to be a significant negative predictor for DFI; this is seen in up to 24% of dogs with differentiated follicular cell thyroid carcinomas with a median survival time (MST) of 2.5 months.[240]

The prognosis for cats with tracheal carcinomas is poor as most historically have been euthanized immediately after or within a few days of diagnosis due to poor quality of life and rapid progression of disease. It is possible intraluminal stenting may improve this outcome in the future as this modality becomes more widely available.

Aggressive management in cats with solid laryngeal and tracheal tumors, including combinations of surgical resection, RT, and chemotherapy, have resulted in MSTs of 4 to 5 months with <10% of cats alive at 1 year.[209] More favorable prognoses with durable remission and survival times (STs) can be expected in cats with laryngeal and tracheal lymphoma after RT, chemotherapy, or combinations of these modalities; the reader is referred to Chapter 33B for a more thorough discussion. One cat with laryngeal SCC was treated with prednisolone and had a ST of 180 days.[230] A combination of local excision, RT, and melphalan and prednisolone was successful in long-term control of a feline laryngeal plasmacytoma.[216] Permanent tracheostomies in five cats with laryngeal carcinoma resulted in STs of 2 to 281 days, with two cats dying from tracheostomy occlusion and three cats from progressive disease.[252]

Comparative Aspects

Laryngeal cancer in humans is primarily related to smoking and alcohol consumption. The vast majority are SCCs. Initial management strategies were aimed at early laryngectomies with wide surgical margins for locoregional control, but this resulted in aphonia. The pendulum then swung toward chemoradiation to preserve the larynx and laryngeal function, but the quality of life and functional outcome did not correlate with an anatomically preserved larynx. Currently, the preferred treatment strategy has evolved into conservative laryngeal resections with preservation of laryngeal function, including good swallowing function without aspiration and speech production.[253] Early stage laryngeal cancer has overall survival rates of over 90%, but this falls to 27% to 39% in advanced cases treated with chemoradiotherapy.[254]

Intraluminal stenting of tracheal masses has been described in humans and is being performed increasingly commonly,[255] although primary tracheal cancer (unrelated to bronchial or lung cancer) is very uncommon.

SECTION D: PULMONARY NEOPLASIA

WILLIAM T.N. CULP AND
ROBERT B. REBHUN

Incidence and Risk Factors

Lung cancer is the leading cause of cancer-related human deaths worldwide, but primary lung cancer remains relatively uncommon in pet dogs and cats. The incidence of primary lung cancer in dogs and cats presenting for necropsy is less than 1%.[256–258] Incidence rates in dogs range from 4.2 per 10,000 dogs per year in the United States to 15 per 100,000 dogs per year in the United Kingdom.[259,260] In contrast, the incidence of pulmonary neoplasia was 8.8% in a closed colony of beagles, with a high incidence of pulmonary tumors in dogs dying after the median lifespan of 13.6 years.[261]

The average age of dogs diagnosed with primary lung tumors is approximately 11 years,[256,262] with the exception of anaplastic carcinomas that occur at an average age of 7.5 years.[263] The Boxer, Doberman, Australian shepherd, Irish setter, and Bernese mountain dog breeds are possibly overrepresented.[256,262,264] The average age of cats with pulmonary tumors is 12 to 13 years.[258,263,265] Persian cats have been reported to be overrepresented.[266]

In people, the risk of developing primary lung cancer is strongly associated with environmental tobacco exposure, but no definitive risk factors have been identified in dogs and cats. Urban living and second-hand smoke exposure have both been implicated as potential causes of lung cancer in dogs but are yet to be clearly demonstrated.[267,268] An increased risk of lung cancer was found in dogs with increased amounts of anthracosis, suggesting an association between inhalation of polluted air and lung cancer.[269] Anthracosis has also been correlated to high EGFR expression in canine primary lung tumors.[270] Cytologic analysis of bronchoalveolar lavage fluid also revealed increased anthracosis in dogs exposed to passive tobacco smoke compared with dogs without a history of exposure.[271] In the experimental setting, laboratory dogs trained to smoke cigarettes through a tracheostoma (in the presence or absence of asbestos exposure) did develop lung cancer at a higher rate than control dogs.[272,273] Experimentally induced exposure to radiation, such as plutonium, also significantly increases the occurrence of lung cancer when inhaled as an aerosol in research dogs.[274,275]

Pathology and Natural Behavior

Pulmonary tumors can arise from any tissue in the lung, but most commonly they originate from the epithelium of the airways or alveolar parenchyma. Tumors derived from epithelium of large airways are typically located near the hilus, whereas parenchymally derived tumors tend to be peripherally located. However, in the most recent World Health Organization (WHO) guidelines on classification of pulmonary neoplasms, lung tumors of domestic animals are largely classified by histologic pattern and not by site of origin.[264]

Approximately 85% of canine primary epithelial lung tumors are bronchoalveolar in origin, whereas adenocarcinoma, adenosquamous carcinoma, and SCC collectively comprise the remaining 13% to 15% of primary epithelial lung tumors.[261,262] Primary pulmonary histiocytic sarcoma (HS) may also represent a significant percentage of diagnosed lung tumors, particularly in predisposed breeds such as miniature schnauzers.[276–278] Adenocarcinoma represents 60% to 70% of feline lung tumors, whereas bronchoalveolar carcinoma, SCC, and adenosquamous carcinoma are less common.[264,265] Small cell carcinoma represents approximately 25% of human pulmonary neoplasms, but rarely occurs in the dog or cat.

Lung tumors can spread by local invasion or via hematogenous and lymphatic routes, resulting in locoregional spread to other areas of the lung or LNs, or distant metastasis. Intrapulmonary metastases are believed to occur through vascular and lymphatic invasion or intraairway seeding. Local vascular or lymphatic invasion was present in 71% of canine pulmonary malignant tumors in one study, and 23% had distant metastasis beyond the tracheobronchial LNs.[262] SCC and anaplastic carcinomas have metastatic rates exceeding 50% and 90%, respectively, and are more likely to metastasize than adenocarcinoma or bronchoalveolar carcinoma.[258]

Metastasis is common in the cat with a reported metastatic rate of 76%.[265] The size of the largest mass has also been associated with metastatic potential in the cat.[266] Metastasis to bone or the nervous system is not uncommon in dogs or cats. Metastasis to the digits, otherwise known as acrometastasis or lung-digit syndrome, is a common and well-described clinical phenomenon in cats.[279,280]

Clinical Signs and Physical Examination Findings

Dogs and cats are often diagnosed with a primary pulmonary tumor incidentally during a routine geriatric screen.[256,261,281] Up to 30% of cases of primary pulmonary tumors will be diagnosed without the presence of clinical signs.[281] The most common clinical sign reported in dogs with pulmonary neoplasia is coughing, which is noted in 52% to 93% of dogs.[256,281–284] Other clinical signs include dyspnea (6%–24%), lethargy (12%–18%), hyporexia (13%), weight loss (7%–12%), hemoptysis (3%–9%), and lameness, likely secondary to hypertrophic osteopathy (HO, 4%).[281–283]

The clinical signs in cats are similar to dogs; however, the occurrence of these signs is variable and gastrointestinal signs may be noted as well.[285,286] As in dogs, signs referable to the respiratory tract are common with dyspnea (20%–65%), cough (29%–53%), tachypnea (9%–14%), and hemoptysis (10%) being noted regularly.[285–289] Recently, a study found that 5 of 35 cats with spontaneous pneumothorax had intrathoracic neoplasia and at least three

VetBooks.ir

of these cats had a primary pulmonary carcinoma.[290] Nonspecific signs, such as lethargy and hyporexia, can be seen in 14% to 43% and 19% to 71% of cats, respectively.[285–289] Vomiting/regurgitation and diarrhea are seen in approximately 19% of cats with primary pulmonary neoplasia.[285,286]

Abnormal physical examination findings consistent with pulmonary neoplasia are often not seen.[282] Increased bronchovesicular sounds may be auscultated in dogs with extensive pulmonary involvement.[282] As pleural effusion can occur in many cases, dull lung and heart sounds may also be noted.[281,285,286] Metastasis to the nervous system has been reported in several cases of primary pulmonary tumors and neurologic abnormalities can be diagnosed on physical examination.[291–294]

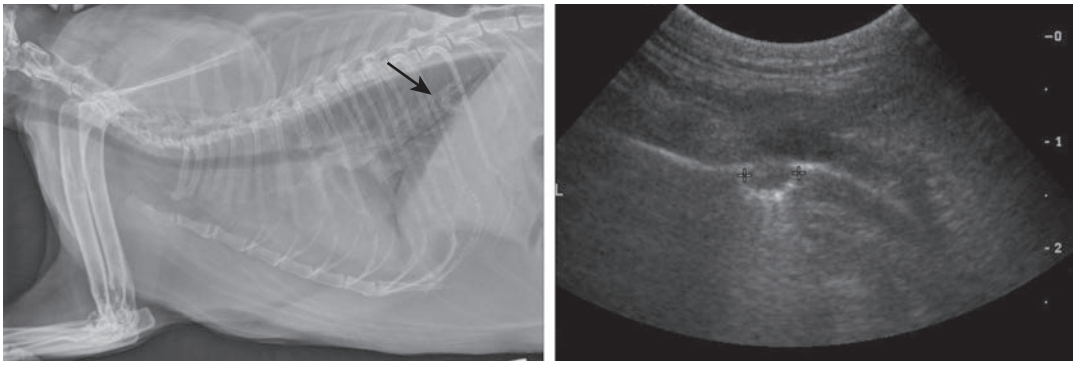
Lameness can occur in dogs and cats associated with primary pulmonary neoplasia for a variety of reasons. HO is a paraneoplastic syndrome commonly associated with primary and metastatic lung tumors, although other malignant and nonmalignant diseases have resulted in HO.[283,295–300] The disease is characterized by periosteal new bone formation at a site distant to the primary tumor. Dogs with HO tend to present with several clinical abnormalities including limb swelling, lameness, ocular signs, and lethargy.[300] The prevalence of ocular signs (occurring in 23 of 30 dogs) in a recent study evaluating HO was an interesting finding; an exact association between HO and ocular signs was not able to be determined retrospectively in that cohort, but it is important to evaluate for this in dogs with HO.[300] Lameness may improve with removal of the lung tumor.[295,298]

Several reports of cats with concurrent pulmonary neoplasia and digit metastasis can be found in the veterinary literature; this phenomenon has been noted with both pulmonary adenocarcinoma and SCC.[279,301–304] Cats naturally have significant blood flow to their digits to allow for heat loss and it has been theorized that this flow and the ability of pulmonary tumors to metastasize hematologically may work together to produce this unique metastatic pattern;[301] however, other factors contributing to a favorable metastatic microenvironment are likely to be involved. Of 36 cats with metastatic bronchogenic carcinoma to the digit in one study, all presented for lameness and none had respiratory signs.[304] The authors of that study concluded that thoracotomy with lung lobectomy and digital amputation should not be recommended as nonrespiratory disease often progressed and metastatic lesions in other digits resulted in continued lameness.[304] The MST for cats undergoing digit amputation was only 67 days.[304]

Diagnostics

Clinical Laboratory Findings

A complete blood count and serum chemistry panel are unlikely to signal the presence of a pulmonary mass.[265,304] These diagnostics, however, are essential to the preanesthetic and overall evaluation of a patient undergoing treatment for a pulmonary neoplasm. In one study, neutrophilia was noted in 50% of dogs with HO.[300]



The presence of pleural effusion at diagnosis is less common in dogs than cats. When pleural effusion is noted, a sample should be obtained via thoracocentesis. The pleural fluid tends to be a clear or blood-tinged modified transudate.[281,285] Fourteen percent to 30% of cats with primary pulmonary tumors have concurrent pleural effusion.[265,287–289] In one study, 13 of 26 cats underwent thoracocentesis to obtain fluid for analysis; fluid was diagnostic for a primary lung tumor in 12 of these cats.[265] However, in a separate study, fluid analysis was diagnostic for a malignant neoplasm in only one of eight cats.[285] Of three dogs with pleural effusion in one study, one dog was diagnosed with carcinoma based on evaluation of fluid obtained by thoracocentesis.[281]

Bronchoalveolar lavage (BAL) and transtracheal washes have been advocated as a method of diagnosing pulmonary neoplasia.[281,305–307] In a series of dogs that underwent BAL to aid in the diagnosis of respiratory tract diseases, carcinomas were identified in 14 dogs. Of those 14 cases, the BAL was definitive, supportive, or not helpful in eight, four, and two dogs, respectively.[306] Transtracheal washes have been less successful; of six dogs in one study with confirmed primary pulmonary neoplasia, none of the washes yielded neoplastic cells.[281]

Thoracic Radiographs

The majority of pulmonary tumors are diagnosed on thoracic radiographs (Fig. 24.12) and (Fig. 24.13). When evaluating 277 dogs from two large case series, 83% of pulmonary tumors were visible on thoracic radiographs.[281,283] Radiographic evidence of solitary or multiple pulmonary masses are present in 67% to 91% of cats with primary pulmonary tumors.[265,286]

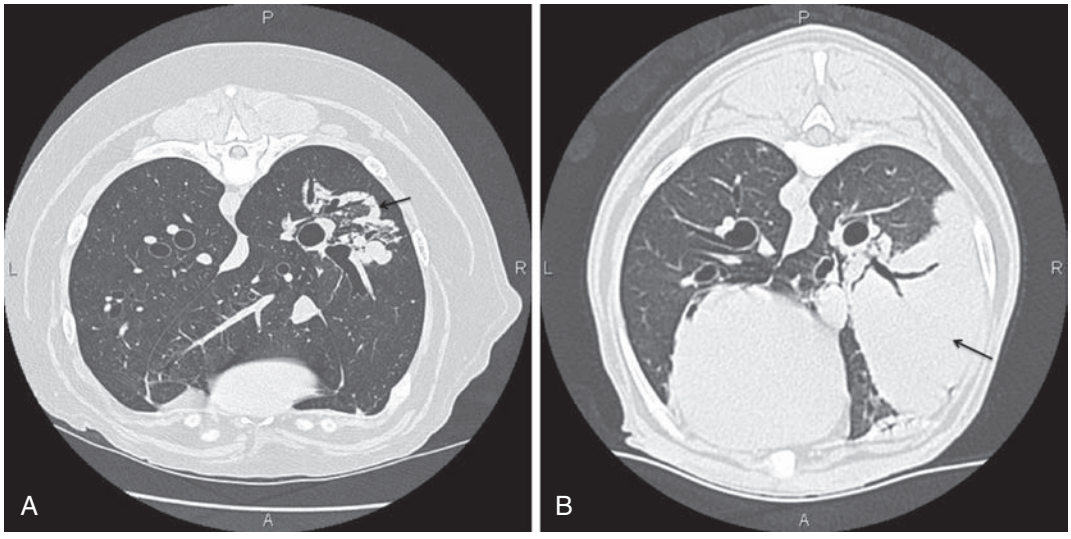
Several studies have evaluated tumor location and number within the lungs.[256,282,283] Single and multiple masses were found in 54% to 87% and 13% to 37% of dogs, respectively, in two studies.[282,283] A side predilection has not been reported with the

• **Fig. 24.12** Right lateral radiograph and ultrasound image of a pulmonary carcinoma (noted by *black arrow*) in the left caudal lung lobe of a cat.

left and right lung lobes affected in 24% to 50% and 50% to 76% of dogs, respectively.[256,282] Clinical signs were not noted until the pulmonary tumor grew to at least 3 cm in size in another study.[261]

In a study of 86 cats with primary pulmonary neoplasia, the location was determined radiographically in all cases.[265] Tumors were left-sided in 26 cats, right-sided in 27 cats, and bilateral in 33 cats.[265] In 45 cats, the tumors were found in a single lung lobe and the right and left caudal lung lobes were more commonly involved (34) than the right and left cranial (9) or right middle lung lobes (2).[265] In one study, 19 cats had a single lung lobe affected whereas two cats had multiple lesions.[286] Of 17 cats in a separate study, all single lesions were left-sided; however, 10 of these cats had multiple lesions (both right and left-sided).[285]

The radiographic pattern of primary pulmonary neoplasia has been variably reported in dogs and cats. Three radiographic patterns were described in a study evaluating 41 cats with primary pulmonary tumors: focal (nodules or masses), localized (lobar or segmental consolidations involving one or more lobes), and diffuse (involved most of both lungs).[308] In the focal group, 65% demonstrated solitary masses and 35% demonstrated multiple masses.[308] Recently, a study in dogs aimed to use radiographic features to distinguish between tumor types and compared pulmonary adenocarcinoma, bronchoalveolar carcinoma, and HS.[309] In this study, HSs were significantly larger than carcinomas and were more commonly found in the right middle (43%) and left cranial (38%) lung lobes.[309] Additionally, 57% of dogs with HS had internal air bronchograms. Adenocarcinomas were more often diagnosed in the left caudal lung lobe (29%).[309] Another study noted that in 19 of 29 dogs with pulmonary HS, the mass was located in the right middle lung lobe and this was significantly more common than other locations.[310]



• **Fig. 24.13** Left lateral radiograph of a Bernese mountain dog with histiocytic sarcoma. A large soft tissue mass in the region of the ventral right middle lung lobe and tracheobronchial lymphadenomegaly are observed.

Thoracic Ultrasound

Thoracic ultrasound may be employed to assess pulmonary neoplasia or to obtain a sample of tissue via FNA or pretreatment biopsy. The ultrasonographic appearance of pulmonary neoplasia has been described in several studies.[311–313] Pulmonary masses may be hypoechoic or exhibit variable echogenicity, and tumors are generally considered to have both a lack of discernable bronchi and normal branching vessels.[311,312]

Thoracic Computed Tomography

Thoracic CT scans are gaining popularity for the preoperative assessment of patients with pulmonary neoplasia (Fig. 24.14). Recently the CT findings of primary lung tumors were described in dogs and cats.[287,288,314] Several characteristics of solitary lung tumors were noted with CT in a majority of canine cases; 17 of 18 were well circumscribed, 16 of 19 were located in a cranial or caudal lobe, and 14 of 18 were located in the center to periphery of the lobe.[314] Internal mineralization was an uncommon finding being diagnosed in only 3 of 19 cases.[314] In one study, no association between the features

• **Fig. 24.14** Transverse computed tomography scan images of (A) a right caudal lung lobe histiocytic sarcoma *(black arrow)* in a 9-year-old Bernese mountain dog; and (B) a right caudal lung lobe pulmonary carcinoma *(black arrow)* in a 10-year-old fox terrier.

noted on CT and tumor type was identified, but intrapulmonary metastasis detected by CT was common, being noted in 53% of cats.[288]

Thoracic CT has been shown to be more accurate than thoracic radiographs in the assessment of tracheobronchial LN metastasis.[284] In 14 dogs with primary pulmonary tumors, the accuracy of CT to determine tracheobronchial LN metastasis was 93% compared with 57% for thoracic radiography.[284] Additionally, five dogs deemed to be free of pulmonary metastasis with thoracic radiographs were found to have pulmonary metastasis with CT.[284] In a separate study evaluating CT characteristics of tracheobronchial LN metastasis, 16 of 18 dogs were diagnosed with primary pulmonary tumors and these dogs were compared with 10 normal dogs.[315] Metastatic disease to LN was significantly more likely when a transverse maximum LN diameter of 12 mm or LN-to-thoracic body ratio of 1.05 were used as cutoffs.[315] Additionally, LN heterogenous and/or ring contrast enhancement patterns were significantly related to metastatic disease.[315]

In a study evaluating the assessment of pulmonary metastatic disease in 18 dogs (two of which had bronchoalveolar carcinoma) by thoracic radiography and CT, only 9% of CT-detected pulmonary nodules were noted on thoracic radiographs.[316] CT was able to detect pulmonary nodules as small as 1 mm, whereas the smallest lesions detected with thoracic radiography were 7 to 9 mm.[316] Overall, CT was significantly more sensitive than thoracic radiography in the identification of pulmonary nodules.[316] In a separate study, CT was able to detect a greater amount of nodules compared with computed and film-screen radiography.[317] Additionally, CT was better at identifying smaller nodules and was associated with greater diagnostic confidence and observer accuracy and agreement.[317]

Other Imaging Modalities

The use of positron emission tomography (PET) is uncommon in veterinary patients, but some early data regarding its use are available.[318–320] In one report, ^{18}fluorodeoxyglucose (^{18}FDG) was administered as a radiotracer to evaluate a dog with pulmonary nodules. Increased ^{18}FDG uptake was noted in four nodules and these were identified as pulmonary adenocarcinoma at necropsy.[319]

Near-infrared (NIR) imaging was recently evaluated in eight dogs with primary pulmonary tumors.[321] In this study, pulmonary tumors and normal lung were both imaged. In situ, the tumor was easily pinpointed with NIR imaging and all eight tumors appeared equally fluorescent to the surgeon.[321] An additional interesting finding was that NIR imaging was able to accurately distinguish normal lung parenchyma from neoplastic tissue, but could not distinguish peritumoral inflammation from neoplastic tissue.[321] The intraoperative use of NIR imaging modality may better facilitate tumor resection.

Fine-Needle Aspiration

FNA of a pulmonary mass may be performed before lung lobectomy to attempt to obtain a cytologic diagnosis. FNA is often performed with ultrasound- or CT-guidance; however, blind aspirates have been reported.[265,313,322,323] Sedation is generally required to prevent iatrogenic trauma during the aspiration process. In dogs, preoperative FNA with cytology has resulted in a diagnosis in 38% to 90% of cases.[281–283] Diagnosis of primary pulmonary neoplasia in cats is reportedly higher with 80% to 100% of cases being diagnosed by FNA and cytology.[265,286,322]

Pretreatment Biopsy

A pretreatment biopsy (biopsy performed before definitive therapy) can be performed before lung lobectomy, although the clinical relevance is questionable.[324] A pretreatment biopsy may be considered if histologic grade or degree of differentiation is required before an owner is willing to consider lung lobectomy or there is suspicion that a pulmonary neoplasm is not a primary tumor (i.e., either metastatic or systemic neoplasia such as lymphoma). However, if the eventual goal is to remove the pulmonary tumor with a lung lobectomy, then a pretreatment biopsy is unnecessary because the biopsy result will not change the surgical recommendation or the owner's willingness to treat. Multiple techniques for performing a pretreatment biopsy have been described, including utilizing a biopsy needle, bronchoscopic biopsy, keyhole incision with staple application, and thoracoscopy.[265,281,283,307,323–325]

Sedation or anesthesia is required to perform a pretreatment needle-core biopsy. The use of ultrasound-, fluoroscopic- or CT-guidance is recommended to improve targeting of the lesion and decrease the risk of iatrogenic trauma to normal structures.[313,323,324] In a study of dogs and cats undergoing CT-guided tissue-core biopsies of intrathoracic lesions (including pulmonary tumors), the diagnostic accuracy was 92% and the sensitivity for diagnosing neoplasia was 80%.[323] A procedural complication rate of 43% was reported with pulmonary hemorrhage (30%) and pneumothorax (27%) the most common complications.[323]

Bronchoscopic biopsy has been performed in dogs and cats with pulmonary neoplasia with mixed success.[265,283] Bronchoscopic findings in patients with primary pulmonary neoplasia include narrowing of bronchi, mucosal erosions, and mucosal swelling and hyperemia.[326] In one series of seven cats, five cats were successfully diagnosed by means of endoscopic bronchiolar brushing.[265]

A keyhole lung biopsy technique has been described for non-neoplastic lung disease.[307] For this technique, a lung biopsy is obtained via a small thoracotomy (3–7 cm) with a surgical stapler applied across the lung lobe to seal vessels and small airways.[307] Thoracoscopy is a minimally invasive surgical option to obtain a pretreatment biopsy.[327] In a study describing the use of thoracoscopy to determine the cause of pleural effusion in 18 cats and dogs, biopsies of several suspicious intrathoracic lesions were performed.[328] In eight cases, neoplasia was the cause of the pleural effusion, although the number of primary pulmonary tumors resulting in pleural effusion was unknown.[328] Thoracoscopy provided a means to both biopsy lung lesions and explore the thoracic cavity.[328]

Differentiating poorly differentiated primary lung tumors from metastatic lesions can occasionally provide a diagnostic challenge, particularly when evaluating cytology. Immunohistochemistry or possibly immunocytochemistry using antibodies directed against thyroid transcription factor-1, cytokeratin, vimentin, or others may be useful in differentiating primary lung tumors from metastatic disease.[329–332] Antibodies against CD18 and CD204 may also be useful for differentiating pulmonary tumors of histiocytic origin.[333–335]

Treatment

Surgery

Surgery is the treatment of choice for dogs and cats with primary pulmonary tumors. The surgical approach to a pulmonary tumor is dependent on the clinician and tumor location, but certain overarching criteria exist. For unilateral tumors, a lateral thoracotomy is preferred, but a median sternotomy approach can also be used. Thoracoscopic lung lobectomy is feasible if the mass is peripherally located and in a suitable location; however, this surgery requires advanced training in minimally invasive procedures. If nodules in multiple lobes are found bilaterally and the goal is to remove all gross disease, then a median sternotomy should be performed.

Both partial and complete lung lobectomies have been described and the elected technique is based on the location of the tumor. In general, a complete lung lobectomy should be performed; however, partial lung lobectomy may be an option for small tumors located in a peripheral position on the lung lobe or for pulmonary metastatectomy. A cuff of normal tissue should be removed with the tumor to increase the chance of obtaining a wide margin.

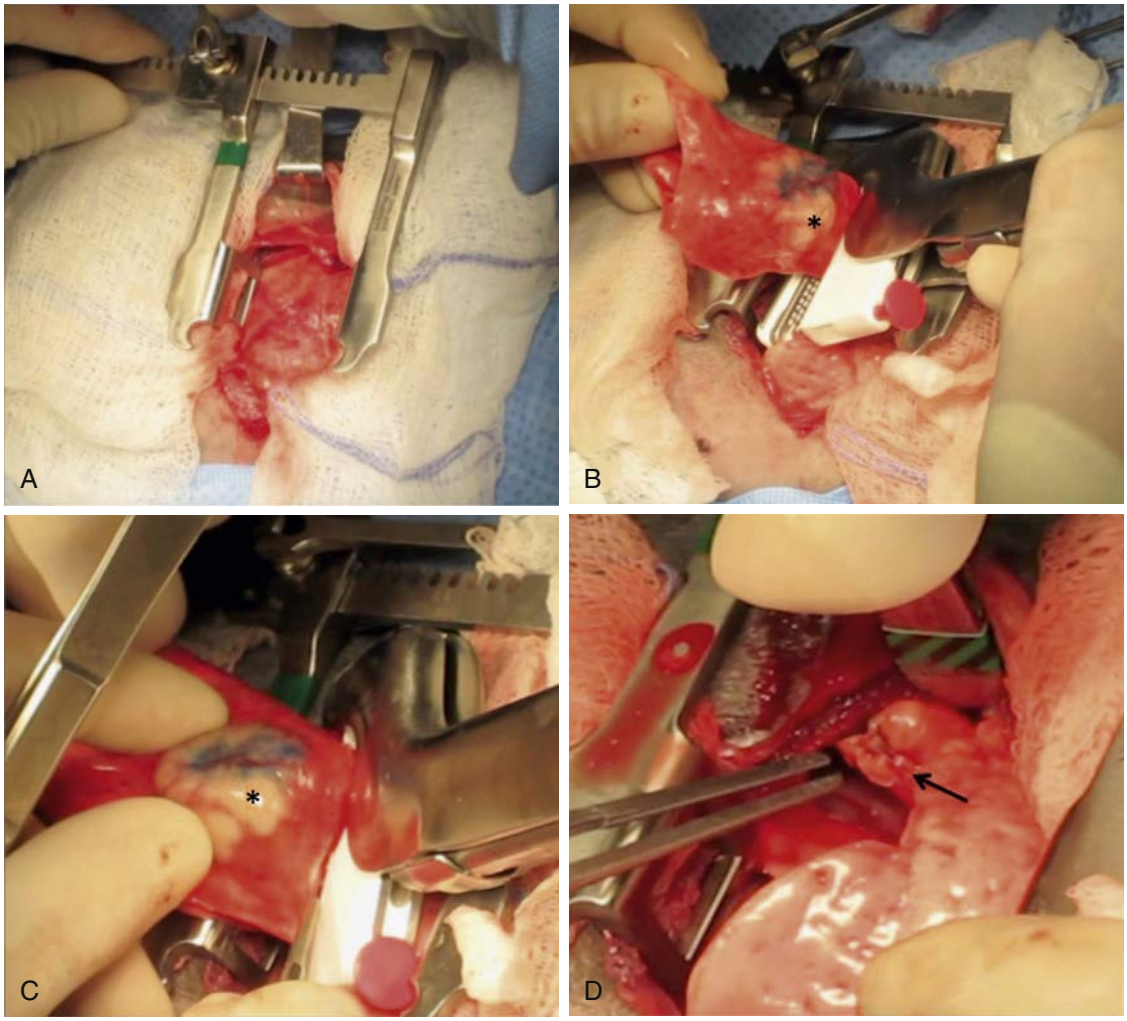
Partial and complete lung lobectomies are generally performed with either a suturing method or the use of a surgical stapler. When performing a partial lung lobectomy with the suture method, the area to be removed is delineated by placing crushing forceps proximal to the lesion.[336] A continuous overlapping suture can then be placed proximal to the clamps.[336] The pulmonary artery and vein are individually ligated, and the bronchi are oversewn to prevent air leakage.[334]

Several studies have evaluated the use of stapling equipment for lung lobectomy.[282,337,338] In a study of 37 dogs and cats undergoing resection of pulmonary lesions (67% were neoplastic) with surgical staplers, complications were minimal and the technique was considered safe, fast, and efficient.[337] Use of surgical staplers is widely considered to be the technique of choice for partial and complete lung lobectomy.

Two recent studies evaluated outcomes after pneumonectomy, which is defined as the removal of the entire left or right lung fields.[339,340] In total, 33 dogs and 17 cats had a pneumonectomy performed and, of these, 18 dogs and 4 cats were diagnosed with pulmonary neoplasia.[339,340] Perioperative mortality rates were low with 94% of dogs and 86% of cats surviving to discharge in one study.[340] The partial pressure of oxygen was significantly higher and alveolar-arterial gradient was significantly lower post-pneumonectomy compared with dogs treated with single lung lobectomy.[340]

Thoracoscopy can be used to explore the thoracic cavity, obtain biopsies (Fig. 24.15),[327,328] and perform thoracoscopic or thoracoscopic-assisted lung lobectomy.[341–345] In the largest study to date, 22 medium-to-large breed dogs underwent video-assisted thoracoscopic surgery (VATS) for lobectomy of primary lung tumors, and this group was compared with a cohort of dogs treated with lung lobectomy via an open thoracotomy.[345] In this study, an endoscopic stapler was used for lung lobectomy via either a three- or four-port technique.[345] Short-term complications were similar between the two approaches, and all VATS patients survived to discharge. Surgery time for VATS was significantly longer than open thoracotomy (120 vs. 95 minutes, respectively).[345] In a second study of nine dogs with either primary or metastatic pulmonary neoplasia, thoracoscopic lung lobectomy was performed successfully in five dogs.[341] Cases that were deemed to be good candidates for thoracoscopic removal in this study included dogs with small masses located distant to the hilus. Caudal lung lobectomy was easier than cranial lung lobectomy; however, both were performed successfully.[341] Conversion rates for thoracoscopic lung lobectomy are between 9% to 23% and conversion is most commonly performed due to poor visualization.[341,344,345] One-lung ventilation should be considered in cases of thoracoscopic lung lobectomy to improve visualization.[341,342,346,347]

Biopsy of tracheobronchial LN is recommended in dogs and cats as a staging tool, as metastatic disease to the LN significantly affects prognosis.[284,287] The LNs are located dorsally along the trachea and bronchi, and hence exposure may be better via a lateral thoracotomy compared with a median sternotomy. Thoracoscopic LN biopsy is performed regularly in human lung cancer patients,[341,348] and this was recently described in dogs.[349] In this report, seven of eight purpose-bred research dogs successfully underwent tracheobronchial LN extirpation. Complications were minor, although further study is needed to determine the use of this technique in clinical patients.[349]



Chemotherapy

Cisplatin-based chemotherapy protocols are considered the standard of care for human lung cancer patients, either in the adjuvant or palliative setting.[350] Relatively little is known about the efficacy of chemotherapy for pulmonary tumors in domestic animals; however, chemotherapy has been largely unrewarding in the gross disease setting. Early clinical trials evaluating the safety and efficacy of doxorubicin in cancer-bearing pet dogs included one dog with papillary pulmonary adenocarcinoma, and this dog had progressive disease.[351] No responses were seen in three dogs with lung adenocarcinoma treated with mitoxantrone.[352] Minimal responses were reported in two dogs treated with vindesine, whereas two dogs treated with the combination of vindesine and cisplatin both experienced greater than 50% reduction in measurable disease.[282] Treatment with vinorelbine resulted in partial responses in two of seven dogs with measurable bronchoalveolar carcinoma.[353] Three additional dogs with microscopic disease were treated with adjuvant vinorelbine in the microscopic disease setting, and these dogs had individual survival times (STs) of 113, 169, and greater than 730 days.[353] Pharmacokinetic studies in humans have concluded that vinorelbine treatment results in 300-fold higher concentration in the lung compared with plasma, which is 3.4- and 13.8-fold higher than lung concentrations of vindesine and vincristine, respectively.[354] Based on observed partial responses in dogs and pharmacokinetic data in people, treatment with vinorelbine or cisplatin appears to hold the most promise for dogs with primary lung carcinoma. CCNU (lomustine) is recommended for dogs with localized pulmonary HS.[355]

Delivery of aerosolized chemotherapy or cytokines has been described and appears well tolerated in dogs with primary or metastatic pulmonary neoplasia. Complete and partial responses have been described in dogs treated with inhalational therapy for metastatic tumors, whereas stable or progressive disease was reported in dogs with primary lung tumors.[356,357]

Treatment with monoclonal antibodies or small-molecule tyrosine kinase inhibitors (TKIs) directed against cell signaling pathways have been shown to be beneficial in distinct subpopulations of human patients with nonsmall cell lung cancer (NSCLC). Such targeted therapies have yet to be thoroughly examined in dogs with primary lung tumors. In a phase I study, monotherapy with

VetBooks.ir

• **Fig. 24.15** (A) A lateral thoracotomy is being performed to allow for removal of a primary pulmonary carcinoma. (B) The lung lobe containing the tumor *(asterisk)* has been exteriorized and a surgical stapler is being positioned. (C) After placement of the surgical staples, the affected lung lobe is being transected to allow for removal. (D) The staple line *(black arrow)* can be seen after removal of the tumor. The line of resection is examined closely for leaks.

toceranib resulted in stable disease >10 weeks in one dog with a primary lung carcinoma.[358] Further research is warranted to determine the clinical efficacy of TKIs in the management of cats and dogs with primary lung tumors.

Malignant pleural effusions can be responsive to systemic chemotherapy, intrapleural chemotherapy, or a combination of both routes. Cisplatin, carboplatin, and mitoxantrone have been used successfully for this purpose, resulting in temporary palliation of clinical signs.[359–362] Sclerosing agents, such as talc or tetracyclines, have been also been used in a palliative setting.[363]

Radiation Therapy

Radiation therapy in physician-based medicine is most often reserved for locally advanced tumors.[364] Technologies such as intensity-modulated radiation therapy, stereotactic radiation therapy, or TomoTherapy can now be used to provide more precise delivery of radiation while sparing unaffected tissues, especially when used together with respiratory gating or breath hold techniques. The use of such modalities in veterinary patients is now becoming more accessible but remains to be systematically investigated in dogs and cats with lung tumors.

Interventional Therapy

Interventional oncologic techniques for the treatment of primary pulmonary neoplasia have not been described in the veterinary literature; however, several treatment options exist in human medicine for pulmonary neoplasia.[365–368] These options are generally reserved for cases of pulmonary metastatic disease, nonresectable pulmonary tumors, or patients for which surgery is contraindicated due to existing comorbidities.[366–369] Research into this field in veterinary patients is ongoing and some of these techniques are currently being investigated.

Thermal ablation (radiofrequency and microwave) and regional chemotherapy administration are two interventional oncology techniques that have been reported in the treatment of pulmonary neoplasia. Radiofrequency ablation (RFA) is performed by placing

VetBooks.ir

an electrode within a tumor and generating heat; the heat results in coagulative necrosis in a defined region.[365,367,368] The goal is to produce a 360-degree region of necrosis around the tumor with a 1 cm thick margin of normal tissue included.[365,367] RFA has been performed in dogs with experimentally induced transmissible venereal tumor of the lung.[370] In five dogs, RFA was applied percutaneously with CT guidance to 14 tumors. Upon harvest of the affected lung lobes, gross and histopathologic evaluations demonstrated complete thermal coagulation necrosis of all treated lesions, and viable tumor was not identified in any dogs.[370]

Regional chemotherapy has been developed with the goal of increasing the efficacy of chemotherapy agents and decreasing systemic side effects.[371] Regional delivery allows for increased concentrations of chemotherapy to be delivered to the tumor by selective catheterization of the tumoral arterial supply.[371] Regional techniques involving the administration of chemotherapy into the bronchial arteries and pulmonary arteries have been described in several human studies.[369,371,372] Recently, in an experimental model study, significantly higher concentrations of chemotherapy agents (gemcitabine and carboplatin) were noted in pulmonary tissue treated with regional techniques (selective pulmonary artery perfusion) than intravenous administration.[372] The indications and clinical use of these treatments, while developing, still remains to be determined in veterinary patients.

Prognosis

In one clinical study of 67 dogs undergoing removal of primary lung tumors, the overall MST was 361 days.[281] Prognostic factors included the presence of clinical signs, clinical stage, tumor type, and histologic grade. Dogs with clinical signs associated with a primary lung tumor had an MST of 240 days compared with 545 days for asymptomatic dogs. Dogs with single solitary lung tumors (T1 clinical stage) had an MST of 790 days, which was significantly longer than dogs with multiple lung tumors (T2 clinical stage, 196 days) and dogs with lung tumors invading into adjacent structures (T3 clinical stage, 81 days). Finally, the MST for dogs with grade I lung carcinomas was 790 days, and this was significantly longer than the MSTs of 251 days and 5 days for dogs with grade II and III lung carcinomas, respectively.[281]

One study evaluated the effect of several variables on remission and survival in dogs with primary lung tumors.[373] Dogs for which surgery was successful in rendering them free of macroscopic disease lived significantly longer than dogs that had gross disease postoperatively.[373] Factors significantly associated with remission included limited degree of primary tumor involvement, normal sized LNs, and lack of metastatic disease.[373] In a separate study of 15 dogs, trends for longer STs were noted in dogs with adenocarcinoma versus SCC, dogs with peripheral lesions versus lesions that involved an entire lobe, and dogs with tumor volume <100 cm^3 compared with dogs with tumor volume >100 cm^3.[282]

The MST for dogs with no evidence of LN (N0) was 452 days, and this was significantly longer than the MST of 26 days for dogs with tracheobronchial LN metastasis (N1).[281] In another study, dogs with LN enlargement diagnosed before surgery survived for a median time of 60 days, whereas dogs without LN enlargement had a MST of 285 days.[373] A similar finding was noted in a more recent study where dogs with lymphadenomegaly had MSTs of 126 days versus a MST that had not been reached in the dogs without lymphadenomegaly.[284] In dogs for which a surgical remission could be achieved, MST is 330 days versus 28 days in dogs that could not be rendered free of visible disease.[373] Although not statistically significant, the mean ST of dogs with SCC was 8 months and the mean ST of dogs with adenocarcinoma was 19 months in one study.[282]

A recent study evaluated 42 dogs with primary lung tumors and based the prognostic evaluation on the WHO classification scheme.[374] In these cases, 34 tumors were carcinomas (26 papillary adenocarcinomas) and eight were sarcomas. Fourteen of the carcinomas and two of the sarcomas were T1N0M0. Dogs with papillary adenocarcinomas and a clinical stage of T1N0M0 had the best overall prognosis with an MST of 555 days; this ST was significantly longer than dogs with any other tumor type or dogs with a worse clinical stage.[374] Dogs with other tumor types had an MST of 72 days.[374]

In regard to localized HS, one retrospective study reported that surgical excision and adjuvant therapy with CCNU resulted in an MST of 568 days.[355] Interestingly, five out of 16 dogs within that study had localized pulmonary lesions.

The prognosis is guarded to poor for cats with primary lung carcinomas. In one retrospective study of 21 cats treated with lung lobectomy,[286] the overall MST was 115 days. The only prognostic factor in this study was histologic grade; the MST for cats with moderately differentiated carcinomas was 698 days compared with only 75 days for cats with poorly differentiated carcinomas. In a separate study, cats with low-grade tumors had an MST of 730 days compared with 105 days for cats with high-grade tumors.[287]

Similar to dogs, LN enlargement in cats significantly decreased MST to 65 days from 498 days for cats with no evidence of lymphadenomegaly.[287] The TNM staging scheme also correlated with ST in cats; cats staged T1N0M0 live significantly longer than cats with higher stages.[286] In this same study, the MST in cats with clinical signs was 4 days compared with 578 days in asymptomatic cats.[289] Pleural effusion has been identified as a negative prognostic factor; in two studies, the MST were less than 3 days and 31 to 467 days in cats with and without pleural effusion, respectively.[287,289]

Comparative Aspects

Lung cancer is the leading cause of cancer deaths in the United States and worldwide.[375] Approximately 85% of human lung cancers are NSCLC, with the remainder being small-cell lung cancer. NSCLC are composed of three distinct histologic subtypes: SCC, adenocarcinoma, and large-cell lung cancer. Large airway origin tumors predominated in humans through the 1960s and were commonly associated with smoking cigarettes. Adenocarcinoma arising from the smaller airways now predominates in human patients, likely a result of changes to tobacco blends and the use of cigarette filters.[376]

If curative-intent resection can be performed, prognosis for human patients with NSCLC is largely dependent on clinical stage with 5-year survival rates greater than 60% to 70% for patients with stage I disease. Five-year survival rates are approximately 30% to 40%, 10% to 30%, and less than 5% for patients with stage II, stage III, and stage IV disease, respectively.[350]

Inherited cancer syndromes caused by germ-line p53 mutations, retinoblastoma (Rb), EGFR, and other genes have been reported to increase the risk of lung cancer. Furthermore, associations between single-nucleotide polymorphism variations have been linked to lung carcinogenesis and may be associated with nicotine exposure. DNA synthesis and repair genes may also play a role in the development and prognosis of lung cancer. Commonly acquired molecular abnormalities in human lung cancer include,

VetBooks.ir

but are not limited to, microsatellite instability, EGFR mutations, P53 inactivation, Rb inactivation, P16INK4a inactivation, allelic loss, and high telomerase activity. K-*ras* mutations have been found in up to 30% of human NSCLC.[377] Close homology exists between canine and human K-*ras*. Interestingly, K-*ras* mutations were detected in five of 21 canine NSCLC specimens by direct sequencing.[262] Further studies concluded that the frequency and type of mutations in canine NSCLC tissues more matched those for tumors from human nonsmokers with K-*ras* mutations than those for smokers.[262]

Recent developments in biomarker driven targeted therapies of lung tumors have improved survival rates for NSCLC patients, including those with EGFR mutations or anaplastic lymphoma kinase (ALK) rearrangements. The FDA has approved the use of several TKIs based on large prospective trials, and these drugs are considered part of first-line standard-of-care in certain molecularly defined subsets of patients with advanced NSCLC. Unfortunately, this pertains to only a minority of patients with NSCLC, and acquired resistance to such therapies is commonplace. EGFR expression has recently been associated with anthracosis and a trend toward shortened STs in dogs with primary lung tumors; however, mutational status of canine primary lung tumors has not been extensively performed.[270] An increased expression of PDGFR-α and ALK receptor phosphorylation has been found in canine pulmonary adenocarcinomas compared with normal lung tissue, but no increases in expression or activity of EGFR and no EGFR mutations were identified. EGFR mutant protein expression is present in 20% of cats with lung tumors, but this has not been evaluated in regard to prognosis or response to therapy.[266]

Even more recently, excitement has been centered around a series of accelerated FDA approvals for immune checkpoint inhibitors such as pembrolizumab (Keytruda), atezolizumab, and nivolumab for the treatment of NSCLC. Some of these approvals are based on tumor expression of PD-L1, but such biomarkers are continuing to be refined. Although PD-L1 expression in lung tumors appears to correlate with response to checkpoint inhibition, there is additional evidence showing that mutational load, neoantigen density, and tumor infiltration by cytotoxic T-cells may also predict response in other tumor histologies. Ongoing research is focused on refining biomarkers to better understand and predict which patients will respond to checkpoint inhibitors in addition to identifying which patients may be more at risk of severe adverse events.[378] Several groups have reported on the potential importance of checkpoint inhibition in naturally occurring canine tumors, and work is ongoing to develop canine checkpoint inhibitors [379–383] However, to date, no studies have thoroughly evaluated PD-1 or PD-L1 in canine lung tumors.

Miscellaneous Lung Condition: Canine Pulmonary Lymphomatoid Granulomatosis

Canine pulmonary lymphomatoid granulomatosis is a poorly understood disease occurring most commonly in young-to-middle aged dogs with no breed or gender predilection.[384] The most common laboratory abnormalities, as reported in seven dogs, were basophilia and leukocytosis. Lung lobe consolidation or large pulmonary granulomas and tracheobronchial LN enlargement are typically seen on thoracic radiographs. Transthoracic FNAs are not diagnostically rewarding. Differential diagnoses include heartworm granulomas, metastatic neoplasia, lymphoma, HS, and primary lung tumors. Traditionally, a definitive diagnosis requires biopsy and histopathology. Characteristic histopathology often demonstrates angiocentric and angiodestructive infiltration of the pulmonary parenchyma by large lymphoreticular and plasmacytoid cells in addition to normal appearing lymphocytes, eosinophils, and plasma cells. This infiltrate is typically centered around small to medium arteries and veins.

The etiology of this disease is unknown but is suspected to be neoplastic or preneoplastic. Clonality has been identified on PARR, but this finding needs to be investigated in a larger series of cases.[385] Additional molecular diagnostics, such as immunohistochemistry in combination with clonality testing, may eventually result in a better understanding of this disease.[386] It is not known whether flow cytometry or PARR testing may possibly improve the diagnostic power of fine-needle aspirates.

In a very limited number of cases, the response to chemotherapy has been quite variable.[387] Of five dogs that were treated with cyclophosphamide, vincristine, and prednisone, three dogs achieved a complete response. The remaining two dogs either showed worsening clinical signs or progressed to lymphoid leukemia within months. Dogs achieving a complete response were alive at 7, 12, and 32 months.

Tumors of the Skeletal System

NICOLE P. EHRHART, NEIL I. CHRISTENSEN, AND TIMOTHY M. FAN

Osteosarcoma in Dogs

Incidence and Risk Factors

Osteosarcoma (OSA) is the most common primary bone tumor in dogs, accounting for up to 85% of malignancies originating in the skeleton.[1–5] OSA is estimated to occur in more than 10,000 dogs each year in the United States; however, this is probably an underestimation because not all cases are confirmed nor recorded.[6,7] The demographics of canine OSA have been well reported.[8–19] It is largely a disease of middle-aged to older dogs, with a median age of 7 years. There is a large range in age of onset, with a reported case in a 6-month-old pup and a small early peak in age incidence at 18 to 24 months.[13] Primary rib OSA tends to occur in younger adult dogs, with a mean age of 4.5 to 5.4 years.[20,21] OSA is classically a cancer of large and giant breeds. In a review of 1462 cases of canine OSA, dogs weighing more than 40 kg accounted for 29% of all cases and only 5% of their tumors occurred in the axial skeleton. Only 5% of OSA occurred in dogs weighing less than 15 kg, but 59% of their tumors originated in the axial skeleton. Increasing weight and, more specifically, height appear to be the most predictive factors for OSA in dogs.[22] The breeds most at risk for OSA are Saint Bernard, Great Dane, Irish Setter, Doberman Pinscher, Rottweiler, German Shepherd, and Golden Retriever; however, size seems to be a more important predisposing factor than breed.[1,2,4,8,9,13,17,19,22] A hereditary basis for the formation of OSA has been suspected based primarily on the breed prevalence of the disease as well as the subjective assessment of increased incidence in some related families. With regard to gender, males are slightly more frequently affected than females (1.1–1.5: 1)[2,3,9,12,13,16] with the exception of the Saint Bernard, Rottweiler, and Great Dane, and for dogs with primary OSA of the axial skeleton (except rib and spine), in which affected females outnumber males.[2,21] Intact males and females have an increased risk for OSA.[22] However, in Rottweilers, male and female dogs that underwent gonadectomy before 1 year of age had an approximate one in four lifetime risk for bone sarcoma and were significantly more likely to develop bone sarcoma than dogs that were sexually intact.[23] There was a highly significant inverse dose-response relationship between duration of lifetime gonadal exposure and incidence rate of bone sarcoma independent of adult height or body weight.

Approximately 75% of OSAs occur in the appendicular skeleton with the remainder occurring in the axial skeleton.[2,21] The metaphyseal region of long bones is the most common primary site, with thoracic limbs affected twice as often as pelvic limbs and the distal radius and proximal humerus as the two most common locations.[11] In the pelvic limbs, tumors are fairly evenly distributed between the distal femur, distal tibia, and proximal tibia, with the proximal femur a slightly less common site.[2] Primary OSA distal to the antebrachiocarpal and tarsocrural joints is relatively rare in dogs.[24] In 116 cases of canine primary OSA in the axial skeleton, 27% were located in the mandible, 22% in the maxilla, 15% in the spine, 14% in the cranium, 10% in ribs, 9% in the nasal cavity or paranasal sinuses, and 6% in the pelvis.[21] Clinically documentable multicentric OSA at the time of initial diagnosis occurs in less than 10% of all cases.[25] OSA of extraskeletal sites is rare, but primary OSA has been reported in mammary tissue, subcutaneous tissue, spleen, bowel, liver, kidney, testicle, vagina, eye, gastric ligament, synovium, meninges, and adrenal gland.[26–31]

Etiology

The etiology of canine OSA is generally unknown. Some have speculated a viral cause because OSA can occur in litter mates and may be experimentally induced by injecting OSA cells into canine fetii.[32] However, an etiologic virus has not been isolated.

Physical Factors

A simplistic theory based on circumstantial evidence is that, because OSA tends to occur in major weight-bearing bones adjacent to late closing physes and heavy dogs are predisposed, multiple minor trauma and subsequent injury to sensitive cells in the physeal region may occur. This may initiate the disease by inducing mitogenic signals increasing the probability for the development of a mutant lineage. One in vitro study comparing the incidence of microdamage in cadaver radii of small and large breed dogs found no difference between the two groups.[33] OSA has been associated with metallic implants used for fracture repair, chronic osteomyelitis, and fractures in which no internal repair was used.[34–37] OSA has also been reported at the site of a bone allograft used for fracture repair 5 years previously.[38] Exposure to ionizing radiation can induce OSA.[31,39–47] In plutonium-exposed people, 29% and 71% of the OSAs were in the appendicular and axial skeleton, respectively, with the spine having the most tumors (36%). An almost identical distribution of plutonium-induced OSA was reported for dogs injected with ^{239}Pu as young adults in experimental studies. This distribution of OSA is quite different from the distributions of naturally occurring OSA for both species and appears to be related to bone volume and turnover. Similar findings were seen for dogs injected with ^{226}R.[47]

A distribution favoring bone marrow volume was seen for dogs exposed to strontium-90.[46] OSA is a rare, late complication of radiation therapy (RT) in dogs, with an incidence of less than 5%.[39,41,43–45]

Genetic Factors

Ample evidence exists implicating the involvement of genetic and heritable factors for the development of OSA in dogs. Currently, the most thoroughly described gene mutation that contributes to OSA formation and/or progression in dogs is p53, which is supported by in vitro and in vivo studies.[48–55] In cell culture, missense point mutations within the DNA-binding domain of p53 have been identified in canine OSA cell lines with consequent loss of p53 functionality demonstrated by inappropriate downstream target gene transcription (p21 and MDM2) after genotoxic insult.[50] Similarly, p53 mutations have been identified in dogs with spontaneously arising OSA through various genetic techniques including single-strand conformational polymorphism (SSCP), polymerase chain reaction (PCR), or Southern blotting, followed by nucleotide sequence analysis, whereby missense mutations involving exons 4 to 8 of p53 have been identified in 24% to 47% of all spontaneously arising OSA samples.[48,52,54,55] In addition to exons 4 to 8, the entire gene sequence of p53 has also been assessed by PCR and SSCP from 59 spontaneously arising appendicular and axial OSA samples with missense point mutations affecting p53 identified as the most common gene abnormality.[49] Finally, through the implementation of targeted microarray-based comparative genomic hybridization analysis of 38 canine OSA cases, similar recurrent cytogenetic aberrations classically present in human OSA samples were also identified in OSA specimens collected from dogs, including loss of heterozygosity (LOH) of the p53 gene in 18% of tumors.[56]

Substantiation for the presence of p53 mutations in sporadic canine OSA has also been documented by immunohistochemical studies, as a hallmark of many p53 mutations is enhanced protein stability of this normally labile protein, enabling detection of protein with methodologies such as immunohistochemistry (IHC).[57] In one study of 106 osteogenic tumors, a greater percentage of appendicular (84%) OSAs overexpressed p53 protein in comparison with OSAs arising from the axial skeleton (56%) and other non-OSA bone tumors (20%).[53] Analogously, in a complementary study focusing on 103 OSA samples, 67% stained positively for p53 protein and associated staining intensity was significantly greater in OSAs derived from the appendicular versus axial skeleton.[51] Recently, a homolog within the p53 family of proteins, specifically ΔNp63, has been identified to be involved in canine OSA cellular survival and metastasis. The functionality of ΔNp63 in canine OSA cell lines contributed to apoptosis resistance through perturbations in the balance of proapoptotic Bcl-2 family members, Puma and Noxa, as well as STAT3 phosphorylation and modulation of angiogenesis and invasion through VEGF-A and IL-8 expressions.[58]

Another tumor suppressor gene likely contributing to OSA development is retinoblastoma (RB). Based upon investigations using five tumorigenic immortalized canine OSA cell lines, the RB gene signaling pathway was dysregulated with the persistence of hyperphosphorylated RB protein in the absence of mitogen stimulation. Despite apparent aberrant RB gene signaling, reduction in RB protein was only identified in one of five cells lines.[50] Corroborating these in vitro findings, the evaluation of 21 spontaneously arising OSAs failed to identify gross RB gene alterations by Southern blotting, and protein expressions of RB were identified in all OSA samples evaluated.[52]

Despite normal protein expression of RB in canine OSA samples, the observed translational normalcy does not exclude the possibility for allelic deletion of the RB gene as prior studies in human OSA samples have demonstrated that LOH at the RB gene locus does not absolutely correlate with inactivation of the RB gene at the protein level.[59] Substantiating the possibility that RB gene may have allelic deletion in spontaneously arising canine OSA, analysis of 38 OSA samples with comparative genomic hybridization techniques identified copy number loss in 29% of cases, resulting in a correlative reduction or absence of RB protein expression in 62% of OSA samples tested.[56] Most recently, the importance of RB functionality in OSA biologic behavior has been explored with aberrant RB-E2F transcriptional regulation contributing to aggressive OSA biologic behavior and worse clinical outcomes. Collectively, these findings support the functional role of the RB-E2F signaling pathway in OSA biology.[60] Based upon these investigative findings, it is likely that aberrations in the RB gene or transcriptional activities participate in sporadic OSA formation and/or progression in dogs.

In addition to p53 and RB gene abnormalities, the phosphatase and tensin homolog (PTEN) tumor suppressor gene is suspected to participate in the genetic pathogenesis of canine OSA. Original in vitro studies conducted with canine OSA cell lines demonstrated that most cell lines (60%) harbored mutations in PTEN. Corroborating the cell line findings, expression of PTEN was either absent ($n = 6$) or variable ($n = 4$) in 15 spontaneously arising OSA samples.[61] Further support for the loss of PTEN gene in canine OSA pathogenesis has been the identification of specific recurrent chromosome copy number aberrations through targeted microarray-based comparative genomic hybridization studies, with the identification of chromosomal region deletions and high recurrent copy number losses encompassing the PTEN gene locus.[56,62] In addition to the PTEN gene, other genes identified by high resolution comparative genome hybridization studies potentially involved in the genetic pathogenesis of OSA included overexpression of RHOC and RUNX2 and under expression of TUSC3.[62] Most recently, through a comparative approach utilizing high resolution oligonucleotide array comparative genomic hybridization, additional disease-associated DNA copy number aberrations have been identified as an ever expanding list of gene candidates that may have functional significance in the development of OSA, including ADAM15, CTC1, MEN1, and CDK7.[63]

A growing body of evidence in dogs supports breed-associated inheritance of OSA, especially in Scottish Deerhounds, Rottweilers, Greyhounds, Great Danes, Saint Bernards, and Irish Wolfhounds.[26,64–69] The presumed hereditary basis for OSA in specific canine breeds has been affirmed through genome-wide analyses whereby 33 genetic loci were identified to contribute to heritable OSA in Greyhounds, Rottweilers, and Irish Wolfhounds. These findings are highly significant and point to a polygenic spectrum of germline risk factors for OSA development in these three breeds with putative genes involved in OSA genesis connected with bone differentiation and growth pathways.[70] Another breed at risk is the Scottish Deerhound with a 15% incidence of OSA[65–67] and a narrow heritability of 0.69, which indicates that 69% of the cause for OSA development in Scottish Deerhounds is due to heritable trait, likely a Mendelian major gene with dominant expression.[67] A confirmatory study of familial OSA development in Scottish Deerhound litters further supports that the inheritance of OSA in

this breed could be explained by a single genetic risk factor residing within an autosome.[71]

Although the putative contribution of specific genes in canine OSA development and biology has been more thoroughly explored, the role of microRNAs (miR) and their differential expression, which might contribute to OSA behavior, has recently been studied. In a comparative investigation with human and canine OSA tissue samples with clinically linked data, decreased expression of orthologous miR-134 and miR-544 in canine OSA samples imparted a reduced likelihood of survival and suggest that miR-134 and miR-544 might transcriptionally regulate target genes involved in aggressive behavior.[72] Similarly, the overexpression of miR-9 in canine OSA cell lines was shown to promote a metastatic phenotype through the upregulation of gelsolin, a protein involved in cytoskeletal remodeling.[73] Additionally, the loss of miR-34a in canine OSA cell lines resulted in the enrichment of genes responsible for cell invasion and motility, whereas the forced expression of miR-34a exerted potential anticancer effects through reduced expressions of KLF4, SEM3A, and VEGFA transcripts.[74] Collectively, these initial findings exploring the regulatory role of miRNAs demonstrate their likely contribution to canine OSA biology and pathogenesis.

Molecular Factors

Given the heterogeneous and chaotic nature of OSA, it has been difficult to definitively ascribe specific molecular derangements responsible for the etiopathogenesis of OSA.[75] Nonetheless, substantive progress has been achieved through experimental, preclinical, and comparative investigations to identify dysregulated intracellular signaling and cell survival pathways likely to participate in the pathogenesis of OSA. Significantly, the identification and tumorigenic consequences of several putative pathways have been characterized in immortalized OSA cell lines and spontaneously arising OSA tissue samples.

Tyrosine Protein Kinase MET

The MET protooncogene encodes a tyrosine kinase receptor which, upon ligation with hepatocyte growth factor (HGF), mediates multiple cellular functions including cell scattering, motility, and proliferation. Given its biologic activities, excessive or dysregulated MET signaling in canine OSA has been demonstrated to promote tumorigenic phenotypes in cell lines.[76–78] Furthermore, in a small pilot study with spontaneously arising OSA samples, the expression of MET protooncogene was identified in the majority (71%) of tumor specimens by northern blot analysis.[79] Additionally, a novel germline mutation resulting in enhanced receptor phosphorylation and aberrant MET signaling has been identified primarily in the Rottweiler breed.[80] In a larger study of 59 primary OSA samples, mRNA expression of MET and HGF was detected by real-time PCR (RT-PCR) in all specimens; this suggested the existence of a putative MET/HGF autocrine or paracrine feedback loop.[81]

Insulin-like Growth Factor

The cellular effects of growth hormone (GH) are mediated through the hepatic production of insulin-like growth factor 1 (IGF-1). In osteoblasts, IGF-1 induces cell mitogenesis and protection from apoptosis, as well as promotes angiogenesis. Derived from experimental and preclinical investigations, aberrant or excessive IGF-1 signaling likely participates in OSA pathogenesis. In three canine OSA cell lines, the expression and functionality of the IGF-1/IGF-1 receptor signaling cascade has been reported.[82] Recently, the activation and prognostic significance of the IGF pathway has been investigated in canine OSA cell lines and pet dogs, respectively. In cell lines, molecular studies demonstrated that IGF-1R is expressed and functionally activated by IGF-1 in a paracrine manner and leads to the activation of both MAPK and AKT signaling nodes. Importantly, the protein expression of IGF-1R in canine OSA tissue samples showed that most (71%) naturally occurring tumors express this receptor and that higher expression levels of IGF-1R correlated with a decreased survival time (ST).[83]

Epidermal Growth Factor

The protooncogene erbB-2 encodes human epidermal growth factor receptor 2 (HER2), which is a tyrosine kinase receptor capable of promoting cell transformation and growth. In both dogs and people, the overexpression of HER2 protein as a result of gene amplification is a negative prognostic factor in mammary carcinoma; however, less clarity exists for the role of HER2 overexpression in OSA.[84,85] To better characterize HER2 expressions in canine OSA, one study evaluated HER2 mRNA transcript and protein expression in seven cell lines and 10 OSA tumor specimens.[86] Based on RT-PCR, six of the OSA cell lines and 40% of primary OSA tumor samples overexpressed HER2; results of the study suggested the possibility of HER2 overexpression as a negative prognostic factor for survival.

Mammalian Target of Rapamycin

The mammalian target of rapamycin (mTOR) is an evolutionary conserved protein kinase downstream of AKT, which acts as a central hub for the integration of cellular signals induced by growth factors, nutrients, energy, and stress for the purposes of regulating cell cycle progression and growth. As such, aberrant signaling through the mTOR pathway contributes to growth, survival, and chemotherapy resistance in multiple tumor types. To characterize the functionality of the mTOR pathway in canine OSA, one study using three canine OSA cell lines investigated the expressions of mTOR and p70S6K, a downstream effector protein of mTOR, and demonstrated pathway activity and capacity to inhibit signaling with rapamycin.[87] In a complementary phase I dose-escalation study to assess the feasibility of mTOR inhibition as a treatment strategy, the pharmacokinetics and pharmacodynamics of rapamycin were investigated in dogs with primary OSAs and demonstrated that modulation of mTOR target proteins by rapamycin was achievable within the bone tumor microenvironment.[88]

Hedgehog and Notch

Hedgehog-GLI and Notch-HES1 signaling pathways have been linked to the growth, survival, and metastases of various human tumor histologies and recently have been investigated for their potential role in canine OSA biology. In one investigation, overexpression and functionality of the Hedgehog (HHG) pathway was confirmed in canine OSA cell lines by demonstrating elevated GLI1 and GLI2 transcription factors with correlative downstream target gene upregulation (PTCH1 and PAX6). Additionally, the functionality and biologic consequences of HHG signaling pathway blockade was assessed whereby inhibition of GLI transcription factors by GANT61 resulted in reduced proliferation and colony-forming capacity in canine OSA cell lines.[89] Analogous to HHG signaling, the involvement of the Notch pathway in canine OSA biology has been evaluated through the inclusion of a dichotomous outcome linked array of canine OSA tissues whereby dogs with OSA were categorized into unfavorable (disease-free interval [DFI] <100 days) versus favorable (DFI >300 days) responders. Gene array analysis of Notch/HES1 associated genes suggested

that upregulation of Notch signaling might contribute to OSA pathogenesis; however, an inverse relationship between Notch/HES1 with survival outcomes was identified, indicating that other mechanisms that do not alter HES1 expression might be responsible for driving OSA aggressive biology.[90]

Additional Pathways

In addition to various growth and survival pathways that potentially contribute to OSA pathogenesis, the ability of OSA cells to interact with their immediate microenvironment found in bone and lung tissues likely influences OSA progression and metastases. Tissue invasion and focal osteolysis are hallmark characteristics of OSA, and local disease progression is promoted by several OSA-associated proteins including matrix metalloproteinases, receptor activator of NF-κB ligand, lysosomal cathepsin K, endothelin-1, and transforming growth factor β.[91–97] Similar to the ability of OSA cells to invade local tissues, specific proteins have been identified to participate in the progression of canine OSA metastasis including ezrin,[98] a cytoskeletal linker protein, and CXCR4,[99,100] a chemokine receptor.

Pathology and Natural Behavior

OSA is a malignant mesenchymal tumor of primitive bone cells. These cells produce an extracellular matrix of osteoid, and the presence of tumor osteoid is the basis for the histologic diagnosis and differentiating OSAs from other sarcomas of bone. The histologic pattern may vary between tumors or even within the same tumor. There are many histologic subclassifications of OSA, which are based on the type and amount of matrix and characteristics of the cells: osteoblastic, chondroblastic, fibroblastic, poorly differentiated, and telangiectatic. Alkaline phosphatase staining on histopathologic and aspiration cytology specimens has been shown to aid in differentiating OSA from other connective tissue tumors.[101–103] In dogs, it has not been well established that there is a difference in the biologic behavior of the different histologic subclassifications or histologic grades. Some investigations indicate that histologic grade is predictive of behavior, whereas other studies cast doubt on the predictive value of routine histologic grading.[104,105] Newer techniques designed to recognize molecular or genetic alterations are being evaluated to determine their potential use in predicting behavior of OSA.[106] The degree of aneuploidy of primary and metastatic tumors, as measured by flow cytometry, is potentially indicative of biologic behavior.[75] OSA has very aggressive local effects and causes lysis, bone production, or both (Fig. 25.1). Pathologic fracture at presentation in people and dogs with OSA does not preclude limb salvage surgery (LSS) and does not carry a worse prognosis than patients without fracture at presentation;[107–110] however, dogs presenting with pathologic fracture or high risk for pathologic fracture are poor candidates for treatment with stereotactic radiotherapy (SRT) and concurrent surgical stabilization given the high rate for major local complications such as infection and implant failure.[111,112]

VetBooks.ir

Metastasis is very common and arises early in the course of the disease, although usually subclinically. Although less than 15% of dogs have radiographically detectable pulmonary or osseous metastasis at presentation, approximately 90% will die within 1 year (median ST [MST] of 19 weeks) with metastatic disease, usually to the lungs, when amputation is the only treatment.[2,16] Metastasis via the hematogenous route is most common; however, on rare occasions, metastasis to the regional lymph node (LN) may occur.[113] Although the lung is the most commonly reported site for metastasis, metastasis to bones or other soft tissue sites occurs with some frequency.[114] An increase in the incidence of bone metastasis after systemic chemotherapy has also been documented in humans and is suspected in dogs.[115,116] Suspected synchronous regional bone metastases (skip metastases) has also been reported.[117] Advanced imaging modalities, including bone scintigraphy, magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET)/CT scans, can aid in detection of occult skip metastases.[118,119] Some differences in metastatic behavior have been observed based on the anatomic location of the primary OSA site as well as anatomic skeletal size. For appendicular OSA arising from less common sites, including the ulna, retrospective investigations suggest that OSA behavior may be slightly less metastatic; however, more thorough studies are necessary to draw firmer conclusions.[120,121] Primary OSA arising from axial sites, such as mandible and calvarium, may have a less aggressive metastatic behavior too, although contradictory evidence exists as local tumor recurrence and subsequent regional disease failure might lead to early death and underestimation of the true metastatic potential of OSA arising from these sites.[122–125] In addition to primary tumor location, metastatic phenotype of OSA might be influenced by breed, size, or, more likely, genetics associated with small breed dogs. One recent investigation described the outcomes of 51 small breed dogs diagnosed with appendicular OSA and identified no difference in MSTs between dogs treated with amputation alone versus curative-intent therapy (local treatment and adjuvant chemotherapy).[126] Although preliminary in nature, these observational findings might suggest that the biologic behavior and associated metastatic potential of appendicular OSA is divergent between dogs of differing skeletal size.

History and Clinical Signs

Dogs with appendicular OSA generally present with a lameness and swelling at the primary site. There may be a history of mild trauma just before the onset of lameness. This history can often lead to misdiagnosis of an orthopedic or soft tissue injury. The lameness worsens and a moderately firm to soft, variably painful swelling may arise at the primary site. Dogs may present with acute, severe lameness associated with pathologic fractures, although pathologic fractures account for less than 3% of all fractures.[127] Up to 60% of these dogs are lame for a period before presentation.[107] Large and giant breed dogs that present with lameness or localized swelling at metaphyseal sites should be evaluated with OSA as a likely diagnosis. The pathophysiology of OSA pain is unclear but may be mediated by loss of mechanical bone strength resulting in microfractures, infiltration or compression of nerves, and the chemotaxis of immune cells with subsequent secretion of cytokines and proteases resulting in inflammatory pain. OSA cells have also been shown to secrete nociceptive ligands potentially resulting in pain generation.[97]

The signs associated with axial skeletal OSA are site dependent. Signs vary from localized swelling with or without lameness (scapular, pelvic, or rib sites) to dysphagia (oral sites), exophthalmos and pain on opening the mouth (caudal mandibular or orbital sites), facial deformity and nasal discharge (sinus and nasal cavity sites), and hyperesthesia with or without neurologic signs (spinal sites). Dogs with tumors arising from ribs usually present because of a palpable, variably painful mass. Respiratory signs are uncommon even when the lesions have large intrathoracic components; malignant pleural effusion is quite rare. Dogs rarely have respiratory signs as the first clinical evidence of pulmonary metastasis; rather, their first signs are usually nonspecific. With radiographically detectable pulmonary metastasis, dogs may remain asymptomatic for many months, but most dogs develop decreased appetite and nonspecific signs such as malaise within 1 month. Hypertrophic osteopathy may develop in dogs with pulmonary metastasis.

Systemic Alterations

Alterations in energy expenditure, protein synthesis, urinary nitrogen loss, and carbohydrate flux have been documented in dogs with OSA, similar to humans with neoplasia.[128] Changes in resting energy expenditure as well as protein and carbohydrate metabolism have been documented in dogs with OSA. These changes were evident even in dogs that did not have clinical signs of cachexia.[128] Although weight loss can occur during therapy for OSA, this has not been associated with worse outcomes.[129] Systemic metabolic derangements reported for dogs with OSA include lower chromium and zinc levels, lower iron and iron binding capacity, and increased ferritin levels compared with normal dogs.[130]

Diagnostic Techniques and Workup

Radiology

Initial evaluation of the primary site involves interpretation of good quality radiographs taken in lateral and craniocaudal projections. Special views may be necessary for lesions occurring in sites other than in the appendicular skeleton. The overall radiographic abnormality of bone varies from mostly bone lysis to almost entirely osteoblastic or osteogenic changes. There is an entire spectrum of changes between these two extremes, and the appearance of primary bone tumors can be quite variable. There are some features, however, that are commonly seen. Cortical lysis is a feature of primary bone tumors and may be severe enough to leave obvious areas of discontinuity of the cortex leading to pathologic fracture. There is often soft tissue extension with an obvious soft tissue swelling, and new bone (tumor or reactive bone) may form in these areas in a palisading pattern perpendicular or radiating from the axis of the cortex (i.e., sunburst). As the tumor invades the cortex, the periosteum is elevated, and new bone is laid down by the cambium layer providing a triangular appearing deposition of dense new bone on the cortex at the periphery of the lesion. This periosteal new bone has been called Codman triangle, but this is not pathognomonic for OSA. OSA rarely crosses articular cartilage, and primary lesions usually remain monostotic. The tumors may extend into periarticular soft tissues, however, and adjacent bones are at risk because of extension through adjacent soft tissue structures. Other radiographic changes associated with primary bone tumors include loss of the fine trabecular pattern in the metaphysis, a long transition zone at the periphery of the medullary extent of the lesion (rather than a sharp sclerotic margin), or areas of fine punctate lysis. Any one or combinations of these

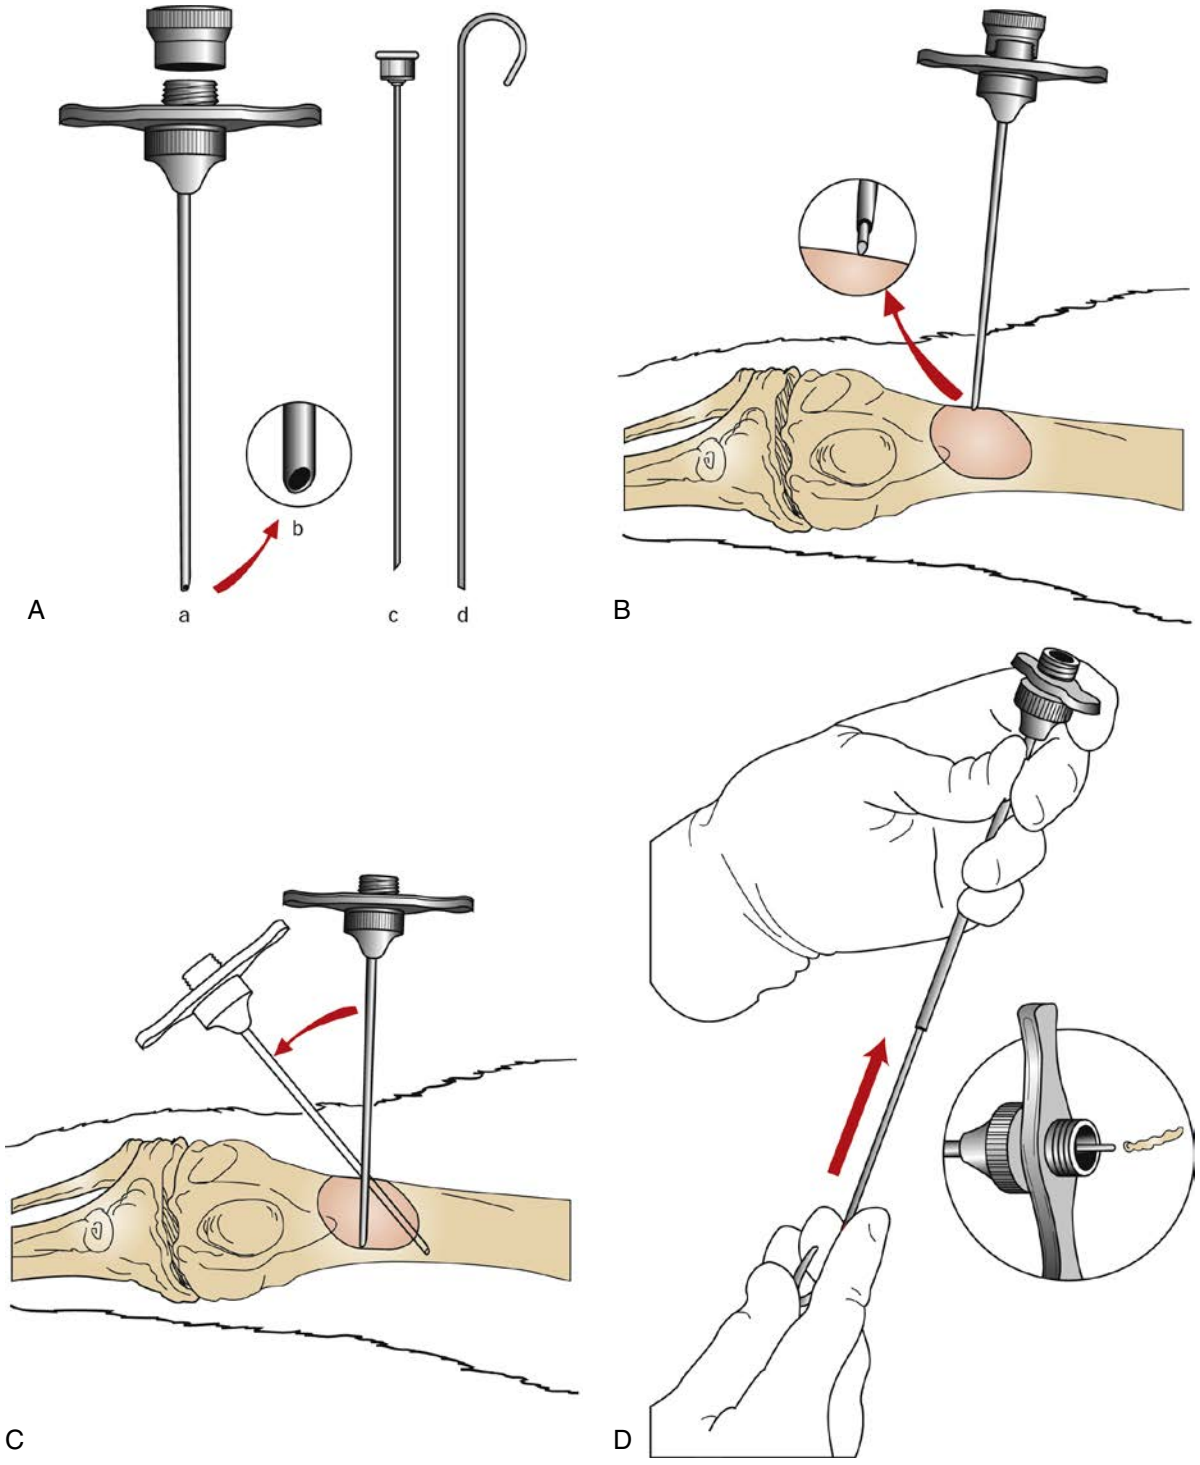
changes may be seen, depending on the size, histologic subtype, location, and duration of the lesion.

Differential diagnoses of lytic, proliferative, or mixed pattern aggressive bone lesions identified on radiographs include: other primary bone tumors (chondrosarcoma [CSA], fibrosarcoma [FSA], hemangiosarcoma [HSA]); metastatic bone cancer; multiple myeloma or lymphoma of bone; fungal osteomyelitis; bacterial osteomyelitis; and, albeit rare, bone cysts. Other primary bone tumors are far less common than OSA but may be suspected, especially in dogs with unusual signalment or tumor location. The radiographic appearance of primary bone tumors is similar to osteomyelitis, specifically fungal osteomyelitis.[131] In cases in which the travel or clinical history might support the possibility of osteomyelitis, a biopsy with submission for histology and culture may be warranted. Metastatic cancer can spread to bone from almost any malignancy, but is most commonly encountered from genitourinary carcinomas.[132] A careful physical examination is important, including a rectal examination, with special attention paid to the genitourinary system to help rule out the presence of a primary cancer. Common sites for metastatic bone cancer are lumbar and sacral vertebrae, pelvis, ribs, and diaphyses of long bones.[132] There are usually other clues for the diagnosis of multiple myeloma, such as hyperproteinemia, and both multiple myeloma and lymphoma of bone are usually associated with radiographic lesions that are almost entirely lytic.

Tissue Biopsy

A diagnosis of primary malignant bone tumor may be suggested by signalment, history, physical examination, and radiographic findings. Cytology has not been thought to be definitive for diagnosis; however, recent evidence indicates a high accuracy for diagnosis of sarcoma and, in combination with alkaline phosphatase staining, high specificity to support the diagnosis of OSA. Consistent cytologic criteria of OSA has recently been described; with repeated evaluations and dependent on experience, cytopathologists may be more definitive in making a diagnosis from cytology alone.[133,134] Alkaline phosphatase staining of cytologic samples has been shown to differentiate OSA from other vimentin-positive tumors;[101] however, in cases in which cytology is equivocal, a definitive diagnosis requires histopathologic assessment of a tissue sample. It is crucial that the biopsy procedure is planned and performed carefully with close attention to asepsis, hemostasis, and wound closure.[135] The skin incision for the biopsy must be small and placed such that it can be completely excised or included with the tumor if limb salvage surgery (LSS) or SRT is chosen. Poorly placed biopsy tracts can result in excessive normal tissue exposure (radiation) or difficulties in closure (LSS). Transverse or large incisions must be avoided. Ideally, the surgeon who is to perform the definitive surgical procedure (especially if this is LSS) should be the person to perform the preoperative bone biopsy.[136]

Bone biopsy may be performed as an open incisional, closed needle, or trephine biopsy (Fig. 25.2). The advantage of the open techniques is that a large sample of tissue is procured, which presumably improves the likelihood of establishing an accurate histologic diagnosis. Unfortunately, this advantage may be outweighed by the disadvantages of an involved operative procedure and risk of postsurgical complications such as hematoma formation, wound breakdown, infection, local seeding of tumor, and pathologic fracture.[137,138] Although biopsy with a trephine yields a diagnostic accuracy rate of 93.8%, there is increased risk of creating pathologic fracture than with a smaller gauge needle.[139] This underscores some of the advantages of a closed biopsy using a Jamshidi bone marrow biopsy needle or similar type of needle. Jamshidi needle biopsy has an accuracy rate of 91.9% for detecting tumor versus other disorders and an 82.3% accuracy rate for diagnosis of specific tumor subtype.[140] Accuracy of diagnoses from needle core samples can be dependent on the experience of the pathologist and comfort level with examination of small samples. Histology reports indicating the presence of reactive bone should not rule out the presence of a primary bone tumor or other pathology, especially if the radiographic changes suggest tumor. In some cases, it can be very difficult to get the diagnosis by preoperative biopsy (i.e., repeated biopsy attempts yield "reactive bone"), and yet the pathologist has no trouble identifying tumor when the entire specimen is available for histopathologic analysis. This is likely because of the heterogeneity of the tumor tissue itself and the large amount of reactive bone present within the tumor.

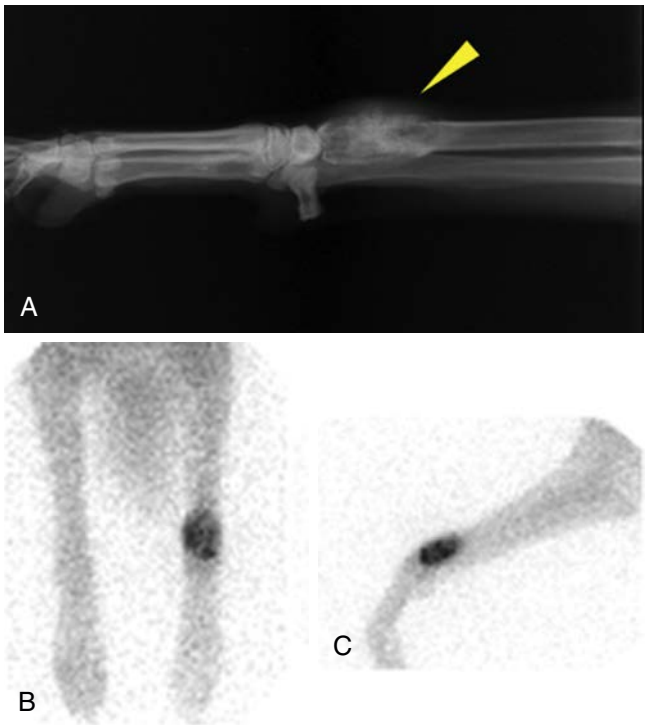


The biopsy site is selected carefully. Radiographs (two projections) are reviewed and the center of the lesion chosen for biopsy. Biopsy at the lesion periphery will often result in sampling the reactive bone surrounding the tumor without a resulting diagnosis.[140] The skin incision is made so the biopsy tract and any potentially seeded tumor cells can be completely removed at the time of definitive surgery. Care is used to avoid major nerves, vessels, and joint spaces. A 4-inch, 8- or 11-gauge needle is used. With the dog anesthetized, prepared, and draped for surgery, a small stab incision (2–3 mm) is made in the skin with a #11 scalpel blade. The bone needle cannula, with the stylet locked in place, is pushed through the soft tissue to the bone cortex. The stylet is removed and the cannula is advanced through the bone cortex into the medullary cavity using a gentle twisting motion and firm pressure. The opposite cortex is not penetrated. The needle is removed and the specimen is gently pushed out of the base of the cannula by inserting the probe into the cannula tip. One or two more samples can be obtained by redirecting the needle through the same skin incision so that samples of the transition zone may also be obtained. Ideal specimens should be 1 or 2 cm in length and not fragmented. Biopsy is repeated until solid tissue cores are obtained. Material for culture and cytology may be taken from the samples before fixation in 10% neutral buffered formalin. Diagnostic accuracy is improved when samples are evaluated by a pathologist thoroughly familiar with bone cancer. Fluoroscopy or advanced imaging (CT) can assist in obtaining needle-core biopsy samples of suspected bone lesions, especially for axial sites.[141]

After tumor removal (amputation or limb sparing), histology should be performed on a larger specimen to confirm the preoperative diagnosis. If the clinical and radiographic features are typical for a primary bone tumor, especially when there is little possibility of fungal or bacterial infection, confirmation of histologic diagnosis after surgical treatment of local disease (amputation or limb sparing) can be considered. Few diseases causing advanced destruction of the bone can be effectively treated without removal of the local disease. If the owners are willing to treat aggressively, surgical removal of local disease with biopsy submission after surgery may be acceptable.

Staging and Patient Assessment

Systemic Staging



Examination for evidence of apparent spread of the disease is important. Regional LNs, although rarely involved, should be palpated and fine needle cytology performed on any enlarged LN.[113] Sites of bone metastasis may be detected by a careful orthopedic examination with palpation of long bones and the accessible axial skeleton. Organomegaly may be detected by abdominal palpation. Usually pulmonary metastases are undetectable by clinical

• **Fig. 25.2** (A) The Jamshidi bone biopsy needle: cannula and screw-on cap *(d)*, tapered point *(b)*, pointed stylet to advance cannula through soft tissues *(c)*, and probe to expel specimen from cannula *(d)*. (B) With the stylet locked in place, the cannula is advanced through the soft tissue until bone is reached. The inset is a close-up view showing stylet against bone cortex. (C) The stylet is removed and the bone cortex penetrated with the cannula. The cannula is withdrawn and the procedure repeated with redirection of the instrument to obtain multiple core samples. (D) The probe is then inserted retrograde into the tip of the cannula to expel the specimen through the base *(inset)*. examination, but careful thoracic auscultation is important to detect concurrent cardiopulmonary disorders.

High detail thoracic radiographs should be taken during inspiration in a conscious patient. Although some controversy exists,[142] three-view thoracic radiographs are recommended for the assessment of pulmonary metastasis: a ventrodorsal or dorsoventral view and both right and left lateral views. OSA pulmonary metastases are generally soft tissue dense and cannot be detected radiographically until the nodules are 7 to 9 mm in diameter. Pulmonary metastasis is uncommon at the time of diagnosis

• **Fig. 25.3** Scintigraphic view of a distal radial osteosarcoma lesion in a dog after technetium-99M-hydroxymethylene diphosphonate injection. (A) Lateral radiograph demonstrating mixed osteolytic/osteoblastic bone lesion affecting distal radius *(yellow arrowhead)*. (B) Anterior posterior and (C) lateral bone scintigraphy images 90 minutes postintravenous injection demonstrate preferential accumulation of technetium-99M at focal site of increased bone turnover.

(less than 10% of dogs). Advanced imaging (e.g., CT, MRI, PET/CT) may play a role in patient staging and is used to evaluate for pulmonary metastases and for evaluation of tumor vascularity, soft tissue and medullary involvement/tumor size, and response to treatment.[143–145] Multiple studies have demonstrated increased sensitivity of thoracic CT compared with thoracic radiography for the detection of pulmonary metastases;[118,119,146,147] however, published treatment and patient outcomes are generally based on patients staged by thoracic radiographs. As advanced imaging becomes more commonplace for staging dogs with OSA, comparisons to previous protocols will be subject to stage-migration and lead-time bias due to earlier detection of metastases.

Bone survey radiography may be useful for identifying second skeletal sites of OSA.[25] Bone survey radiographs include lateral radiographs of all bones in the body and a ventrodorsal projection of the pelvis using standard radiographic technique appropriate for the region radiographed. There are conflicting reports on the usefulness of nuclear scintigraphy (Fig. 25.3) for clinical staging of dogs with OSA.[148–152] Bone scintigraphy was used in one study to identify suspected second bone sites in 14 of 25 dogs with appendicular OSA;[149] seven of these lesions were biopsied and confirmed to be OSA. Another study of 70 dogs with appendicular primary bone tumors resulted in only one scintigraphically detectable occult bone lesion.[148] In a third report of 23 dogs with suspected skeletal neoplasia evaluated with scintigraphy and radiography, four dogs had second skeletal sites suspected to be neoplastic.[152] The suspicious site in one of these dogs was found on histologic evaluation to be normal bone. Another study found secondary sites considered highly suspect of bony metastasis in 7.8% of (399) cases; however, most suspected lesions were not confirmed histologically.[150] A recent pilot study compared the utility of survey radiography, whole body CT, and nuclear scintigraphy for the detection of OSA metastasis in 15 dogs.[119] Nuclear scintigraphy was found to be the most useful modality for the detection of occult bone metastases; however, false positives did occur, and the diagnosis of metastasis was based on a gold standard reference constructed using all available imaging modalities, history, and signalment rather than histopathologic confirmation.

Abdominal ultrasound has been recommended by some veterinary oncologists to stage for visceral organ metastasis. Two recent retrospective studies documented abdominal metastases in 0% to 2.5% of cases, with sites of metastasis including the kidney, liver, and iliac LNs.[153,154] In four of 80 cases (5%), a second primary neoplasm was diagnosed, and in two of these cases, the mass was palpable on physical examination. Both studies suggest abdominal ultrasound is a low-yield diagnostic test but is warranted in patients with palpable abdominal abnormalities.

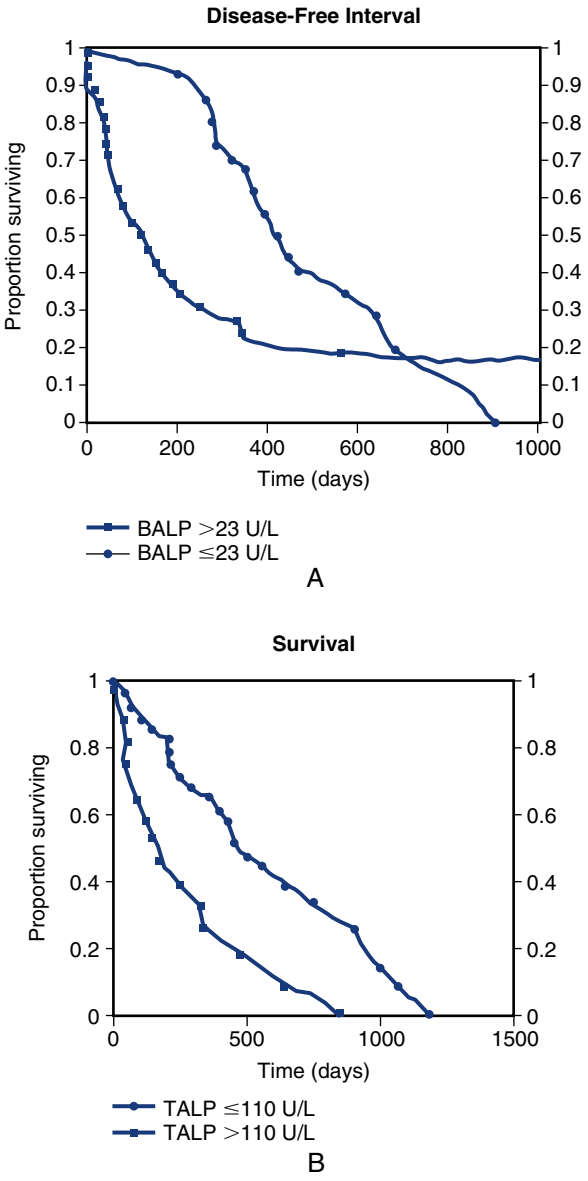
Surgical Staging

A surgical staging system for sarcomas of the skeleton has been devised for people.[155] This system is based on the histologic grade (G), the anatomic setting of the primary tumor (T), and regional or distant metastasis (M). There are three stages: stage I—low-grade (G_1) lesions without metastasis; stage II—high-grade (G_2) lesions without metastasis; and stage III—lesions with regional or distant metastasis regardless of histologic grade. The stages are subdivided by the anatomic setting with A being intracompartmental (T_1) and B being extracompartmental (T_2). According to this system, most dogs with OSA present with stage IIB disease. CT or PET/CT can be used to evaluate the degree of bone involvement from a primary bone tumor and distant metastasis.[145,156] Scintigraphy has also been used to determine extent of local disease, but in one study, scintigraphy overestimated the length of OSA disease in LSS patients by 30%.[157] CT may be useful to plan surgical margins, especially for tumors located in the axial skeleton; however, one study reported that survey radiographs were as accurate as advanced imaging (CT, MRI) in predicting true length of tumor involvement.[158] In contrast, it is anticipated that PET/CT, with its dual molecular and anatomic imaging capabilities, will have high sensitivity for assessing local tumor size, as well as detecting the presence of distant metastases.

Known or Suggested Prognostic Factors

Anatomic Location and Signalment

In a multiinstitutional study of 162 dogs with appendicular OSA treated with amputation alone, dogs younger than 5 years of age had shorter survival than older dogs; however, a recent large meta-analysis study did not identify age as being prognostic for the development of metastases.[16,159] Additional studies have found that large tumor size[13,160,161] and humeral location[162,163] are associated with a poor outcome, and a recent meta-analysis supports that proximal humeral OSA is a significant negative prognostic factor for both DFI and ST.[164] For OSA originating from flat bones, small dog size and completeness of excision were positive prognostic indicators.[124,165] Although strong conclusions cannot be made, a recent study suggested that small breed dogs with appendicular OSA may have improved STs compared with large breed dogs after the institution of curative-intent therapies.[126]



VetBooks.ir

Higher histologic grade and mitotic index may be predictive for a poorer prognosis; however, the prognostic value of histologic grade for predicting biologic behavior remains controversial as study results are contradictory.[104,105]

The biologic behavior for less common appendicular (ulna) and nonappendicular sites of OSA appears to be similar (aggressive), with the exception of the mandible and possibly other calvarial sites.[120,122,123,166–168] OSA of the head (mandible, maxilla, and skull) is locally aggressive but has a lower metastatic rate than appendicular OSA.[124] In a study of 183 dogs, local recurrence or progression occurred in 51.3% of dogs, and 38.5% of dogs developed distant metastases; the overall MST was 239 days.[124] Dogs with OSA of the mandible treated with mandibulectomy alone had a 1-year survival rate of 71% in one study,[122] suggesting a less aggressive biologic behavior. A second study of 50 dogs with mandibular OSA also confirmed improved STs relative to appendicular OSA; however, the majority of dogs (58%) still developed metastatic disease, and the addition of adjuvant chemotherapy to mandibulectomy resulted in a significantly improved ST.[125] In contrast, maxillary OSA has a MST of 5 months after maxillectomy.[167,168] The MST for dogs with rib OSA lesions is 3 months after chest wall resection alone and 8 months after treatment with chest wall resection and adjuvant chemotherapy.[169–172] Scapular OSA has a guarded prognosis when treated with subtotal scapulectomy surgery and chemotherapy;[165,173,174] The DFI and MST in dogs diagnosed with scapular OSA were 210 days and 246 days, respectively.[121] Limb function after subtotal scapulectomy is good to excellent.[121] Survival of dogs with OSA distal to the antebrachiocarpal or tarsocrural joints was somewhat longer (MST 466 days) than survival of dogs with OSA of more common appendicular sites; however, OSA in these sites is aggressive with a high potential for metastasis.[24] Vertebral OSA is uncommon, but it is locally aggressive and local tumor recurrence or progressive disease is common after conservative surgical approaches.[21,175] In 15 dogs treated with a combination of surgery, RT, and chemotherapy, the MST was 4 months.[175] For dogs with pelvic OSA treated with hemipelvectomy, the local recurrence and metastatic rates were 21% and 46%, respectively, with a mean ST of 533 days and 1- and 2-year survival rates of 53% and 35%, respectively.[176] The biologic behavior of OSA in other nonappendicular bone sites has not been thoroughly evaluated.

Extraskeletal OSA is rare and most commonly affects visceral sites (gastrointestinal [GI] tract, spleen, liver, kidney, urinary bladder), skin or subcutaneous tissue, or mammary glands. Extraskeletal (soft tissue) OSA sites also appear to have aggressive systemic behavior with a high metastatic rate. In one report, dogs with extraskeletal OSA treated with surgery alone had a MST of only 1 month, and dogs treated with surgery and adjuvant chemotherapy had a MST of 5 months.[27] In a larger study, soft tissue and mammary OSAs were separated; the MST for dogs with nonmammary gland soft tissue OSA was 1 month and 3 months for dogs with mammary gland OSA after surgical resection alone.[28] The major cause of death was local recurrence (92%) in dogs with soft tissue OSA cases and pulmonary metastasis (62.5%) in dogs with mammary gland OSA.

Dogs presenting with stage III disease (measurable metastasis) have a very poor prognosis; however, improved survival may be achievable when appropriate metastasectomy (tumor control >300 days and <3 pulmonary nodules) is performed.[114,177] The MST for 90 dogs with stage III disease at presentation was 76 days. Dogs with bone metastasis (132 days) had a longer ST (132 days) than dogs with lung metastasis (59 days) or lung and other soft tissue metastases (19 days). Dogs with LN metastasis have a significantly shorter MST (59 days) than dogs without LN metastasis (318 days).[113,114] In dogs with stage III disease treated with metastasectomy, the MST (232 days) was significantly longer than for dogs not treated with metastasectomy (49 days).[177]

• **Fig. 25.4** (A) Disease-free interval outcome of dogs treated for osteosarcoma comparing preoperative bone alkaline phosphatase levels higher than and lower than 23 U/L. Serum Alkaline Phosphatase

Elevated alkaline phosphatase (ALP) has been clearly associated with a poorer prognosis for dogs with appendicular and rib OSA in several individual studies[113,162,178–181] and two recent large meta-analyses.[159,164] A preoperative elevation of either total (serum) or bone isoenzyme of ALP (greater than 110 U/L or 23 U/L, respectively) is associated with a shorter DFI and ST (Fig. 25.4).

VetBooks.ir

The reasons for why serum ALP may impart a negative prognosis have been incompletely explored; however, two recent investigations postulate putative mechanisms. In one study of 96 dogs with appendicular OSA, a positive correlation between serum bone ALP and absolute tumor size was identified; in dogs with progressive OSA metastatic burden, serum bone ALP increased and coincided with the development of macroscopic metastases.[182] Based upon these findings, the association between increased pretreatment bone ALP and negative clinical prognosis may simply be attributed to a greater initial tumor burden and advanced clinical stage of disease.[182] In a second study, increased bone ALP was suggested as an epiphenomenon to active endothelin-1 signaling by malignant OSA cells whereby the secretion of endothelin-1 by OSA cells endowed a protumorigenic advantage and secondary "passenger" bone ALP production given the osteoblastic properties of endothelin-1 signaling.[96] These two studies suggesting that elevations in bone ALP may be an epiphenomenon of either tumor burden or osteoblastic signaling pathways are consistent with a third study demonstrating that canine OSA cell lines derived from dogs with differing bone ALP concentrations (normal versus high) do not differ in their in vitro protumorigenic potentials.[183]

Molecular, Genetic, and Immunologic Indices of Prognosis

The expression of several molecular proteins, including ezrin, recepteur d'origine Nantaise (RON), survivin, vascular endothelial growth factor (VEGF), cyclooxygenase-2 (COX-2), and heat shock protein (HSP), has been reported to influence DFIs and STs in dogs.[98,184–188] Ezrin is a cellular protein belonging to the ezrin-radixin-moesin family and serves as a physical and functional anchor site for cytoskeletal F-actin fibers. Given the involvement of ezrin in cytoskeletal remodeling, it has been demonstrated in murine preclinical models that ezrin is necessary for OSA metastases.[98] Through the use of a canine tissue microarray with known clinical outcome data, the presence of high ezrin staining in primary tumors was associated with a significantly shorter median DFI (116 days) compared with dogs with low primary tumor ezrin staining (188 days).

Hepatocyte growth factor receptor (MET) and RON are members of the MET protooncogene family of receptor tyrosine kinases, and signaling through MET or RON promotes tumorigenesis and the formation of metastases. MET and RON are capable of heterodimerization with one another, resulting in cellular crosstalk that may alter the strength and duration of signal transduction with resultant protumorigenic effects. Given the role of MET and RON in metastases, their expression in OSA has been evaluated in dogs.[184] Through the use of a canine OSA tissue array with linked outcome data, expression of RON, but not MET, was prognostic for survival. Dogs with high RON expression in their primary tumors had significantly decreased STs than dogs with absent, low, or intermediate RON expression.

Survivin is a small protein belonging to the inhibitor of apoptosis family and participates in the processes of cell division as well as apoptosis inhibition. As a dimer, survivin inhibits both caspase-dependent and -independent mediated apoptosis, and its expression can promote tumorigenesis. Given the antiapoptotic properties of survivin, its overexpression may provide a survival advantage to cancer cells and be associated with a negative prognosis. In one study, the expression of survivin was characterized in 67 primary OSA samples with known outcome data.[186] Survivin expression was detected in 65 tissue samples and expression intensity was associated with DFI. Dogs with primary tumors expressing low survivin immunoreactivity scores achieved a significantly longer DFI (331 days) than dogs with high survivin immunoreactivity scores within the primary tumor (173 days).

VEGF and the enzymatic activities of COX-2 serve as potent regulators of angiogenesis, and their independent expressions have been associated with poorer prognosis for a variety of cancers. Given that angiogenesis is a necessary step for tumor growth and metastases, both VEGF and COX-2 have been investigated in dogs with OSA.[185,187,189] In one study of 25 dogs treated with definitive surgery and systemic chemotherapy, baseline platelet-corrected serum VEGF concentrations were associated with DFI, but not ST.[187] Dogs with VEGF concentration in the lower 50th percentile achieved a significantly longer DFI (356 days) than dogs with VEGF levels in the upper 50th percentile (145 days). In two studies, COX-2 expression was characterized in primary tumors derived from 44 dogs and 27 dogs, respectively, with positive COX-2 staining identified in 88% and 93% of tumors evaluated [185,189] In dogs treated with amputation and doxorubicin (DOX), COX-2 immunoreactivity score, a product of stain intensity and percentage of positive cells, was potentially correlated with disease outcome. Dogs with primary tumors demonstrating strong stain intensity had a significantly shorter MST (86 days) than dogs with tumors staining negative (MST 423 days), poor (MST 399 days), or moderate (MST 370 days) for COX-2. Recently, global gene expression analysis of canine OSA stem cells identified that COX-2 gene transcription was expressed 141-fold greater in canine OSA stem cells compared with non-stem cells; this suggests that COX-2 activity may play a role in tumor initiation and progression.[190]

HSPs play a critical role in cellular responses to stress and aid in appropriate protein folding and protection cells after endoplasmic reticulum stressors, which otherwise would induce programmed cell death. Cancer cells may deregulate HSP expression to favor survival and HSP gene expression has been investigated in canine OSA. In a study of dogs with OSA, a significantly increased expression of HSP60 was found to be associated with reduced DFIs and STs in a subset of patients achieving long-term disease control. Mechanistic studies demonstrated that knockdown of HSP60 reduced cell proliferative capacity and induced apoptosis. These collective findings suggest that HSP60 overexpression might be associated with poor prognosis in dogs with OSA.[188]

With the near complete sequencing of the canine genome and the commercial availability of canine-specific gene microarrays, it has become possible to characterize and validate specific tumor-associated genetic determinants associated with clinical outcomes and prognosis. In one gene expression profiling study, primary OSA tissues were analyzed from two groups of dogs with different clinical outcomes, specifically dogs achieving DFIs either less than 100 days or more than 300 days after uniform treatment with amputation and systemic chemotherapy.[106] Derived from microarray analysis and confirmed by RT-PCR, eight specific gene transcripts were significantly different between poor responders (<100 days) and good responders (>300 days). In dogs categorized as poor responders, six transcripts, including insulin-like growth factor II and alcohol dehydrogenase were downregulated, and two transcripts were upregulated in comparison to good responders. To better characterize the molecular pathways associated with the differentially expressed genes identified in microarray analysis, a broader systems approach was used to identify changes in groups of interacting genes or pathways that may contribute to metastatic progression or chemotherapy resistance. In general, pathway expression differences

between good and poor responders involved oxidative phosphorylation, bone development, PKA signaling, cell adhesion, cytoskeletal remodeling, and immune response.[106]

In a similar expression profiling study, prognostic gene profiles were derived from 32 primary OSA tumors derived from two groups of dogs based upon ST.[191] Dogs surviving for less than 6 months or more than 6 months were categorized as either poor or good responders respectively. Gene profiling identified 51 gene transcripts to be differentially expressed. Within the poor responder group, genes uniformly overexpressed were associated with biologic pathways involved in proliferation, drug resistance, and metastases. In addition to identifying differentially expressed genes and associated pathways between dogs categorized as good and poor responders, the findings from the study further substantiated the molecular pathway similarities shared between humans and dogs, including Wnt, integrin, and chemokine/cytokine signaling.

Lastly, a highly influential study was conducted that leveraged the more homogeneous genetic background of dogs diagnosed with OSA to detect underlying and conserved gene expression patterns previously undetectable in historic canine and human gene microarray analysis.[192] By differential gene expression profiling of early passage immortalized OSA cell lines derived from primary tumors, the investigators were able to identify gene signatures associated with G2/M transition and DNA damage checkpoint, as well as microenvironment interactions, which permitted the unbiased segregation of OSA samples into distinct molecular subclassifications and predicted outcome. Most significantly, the same genetic signatures identified in dogs also allowed for prognostic molecular classification of human OSA, powerfully underscoring the scientific merit derived from comparative oncologic studies.

Perturbations of the immune system are common among cancer patients, and regulatory T cells (Tregs) and myeloid-derived suppressor cells have the capacity to attenuate effective antitumor immune responses with the potential to negatively affect prognosis. Tregs have been characterized in healthy and cancer-bearing dogs,[193–195] with some studies demonstrating that dogs with OSA have increases in the percentage and absolute counts of circulating Tregs.[196] The clinical significance of Tregs on OSA prognosis has recently been characterized in a study of 12 dogs treated with amputation and systemic chemotherapy.[196] Dogs with high (higher than the mean) versus low (lower than the mean) percentages of Tregs identified in blood or tumor tissue did not have differences in DFI or ST; however, high or low CD8/Treg ratio in the blood was associated with clinical outcomes as dogs with low CD8/Treg ratios had a significantly shorter ST than dogs with high CD8/Treg ratios.

In addition to Tregs and their potential prognostic value in OSA, one study has demonstrated that routine hemogram parameters—specifically lymphocyte and monocyte counts—can also predict clinical outcomes in dogs with OSA.[163] In 69 dogs treated with amputation and systemic chemotherapy, baseline lymphocyte and monocyte counts were associated with DFI. Shorter DFIs were observed in dogs initially presenting with relative lymphocytosis (≥1000 cell/uL) and relative monocytosis (≥400 cell/uL), and these original conclusions were further substantiated by a second population of OSA dogs treated in an identical manner. Mechanistically, it was hypothesized that the association of relative monocytosis and reduced DFI could be the presence of myeloid-derived suppressor cells, a population of cells characterized by their ability to suppress antitumor immune responses.

Recently, the putative role of monocyte and macrophage regulatory roles in dogs with OSA were evaluated in an attempt to understand how monocyte phenotype and chemotactic function might be perturbed in dogs with OSA.[197] In 18 dogs with OSA, the cell surface expression of multiple chemokine receptors, in particular CCR2 and CXCR2, were downregulated in peripheral blood monocytes, potentially leading to reduced directional migration and extravasation. Additionally, the monocytes from dogs with OSA were functionally impaired as exhibited by decreased chemotaxis ex vivo. These findings could explain why dogs with OSA may have elevations in circulating monocytes as well as provide potential mechanisms by which OSA cells might evade the innate immune system through the induction of monocyte chemotactic dysfunction.

Another study characterized the immune microenvironment of canine primary OSA through the association of macrophage ($CD204^+$) and lymphocyte infiltrates (both effector $CD3^+$ and regulatory Foxp3 T-cells) within the primary tumor with DFI and ST in 30 dogs treated with amputation and carboplatin therapy.[198] Although the extent and phenotype of primary tumoral lymphocyte infiltrates did not influence outcomes, the surface area of macrophage infiltration did have an effect on outcomes. Dogs with more than 4.7% surface area infiltrate with $CD204^+$ macrophages experienced a significantly longer DFI. These findings suggest that tumor-infiltrating macrophages may contribute to inhibiting localized OSA metastatic progression.

Therapy Directed at the Primary Tumor

Surgery

Table 25.1 provides an overview of surgical options for primary bone tumors based on anatomic site.

Amputation

Amputation of the affected limb is the standard local treatment for canine appendicular OSA. Even large and giant breed dogs will usually function well after limb amputation, and most owners are pleased with mobility and quality of life of their pets after surgery; 88% of dogs have the same or near same quality of life after amputation, and 73% of dogs return to their preamputation activity levels after surgery.[199,200] Most dogs will readily compensate and, although the osteoarthritis may progress more rapidly in the three-legged dog, this rarely results in a clinical problem. Physical therapy and rehabilitation is an important adjunct to postamputation recovery and should be considered as part of the routine postoperative care for amputation patients. Severe preexisting orthopedic or neurologic conditions may cause poor results in some cases and careful preoperative examination is important. Complete forequarter amputation is recommended for thoracic limb tumors and coxofemoral disarticulation (amputation) for pelvic limb lesions. This level of amputation assures complete removal of the local tumor and also results in a more cosmetic and functional outcome. For proximal femoral tumors, complete amputation and en bloc acetabulectomy is recommended to obtain proximal soft tissue margins (Fig. 25.5).

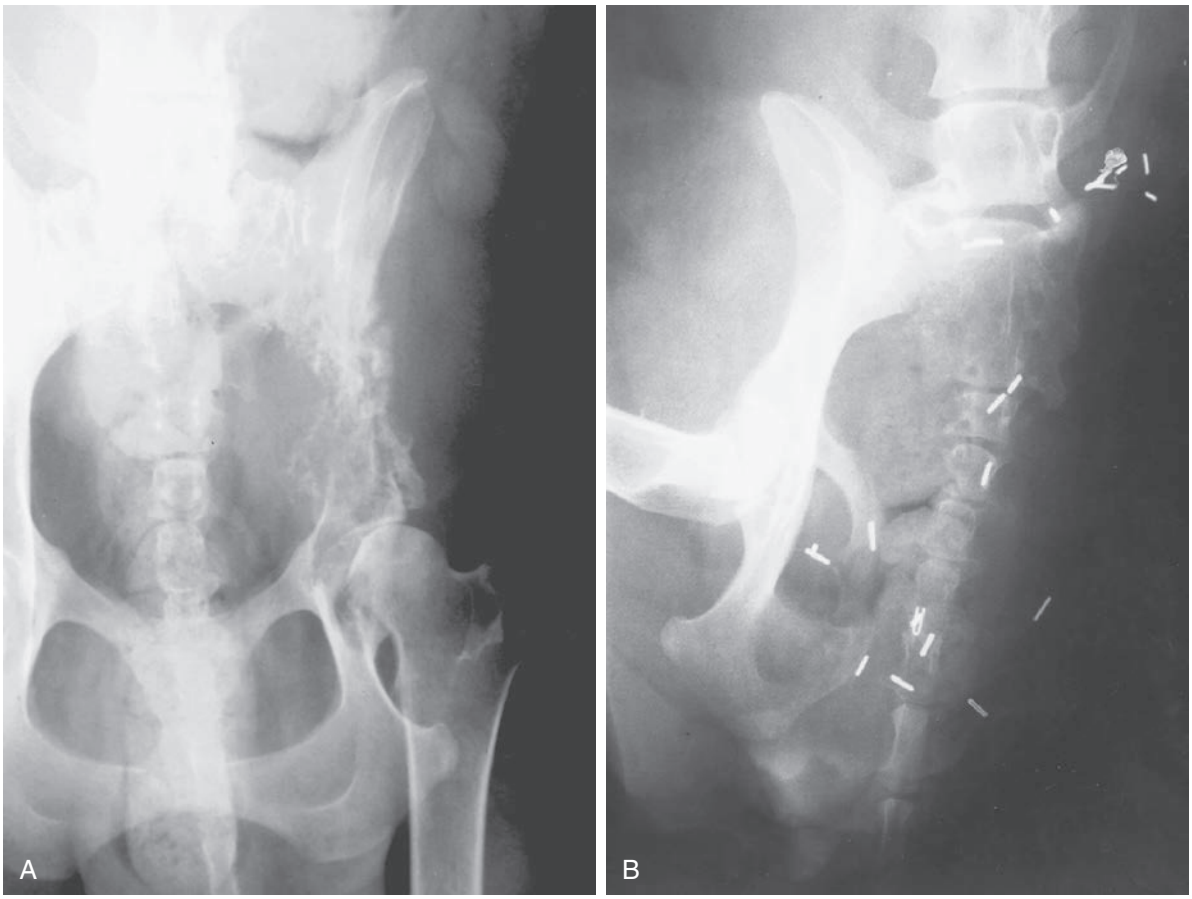
Limb Salvage

Although most dogs function well with amputation, there are some dogs for which LSS would be preferred over amputation, such as dogs with severe preexisting orthopedic or neurologic disease or dogs whose owners absolutely will not permit amputation. Until relatively recently, only a few reports of LSS in dogs, with

VetBooks.ir

TABLE 25.1 Treatment Options for Osteosarcoma by Site

Site	Treatment Options	Comments
Humerus, femur, tibia	Limb amputation Limb salvage (stereotactic radiation therapy)	Generally high complication rate for limb salvage[162] Diaphyseal locations amenable to intercalary allografts[209] Total hip salvage possible for proximal femoral tumors[214,217] Intraoperative extracorporal radiation technique may apply[225]
Radius	Limb amputation Limb salvage (allograft,[201–206] endoprosthesis,[214] intercalary bone graft,[209] ulnar transposition,[223,224] bone transport osteogenesis,[218,219,221,222] intraoperative extracorporal radiation therapy[225])	-
Ulna	Limb amputation Ulnectomy[255]	Often does not require allograft reconstruction
Scapula	Limb amputation Scapulectomy[173,253,248]	Proximal lesions best; partial and total scapulectomy described
Pelvis	Pelvectomy with or without limb amputation[176,246]	Lateral portion of sacrum can be excised; may include body wall
Metacarpus/metatarsus	Digit amputation[250] Partial limb amputation with prosthesis	Limb function dependent on prosthetic design and patient tolerance
Mandible	Mandibulectomy[122]	Often requires total mandibulectomy Bilaterally limited to fourth premolar
Maxilla/orbit	Maxillectomy[256] Orbitectomy[260]	Limited by midline palate or cranial vault invasion Combined approach may assist exposure
Calvarium	Resection ± Radiation	Resection dependent on venous sinus involvement
Vertebrae	Decompression (palliative) ± Radiation ± Chemotherapy[175]	Vertebrectomy techniques not well developed; limited local disease control
Rib	Rib resection[170–172,181]	Requires removal of normal rib cranial and caudal to the tumor



limited follow-up, were published.[201–205] To date, more than 600 LSSs have been performed at Colorado State University's Flint Animal Cancer Center (CSU-FACC). Limb function has been fair to good in most dogs, and survival has not been adversely affected by removing the primary tumor with marginal resection.[206]

Suitable candidates for LSS include dogs with nonmetastatic OSA and when the primary tumor affects <50% of the bone (as determined radiographically). Other criteria for consideration include absence of pathologic fracture, less than 360-degree involvement of soft tissues, and a firm/definable soft tissue mass rather than an edematous lesion. Early on in the development of LSS procedures, many dogs treated at CSU-FACC received some form of preoperative treatment, (i.e., primary or neoadjuvant intraarterial [IA] cisplatin, intravenous [IV] cisplatin, RT to the tumor bone, or a combination of RT with IV or IA cisplatin). Results from 21 dogs treated with RT alone given in large doses per fraction before LSS were unsatisfactory for preservation of life or limb.[203] Many of the dogs treated with two preoperative IA cisplatin doses 21 days apart, with the last treatment 21 days before LSS, showed marked decrease in the degree of vascularization of the tumor. This represented a high degree of induced tumor necrosis in the resected specimen, especially when combined with RT, and facilitated LSS.[205,207] Most dogs at CSU-FACC receive systemic carboplatin, DOX, or combination therapy after surgery.[208]

The most suitable cases for LSS are dogs with tumors in the distal radius or ulna, as function after LSS and carpal arthrodesis is good. Arthrodesis of the scapulohumeral, coxofemoral, stifle, or tarsal joints after LSS generally results in only fair to poor function.[162] Resulting poor function, combined with a high complication rate, has generally led surgeons away from recommending LSS near these joints. LSS is a complicated process and requires a coordinated team effort between surgical and medical oncologists, radiologists, pathologists, and technical staff. Several methods of LSS have been described, each with unique advantages and limitations. The choice of LSS method depends on several factors, including owner choice, patient personality, and individual risk factors. At the CSU-FACC, owners are given a choice of LSS options and informed about the risks and benefits of each method compared with amputation. A brief description of the surgical options for a distal radial location (most common) follows. Meticulous aseptic technique is essential.

Allograft limb salvage surgery. For a distal radial site, the dog is placed in lateral or dorsal recumbency with the affected limb uppermost. A skin incision is made on the dorsolateral aspect of the antebrachium from a point just distal to the elbow to just proximal to the metacarpophalangeal joint. Any biopsy tracts are excised en bloc. Soft tissue is dissected to the level of the tumor pseudocapsule. Care is taken not to compromise the tumor capsule. The bone is osteotomized with an oscillating bone saw 3 to 5 cm proximal to the proximal radiographic (or scintigraphic) margin of the tumor. Extensor muscles attached to the tumor pseudocapsule are transected at this level to maintain 2- to 3-cm soft tissue margins. The joint capsule is incised, keeping close to the proximal row of carpal bones. For tumors of the mid diaphysis, tumor resection follows similar guidelines with the exception that the extensor and flexor muscle groups should be spared as the

VetBooks.ir

• **Fig. 25.5** (A) Ventrodorsal radiographic view of an osteosarcoma of the ilium of a dog. (B) Ventrodorsal radiographic view of the same dog 3 years after hemipelvectomy and amputation followed by cisplatin chemotherapy.

joint (above and below) may be spared.[209] The ulna is sectioned sagittally with an osteotome, and the medial ulnar cortex adjacent to the tumor is removed en bloc with the radius. For tumors that have extension to the ulna (rare), the ulna is also cut with a bone saw, and the distal one-third or more is removed with the tumor. Care is taken to preserve as much vasculature as possible, especially on the palmar surface.

Large vessels associated with the tumor are ligated or sealed and divided. The specimen is radiographed and then submitted for histologic evaluation, including assessment of completeness of surgical margins. In addition, a sample of bone marrow in the radius proximal to the resection level is obtained for histologic evaluation of marrow involvement. A fresh-frozen cortical allograft is thawed in 1 liter of an antibiotic in saline solution, the articular cartilage is removed, the graft is cut to fit, and the medullary cavity flushed to remove residual fat and cellular debris.[210,211] The articular cartilage of the proximal carpal bones is removed and the allograft is stabilized in compression using Association for the Study of Internal Fixation (ASIF/AO) principles. A locking compression plate with a minimum of three screws proximal and four screws distal to the graft is used; 3.5 mm broad locking plates of up to 22 holes or a custom-designed limb salvage plate are appropriate in most cases, but 4.5 mm narrow or broad plates may be required for very large breed dogs. The plate is fixed in the patient to the allograft with two or three screws, removed from the surgery site, and the medullary canal of the allograft is filled with polymethylmethacrylate bone cement containing amikacin (1 g amikacin to 40 g of polymer powder). This provides support for the screws during revascularization of the graft and acts as a reservoir for antibiotics. The healing of the allograft is not significantly impeded by the presence of the bone cement and has been shown to significantly decrease the incidence of orthopedic failure, including allograft fracture and screw pullout.[212,213] The plate extends proximally on the remaining radius and distally to a level just proximal to the metacarpophalangeal joint (Fig. 25.6). For intercalary LSS the plate extends proximally and distally to meet or exceed ASIF standards with the intent to spare joint motion.

The wound is thoroughly lavaged with saline. A closed suction drain is inserted adjacent to the allograft, and the wound is closed. The limb is supported in a padded bandage. The drain is removed the day after surgery in most cases. An Elizabethan collar or other preventative measures should be used as necessary to prevent self-mutilation after surgery. No external coaptation is used, and most dogs use the limb relatively well by 10 days after surgery. Postoperative foot swelling can be considerable and should be carefully monitored but usually resolves by 2 weeks. Exercise restriction and physical therapy are recommended for 4 to 6 weeks. Thereafter, return to activity is recommended on a case-by-case basis.

The advantages of allograft LSS include the absence of external fixation, and minimal owner involvement is required in the postoperative period aside from bandage changes in the first several weeks. The disadvantages are the high infection rate and the need for permanent internal hardware. Canine LSS patients have an infection rate of approximately 40% to 50%. Once an infection

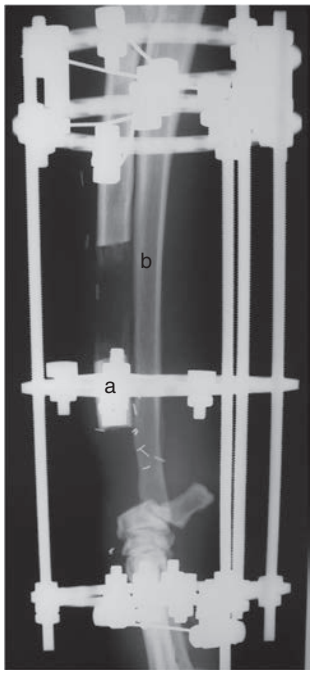
occurs, it may be controlled with long-term antibiotic therapy, but infections are rarely resolved with antibiotics.[162] Infection may result in soft tissue defects from draining tracts, exposure of the plate or allograft, and hardware loosening. Revision surgeries, either for hardware complications or soft tissue reconstruction, are not uncommon. Additionally, amputation for catastrophic implant failure, local recurrence, or unmanageable infection is sometimes required.



Metal endoprosthesis. This technique utilizes a commercially available metal endoprosthesis with a modified bone plate (Fig. 25.7), 3D printed, or custom-designed endoprostheses. The surgery is nearly identical to the procedure described for cortical allografts with an endoprosthesis used instead of an allograft. A prospective comparison of complications between cortical allograft and commercially available endoprosthesis LSSs was published in 2006.[214] No significant differences in the number of complications were noted between endoprostheses and allografts. In a recent study comparing clinical outcome in 45 dogs treated with either first or second generation endoprosthesis LSS, the overall complication rate was 96%, including infection in 78%, implant-related complications in 36%, and local recurrence in 24% of dogs.[215] An endoprosthesis is an attractive alternative to cortical allografts for LSS of the distal aspect of the radius in dogs because surgical and oncologic outcomes are similar. The commercially available endoprosthesis is an off-the-shelf implant with no need for tissue banking. Various patient-specific, 3D-printed endoprostheses have been utilized with good results.[216,217]

Longitudinal bone transport osteogenesis. Longitudinal bone transport osteogenesis (BTO) is a limb salvage technique reported in dogs (Fig. 25.8)[218–220] that utilizes Ilizarov (circular) fixators

VetBooks.ir

• **Fig. 25.7** Lateral radiographic projection of a limb salvage technique using a commercially available endoprosthesis with a modified bone plate in a dog with distal radial and ulnar osteosarcoma. A limb-sparing plate spans the radius and metacarpus, connected to the implant, which abuts the host radius proximally and the radial carpal bone distally. A negative suction drain has also been placed at the surgical site to decrease postoperative fluid accumulation.

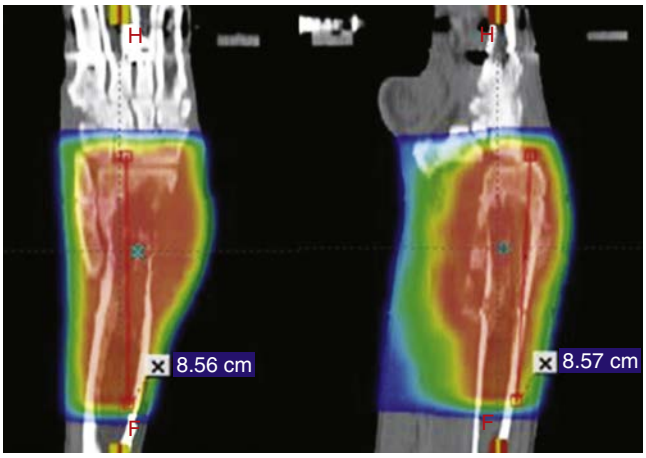
• **Fig. 25.8** Lateral radiographic projection of a limb salvage technique using longitudinal bone transport osteogenesis (BTO). In this case a distal radial osteosarcoma was removed, and BTO was accomplished using circular fixators and the principles of distraction osteogenesis to create bone in the defect remaining after tumor resection. Briefly, a longitudinal section of normal bone *(a, termed the "transport segment")* from the radius is osteotomized and attached to the transport ring and the osteotomized bone segment is slowly transported into the defect at a rate of 1 mm per day. Distraction osteogenesis occurs in the trailing distraction pathway *(b)*.

and the principles of distraction osteogenesis to create bone in the defect after tumor resection. Before surgery, a five- to six-ring circular fixator is constructed to allow one central ring (termed a transport ring) to move independently of the remainder of the fixator. Using the same procedure for removal of the tumor and preparation of the radiocarpal bone described earlier, the circular fixator is placed on the limb and attached to the remaining radius using tensioned, 1.6-mm diameter wires. A longitudinal section of normal bone (termed the transport segment) from the radius immediately proximal to the defect is osteotomized and attached to the transport ring with wires. After a 3- to 7-day delay period, the osteotomized bone segment is slowly transported into the defect at a rate of 1 mm per day. Distraction osteogenesis occurs in the trailing distraction pathway. New bone continues to form longitudinally within the defect proximal to the transport segment for as long as the steady, slow distraction continues. When the transport segment reaches the radiocarpal bone (docking), the transport segment is compressed to the radiocarpal bone and heals to create an arthrodesis. The circular fixator remains on the limb as the newly formed bone remodels and the arthrodesis occurs. This technique is compatible with adjuvant cisplatin, carboplatin, and combination chemotherapy.[219,221]

The advantages to BTO LSS are the low risk of infection due to the autologous, vascularized nature of the replacement bone and the ability of the new bone tissue to remodel over time. Patients are typically weight-bearing within the first 48 hours and, once the incision has healed, do not require exercise restriction. The disadvantages of the BTO procedure are the extensive client involvement required to perform the daily distractions on the fixator and the extended amount of time the fixator remains on the limb. Double level longitudinal BTO and translational transport of the ulna can significantly diminish the time required for distraction and has been used successfully in a case of limb salvage for a distal tibial OSA.[222]

Ulnar transposition. The vascularized ulnar transposition technique uses the ipsilateral distal ulna as an autograft to reconstruct the distal radial defect by rotating the graft into position while preserving the caudal interosseous artery and vein.[223,224] After excision of the tumor as described previously, two transverse osteotomies of the ulna are made. The distal osteotomy is performed at the level of the isthmus proximal to the facet that articulates with the radius. The proximal ulnar osteotomy is performed 1 to 2 mm distal to the level of the radial osteotomy. Direct visualization of the caudal interosseous artery and vein allows these structures to be preserved during dissection of the autograft. The ulnar graft is "rolled over" into the radial defect and fixed using a bone plate that extends from the proximal radius to the distal one-third of the fourth metacarpal bone (i.e., pancarpal arthrodesis).

Advantages to the ulnar transposition technique are that there is no distant donor site morbidity, the replacement bone is autologous, and the graft is vascularized, making it less likely to get infected and possibly more rapid healing. The disadvantages to this technique are that the ulnar transposition technique may be more prone to biomechanical complications in the postoperative period due to its smaller size relative to the radius and the need for permanent internal hardware.[223]



Nonsurgical Limb Salvage

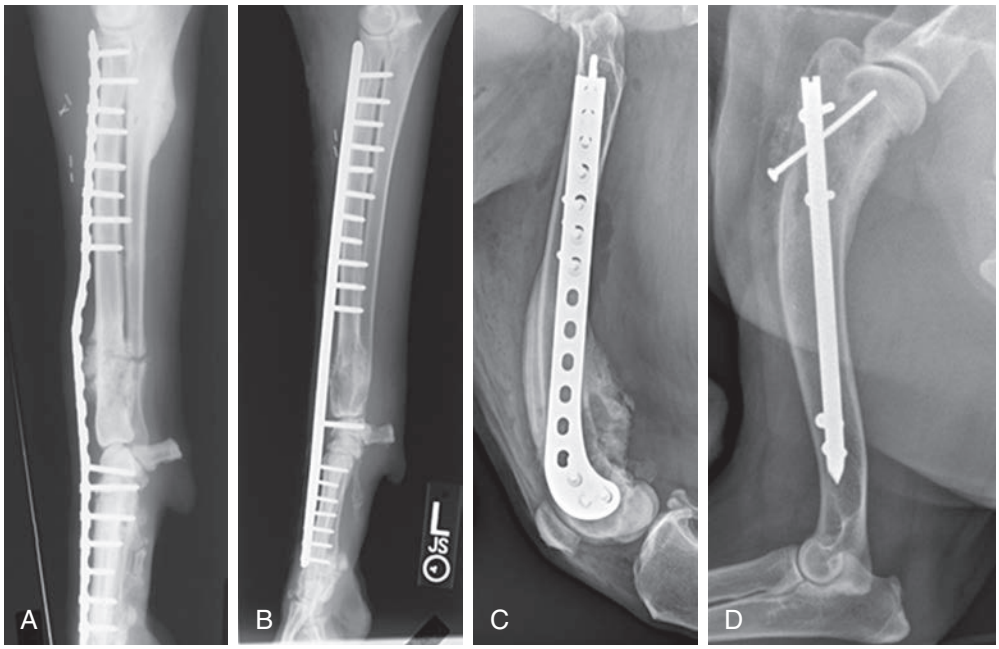
Intracorporeal and Extracorporeal Intraoperative Radiation Therapy

Intraoperative RT (IORT), using either an intracorporeal or extracorporeal approach, for limb sparing has been utilized in a small number of canine OSA patients[225,226] as well as human patients with extremity bone tumors.[227–229] This limb salvage technique involves a surgical approach to the bone with osteotomy proximal or distal to the affected site (depending on the anatomic location of the tumor) and reflection of normal soft tissues from the tumor affected bone. The neurovascular bundle, muscle, and skin are retracted away from the affected bone, and the tumor is pivoted from the site on the intact joint tissue. The patient is then transported to the radiation suite and a single dose of 70 Gy is then delivered to the tumor, taking care to spare the distracted neurovascular bundle. The irradiated bone is then anatomically replaced and surgical fixation of the osteotomy is achieved with either dynamic compression plating or an interlocking nail system. One advantage of IORT for limb salvage over LSS is that it can be used to preserve limb and joint function in anatomic sites that are not amenable to LSS with arthrodesis of the adjacent joint (e.g., proximal humerus).[162] Patients treated with IORT had good limb function in the immediate postoperative period; however, complications related to surgery or RT led to implant revisions in 69% of cases within 5 to 9 months of initial surgery, including four amputations. Pathologic fracture of the irradiated bone was the most common complication. Additionally, local tumor recurrence occurred in four dogs and infection in four dogs. A modification of this technique includes complete temporary removal of diaphyseal tumors, performing extracorporeal IORT, and then reimplantation and stabilization of the irradiated bone segment. In situ radiation of distal femur and any tibial tumors can be performed without osteotomy. The disease-free and overall limb and joint salvage rates for extracorporeal IORT as assessed at the time of death or data analysis were 46% and 54%, respectively. The MST for dogs with appendicular sarcoma treated with limb- and joint-sparing extracorporeal IORT was 298 days.

Stereotactic Radiation Therapy

SRT or stereotactic radiosurgery (SRS) offer the ability to deliver high dose RT to the tumor volume with relative sparing of the surrounding normal tissues by use of accurate patient immobilization, image guidance, and a rapid dose fall-off from the tumor margins (Fig. 25.9). In this respect, it is a refinement of the IORT technique that avoids the need for surgical exposure. A nonsurgical limb salvage technique using a single fraction SRS was developed at the University of Florida, and initial results were reported in 11 dogs.[230] Adjuvant carboplatin chemotherapy was used in six dogs immediately before RT for its potential radiosensitization action in addition to its conventional cytotoxic effects, and five dogs were treated with SRS alone. Four dogs developed pathologic fractures and one dog developed infection. Acute effects to the skin were generally mild to moderate; however, one dog developed an open skin wound 3 months after treatment, and another dog developed a full thickness skin wound under a splint used during the treatment of a pathologic fracture. Limb use in the dogs treated with SRS and chemotherapy was excellent. The overall MST was 363 days. In a follow-up retrospective study, the same group reported the outcome of 46 patients treated with a similar single fraction SRS technique (median prescribed dose 30 Gy).[231] Forty-five dogs received conventional maximal tolerated dose chemotherapy. The

• **Fig. 25.9** Dose color wash map of radiation distribution for stereotactic radiation therapy of distal radius osteosarcoma lesion showing a steep dose gradient drop off between tumor volume and normal tissues.



MST was 9.7 months. Of the patients with complete medical records, 63% developed pathologic fracture at a median of 5.9 months. Acute and late skin toxicities developed in 58% and 16% of dogs, respectively. Involvement of subchondral bone appeared to be predictive of shortened time to fracture.

Many veterinary radiation oncology facilities currently offer SRT for OSA. SRT protocols for the treatment of OSA typically involve two to three fractions with doses ranging from 8 to 13 Gy per fraction, and the most common protocol is three fractions of 10 Gy. These fractions are delivered daily or, less commonly, every other day.

In an orthotopic, athymic, rat model inoculated with canine OSA cells, three fractions of 12 Gy SRT was shown to induce complete tumor necrosis in 92% of rats treated.[232] Previous canine studies have indicated that therapies which induce more than 80% local tumor necrosis are associated with an increase in local tumor control.[233] The same athymic rat model also indicated that zoledronic acid combined with parathyroid hormone could increase bone volume after SRT. Many oncologists advocate the use of bisphosphonates before or after SRT. As SRT is a localized therapy, adjuvant chemotherapy is recommended to delay the onset of metastatic disease. Chemotherapy can also be considered as a radiation sensitizer as reported in the studies of single fraction SRS for canine OSA.[231] Radiation recall (recurrence of acute skin toxicities after initial resolution) has been observed in some patients treated with adjuvant DOX chemotherapy.

Pathologic fracture is the most frequent complication associated with SRT and SRS. Fracture is postulated to be due to the amount of preexisting tumor associated osteolysis and postirradiation bone necrosis resulting in loss of dynamic bone remodeling and healing capacity after SRT. Smaller, more blastic lesions may be better candidates for SRT limb salvage than larger, more lytic lesions. There is some evidence that lysis of subchondral bone may be associated with a higher rate of fracture.[231] Pathologic fracture has been treated by internal fixation, external coaptation, or amputation.[112] Preemptive stabilization has also been used for more concerning lesions or those with evidence of pathologic fracture at the time of SRT (Fig. 25.10).[111] In a recent study, seven dogs underwent surgical stabilization for fractures documented at the time of SRT, and 11 dogs were stabilized preemptively. Infection occurred in 15 dogs and was considered a major complication in 13 of these dogs and ultimately

VetBooks.ir

• **Fig. 25.10** Radiographs of internal fixation after fracture (A) and preemptive stabilization (B, C, and D) for stereotactic radiation therapy limb salvage cases with lytic lesions.

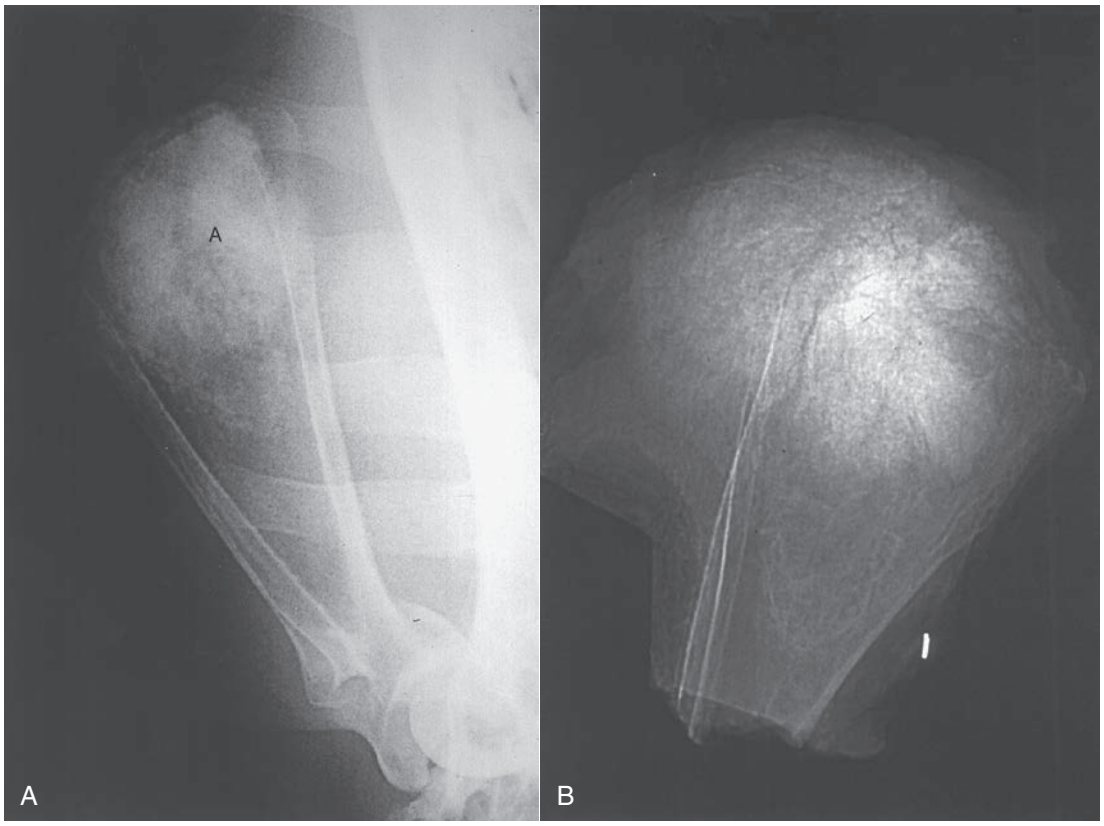
contributed to amputation or euthanasia. The high rate of complications in this study resulted in the authors not recommending stabilization concurrently with SRT.

Theoretically, fractionated SRT may offer a reduction in the rate of pathologic fracture in comparison to severely hypofractionated SRS, which results in pathologic fracture in 63% of patients. The rate of fracture after SRT has not been published to date. In a recent study of an accelerated palliative protocol, in which dogs were manually planned to receive two daily fractions of 10 Gy using parallel opposed geometry, the rate of fracture was 35.7% after RT.[234]

The advantages of SRS/SRT techniques include limb preservation in anatomic sites not amenable to LSS, the normal tissue-sparing effects of SRT compared with conventional RT, a lack of surgical alternatives, and good to excellent limb function. Disadvantages of the technique include limited but increasing access to equipment capable of delivering SRT and the high rate of postirradiation pathologic fracture.

Isolation of Limb Circulation and Perfusion

Isolated limb perfusion (ILP) with chemotherapy has been used in people and dogs with sarcomas and melanomas as a sole treatment or to downstage local disease to allow LSS.[235–237] ILP allows delivery of high concentrations of chemotherapy as well as delivery of compounds that are poorly tolerated systemically. Varying degrees of local toxicity are reported and these are dependent on the drugs used. Successful use of ILP in canine OSA has been reported.[235] One study determined that appendicular bone tumors have significantly higher interstitial fluid pressure and lower blood flow than do adjacent, unaffected soft tissues.[238] ILP may be a method to facilitate delivery of therapeutic drug concentrations to primary tumors for preoperative downstaging before LSS.



Systemic administration of ^{153}Samarium ethylenediaminetetramethylene phosphonate (^{153}Sm-EDTMP) is limited by systemic myelotoxicity. In a study at CSU-FACC, ^{153}Sm-EDTMP (37 MBq/kg) was administered via ILP through isolated limb circulation for 1 hour in nine dogs with primary appendicular OSA 3 weeks before amputation to evaluate the potential for decreased systemic toxicity and to induce clinically meaningful tumor necrosis before primary tumor removal. No systemic toxicity was observed. Despite good dosimetry to the lesion, the mean percentage TN was 27.6%, which was similar to mean percentage TN of 26.8% in untreated OSA cases.[233] This low percentage TN may be due to incomplete perfusion of the ^{153}Sm-EDTMP, the heterogenous nature of OSA, and the inability of the beta particles to exert a cytotoxic effect on the noncalcified regions of the tumor due to their short track length (3 mm).

Summary of Outcome After Limb Salvage for Dogs with Osteosarcoma

There is no significant difference in survival rates for dogs treated with amputation and cisplatin compared with dogs treated with LSS and cisplatin.[206] Overall, limb function has been satisfactory with approximately 80% of dogs experiencing good to excellent limb function.[17] LSS requires a dedicated owner and clinical team. LSS is usually combined with some form of adjuvant therapy, and complications can arise in any or all phases of treatment (chemotherapy, RT, or surgery). High dose, external beam RT may complicate wound and bone healing and potentiate infection.[203] Moderate dose, external beam RT in combination with chemotherapy may, however, be useful for control of local disease, as indicated by tumor necrosis data.[205,239] The major complications related to LSS are infection, local recurrence, and implant complications. In a review of 220 LSSs performed at CSU-FACC, the 1-year local recurrence-free rate was 76% with 60% of dogs alive at 1 year.[206] Local disease control was improved with certain treatments such as pretreatment with moderate doses of RT and intra-arterial cisplatin or local implantation of biodegradable cisplatin polymer. The percentage of TN has been shown to be predictive of outcome.[7]

In two case series, 40% and 47.5% of dogs, respectively, developed allograft infections.[206,240] The majority had their infections adequately controlled with systemic antibiotics with or without local antibiotics (antibiotic-impregnated polymethylmethacrylate

VetBooks.ir

• **Fig. 25.11** (A) Preoperative radiograph of an osteosarcoma of the proximal scapula. (B) Specimen radiograph after partial scapulectomy.

beads).[162] Many of these dogs continued to have evidence of infection; however, their function was not severely affected. In severe and uncontrolled infections, allografts had to be removed, and a small number of dogs required amputation. An unexpected finding has been that dogs with LSS infections experienced a statistically significant prolongation of overall STs compared with dogs with LSS without infection.[214,241,242] This finding has also been reported in people with deep infections after LSS for OSA.[243] A mouse model of OSA examined the effects of infection on tumor angiogenesis and innate immunity and demonstrated that chronic localized bacterial infection could elicit significant systemic antitumor activity dependent on natural killer cells and macrophages.[244]

Surgery for Nonappendicular and Less Common Appendicular Sites of Osteosarcoma

Certain primary bone tumors of the pelvis can be removed by hemipelvectomy and, although these surgeries are difficult, function and cosmetic outcome are excellent.[245,246] Excellent reviews of the surgical techniques for hemipelvectomy and the surgical and oncologic factors to be considered with this surgery have been published.[245,247]

Vertebral OSAs are challenging to manage because of difficulty in adequately treating local disease. Total en bloc vertebrectomy techniques are not well established in veterinary medicine,[248,249] and surgery is often palliative to decompress dogs with neurologic deficits or intractable pain and to obtain a diagnosis.[175] Present recommendations are to perform surgery in cases that require decompression (with or without stabilization) and institute RT (discussed later) and chemotherapy.

A combination allograft and custom total joint arthroplasty has been described for successful LSS of a proximal femur OSA,[250] and a patient-specific, 3D-printed endoprosthetic reconstruction of the proximal femur and hemipelvis has been reported in a dog with a histiocytic sarcoma.[217] An intraosseous transcutaneous amputation prosthesis (ITAP) for limb salvage has been described in four dogs with distal radial or tibial OSA lesions.[251] A case report using an ITAP prosthesis for a traumatic distal tibia injury has also been reported.[252] The success of an ITAP prostheses require a biologic seal to be formed between the skin and the prosthesis to minimize the risk of deep infection.

Bone tumors originating in the scapula can be successfully removed by partial or total scapulectomy (Fig. 25.11).[173,253,254] Significant gait abnormalities may occur after total scapulectomy by disarticulation at the scapulohumeral joint; however, lameness typically improves or resolves with rehabilitation and time.[254] Small primary tumors of the ulna can be removed by partial ulnectomy, and reconstruction is rarely needed.[255] Tumors located in the metatarsal and metacarpal bones can be treated with local resections or partial foot amputation.[250] Mandibulectomy and maxillectomy are appropriate surgeries for primary bone tumors of oral sites.[166,167,256–259] In a survey of owners of dogs undergoing partial mandibulectomy or maxillectomy, 85% were satisfied with the outcome despite 44% citing difficulty in eating as a complication.[257] Tumors of periorbital sites can be removed by orbitectomy.[260] Rib tumors can be removed by thoracic wall resection and the defect reconstructed with polypropylene mesh with plastic plates for large defects or by muscle flap techniques.[170–172,261] Diaphragmatic advancement can be used for caudally located defects.

Radiation Therapy

At present, the role of RT for curative-intent local tumor control is still evolving in veterinary medicine. The most common role of

VetBooks.ir

RT in dogs with appendicular OSA is for palliation of bone pain. RT at relatively high total doses can cause considerable necrosis of primary OSA in dogs and people either before LSS to downstage the primary tumor to improve the success of local disease control after removal or as a primary therapy for unresectable tumors.[203,205,262–264] As a primary therapy, a MST of 209 days was reported in 14 dogs with appendicular OSA treated with fractionated high-dose RT (median dose of 57 Gy) to their primary tumor and systemic chemotherapy.[265] The introduction of SRT has allowed for delivery of high doses of radiation to the tumor volume with good local tumor control and relative sparing of the surrounding normal tissues.

Radioisotopes

A beta emitter radioisotope, ^{153}Sm-EDTMP, has been used to treat primary OSA and metastatic bone neoplasia in dogs and humans via systemic IV administration. ^{90}Yttrium-hydroxide (Y90) has been reported as an intralesional liquid brachytherapy in a dog with tibial OSA. ^{90}Y was deposited locally in the bone, bone marrow, and soft tissue components of the tumor using specialized cannulas. Localized, high-dose RT can be delivered in such a manner, and, in addition, a minor portion of the breakdown product of ^{90}Y can be imaged by PET/CT to confirm the presence of the agent at the tumor site.[266,267]

Systemic Adjuvant Therapy for Dogs with Osteosarcoma

For the most effective management of canine OSA, multimodality therapy is required to address both local and metastatic disease. Although amputation and LSSs, as well as nonsurgical techniques such as SRT, have proven highly effective for local OSA management, the ability to cure or durably control OSA metastases remains a clinical challenge; substantive improvements in DFIs and STs await advances in systemic antimetastatic treatment options.

Although systemic chemotherapy remains the backbone for the management of OSA metastases, it is improbable that the discovery of new chemotherapeutic agents or dose-intensification with existing agents will dramatically improve current clinical outcomes. Rather, the future of OSA management will likely depend on combining conventional cytotoxic agents with targeted molecular therapeutics or immunomodulatory agents. As such, considerable research focus has been committed to discovering and validating new combination therapies for improving the long-term prognosis of canine OSA.

Chemotherapy

Table 25.2 provides an abbreviated summary of conventional chemotherapeutic agents used in the adjuvant setting, evaluated as single agents or in combination. Table 25.2 is not an exhaustive description of all reported studies conducted to date, but rather presents findings from studies derived from sample populations of greater than 20 dogs per investigation.

Single-Agent Carboplatin Chemotherapy

Carboplatin is a second-generation platinum compound that is less nephrotoxic than cisplatin. Given its ease of administration, carboplatin has largely supplanted the use of cisplatin in the postoperative setting. In the first study reporting the tolerability and activity of carboplatin, 48 dogs with OSA were treated with amputation and intent-to-treat with four doses of carboplatin (300 mg/m^2 every 21 days).[160] Carboplatin was well-tolerated with neutropenia identified as the dose-limiting toxicity. For the entire study population, the median DFI and MST were 257 and 321 days, respectively. For dogs receiving the planned four doses of carboplatin, median DFI and MST were extended to 327 and 383 days, respectively.

Despite the initial report of carboplatin's comparable activity to cisplatin,[160] two prospective randomized studies using single-agent carboplatin as a comparator arm demonstrated less impressive antimetastatic effects.[268,269] In one study, dogs were treated with a single neoadjuvant dose of carboplatin and amputation 7 days later, then received two additional treatments with carboplatin (300 mg/m^2) every 21 days. Upon completion of carboplatin, dogs were then randomized to receive either placebo or a long-acting somatostatin analog.[268] For dogs treated with carboplatin and placebo, the median DFI and MST were 196 and 230 days, respectively. In a second study comparing the activity of a liposome-encapsulated cisplatin formulation (SPI-77) versus single-agent carboplatin, 40 dogs were treated with a single neoadjuvant dose of either SPI-77 (350 mg/m^2) or carboplatin (300 mg/m^2) 1 week before amputation and then received an additional three treatments of SPI-77 or carboplatin every 21 days.[269] No difference was identified between treatment groups; dogs treated with single-agent carboplatin had a median DFI and ST of 123 and 207 days, respectively.

Two relatively large retrospective studies have been conducted to substantiate the activity of carboplatin for managing pulmonary micometastases.[270,271] In a study initiated by the Veterinary Cooperative Oncology Group (VCOG), 155 dogs treated with amputation and carboplatin (variable dosage and schedule) had a median DFI and STs of 256 and 307 days, respectively.[270] In a second retrospective investigation, 65 dogs treated with amputation and carboplatin at a dosage of 300 mg/m^2 every 21 days for four to six treatment cycles had a median DFI and ST of 137 and 277 days, respectively.[271]

Single-Agent Doxorubicin Chemotherapy

DOX is considered effective for delaying the development and progression of metastatic disease in dogs with OSA. The antimetastatic effects of DOX are more definitively substantiated when administered every 2 weeks rather than every 3 weeks. In one study, DOX was administered at a dose of 30 mg/m^2 every 2 weeks for five treatments to 35 dogs with appendicular OSA in a neoadjuvant setting. Dogs were treated with two or three doses of DOX before amputation and continued to receive DOX postoperatively for a total of five treatments.[272] The 1- and 2-year survival rates were 50.5% and 9.7%, respectively. In a second study evaluating the activity of a matrix metalloproteinase inhibitor (BAY 12-9566), 303 dogs were treated with amputation and DOX (30 mg/m^2 every 2 weeks for a total of five treatments), and then randomized to receive a daily oral placebo or BAY 12-9566.[180] No difference in ST was identified between dogs receiving placebo or BAY 12-9566, and the overall MST was 8 months.

Doxorubicin-Carboplatin Combined Chemotherapy

Given the modest to severe toxicity associated with DOX-cisplatin combination therapy,[273,274] one study investigated if combination tolerability could be improved by replacing cisplatin with carboplatin. The rationale to use carboplatin was based upon its comparable anticancer activities and improved side effect profile relative to cisplatin, which removes the need for saline diuresis and minimizes the likelihood of severe emesis. Twenty-four dogs were treated with definitive surgery

VetBooks.ir

TABLE 25.2 Abbreviated Summary of Historic and Adjuvant Chemotherapy Protocols Derived From Studies With a Minimum of 20 Dogs

Drug	Dose Regime and Number of Dogs	Disease-Free Interval	Survival Outcomes	Comments
Cisplatin[17] Single agent	70 mg/m^2 IV for two treatments, every 21 days n = 36	Median 177–226 days	Median 262–282 days 1-year survival rate 38%–43% 2-year survival rate 16%–18%	No significant difference in survival data for dogs given cisplatin before or after amputation
Cisplatin[201] (some dogs treated with limb salvage surgery) Single agent	60 mg/m^2 IV for one to six treatments, every 21 days n = 22	-	Median 325 days 1-year survival rate 45.5% 2-year survival rate 20.9%	Apparent increase in treatment failures due to bone metastasis
SPI-77[269] liposome encapsulated cisplatin Single agent	350 mg/m^2 IV for four treatments, every 21 days n = 20	Median 156 days	Median 333 days	Dramatic increase in cumulative cisplatin dose without the need for diuresis
Lobaplatin[407] Single agent	35 mg/m^2 IV for four treatments, every 21 days		1-year overall survival rate 31.8% 1-year disease-free survival rate 21.8%	No need for diuresis with this platinum analog
Doxorubicin and cisplatin[408] Concurrent combination	Doxorubicin at 12.5–25 mg/m^2 IV followed in 2 hours by cisplatin at 60 mg/m^2 IV or three treatments n = 102	-	Median 345 days 1-year survival rate 48% 2-year survival rate 28%	Unacceptable toxicity with doxorubicin at 25 mg/m^2
Doxorubicin and cisplatin[273] Concurrent combination	Cisplatin at 50 mg/m^2 IV on day 1 and doxorubicin at 15 mg/m^2 IV on day 2 for four treatments n = 35	Median 240 days	Median 300 days	Much better tolerated protocol compared with concurrent cisplatin-doxorubicin[408]
Doxorubicin and cisplatin[409] Alternating combination	Doxorubicin at 30 mg/m^2 IV followed by cisplatin at 60 mg/m^2 IV 21 days later for two treatments, every 21 days n = 38		Median 300 days	Alternating combination well tolerated with no grade III or IV dose-limiting toxicities
Carboplatin and gemcitabine[410] Concurrent combination	Carboplatin at 300 mg/m^2 IV then gemcitabine 2 mg/kg IV as a 20-minute infusion 4 hours postcarboplatin for four treatments, every 21 days n = 50	Median 203 days	Median 279 days 1-year survival rate 29.5% 2-year survival rate 11.3%	Well-tolerated protocol with low incidence of grade III or IV hematologic toxicities

followed by combination chemotherapy consisting of carboplatin (175 mg/m^2) administered on day 1, followed by DOX (15 mg/m^2) on day 2.[275] Combination DOX-carboplatin was administered every 21 days for a maximum of four treatment cycles. Nineteen dogs completed four treatment cycles. The tolerability of the combination was good with mild GI toxicity reported in approximately 50% of dogs; grade III hematologic toxicity or greater was rare. The median DFI and MST were 195 and 235 days, respectively, and not considered superior to historical single-agent studies.

Doxorubicin-Carboplatin Alternating Chemotherapy

The tolerability and activity of full-dose, alternating combinations with DOX and carboplatin have been investigated. In one study, 32 dogs were treated with amputation or LSS and then with adjuvant carboplatin (300 mg/m^2 or 10 mg/kg if <15 kg) followed 21 days later with DOX (30 mg/m^2 or 1.0 mg/kg if <15 kg).[276] Dogs were treated with up to three treatment cycles (three carboplatin and three DOX). Alternating carboplatin and DOX therapy was well tolerated; only one grade III neutropenia, one grade III thrombocytopenia, and one grade III vomiting were recorded from a total of 88 doses of carboplatin and 82 doses of DOX administered. The median DFI and MST were 227 and 320 days, respectively, with 1- and 2-year survival rates of 48% and 18%, respectively.

In a second study, 50 dogs were treated with amputation and, 10 to 14 days postoperatively, alternating combination chemotherapy with carboplatin (300 mg/m^2) and DOX (30 mg/m^2) every 21 days for three cycles (three carboplatin and three DOX).[277] Adverse events, including grade III or IV hematologic toxicity, were reported in 18% of dogs and grade III or IV GI toxicity was recorded in 12% of dogs. The median DFI and MST were 202 and 258, respectively.

Doxorubicin-Carboplatin Modified Combination Sequencing or Dose Interval

Combination sequencing or dose interval alterations with carboplatin and DOX have been investigated to assess whether this may

improve the outcome in dogs with OSA. In one study, the safety and efficacy of adjuvant chemotherapy, consisting of two doses of DOX (30 mg/m^2 or 1 mg/kg in dogs <15 kg) given 2 weeks apart, followed by four consecutive doses of carboplatin (300 mg/m^2) every 3 weeks, was evaluated retrospectively in 33 dogs after amputation. Tolerability to this protocol was reasonable with the greatest hematologic toxicity occurring post-DOX administration; approximately 10% of dogs experienced grade III or IV neutropenia. Similarly, 16% of dogs experienced grade III to IV GI toxicity. The drug combination also exerted anticancer activities with dogs achieving median DFI and overall MST of 232 and 247 days, respectively.[278]

In another study, 38 dogs were treated with amputation and a combination of three doses of DOX (30 mg/m^2 or 1 mg/kg in dogs <15 kg) every 14 days, followed by three consecutive doses of carboplatin (300 mg/m^2 for dogs ≥15 kg or 250 mg/m^2 for dogs <15 kg) every 21 days. This combinatorial strategy was tolerable with 5.2% of dogs requiring hospitalization for complications associated with toxicity. Additionally, anticancer activity were comparable to most treatment protocols with dogs achieving a MST of 317 days and 1- and 2-year survival rates of 43.2% and 13.9%, respectively.[279]

Head-to-Head Comparison Studies

Despite multiple published studies evaluating the anticancer activities of carboplatin, DOX, or the combination in dogs with OSA, few investigations can offer prescriptive recommendations on the best adjuvant treatment options, either due to insufficient power as a consequence of small study populations or limited study design being either retrospective in nature or the absence of relevant contemporaneous comparator arms. To address some of these limitations, two recent studies have been published. The first investigation, although retrospective in nature, included a large number of dogs with OSA treated at a single institution and compared carboplatin and DOX-based chemotherapy protocols in 470 dogs after amputation. Five different chemotherapy protocols were compared for tolerability and anticancer effects: carboplatin 300 mg/m^2 IV every 21 days for four or six cycles; DOX 30 mg/m^2 IV every 14 or 21 days for five cycles; and alternating carboplatin 300 mg/m^2 IV and DOX 30 mg/m^2 IV every 21 days for three cycles. Overall, the median DFI and MST were 291 and 284 days, respectively. Although no chemotherapy protocol proved superior, a lower proportion of dogs treated with six cycles of carboplatin experienced adverse effects, necessitating treatment delay, dose reduction, or hospitalization.[208]

In a second study, carboplatin and alternating carboplatin and DOX were evaluated in a randomized, open-label trial study. Dogs were treated with either six doses of carboplatin (300 mg/m^2 IV) every 3 weeks or three cycles of alternating carboplatin (300 mg/m^2 IV) and DOX (30 mg/m^2 IV) every 3 weeks. Of the 50 dogs recruited at a 1:1 ratio for either carboplatin alone or alternating carboplatin and DOX, 32 dogs completed their planned chemotherapy protocols and the remaining 18 dogs developed metastatic disease before completion of their targeted chemotherapy course. Toxicity was similar in both treatment arms. Dogs treated with carboplatin alone had a significantly longer DFI (425 days) than dogs treated with the alternating protocol (135 days).[280]

Conventional Chemotherapy Combined with Metronomic Therapies

Several studies have investigated the combination of systemic chemotherapy with concurrent and/or maintenance metronomic chemotherapy. In one retrospective study of 30 dogs treated with amputation, dogs received one of two chemotherapy protocols (carboplatin alone [300 mg/m^2 IV every 21 days for six cycles] or alternating carboplatin [300 mg/m^2 IV] and DOX [30 mg/m^2 IV] every 21 days for a total of five treatments [three carboplatin and two DOX]) and concurrent daily piroxicam (0.3 mg/kg PO) and cyclophosphamide (10–12 mg/m^2 PO). The initiation of combinatorial systemic therapies was started 2 days postamputation and metronomic chemotherapy continued indefinitely after the completion of systemic chemotherapy. Although adverse side effects were tolerable for both combinatorial protocols, grade III to IV toxicities were more commonly observed in dogs treated with carboplatin alone plus piroxicam/cyclophosphamide therapy. No significant difference in DFI was identified between the protocols.[281]

In a second study, the potential benefit of metronomic cyclophosphamide and meloxicam administered as a maintenance therapy after amputation and carboplatin was evaluated retrospectively in 39 dogs. Carboplatin therapy (300 mg/m^2 IV every 21 days for four to six cycles) was started 10 to 14 days postamputation. Of the 39 dogs evaluated and treated with carboplatin, 19 dogs were treated with maintenance metronomic cyclophosphamide (15 mg/m^2 PO daily) and meloxicam (0.1 mg/kg PO daily), and the remaining 20 dogs were not treated with maintenance metronomic chemotherapy. Sterile hemorrhagic cystitis was reported in 58% of dogs treated with metronomic chemotherapy. The median progression-free (PFS) and MST were 402 and 464 days, respectively. Though dogs receiving maintenance metronomic chemotherapy did achieve longer median PFS (480 days) and MST (480 days) than dogs treated with carboplatin alone (244 days and 458 days, respectively), the differences were not statistically significant.[282]

Chemoimmunotherapy

Harnessing and directing the immune system is a highly desirable anticancer strategy. Despite the various forms of immunotherapies, such as monoclonal antibodies and dendritic cell vaccines, currently used for the treatment of metastatic tumors in people, only a few canine immunotherapy studies have been conducted as randomized, double-blind trials. The best documented and clinically effective immunotherapy trials for dogs with OSA have evaluated the anticancer immune effects of liposome-encapsulated muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE). Being a lipophilic derivative of muramyl dipeptide, a synthetic analog of a Mycobacterium cell wall component, L-MTP-PE has been demonstrated to augment canine alveolar macrophage tumoricidal properties with enhanced cytotoxicity against OSA cells in vitro.[283]

In an initial clinical study of 27 dogs, the single-agent activity of IV L-MTP-PE was assessed immediately after amputation. Dogs were treated twice weekly with either L-MTP-PE or empty liposomes for 8 weeks. Dogs treated with L-MTP-PE had a significantly longer median DFI (168 days) than dogs treated with empty liposomes (58 days). Similarly, the MST was significantly longer for dogs treated with L-MTP-PE (222 days) than for dogs treated with empty liposomes (77 days).[284] Based upon these findings, it was concluded that L-MTP-PE induced beneficial immunobiologic effects capable of delaying the development of pulmonary metastasis.

After establishing the anticancer activity of single-agent L-MTP-PE when used in the adjuvant setting, two subsequent randomized, double-blind studies were conducted to determine the effectiveness of combining L-MTP-PE with cisplatin.[285] In

VetBooks.ir

one study, dogs were treated with limb amputation and cisplatin every 4 weeks for four treatments. Upon completion of cisplatin therapy, 25 dogs without overt evidence of pulmonary metastasis were randomized to receive either L-MTP-PE or empty liposomes twice a week for 8 weeks. Dogs treated with L-MTP-PE had a significantly longer MST (14.4 months) than dogs treated with empty liposomes (9.8 months).

Unlike the first study in which cisplatin and L-MTP-PE was administered serially, the second study investigated the anticancer activities of concurrently administered cisplatin and L-MTP-PE in 64 dogs. All dogs were treated with limb amputation and cisplatin every 3 weeks for four treatments. Within 24 hours after the first cisplatin treatment, dogs were randomized to concurrently receive either L-MTP-PE twice weekly, L-MTP-PE once weekly, or empty liposomes once weekly for 8 weeks. Dogs treated with concurrent L-MTP-PE (once or twice weekly) and cisplatin did not have an improvement in median DFI or MST compared with dogs treated with concurrent empty liposomes and cisplatin. The MSTs for the twice weekly, once weekly L-MTP-PE, and empty liposome groups were 10.3, 10.5, and 7.6 months, respectively.

These studies suggest that innate immune activation may be a strategy for improving outcomes in dogs with OSA. This priming of the innate immune system has been leveraged through different strategies. The potential to create localized inflammation, apoptosis, and necrosis within the immediate tumor microenvironment with subsequent adaptive immune cell priming was evaluated in dogs with OSA receiving an intratumoral adenoviral vector for FasL (Ad-FasL). Through an open-label clinical trial, 52 dogs with OSA were treated with intratumoral Ad-FasL and subsequent limb amputation 10 days post-Ad-FasL administration and carboplatin chemotherapy. After amputation, histologic examination of the primary tumor was performed to characterize degree of inflammation, apoptosis, necrosis, and lymphocyte infiltration. Dogs with greater inflammation and lymphocyte infiltration scores had improved median DFIs and MSTs. When inflammation induced by Ad-FasL was categorized into low (score 1) versus high (score 2 or 3), the MSTs were 198 versus 359 days, respectively. Collectively, these studies support the notion that creating a robust innate immune response within the immediate primary tumor microenvironment has the capacity to induce sufficient immunogenic abscopal effects to delay the onset of metastatic disease.[286]

In addition to innate immune activation strategies, a vaccine approach to specifically induce tumor-specific T-cell responses against the dominant immune epitopes of HER2/neu expressed by canine OSA cells has been reported. Through the generation and IV administration of a highly attenuated, recombinant *Listeria monocytogenes* expressing a chimeric human HER2/neu$^+$ fusion protein (ADXS31-164), the capacity to elicit a HER2-specific immune response was evaluated in 18 dogs with OSA treated with three consecutive dosages of ADXS31-164 every 3 weeks after the completion of conventional therapy (amputation or LSS and four doses of carboplatin chemotherapy). In 15 dogs, HER2-specific responses could be serially assessed through the quantification of antigen-induced T-cell interferon-gamma (IFNγ) secretion, and this served as an immune biomarker to measure the immune reaction elicited by vaccination with ADXS31-164. Although T-cell IFNγ secretion profiles did not correlate with long-term survival outcomes, the magnitude of white blood cell, neutrophil, and monocyte elevations 24 hours after ADXS31-164 administration were significantly greater in dogs with STs exceeding 18 months. These collective findings would suggest that innate immune responses are contributing to the anticancer immune effects exerted by ADXS31-164. Overall, the adjuvant use of ADXS31-164 after standard-of-care therapy was well tolerated, and treated dogs achieved prolonged disease control with a median DFI and MST of 615 and 956 days, respectively.[287]

Molecular Targeted Therapies for Dogs with Osteosarcoma

The GH and IGF-1 growth factor signaling cascade has been thoroughly investigated in OSA. The putative roles of GH and IGF-1 in OSA pathogenesis are supported by several clinical observations in both humans and dogs. Given the central roles of GH and IGF-1 in skeletal growth and homeostasis, as well as their role in cell survival, it has been hypothesized that aberrant or excessive GH and IGF-1 signaling is likely involved in OSA pathogenesis.[288] To investigate the biologic consequences of attenuating GH and IGF-1 autocrine and/or paracrine signaling in OSA, a randomized clinical trial of 44 dogs with OSA was conducted in which circulating IGF-1 concentrations were suppressed with the administration of a long-acting somatostatin analog (OncoLAR).[268] All dogs were treated with amputation and carboplatin in combination with either OncoLAR or control vehicle. The administration of OncoLAR resulted in a 43% reduction in circulating IGF-1 concentrations in comparison to baseline values; however, incomplete suppression in IGF-1 did not result in improved DFIs or overall MSTs in comparison to dogs treated with carboplatin and the vehicle.

Molecular therapies with the capacity to delay or inhibit the development of pulmonary metastases would dramatically improve current treatment outcomes. As such, novel anticancer agents have been designed to selectively inhibit obligate steps necessary for successful tumor cell invasion and metastasis. One specific strategy has been the inhibition of matrix metalloproteinases (MMPs), which are proteolytic enzymes involved in local tissue invasion and metastases. Based upon documented gelatinolytic activities of MMP-2 and MMP-9 in canine cell lines and OSA samples,[91,93] it has been rationalized that specific inhibitors of MMP activity may have the potential to increase the metastasis-free period after amputation and systemic chemotherapy. A prospective, double-blind, randomized, placebo-controlled clinical trial evaluating the adjuvant activity of a MMP-2 and -9 inhibitor (BAY 12-9566) was conducted in 223 dogs with nonmetastatic OSA.[180] After amputation and DOX therapy, dogs were randomized and treated with either BAY 12-9566 (10 mg/kg) or placebo control daily until clinical failure. The addition of BAY 12-9566 did not improve DFI or MST in comparison to placebo control. Correlating with the absence of biologic effect, serum MMP-2 and -9 activities were not different between dogs receiving BAY 12-9566 or placebo.

With the approval of toceranib phosphate (TOC) in veterinary medicine, this small molecule inhibitor of multiple kinase signaling pathways (KIT, VEGF receptor 2 [VEGFR2], platelet-derived growth factor receptor [PDGFR]) has generated scientific interest for its inclusion as an adjuvant treatment for dogs with appendicular OSA. In a randomized, prospective clinical trial, 126 dogs with OSA were treated with amputation and four doses of carboplatin and, if there was no evidence of metastatic disease, this was followed by either oral metronomic therapy (cyclophosphamide and piroxicam) alone or oral metronomic therapy and TOC. Although the inclusion of toceranib phosphate was tolerable, there was no statistical difference in the median DFI for dogs treated with the control protocol (215 days) or TOC (233 days).

Similarly, the MSTs were not different between control (242 days) and TOC (318 days) groups.[289]

Increasing the sensitivity of OSA cells to conventional cytotoxic therapies has the potential to delay the development of metastatic disease. Suramin, a polysulfonated napthylurea, has shown promise to increase tumor sensitivity to chemotherapy and has been evaluated in combination with DOX in 47 dogs with OSA. Suramin was administered at a dose of 6.75 mg/kg IV, and this was followed 4 hours later with 30 mg/m^2 IV DOX every 14 days for a total of five treatments. The combination of suramin and DOX was well tolerated; the median DFI and overall MST were 203 and 369 days, respectively. Although principally a feasibility study, the single-arm design precluded any definitive conclusions to be drawn regarding the ability of adjuvant suramin to augment the anticancer activities of DOX.[290]

Treating Gross Metastatic Disease

Surgery for Gross Metastatic Disease

Resection of pulmonary metastasis from OSA or other solid tumors has been reported in dogs and people.[207,291] In one study of 36 dogs with metastatic OSA to the lungs, metastasectomy was performed by either local resection or partial or total lung lobectomy. Chemotherapy was not administered after pulmonary metastasectomy. Although the initial treatments varied among dogs, the overall MST was 487 days. The MST after pulmonary metastasectomy was 176 days. The criteria established for case selection for pulmonary metastasectomy to maximize the probability of long survival periods were: (1) primary tumor in complete remission, preferably for >300 days; (2) one or two nodules visible on survey thoracic radiographs; (3) metastasis confined to the lungs (negative bone scan); and perhaps (4) long doubling time (>30 days) with no new visible lesions within this time. In a small series, pulmonary metastasectomy was also effective in ameliorating the clinical effects of hypertrophic osteopathy in four dogs with metastatic appendicular OSA.[292]

Chemotherapy and Receptor Tyrosine Kinase Inhibitors for Gross Osteosarcoma

The treatment of gross measurable OSA with conventional cytotoxic agents or receptor tyrosine kinase inhibitors remains unsatisfactory. In part, the ineffectiveness of systemic therapies to cytoreduce gross measurable OSA lesions is likely secondary to drug-resistant clones in conjunction with unfavorable and altered drug biodistribution within large tumor microenvironments. Because formidable biologic barriers exist within macroscopic tumors that favor cancer cell survival, the majority of studies demonstrate only marginal effectiveness of conventional cytotoxic agents or receptor tyrosine kinase inhibitors for the management of gross, measurable OSA.

In one study, 45 dogs that had either developed gross metastatic OSA after standard-of-care therapy (amputation and systemic chemotherapy) or diagnosed at presentation with metastatic OSA were treated with single-agent chemotherapies including cisplatin, DOX, or mitoxantrone.[293] Only one dog achieved a short-lived (21 days) partial response. These findings suggest that conventional cytotoxic agents, which are effective in the adjuvant setting, are not efficacious for managing macroscopic metastatic OSA. In a second study evaluating the tolerability and anticancer activities of paclitaxel in dogs with measurable tumor burdens, two of nine dogs with macroscopic pulmonary metastatic OSA achieved a partial response, suggesting that inhibitors of microtubule depolymerization might have modest activity for the management of gross measurable OSA lesions.[294]

In addition to cytotoxic agents, TOC has recently evaluated for anticancer activity across a broad range of tumor histologies, including metastatic pulmonary OSA.[295] Based on the ability of TOC to inhibit multiple signaling pathways, its potential activity was evaluated retrospectively in 23 dogs with measurable pulmonary OSA metastases.[296] TOC was orally administered at a median dose 2.7 mg/kg (every other day or Monday-Wednesday-Friday). A partial response was noted in one dog (4.3%) and stable disease in 10 dogs (43.5%). Given the initial potential activity of TOC phosphate in dogs with macroscopic pulmonary metastatic disease, its activity was further evaluated in two subsequent follow-up studies. In one prospective study, 22 dogs with measurable pulmonary metastases were treated with TOC at a target dosage of 2.75 mg/kg PO on Monday-Wednesday-Friday schedule. Dogs were reevaluated at weeks 2, 3, 4, and 8 week to assess for biochemical tolerability, and at 8 weeks for radiographic response. In addition to radiographic response, changes in circulating VEGF and Tregs associated with TOC therapy were quantified. Nine dogs were withdrawn from study before radiographic assessment due to reduced quality of life and/or disease progression. Stable and progressive disease was documented in 17.6% and 83.4% of the remaining dogs, respectively. The median PFS and overall MSTs were 57 and 89 days, respectively. Circulating VEGF increased with TOC treatment, but there was no effect on Tregs.[297] A second retrospective study in 20 dogs confirmed the overall low efficacy of TOC in the treatment of dogs with pulmonary metastases. In this second study, TOC was administered at a median dose of 2.52 mg/kg. A partial response and stable disease was documented in one dog each for an overall 10% clinical benefit rate. The median PFS and overall MST were 36 and 90 days, respectively.[298] Based upon these two studies, the anticancer activities of TOC as a single agent managing macroscopic OSA metastases is relatively low.

Strategies to enhance the susceptibility of metastatic cancers to conventional chemotherapeutic agents have also been investigated. By virtue of their chromatin remodeling effects, histone deacetylase inhibitors (HDACi) used in combination with cytotoxic agents may enhance the nuclear accumulation of cytotoxic agents and improve therapeutic outcomes. Based on this premise and a systems biology approach to identifying molecular pathways altered by HDAC inhibition in OSA,[299] a phase I dose-escalation study combining valproic acid and DOX was conducted in dogs with various spontaneous tumors to determine the tolerability and activity of this HDACi-chemotherapy combination.[300] Three dogs with macroscopic OSA pulmonary metastases were treated with valproic acid and DOX, and one dog achieved durable stable disease.

Investigational Therapies for Gross Metastatic Disease

Aerosol Drug Delivery

Two studies have been conducted to evaluate the feasibility, tolerability, and anticancer activities of aerosolized cytotoxic therapies in dogs diagnosed with pulmonary OSA metastases.[301,302] In one study, six dogs with pulmonary OSA metastasis were treated with inhaled DOX, paclitaxel, or both every 14 days for a total of six treatments.[301] Aerosolization therapy was well tolerated with no dose-limiting hematologic or biochemical toxicity; however, in dogs treated with aerosolized DOX, pulmonary histologic

changes were identified at necropsy in some patients, consisting of toxin-induced pneumonitis, multifocal interstitial fibrosis, alveolar histiocytosis, and type II pneumocyte proliferation. A partial response was documented in two dogs treated with inhaled DOX and a complete response in one dog treated with inhaled paclitaxel. In the one dog with a complete response, the response was durable and persisted for more than 325 days.

In addition to DOX and paclitaxel, aerosolized gemcitabine has been evaluated in dogs with metastatic OSA. Gemcitabine, a pyrimidine antimetabolite belonging to the nucleoside analog family, has anticancer activity when administered through an aerosolized route in mouse OSA xenograft models; these are mediated though the upregulation of Fas receptor expression on the surface of pulmonary metastatic OSA cells.[303] Because lung epithelium basally expresses Fas ligand, the restoration of Fas receptor expression by OSA cells would consequently render them susceptible to Fas receptor/Fas ligand-mediated apoptosis. Based on this preclinical information, a comparative study with aerosolized gemcitabine was conducted in 20 dogs with pulmonary OSA metastasis.[302] Dogs were treated twice weekly with inhalation gemcitabine and monitored for toxicity and anticancer activity. Aerosolized gemcitabine was well tolerated with no dose-limiting hematologic or biochemical toxicity reported and minimal histologic lung pathology after inhalation therapy. Mechanistic anticancer activities of aerosolized gemcitabine were supported by the identification of increases in percent necrosis, Fas receptor expression, and TUNEL positivity in macroscopic pulmonary OSA metastatic lesions; however, clinically relevant responses were not documented.

Augmentation of Antitumor Immunity

Cytokines are cellular peptides that actively aid or stimulate the immune system to recognize and attack cancer cells. Although numerous cytokines participate in shaping the strength, specificity, and longevity of antitumor immune responses, interleukin-2 (IL-2) is a critical cytokine necessary for stimulating the growth, differentiation, and survival of antigen-specific cytotoxic T cells. Additional immune effects orchestrated by IL-2 include the facilitation of immunoglobulin production by B cells and the differentiation and proliferation of natural killer cells. Despite the pleiotropic and desirable antitumor immune activities of IL-2, its systemic administration has been clinically limited due to severe toxicities. As such, alternative delivery strategies have been investigated to attenuate IL-2 associated toxicities yet maximize its potent immunomodulatory effects.

For the treatment of pulmonary metastasis, the localized deposition of IL-2 or the preferential gene expression of IL-2 within the lung parenchyma has been investigated as a novel treatment option in dogs with metastatic OSA. Initial studies evaluated the antitumor activities of inhaled liposomal IL-2.[304] Dogs were nebulized with liposomal IL-2 daily for 30 days. The immunomodulatory effects of IL-2 were confirmed by increases in bronchoalveolar lavage effector cell numbers and lytic activities with resultant complete regression of macroscopic pulmonary OSA metastasis in two of four dogs. The duration of this response was between 12 and 20 months. IV gene therapy as liposome-DNA complexes encoding IL-2 has also been investigated as an alternative to inhaled liposomal IL-2 delivery strategies.[305] Based on its preferential accumulation and subsequent transgene expression within the lung parenchyma, the tolerability, immunomodulatory effects, and antitumor activity of IV liposome DNA complexes encoding IL-2 were evaluated in 20 dogs with chemotherapy-resistant OSA metastasis. After administration, the immunomodulatory effects of liposome DNA complexes were substantiated by the induction of fever, leukogram changes, monocyte activation, and increased natural killer cell activities. After completion of 12 consecutive weekly IV treatments with liposome DNA complexes, measurable responses were achieved in three dogs with one complete response and two partial responses.

Other investigations have evaluated alternative strategies for activating the immune system, including IV administration of a genetically modified and attenuated bacterial species, *Salmonella typhimurium* (VNP20009).[306] Based on the premise that anaerobic bacteria have potential as novel immunomodulatory cancer therapeutics, a phase I dose escalation study was conducted with VNP20009 in 41 dogs with spontaneous cancers. Dose-limiting toxicity included fever and vomiting; both were attributed to systemic immune activation. Importantly, preferential tumor tissue tropism of VNP20009 was confirmed by gene transcription and bacterial culture techniques in a substantial proportion of tumor samples. In a subset of four dogs with OSA pulmonary metastasis, one dog had a partial response for a duration of 68 days.

Palliative Treatment: Primary and Metastatic Bone Cancer Pain

Palliative Radiation Therapy

RT is considered the most effective treatment modality for the management of osteolytic bone pain in human cancer patients and, likewise, has been investigated and extensively applied for alleviating bone cancer pain in dogs with primary bone tumors. Mechanistically, the analgesic effects of ionizing radiation can be partially attributed to the induction of cell death in both malignant osteoblasts and resorbing osteoclasts,[307] and this has been documented in dogs by an assessment of percentage TN.[205,239,308] As such, ionizing radiation may reduce overall tumor burden and attenuate the degree of osteoclast resorption. The rapid onset of analgesia that occurs before a change in tumor volume suggests other, as yet unknown, mechanisms are involved in the analgesic effects of RT. Other proposed mechanisms of radiation-induced analgesia include depletion of local inflammatory cells and inhibition of osteoclast precursor recruitment.[309]

Multiple palliative RT protocols have been evaluated and reported in the veterinary literature with the majority of dosing schemes using two to four fractions of 6 to 10 Gy. Although variable and subjectively reported in these studies, the alleviation of bone cancer pain was achieved in 74% to 93% of dogs. Although the majority of dogs symptomatically improved after palliative RT, the median time interval of subjective pain alleviation was not durable and ranged from 53 to 130 days.[234,310–314] Given that most conventional palliative RT protocols only include two to four fractions, the total cumulative radiation dose administered is relatively low (<32 Gy). As a result, acute and late radiation toxicities are not a limiting factor for the majority of patients treated. Although megavoltage palliative RT appears effective when used as a single-agent treatment option for short-term pain management, some investigations suggest that the concurrent administration of IV systemic chemotherapy along with palliative RT may enhance analgesic response rates, durations of responses, and overall STs.[313,315]

Radiopharmaceuticals

^{153}Sm is a radioisotope that undergoes gamma (103 keV) and beta decay (max 810 keV), allowing for concurrent biodistribution tracking studies as well as therapeutic ionizing radiation

VetBooks.ir

delivery within a 2 to 3 mm deposition radius. When ^{153}Sm is conjugated to EDTMP, which is a bisphosphonate, the resultant ^{153}Sm-EDTMP compound preferentially concentrates in areas of increased osteoblastic activity and binds to exposed hydroxyapatite crystals.[316] By virtue of its osteotropism and defined radius of ionizing radiation deposition, ^{153}Sm-EDTMP is currently used as a radiopharmaceutical for the palliative treatment of multifocal skeletal metastases in people with breast or prostate carcinoma.[317]

Similar to people diagnosed with skeletal malignant osteolysis, the use of ^{153}Sm-EDTMP has been investigated for alleviating bone cancer pain in dogs with appendicular and axial OSA.[318–322] In dogs treated with ^{153}Sm-EDTMP, the predicted radiation dose equivalent achieved within the immediate bone tumor microenvironment has been estimated to approximate 20 Gy,[318] although its intratumoral biodistribution is expected to be nonhomogenous based upon regional differences in reparative osteoblastic activities. After IV ^{153}Sm-EDTMP administration, the 63% to 83% of dogs with OSA demonstrate improved lameness scores and activity levels, suggesting palliation of pain.[318–321] In axial skeletal lesions, four dogs were documented to have an improvement at 21 days posttreatment based on reduced tumor size or improved clinical signs, whereas 13 dogs had progressive disease based on worsening of clinical signs or tumor growth.[322]

^{177}Lutetium (^{177}Lu) is an isotope that emits gamma photons (208 keV) and beta particles (max 497 keV). ^{177}Lu has been investigated when complexed with EDTMP or DOTMP, a macrocyclic analog of EDMTP.[266] ^{177}Lu is proposed to offer greater bone marrow sparing effects in comparison to ^{153}Sm-EDTMP due to a lower soft tissue penetration of 670 μm. The toxicity profile of ^{177}Lu-DOTMP has been evaluated in normal dogs and no significant changes in platelet or white cell counts were observed, but mild changes in red cell counts were noted on day 84.[323] A pilot study was performed in four dogs with primary or metastatic skeletal lesions, and analgesic effect was demonstrated in three dogs.[324] In human patients, ^{177}Lu-EDTMP appears equally effective at inducing analgesia compared with ^{153}Sm-EDTMP with a similar toxicity profile.[325]

Aminobisphosphonates

Aminobisphosphonates (NBPs) are synthetic analogs of inorganic pyrophosphate that were initially utilized for diagnostic purposes in bone scanning based on their ability to preferentially adsorb to sites of active bone mineral remodeling. The pharmaceutical use of NBPs has gained wide acceptance in the therapy of human nonneoplastic bone resorptive disorders such as osteoporosis and Paget's disease.[326] In addition to the management of these metabolic disorders, NBPs are considered first-line options for the treatment of malignant skeletal osteolytic conditions, including paraneoplastic hypercalcemia, multiple myeloma, and metastatic bone diseases in human cancer patients.[327,328]

The effective treatment of bone disorders by NBPs is attributed to their differential effect on bone resorption and bone mineralization. At concentrations safely achievable in vivo, NBPs inhibit bone resorption without inhibiting bone mineralization. Mechanistically, the bone protective effects exerted by NBPs are through the induction of osteoclast apoptosis, which results in the net attenuation of pathologic bone resorption.[329,330] Specifically, NBPs interfere with posttranslational prenylation of small GTP-binding proteins, including Ras, Rho, and Rac.[331] The disruption of these small GTP-binding protein results in the failure of normal intracellular signaling and interaction with the extracellular matrix, thereby triggering osteoclast apoptosis.

Given that OSA is characterized by focal and aggressive malignant osteolysis, the investigation of NBPs has been a focus of clinical interest. The first reported description in the veterinary literature was the use of oral alendronate for the palliative management of two dogs with OSA.[332] Based upon the unexpectedly long STs reported in this anecdotal study, the authors suggested that NBPs therapy may have a role in managing dogs malignant bone diseases. Given that IV NBPs have been historically used for the management of malignant osteolysis in people, a prospective study principally evaluating the safety of IV pamidronate (PAM) was conducted in 33 dogs diagnosed with primary and secondary skeletal tumors.[333] IV PAM (1.0 mg/kg diluted with 0.9% sodium chloride to a total volume of 250 mL) as a 2-hour constant rate infusion (CRI) every 28 days was well-tolerated and, in a subset of dogs, the bone biologic and clinically relevant therapeutic effects of IV PAM were documented with significant reductions in urine N-telopeptide (NTx) concentrations, increases in relative primary tumor bone mineral density (rBMD) as assessed by dual-energy x-ray absorptiometry (DEXA), and subjective pain alleviation.

After the established safety of IV PAM in dogs with skeletal tumors, a second study of 43 dogs treated with IV PAM (1.0 mg/kg versus 2.0 mg/kg) was conducted to further characterize the biologic activity of PAM specifically for the management of appendicular OSA associated bone pain and pathologic bone resorption.[334] Overall, 28% of 43 OSA-bearing dogs achieved pain alleviation for more than 4 months. In addition to the subjective analgesic effects of PAM reported by pet owners, changes in urine NTx concentrations and DEXA-assessed rBMD correlated with therapeutic response.

Although original studies have focused on the palliative effects of PAM when used as a single-agent, a recent study documented the synergistic activity of PAM when coupled with palliative RT in dogs with appendicular OSA.[335] In a prospective, double-blind, randomized, placebo controlled clinical trial, 17 dogs with appendicular OSA were treated with palliative RT (8 Gy on days 1 and 2) and either 0.9% saline infusion or PAM once every 4 weeks for three treatments. Before initial palliative RT and after each IV treatment with either 0.9% saline or PAM, all dogs were evaluated by force plate gait analysis, urine NTx concentrations, numerical lameness evaluation, and owner quality of life (QOL) questionnaires. The saline placebo group dogs experienced a significant increase in numerical lameness score between weeks 0 and 12, and PAM significantly lowered the lameness scores on week 12 compared with saline. In addition, dogs receiving PAM had a significantly greater vertical impulse and total stance time from week 4 to week 12. Based on these findings, the addition of PAM to palliative RT appeared to improved limb function compared with palliative RT alone.

In a double-blind, placebo-controlled study, 50 dogs with OSA were treated with palliative RT, DOX, and either a saline placebo or PAM .[336] The median pain-free intervals for dogs treated adjuvant PAM or saline was 76 days and 75 days, respectively. Despite the apparent lack of pet owner-perceived analgesia, dogs treated with adjuvant PAM had better QOL scores and, more importantly, decreased malignant bone resorption in the primary tumor. Collectively, these findings suggest that adjuvant PAM may not subjectively improve analgesia when dogs are already receiving treatment with megavoltage RT and DOX, but PAM still exerts beneficial bone biologic effects within the bone tumor microenvironment in dogs with OSA.

Although most palliative studies have documented the effects of PAM, other more potent IV NBPs for managing malignant

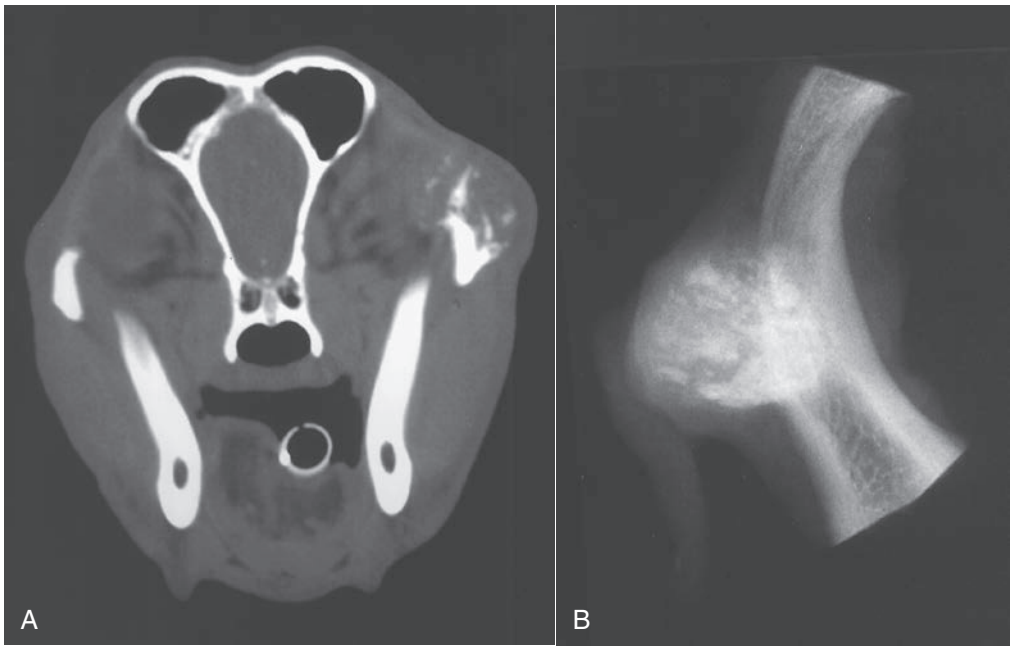
bone pain have been evaluated in dogs with skeletal tumors. Zoledronate (ZOL) has a 100-fold greater antiresorptive potency than PAM and has the advantage of being safely administered over a shorter period of time than other NBPs. In one case report, IV ZOL administered every 28 days was effective for the long-term pain management of a dog with a distal radial OSA.[337] The bone biologic effects of IV ZOL were evaluated in 10 dogs with primary and secondary skeletal tumors.[338] ZOL was administered at a dose of 0.25 mg/kg as a 15-minute CRI every 28 days. This was well tolerated with no overt biochemical evidence of renal toxicity in patients receiving multiple monthly infusions. Pain was alleviated in 50% of the 10 dogs with appendicular OSA for more than 4 months. These dogs demonstrated significant increases in rBMD, which suggests that ZOL inhibits local malignant osteolysis and the generation of pain within the immediate bone tumor microenvironment. Although studies evaluating the safety of long-term PAM or ZOL in dogs with primary and secondary bone tumors have not been thoroughly evaluated, infrequent and severe bone metabolic changes, such as osteonecrosis of the jaw, have been reported in one dog treated with monthly ZOL (0.1 mg/kg IV, 15-minute CRI) for 43 consecutive months.[339]



Comparative Aspects

Animal models for the study of human diseases are important to better understand the mechanisms and etiology of diseases and to develop and refine therapeutic strategies. Spontaneously developing diseases in animal populations are particularly useful for translational purposes.[340–342] Canine OSA has many similarities to human OSA in terms of genetic similarities, clinical presentation, biologic behavior, and metastatic progression and has been shown through many studies to be a valuable comparative model for study (Table 25.3).[7,341] OSA is more common in dogs than in humans, and therefore case accrual is more rapid. Because disease progression is more rapid in dogs than in humans, results of novel treatment protocols can be reported earlier than in similar trials in humans. Research costs for clinical trials in dogs are less compared with those in human clinical trials, and, from an animal welfare standpoint, no disease is induced and dogs with cancer can potentially be helped through the course of the research.

OSA is an uncommon cancer in humans, affecting mainly adolescents in their second decade of life, and it remains a very serious, aggressive tumor. Fortunately, there has been an improvement in survival rates with the use of established multidrug adjuvant protocols incorporating high-dose methotrexate, DOX, and cisplatin. The long-term survival rate for human OSA is presently 60% to 70% at 5 years, which contrasts with the 20% 5-year survival rate of the early 1980s. A recent retrospective study of 251 patients showed that the 5-year survival rate increased from 36% in the 1980s to 67% in the early 2000s. During the same period, LSS for local disease control increased from 53% to 97%, and the need for amputation due to failure of the LSSs concurrently decreased, indicating that the increased adoption of LSSs did not negatively affect outcome.[343]

Poor prognostic factors include older age, advanced local or systemic stage, axial location, larger size, and percentage TN.[344] Tumor necrosis of more than 90% after neoadjuvant chemotherapy is highly prognostic for improved patient outcome with 5-year survival rates of 75% to 80% compared with 45% to 50% for those with less than 90% necrosis. A recent phase III

trial randomly assigned 618 patients with less than 90% tumor necrosis after neoadjuvant chemotherapy to a protocol that incorporated ifosphamide and etoposide in addition to the standard-of-care drugs methotrexate, DOX, and cisplatin. This study failed to show any prolongation in PFS after administration of the additional chemotherapy agents and resulted in more frequent grade IV hematologic toxicity.[345]

Bone Surface Osteosarcoma

OSA usually originates from elements within the medullary canal of bones (intraosseous OSA); however, there are forms of this cancer that originate from the outer surface of bones. Periosteal OSA is a high-grade form of surface OSA and seems to arise from the periosteal surface but has invasive characteristics that can be seen radiographically.[346] There is cortical lysis with extension of the tumor into the bone and surrounding soft tissues. These tumors are histologically similar to intraosseous OSA and have a similar aggressive biological behavior.

In contrast, parosteal or juxtacortical OSA arises from the periosteal surface of bones but is less aggressive than periosteal OSA both radiographically and biologically. Parosteal OSAs are uncommon and have a moderately well-circumscribed radiographic appearance. These tumors grow out from the periosteal side of a cortex, and cortical lysis is usually very mild on radiographs. Histologically, these tumors look more benign compared with intraosseous or periosteal OSA. These tumors contain well-differentiated cartilage, fibrous tissue, and bone with sparse regions of sarcoma cells adjacent to tumor osteoid. Histologic specimens must be evaluated carefully because it is often easy to miss the areas of tumor cells and misdiagnose the lesion as an osteoma, chondroma, or reactive bone. They generally do not invade the medullary canal and tend to grow out from the bone on broad pedicles. Diagnosis is based on typical histologic and radiographic findings.

Parosteal OSA is usually slow growing, but can induce pain at the local site. Metastasis can occur, but the prognosis for long-term survival is much better than for intraosseous OSA.[347,348] Control of parosteal OSA can be achieved by en bloc resection of the tumor with the adjacent cortical bone, as has been reported for tumors of the zygomatic arch (Fig. 25.12).[348] If full thickness cortex needs to be removed for tumors in the long bones, reconstruction may be performed using autogenous corticocancellous bone such as a rib, ileal crest, or allogeneic cortical bone.

Other Primary Bone Tumors of Dogs

Primary bone tumors other than OSA account for 2% to 15% of bone malignancies in dogs. These tumors include CSAs, FSAs, HSAs, lymphomas, and plasma cell tumors.

It can be difficult to distinguish chondroblastic OSA from CSA, fibroblastic OSA from FSA, and telangiectatic OSA from HSA when only small amounts of tissue are evaluated.[140] This makes interpretation of older reports difficult in terms of trying to establish the true incidence of the different types of primary bone tumors; however, more recent studies have identified IHC markers which may aid in bone sarcoma differentiation.[349–351]

Chondrosarcoma

CSA is the second most common primary tumor of bone in humans and dogs and accounts for approximately 5% to 10% of all canine primary bone tumors.[2–5,352] CSAs are characterized histologically by anaplastic cartilage cells that elaborate a cartilaginous matrix. There is a spectrum of degree of differentiation and maturation of the cells within and between each tumor. Histologic grading systems have been described. The etiology is generally unknown, although CSA can arise in dogs with preexisting multiple cartilaginous exostosis.[353,354] In a clinicopathologic study of 97 dogs with CSA, the mean age was 8.7 years, and Golden

VetBooks.ir

Retrievers were at a higher risk of developing CSA than any other breed.[355] There was no sex predilection, and 61% of the tumors occurred on flat bones. CSA can originate in the nasal cavity, ribs, long bones, pelvis, extraskeletal sites (such as the mammary gland, heart valves, aorta, larynx, trachea, lung, and omentum), vertebrae, facial bones, digits, and os penis.[29,355–362] The nasal cavity is the most common site for canine CSA.[355]

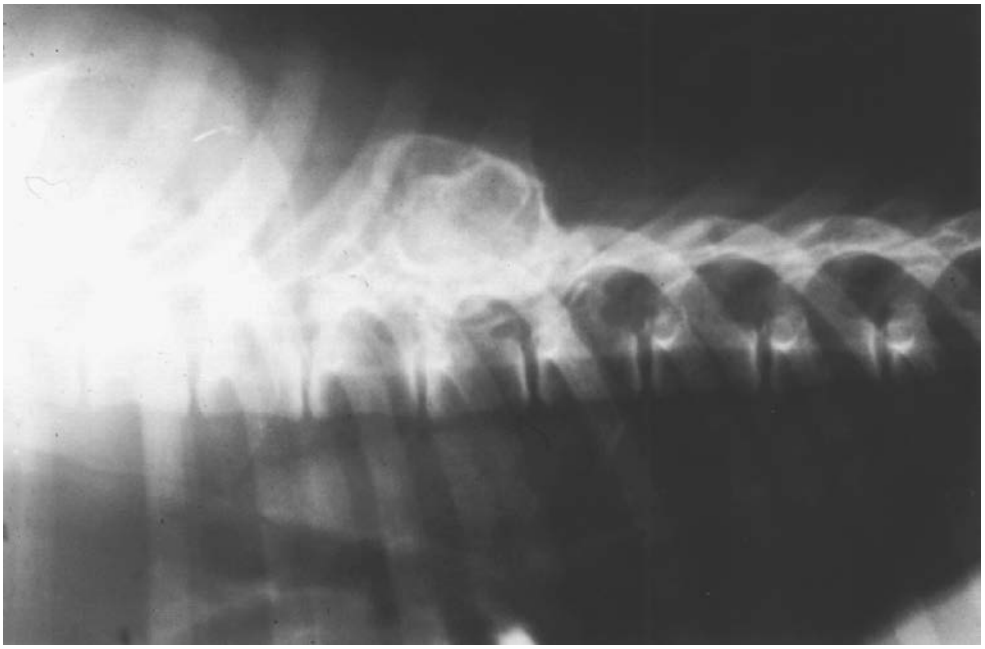
CSA is generally considered to have a lower metastatic rate than OSA; however, a more aggressive variant, dedifferentiated CSA, has been described in seven dogs and one cat, and the metastatic rate in these animals was 63%.[363] Tumor location rather than histologic grade was prognostic in one study,[344] but histologic grade was prognostic in two other studies.[364,365] The MST for dogs with nasal CSA ranges from 210 days to 580 days with various treatments (RT, rhinotomy and RT, and rhinotomy alone).[355,366] Metastatic disease is rare in dogs with nasal CSA. The MST for dogs with CSA of ribs varies widely.[20,171,367] Reports before 1992 contained few cases that were treated with intent to cure, but MSTs in more contemporary reports range from 1080 days to more than 3820 days.[172,181,364,365] The overall MST for 25 dogs with appendicular CSA treated with limb amputation alone was 979 days, but outcomes were dependent on histologic grade. The metastatic rates and MSTs for grade I, II, and III appendicular CSAs were 0% and 6.0 years, 31% and 2.7 years, and 50% and 0.9 years, respectively. A reliable adjuvant chemotherapeutic agent is not known for canine CSA.

Hemangiosarcoma

Primary HSA of bone is rare and accounts for less than 5% of all bone tumors. This disease generally affects middle-aged to older dogs and can occur in dogs of any size. This is a highly metastatic tumor, and most dogs affected will develop metastatic disease within 6 months of diagnosis. Metastases can be widely spread throughout various organs such as lungs, liver, spleen, heart, skeletal muscles, kidney, brain, and bones. Dogs can present with multiple lesions making it difficult to determine the site of primary disease. Histologically, HSA is composed of highly anaplastic mesenchymal cells, which are precursors to vascular endothelium. The cells are arranged in chords separated by a collagenous background and may appear to be forming vascular channels or sinuses. Cellular pleomorphism and numerous mitotic figures are features of this highly malignant disease. There is profound bone lysis, and the malignant cells aggressively invade adjacent normal structures. Appendicular HSA may be confused with telangiectatic OSA, especially if the diagnosis is based on small tissue samples.[349] The dominant radiographic feature is often lysis; however, HSA does not have an unequivocally unique radiographic appearance, and diagnosis is based on histology.

If HSA is diagnosed, the dog must be thoroughly staged with thoracic and abdominal films, bone survey radiographs or bone scintigraphy, and ultrasonographic evaluation, particularly of the heart and abdominal organs. Right atrial HSA may be present without clinical or radiographic signs of pericardial effusion. Cyclophosphamide, vincristine, and DOX have been used in combination as an adjuvant protocol, and the reported MST for dogs with nonskeletal HSA is 172 days.[368] In a recent study of 41 dogs with primary appendicular HSA, a predilection for the pelvic limb was noted, especially the tibia. The overall MST was 299 days after treatment with limb amputation and chemotherapy.[350]

• **Fig. 25.13** Specimen radiograph of a multilobular osteochondrosarcoma arising from the vertical ramus of the mandible in a dog. These tumors have a granular radiographic appearance often referred to as "popcorn ball."



Fibrosarcoma

Primary FSA is also a rare tumor of dogs and accounts for less than 5% of all primary bone tumors.[4] Unfortunately, the difficulty in distinguishing FSA from fibroblastic OSA histologically renders study of this tumor difficult. In one report, 11 dogs thought to have appendicular FSA were reevaluated after complete resection and the histologic diagnosis was changed to OSA in six dogs.[369] Histologic characteristics of FSA include interwoven bundles of fibroblasts within a collagen matrix of permeating cancellous and cortical bone that is not associated with osteoid produced by the tumor cells. Limb amputation or LSS may be curative, although metastatic potential may be considerable. There is no good evidence that adjuvant chemotherapy is beneficial in preventing metastatic disease. It has been postulated that primary FSA of bone has a propensity to metastasize to such sites as heart, pericardium, skin, and bones rather than lung.[369]

Multilobular Osteochondrosarcoma

Multilobular osteochondrosarcoma (MLO) is an uncommon tumor that generally arises from the skull of dogs.[162,370–372] Many names have been used to describe this disease, including chondroma rodens, multilobular osteoma, and multilobular tumor of bone. These tumors have a characteristic appearance on radiographs, CT, and MRI; the borders of the tumor are sharply demarcated with limited lysis of adjacent bone, and there is a coarse granular mineral density throughout (Fig. 25.13).[373,374]

VetBooks.ir

• **Fig. 25.14** Lateral radiograph of a multiple cartilaginous exostosis lesion of the dorsal spinous process in a dog.

There is one report of an MLO of the vertebra that did not have radiographic abnormalities.[375] Histologically, these tumors are composed of multiple lobules, each centered on a core of cartilaginous or bony matrix that is surrounded by a thin layer of spindle cells. A histologic grading system has been described.[162,371] In one report of 39 dogs with MLOs, the median age was 8 years, the median weight was 29 kg, and there was no breed or sex predilection.[373] Local tumor recurrence was reported in 47% of dogs after a median time of 797 days.[373] Metastasis was reported in 56% of dogs; however, time to metastasis was prolonged with a median of 542 days. The MST was 800 days. Local tumor recurrence and metastasis after treatment were predicted by histologic grade and the ability to obtain histologically complete resection.[373] Local tumor excision with histologically complete surgical margins appears to offer a good opportunity for long-term tumor control, especially for low-grade lesions. When metastatic lesions are identified by thoracic radiography, dogs may remain asymptomatic for their lung disease for 1 year or more. The role of chemotherapy and RT in the management of MLO is not well defined.

Metastatic Tumors of Bone

Almost any malignant tumor can metastasize to bone via the hematogenous route. The lumbar vertebrae, femur, humerus, rib, and pelvis are common sites for metastasis, possibly because these are predilection sites for bone metastasis from urinogenital malignancies such as prostate, bladder, urethral, and mammary cancer.[376] Metastatic lesions in long bones frequently affect the diaphysis, likely because of the proximity to a nutrient foramen. Nuclear scintigraphy is a sensitive technique to detect bone metastasis. A whole-body bone scan or PET/CT imaging is recommended when metastatic bone cancer is suspected because it is common for multiple sites of metastasis to be present, even if the patient is symptomatic for only one bone.

Benign Tumors of Bone

Osteomas

Osteomas are benign tumors of bone.[377] Radiographically, these are well circumscribed, dense bony projections that are usually not painful on palpation. Histologically, they are composed of tissue nearly indistinguishable from reactive bone. The diagnosis is made after considering the history and physical examination as well as the radiographic and histologic findings. The most important differential diagnosis is MLO when the lesion occurs on the skull. Treatment for osteoma is simple surgical excision and this is usually curative.

Multiple Cartilaginous Exostosis

Multiple cartilaginous exostosis (MCE) is a developmental condition of growing dogs. There is evidence that the etiology of this condition may have a heritable component.[354,378] The actual incidence of MCE is difficult to determine because affected dogs may show no clinical signs and the diagnosis is often incidental. Endochondral ossification is responsible for formation of these lesions with new bone being formed from a cartilage cap analogous to a physis. Lesions are located on bones that form from endochondral ossification, and lesions stop growing at skeletal maturity. Malignant transformation of MCE lesions has been reported, but generally they remain as unchanged, mature, bony projections from the surface of the bone from which they arose.[353]

Dogs typically present because of a nonpainful or moderately painful palpable mass on the surface of a bone or bones. The pain and lameness is thought to be due to mechanical interference of the mass with overlying soft tissue structures. In the case of MCE of vertebral bodies, animals can present with clinical signs associated with spinal cord impingement. Radiographically, there is a bony mass on the surface of the affected bone that has a benign appearance and a fine trabecular pattern in the body of the mass (Fig. 25.14). To obtain a histologic diagnosis, biopsy material must be collected so that sections include

VetBooks.ir

the cartilaginous cap and the underlying stalk of bone. Histologically, this cartilaginous cap gives rise to an orderly array of maturing bone according to the sequence of endochondral ossification. The cortical bone surfaces of the mass and the adjacent bone are confluent.[353] A strong presumptive diagnosis is made by evaluation of the history, physical examination findings, and radiographic features.

Treatment involves conservative surgical excision, but this is only necessary if clinical signs do not abate after the dog reaches skeletal maturity. Because of the likelihood of a heritable etiology, affected dogs should be neutered. Owners should also be advised of the possibility of late malignant transformation. Dogs with a previous history of MCE should be carefully evaluated for bone malignancy if clinical signs return later in life.

Bone Cysts

Cysts are rare, benign lesions of bone. The majority of the veterinary literature pertaining to bone cysts centers on several small series of cases or single case reports.[379–381] Affected animals are often young and present because of mild or moderate lameness; however, pathologic fracture can occur through cystic areas of long bones leading to severe lameness. There appears to be a familial tendency in Doberman Pinschers and Old English Sheepdogs. These lesions are usually in metaphyseal regions of long bones, and they can cross an open growth plate; however, unicameral bone cysts can sometimes be diaphyseal or epiphyseal. The etiology and pathogenesis are unknown, but it is speculated that the lesions may be the result of trauma to the growth plate interfering with proper endochondral ossification. Others have theorized that with the rapid resorption and deposition of bone occurring in the metaphysis of a young animal, a cyst might develop if resorption is so rapid that a focus of loose fibrous tissue forms. The focus of fibrous tissue may then obstruct the thin-walled sinusoids causing interstitial fluid to build up and form a cyst. Cysts have been described in bone immediately below articular cartilage (subchondral bone cysts or juxtacortical bone cysts).[376,379,381] In these, it is possible to demonstrate a direct communication with the articular synovial membrane. Radiographically, bone cysts are either single or, more commonly, multilocular, sharply defined, centrally located, radiolucent defects in the medullary canal of long bones. Variable degrees of thinning of the cortex with symmetric bone "expansion" are often a radiographic feature. Diagnosis of bone cyst relies on the histologic finding of a thin, fibrous wall lined by flat to slightly plump layers of mesothelial or endothelial cells. Treatment consists of meticulous curettage and packing the space with autogenous bone graft.

Aneurysmal bone cysts (ABCs) are spongy, multiloculated masses filled with free-flowing blood. The walls of an ABC are rarely lined by epithelium, and the lesion possibly represents an arteriovenous malformation. A proposed pathogenesis of ABCs is that a primary event, such as trauma or a benign bone tumor, occurs within the bone or periosteum. This event disrupts the vasculature, resulting in a rapidly enlarging lesion with anomalous blood flow that damages the bone mesenchyme. The bone reacts by proliferating. As the vascular anomaly becomes stabilized, the reactive bone becomes more consolidated and matures. The age of affected dogs ranges from 2 to 14 years, but it has been reported in a 6-month-old dog.[380] Treatment options include en bloc resection and reconstruction or extensive curettage with packing of the defect with autogenous bone graft.

Periarticular Tumors

Periarticular tumors in dogs include histiocytic sarcoma (HS), synovial myxoma/myxoma sarcoma, malignant fibrous histiocytoma, and synovial cell sarcoma (SCS). Typical presenting clinical signs include lameness and a firm mass or swelling near the joint. These tumors typically occur in the large joints (particularly the stifle) of the extremities and occur most commonly in large breed, middle-aged dogs. Radiographs show lytic and/or proliferative changes in the bones surrounding the involved joint. The involvement of more than one bone near an affected joint distinguishes the radiographic appearance of a periarticular tumor from a primary bone tumor. The gold standard for the diagnosis of periarticular tumors is biopsy with IHC staining to differentiate the various tumor types. Classic IHC markers include cytokeratin, CD18, vimentin, and smooth muscle actin. The distinction between SCS and periarticular HS is important as these two tumors have differing biologic behaviors and recommended treatments. SCS is typically vimentin positive, cytokeratin positive, and CD18 negative, whereas HS is typically vimentin positive, CD18 positive, and cytokeratin negative. Thus to avoid confusion, some authors suggest that SCS should be replaced with cytokeratin-positive joint associated sarcoma because this better describes the distinction between HS and the classical SCS.[382] Canine SCS can be further subclassified into monophasic or biphasic depending on the presence or absence of an epithelioid component (biphasic) in addition to the spindle cells typically noted with SCS. Amputation is recommended as more conservative resections result in a significantly worse outcome. The overall MST for dogs with SCS is 455 to 967 days, but STs are also dependent on histologic grade. The MSTs for dogs with grade I, II, and III SCSs are 365 to 1460 days, 156 to 1095 days, and 183 days, respectively. The metastatic rate for dogs with SCS is 8% to 32%[383] but up to 91% for dogs with periarticular HS. Treatment for dogs with periarticular HS should include amputation and adjuvant CCNU as MSTs are superior with this multimodality therapy (568 days) than amputation alone (161 days).[382,384,385]

Myxoma sarcomas have a similar radiographic appearance to SCS but, on histology, typically contain multiple myxomatous islands containing widely spaced stellate cells. On gross inspection, these tumors are composed of gelatinous nodules that fill the joint cavity and exude viscous fluid when incised. They occur in the stifle and digits most commonly. They are distinguishable from SCS and HS because they stain positive for vimentin and HSP, variably positive for CD18 (20%–40%), and negative for cytokeratin. Myxomas of the joint are treated with either amputation or local resection (synovectomy) and can have long STs (>2 years) even with incomplete excision.[384]

Primary Bone Tumors of Cats

Incidence and Risk

Primary tumors involving the bones of cats are rare. An estimate of the incidence of all bone tumors in cats is 4.9 per 100,000.[386] Between 67% and 90% of bone tumors in cats are histologically malignant. OSAs are the most common primary bone tumor in cats and account for 70% to 80% of all primary malignant bone cancers of cats. Feline OSA occurs in appendicular and axial skeletal sites and extraskeletal sites. OSA occurs in the appendicular skeleton approximately twice as often as in axial sites;[387,388] however, in one study, 55% of 90 skeletal OSA cases were appendicular and 44% occurred in the axial skeleton.[389] Axial OSA originates

VetBooks.ir

most commonly in the skull (especially oral cavity) and pelvis but has also been reported in the ribs and vertebrae. The disease in cats differs from that in dogs in that the primary lesions occur more often in pelvic limbs in cats (distal femur and proximal tibia) and it is less metastatic than in dogs.[390] In a series of 146 cats with OSA, 56 cats had extraskeletal OSA; these were most commonly associated with common injection sites, but other locations included ocular/orbital, oral, intestinal, and mammary sites.[389] There is no difference in histopathologic findings for extraskeletal, axial, or appendicular sites.[388] There are also reports of feline extraskeletal OSA in the flank, liver, spleen, kidney, stomach, duodenum, mammary gland, and subcutaneous tissues.[388,391–394]

OSA generally affects older cats with mean ages of 8.5 to 10.7 years,[387,388,390] but OSA has been reported in cats as young as 5 months and as old as 20 years.[394] The age at presentation for axial OSA is greater than appendicular OSA.[389] Conflicting reports on gender predisposition exist with either no difference between sexes or a slight male predisposition.[387–390] OSA has been reported to arise after fracture repair in two cats and after RT in another cat.[34,395] OSA has also been diagnosed at a site of prior surgical resection of a unicameral bone cyst.[396]

Osteochondroma and the multicentric form (osteochondromatosis or MCE) have both been reported in the cat.[397–399] Osteochondromas are solitary lesions composed of hard, irregular exostoses having a fibrous and cartilaginous cap.[400] Endochondral ossification occurs from the cartilage cap and extends to a variable thickness. This cap tends to blend with adjacent tissue, making surgical removal difficult. The lesions in cats differ from dogs because they continue to develop after skeletal maturity and in sites not associated with endochondral ossification, such as the skull. Osteochondromas in cats have a potential for malignant transformation and metastasis.

MCE or osteochondromatosis also occurs after skeletal maturity in cats. In contrast to dogs, the lesions seldom affect long bones, are rarely symmetric, and are probably of viral rather than familial origin. There does not appear to be any breed or sex predisposition, although early reports of this condition were in Siamese cats.[401] Affected cats range in age from 1.3 to 8 years (mean 3.2 years). Virtually all cats with MCE are FeLV positive. This disease has an aggressive natural behavior.

Pathology and Natural Behavior

The histologic characteristics of feline OSA are like canine OSA. OSA of cats is composed of mesenchymal cells embedded in malignant osteoid. There may be a considerable amount of cartilage present, and osteoid may be scant. A feature of some feline OSA cases is the presence of multinucleate giant cells, which may be numerous. Reactive host bone and remnants of host bone are often present in specimens. Tumors are seen to be invasive; however, some surrounding soft tissue may be compressed rather than infiltrated. There is often variation of the histologic appearance within the tumor with some portions having a more fibrosarcomatous appearance and others more cartilaginous. Feline skeletal OSA appears similar with respect to grade and histology to canine OSA; however, mitoses are seen almost half as frequently.[388] Some authors have described subtypes that resemble those seen in dogs: chondroblastic, fibroblastic, and telangiectatic, as well as the giant cell variant. These histologic subtypes, however, do not appear to confer any prognostic predictive value.[402,403] OSAs in cats are locally aggressive but have a low metastatic rate compared with canine OSA.

More recently, several studies have compared cellular protein expression in canine and feline OSA to investigate their behavioral disparity. The expression of the cytoskeletal linker proteins ezrin and moesin were found to differ between dogs and cats; however, the implication of these differences is unclear. Cats more commonly expressed the phosphorylated (active) form of ezrin, but dogs more commonly expressed it in a membranous location suggesting greater biologic activity.[404] KIT IHC expression was present in 79% of canine OSA but absent in all feline cases. Canine KIT mRNA expression was also higher when assessed with RT-PCR.[405] MMP-9 and -2 have also been shown to be expressed at higher levels in canine OSA compared with feline OSA, and this may be associated with greater invasive and metastatic behaviors.[406]

History and Clinical Signs

The most common clinical signs associated with appendicular OSA in cats are lameness, swelling, and deformity, depending on the location of the lesion. Radiographically, feline OSA appears similar to OSA in dogs with mixed osteoblastic and osteolytic changes and an ill-defined zone of transition between normal and neoplastic bone; however, juxtacortical OSA has also been reported in cats.[387] Tumors can reach a large size without evidence of severe clinical signs. It is rare for cats to have metastasis at presentation.

Cats with virally associated MCE have rapidly progressing, conspicuous, hard swellings over affected sites causing pain and loss of function. Common sites for MCE include the scapula, vertebrae, and mandible; however, any bone can be affected. Radiographically, the lesions are either sessile or pedunculated protuberances from bone surfaces, and the borders between the mass and normal bone are indistinct. There may be a loss of smooth contour with evidence of lysis, particularly if there is malignant transformation.

Diagnostic Workup

Both OSA and MCE may be suspected based on the radiographic appearance of the lesions and the FeLV status of the cat. Definitive diagnosis is made by histopathologic evaluation of properly collected biopsy tissue. Although metastatic rates for cats with primary bone tumors are low compared with dogs (5%–10% compared with >90%), three-view thoracic radiographs are recommended as part of the clinical staging process. Presurgical evaluation with a complete blood count, serum biochemistry profile, and urinalysis are recommended to rule out concurrent disease.

Therapy and Prognosis

Amputation is the recommended treatment for nonmetastatic appendicular OSA. Complete surgical excision of the primary tumor is prognostic for increased ST, DFI, and PFS.[388] Due to the low metastatic rate and prolonged MSTs of 24 to 44 months with limb amputation alone,[366,368] adjuvant chemotherapy is not indicated or recommended in cats. The MST for cats with axial OSA (6.7 months) is lower than either appendicular or extraskeletal OSA.[389] This most likely reflects the difficulty of achieving complete resection and local tumor control in axial sites rather than a difference in their biologic behavior. A combination of surgical resection and RT may be appropriate in these cases. SRT has been used in several cats with appendicular and axial OSA for local tumor control.

Histologic grade, using a grading scheme that evaluates tumor vascular invasion, pleomorphism, mitotic index, and tumor matrix and cell necrosis, is prognostic for survival.[388] The overall metastatic rate is 5% to 10%, and reported anatomic sites include lung, kidney, liver, brain, and spleen. Cats with MCE have a guarded prognosis. Lesions may be removed surgically for palliation; however, local recurrences and/or the development of new lesions are common. An effective treatment protocol is not known for MCE in cats.

Fibrosarcoma, Chondrosarcoma, and Hemangiosarcoma

Non-OSA primary bone tumors in cats are rare. FSA is the second most common primary bone tumor of cats,[402] followed by CSA and then rarely HSA.[390] Little is known about the biologic behavior of these rare bone tumors in cats. Aggressive surgical resection is the preferred treatment for these tumors. The metastatic rate is low; however, metastasis have been reported in cats with primary bone CSA and HSA.[390,403]

Tumors of the Endocrine System

KATHARINE F. LUNN AND SARAH E. BOSTON

Pituitary Tumors

Primary tumors of the pituitary gland can arise from several different cell types, including corticotrophs, somatotrophs, thyrotrophs, gonadotrophs, and lactotrophs. The clinical signs associated with these tumors depend on the tumor's size and secretory properties. In a recent study of pituitary glands collected from 136 dogs and 65 cats during routine necropsy, pituitary neoplasia was detected in 14% of the middle-aged and old dogs; however, in most cases the lesions were considered to be incidental.[1] Pituitary tumors also may be detected incidentally when brain imaging is performed for unrelated reasons.[2] The most clinically important pituitary tumor in the dog is the corticotroph adenoma. This tumor produces chronically excessive amounts of adrenocorticotrophic hormone (ACTH) and is associated with clinical signs of hypercortisolism. In the cat, the most clinically significant pituitary tumor is the growth hormone (GH)–secreting somatotroph adenoma, which causes hypersomatotropism and acromegaly.

Nonfunctional pituitary tumors become clinically significant when they are large enough to cause neurologic signs, including obtundation, stupor, behavioral changes, decreased appetite, gait abnormalities, seizures, blindness, narcolepsy-cataplexy, and other cranial nerve abnormalities.[3–7] The pituitary gland may also be affected by secondary tumors, either through direct extension or by metastatic spread from a distant site.[1] Locally invasive or compressive primary or secondary pituitary tumors also have the potential to cause loss of pituitary function, resulting in hypothyroidism, hypocortisolism, gonadal atrophy, or central diabetes insipidus.[8]

Pituitary Corticotroph Tumors: Hyperadrenocorticism

Pathogenesis

Hyperadrenocorticism (HAC), also termed *hypercortisolism* or *Cushing's syndrome*, is a common endocrine disease of middle-aged and older dogs.[9] It is uncommon in cats. This clinical syndrome results from chronic exposure to excessive blood levels of glucocorticoids. Naturally occurring canine and feline HAC is usually either pituitary dependent or a result of excessive glucocorticoid secretion from an adrenocortical tumor.

Pituitary-dependent hypercortisolism (PDH) is the most common form of spontaneous HAC in dogs and cats, accounting for 80% to 85% of cases in these species. This disorder is a consequence of autonomous synthesis and secretion of ACTH from a pituitary tumor. The secretion of ACTH from the pituitary tumor is chronically excessive, leading to bilateral adrenal cortical hyperplasia and hypercortisolemia. The pituitary tumor is relatively insensitive to negative feedback by cortisol, and a loss of hypothalamic control over ACTH release occurs because corticotropin-releasing hormone (CRH) secretion is suppressed by the chronic hypercortisolemia.[10]

Pituitary tumors that secrete ACTH are derived from pituitary corticotroph cells; approximately 70% to 80% arise from the pars distalis of the pituitary gland, which is mainly under the control of CRH. The remainder of these tumors arise from the pars intermedia, which is predominantly under dopaminergic and serotoninergic control, with less regulation by CRH. This distinction between pars intermedia and pars distalis tumors typically is not made clinically or from the results of diagnostic testing, but it does potentially help explain why some pituitary-directed medical therapies are not efficacious in all dogs with PDH. The specific molecular defects that lead to the development of canine corticotroph tumors continue to be investigated, and it generally is believed that these tumors result from somatic mutations that occur within the corticotroph cells, rather than from chronic stimulation of the corticotrophs by hypothalamic factors in combination with decreased dopaminergic tone.[10] There is only one clearly documented report of ectopic ACTH secretion in the dog,[11] which may reflect the fact that it is very difficult to prove this diagnosis.

Pituitary tumors may be described as macrotumors or microtumors. The latter distinction is derived from human medicine: microtumors are less than 1 cm in diameter, and macrotumors are 1 cm or larger in diameter. The use of this size-based classification is controversial in veterinary medicine, at least partly because of variability in patient size and conformation.[4] Pituitary tumors may also be classified as noninvasive adenomas, invasive adenomas, or adenocarcinomas. The latter term is reserved for tumors in which there is demonstrated evidence of metastatic disease. Canine pituitary adenocarcinomas are uncommon. In a study of 33 dogs with pituitary tumors that underwent necropsy evaluation after brain imaging, 61% had a pituitary adenoma, 33% had an invasive adenoma, and 6% had an adenocarcinoma.[3]

VetBooks.ir

Adrenal-dependent hypercortisolism (ADH) refers to disease of the adrenal cortex, including neoplasia, dysplasia, or hyperplasia, and is discussed in the section on adrenal gland tumors.

Clinical Findings and Diagnostic Evaluation in Dogs

Most dogs with PDH are older than 9 years of age, and female dogs are slightly overrepresented. Breed predispositions have been noted in dachshunds, terrier breeds, German shepherd dogs, and poodle breeds. The onset of canine Cushing's syndrome is often slow, and the signs can progress slowly. Affected dogs are often not considered by their owners to be sick; they have a good appetite and do not show signs such as vomiting, diarrhea, coughing, or weight loss. Because spontaneous HAC typically affects elderly dogs, the signs initially may be attributed to normal aging. The progress of the disorder is generally insidious, but eventually the owners of affected dogs seek veterinary care because of frustration with signs such as polyuria, polydipsia, panting, and exercise intolerance.

The clinical signs in dogs with HAC are the result of the gluconeogenic, catabolic, immunosuppressive, and anti inflammatory effects of excessive circulating glucocorticoids. These signs include polyuria, polydipsia, polyphagia, abdominal enlargement, lethargy, panting, exercise intolerance, muscle weakness, alopecia, calcinosis cutis, thinning of the skin, poor wound healing, muscle wasting, decreased bone density, and reproductive abnormalities. Dogs with HAC are also predisposed to diabetes mellitus and are more susceptible to infection, particularly urinary tract infections. More serious disorders associated with canine HAC include hypertension and proteinuria. Although uncommon, pulmonary thromboembolism is another potentially life-threatening complication of HAC.

The most commonly used screening tests for HAC are the low-dose dexamethasone suppression test (LDDST) and the ACTH stimulation test. For patients with typical clinical signs of HAC and positive results on a screening test, further testing is often necessary to differentiate between pituitary- and adrenal-dependent disease. Differentiation tests that are commonly used include the high-dose dexamethasone suppression test (HDDST) and the measurement of endogenous ACTH levels. The interested reader should consult the many excellent resources that provide further detail on the clinical and clinicopathologic findings in dogs with HAC, in addition to extensive discussion of the pros and cons of the different screening and differentiation tests.[9,10,12]

The results of imaging studies, including ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), may assist in distinguishing between PDH and ADH. Abdominal ultrasonography should not be used as a screening test for HAC, and it should also not be used as the sole mechanism for discriminating between PDH and ADH; however, it can provide useful information.[13–17] The adrenals of patients with PDH are often bilaterally enlarged with increased thickness; they typically maintain a normal shape and are homogeneous in echogenicity.[14] However, there can be overlap between adrenal gland measurements in normal dogs, dogs with nonadrenal disease, and dogs with HAC. Adrenal gland asymmetry may also be detected in dogs with PDH because of nodular hyperplasia. In some cases this appearance can be confused with adrenal neoplasia. To further complicate the diagnostic accuracy of abdominal ultrasonography, a small percentage of patients with HAC may have concurrent PDH and ADH.[18] Bilateral adrenal tumors may also occur, including both functional or nonfunctional adrenocortical tumors and pheochromocytomas.[16,19–23] Thus ultrasound findings must always be interpreted concurrently with clinical findings and endocrine test results. Abdominal CT is used less commonly than ultrasonography to evaluate the adrenals, but CT findings may also assist in the discrimination between PDH and ADH.[24,25] This technique also demonstrates overlap between adrenal volume in dogs with PDH and dogs with nonadrenal disease and also confirms that dogs with PDH can have nodular adrenal lesions.[25]

Although 80% to 85% of dogs with spontaneous HAC have PDH and the great majority of cases of PDH are the result of the presence of a pituitary tumor, canine patients do not often show clinical signs directly referable to the local effects of the tumor. Most patients initially are presented for veterinary care because of the typical clinical signs of HAC, particularly once they affect the quality of life of the patient or the owner. Pituitary tumors may be detected by CT,[4,6] dynamic CT,[26,27] MRI,[4,6,28–32] or dynamic MRI[33]; however, these techniques are not routinely performed in all dogs diagnosed with PDH. In most cases the diagnosis is based on the presence of typical clinical signs and clinicopathologic changes of hypercortisolemia, together with the results of endocrine testing.

As noted previously, brain imaging is not performed in most dogs with PDH, and most receive treatment to address adrenal hyperfunction rather than the pituitary tumor itself. This is most likely because brain imaging and pituitary surgery or radiation therapy (RT) is not affordable or accessible to many clients. Although medical therapy for PDH has a long history of successful use, it is important to note that the pituitary lesion in dogs with PDH will progress over time. In a study of 13 dogs that underwent MRI evaluation of the brain at the time of diagnosis of PDH and before medical therapy was instituted, eight of the dogs had a visible pituitary mass and none of the dogs had clinical signs of neurologic disease.[31] Four of the dogs showed enlargement of the pituitary tumor on MRI 1 year later, and a pituitary tumor also was detected in two dogs that did not have a visible mass on the initial MRI. Two of the 13 dogs had developed neurologic signs at the time of the 1-year follow-up MRI. In a study evaluating diagnostic imaging findings in 157 dogs with PDH with and without neurologic signs, central nervous system (CNS)–specific signs such as circling, seizures, and ataxia were neither sensitive nor specific for predicting the presence of a pituitary macrotumor.[6] However, signs such as lethargy, mental dullness, and decreased appetite were highly specific for detection of a pituitary macrotumor but not highly sensitive. Other studies also have documented that mentation and appetite changes are the most common signs associated with pituitary tumors.[5,34]

When considering brain imaging in dogs with PDH, several factors should be taken into account: 40% to 50% of dogs with PDH have tumors that are not visible on CT or MRI, and these dogs are unlikely to develop neurologic signs associated with the tumor; 15% to 25% of dogs with PDH are at risk for the development of neurologic signs as the result o the presence of an enlarging tumor, and these signs typically develop within 6 to 18 months of the diagnosis of PDH; brain imaging may be helpful in predicting dogs likely to develop neurologic signs in patients with PDH that initially have no signs directly attributable to the tumor[35]; and if RT is being considered, early treatment will likely improve the prognosis.[5,36] One approach that has been suggested is that CT or MRI should be considered at the time of diagnosis of PDH, with medical therapy alone recommended if no mass is seen. If a pituitary mass is detected but is less than 8

VetBooks.ir

mm in diameter, medical therapy and repeat imaging in 12–18 months should be recommended. For masses greater than 8 mm in diameter, RT should be recommended.[9] Unfortunately this approach is not available or feasible for many clients, and medical therapy alone is often the mainstay of treatment. Theoretically, measurement of plasma ACTH precursor concentrations could help in the selection of patients for brain imaging because it has been shown that pro-opiomelanocortin/pro-ACTH levels in plasma are correlated with pituitary tumor size in dogs with PDH. However these tests are not commercially available.[37,38] Unfortunately, plasma cortisol concentrations at baseline and 4 or 8 hours after administration of a low dose of dexamethasone do not appear to correlate with the development of neurologic signs.[6] Consequently, there is no readily available, inexpensive, simple diagnostic test that can predict pituitary tumor size in dogs with PDH.

Treatment of Canine Pituitary-Dependent Hypercortisolism

Medical Therapy

Although PDH is a disease of the pituitary gland, most dogs with this disorder are treated with medical therapies that address adrenocortical hyperplasia and hyperfunction. The most commonly used medications are trilostane and mitotane. Mitotane (o,p′-DDD, Lysodren) is a potent adrenocorticolytic agent that is cytotoxic to the adrenal cortex, particularly the zona fasciculata and zona reticularis. Trilostane (Vetoryl) is an orally active synthetic corticosteroid analog that competitively inhibits 3-β-hydroxysteroid dehydrogenase.[39] This enzyme is essential for synthesis of cortisol and other steroids, such as corticosterone, androstenedione, and aldosterone. Both mitotane and trilostane are widely and successfully used in the management of PDH, and each has its own advantages and disadvantages.[40–43] A detailed discussion of these treatment modalities for PDH is beyond the scope of this chapter, and readers are strongly encouraged to consult any of several excellent reviews of this subject before initiating medical therapy in any patient.[9,10]

As noted previously, the two medications most commonly used to treat PDH in dogs are trilostane and mitotane. But several other medications also have been used in dogs with PDH, some of which are targeted against the pituitary lesion in these patients. When canine pituitary corticotroph adenomas were evaluated for expression of receptors that are potential therapeutic targets for human Cushing's disease, it was found that canine tumors removed after transsphenoidal surgery expressed a predominance of somatostatin receptor subtype 2 (SST2), in contrast to human tumors, which express predominantly subtype 5 (SST5). Canine tumors express much lower levels of SST5 and express the dopamine receptor D2 at levels that were described as moderate and comparatively less than expressed in tumors from humans.[44] Pasireotide is a somatostatin receptor analog that binds to receptors of the subtypes SST1, SST2, SS, and SST5. In a small study of 20 dogs with PDH, pasireotide therapy produced improvements in plasma ACTH concentrations, urine cortisol:creatinine ratios, tumor size, and clinical signs in most dogs, although three dogs developed diabetes mellitus.[45] In a more recent study, pasireotide therapy was combined with trilostane therapy (eight dogs) or mitotane therapy (one dog) in nine dogs with PDH resulting from a macroadenoma. No adverse effects were noted, and tumor volume decreased in six of the nine dogs, but it increased in three of the nine.[46] Unfortunately pasireotide is extremely expensive, which may limit its current use in many patients. Selegiline (L-deprenyl, Anipryl) acts by inhibiting degradation of dopamine, thereby potentially inhibiting ACTH secretion from the intermediate lobe of the pituitary gland; unfortunately only 20% of canine PDH cases arise from disease in this area. Additional disadvantages are documented poor efficacy,[47] expense, and inability to monitor response with ACTH stimulation testing. Cabergoline is a dopamine D2 receptor agonist that also acts to reduce pituitary ACTH secretion by increasing dopaminergic tone. In the only published study of cabergoline use in dogs with PDH, 17 of 40 dogs showed a favorable clinical response. Decreases in ACTH concentrations, urine cortisol:creatinine ratios, and pituitary tumor size also were reported.[48] Further studies are needed before this is likely to become a widely adopted treatment for canine PDH. Bromocriptine is a dopamine agonist and also acts to reduce plasma ACTH concentrations. Because of adverse effects and lack of demonstrated efficacy, it is not recommended for treatment of canine PDH.[49] Use of the antiserotoninergic medication cyproheptadine arose from the hypothesis that excessive ACTH secretion could result from excessive serotoninergic stimulation of the pituitary gland. This drug has been shown to be ineffective in clinical cases.[50] Retinoic acid also has been used in the management of canine PDH. This medication may inhibit pituitary tumor development, reduce ACTH production, and inhibit cell proliferation. One study showed promise in terms of a decrease in the size of pituitary tumors and subjective improvement in clinical signs.[51] Unfortunately experience with this medication is very limited, particularly when contrasted with proven therapies such as trilostane and mitotane. Availability and cost of the appropriate formulation of retinoic acid are also significant concerns.

Surgery

Hypophysectomy is the treatment of choice for PDH in humans and can be successful in dogs.[2,52–55] Once PDH is diagnosed, if surgical management is an option, advanced imaging is required. Both CT and MRI have been used to evaluate the pituitary gland before surgery.[53,56–58] The relative size of the pituitary gland is assessed by evaluating the pituitary height:brain area (P:B) ratio; a P:B ratio >0.31 is consistent with pituitary enlargement.[56,59]

Transsphenoidal hypophysectomy first was reported in a large cohort of dogs in 1998.[53] In that study the 1- and 2-year estimated survival rates were 84% and 80%, respectively. Forty-three dogs went into remission, and recurrence of HAC was reported in five dogs.[53] The same group since has published the largest cohort of dogs with PDH treated with transsphenoidal hypophysectomy to date, reporting the outcomes in 306 dogs.[56] In that study 91% of the dogs survived the 4-week perioperative period. The median survival time (MST) was 781 days, and the median disease-free interval (DFI) was 951 days. The recurrence rate was 27%, and recurrence of HAC was diagnosed a median of 555 days from surgery. When the pituitary gland size was evaluated using the P:B ratio, dogs with larger tumors had a shorter survival time (ST) and an increased risk of recurrence.[56] Postoperative ACTH and cortisol concentrations may give some indication of the risk of residual disease. However, this should be evaluated in light of the tumor size, baseline ACTH levels, and individual patient hormone profiles.[60] Postoperative management includes lifelong administration of thyroid hormone and glucocorticoids, and either short- or long-term administration of desmospressin.[53,56]

VetBooks.ir

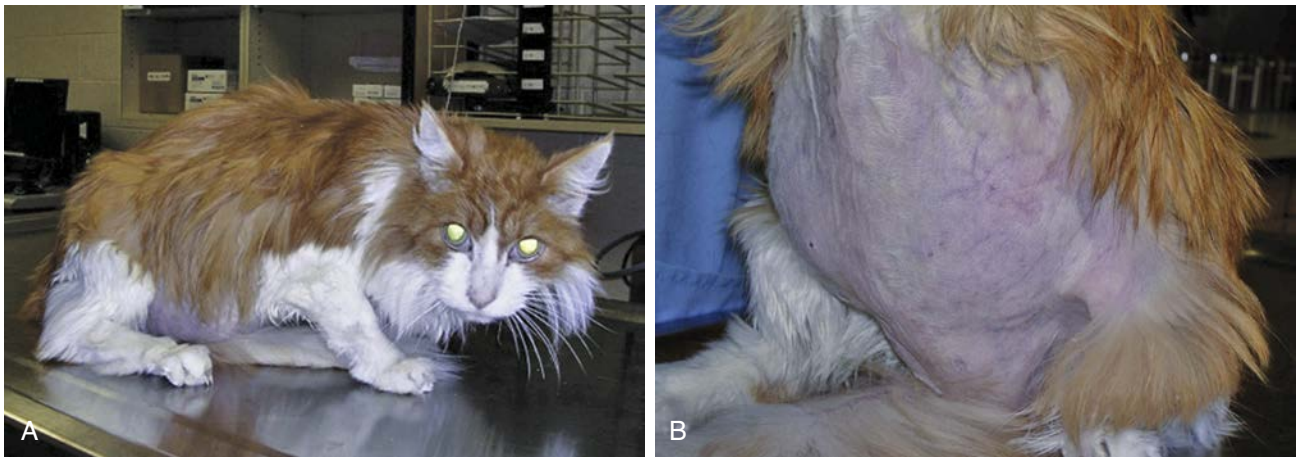
In a prospective study of 150 dogs treated with transsphenoidal hypophysectomy for PDH, the 1-, 2-, 3-, and 4-year estimated survival rates were 84%, 76%, 72%, and 68%, respectively. Twelve dogs died postoperatively, and 127 went into remission, of which 32 later experienced a recurrence of disease. Complications included central diabetes insipidus in 53% of dogs undergoing remission and incomplete hypophysectomy in nine dogs. The overall success rate of transsphenoidal hypophysectomy was determined to be 65% in this study.[54] Reported complications of transsphenoidal hypophysectomy include hemorrhage, electrolyte imbalance, postoperative neurologic deficits, decreased tear production, thromboembolic disease, recurrence of PDH, and perioperative death.[54,56] However, the overall outcome of this procedure is favorable, resulting in rapid resolution of disease and a long period of remission or complete resolution in patients that survive the perioperative period.[53,56]

Although most of the publications on the surgical management of canine pituitary tumors originated in Europe, this technique is becoming more widely available in the United States. A recent publication documented the outcome of transsphenoidal surgery using a high-definition video telescope, and this approach is now available at Washington State University Veterinary Teaching Hospital. In this case series of 26 dogs with PDH, the overall mortality associated with the surgery was 19%; however, the five deaths occurred in the first 10 dogs treated, with no mortality in the subsequent 16 dogs.[55] This serves as a reminder that transsphenoidal hypophysectomy is a specialized procedure with a steep learning curve. A successful outcome is most likely with careful patient selection and a coordinated approach from a team of specialists in surgery, medicine, neurology, and critical care.[2]

Radiation Therapy

Several reports have been published on the successful use of radiation in the treatment of canine PDH.[5,36,61–65] Dow and colleagues treated six dogs with functional pituitary macrotumors; the dogs were given 40 Gy in 10 equal fractions. The MST was 743 days; neurologic signs resolved in all the dogs; and ACTH levels remained high for at least 1 year after therapy.[61] Cobalt 60 RT was used to treat six dogs with PDH caused by a pituitary tumor that was detectable on MRI; tumor size was significantly reduced in all cases, but clinical signs of PDH were adequately controlled only in one dog.[62] The effects of megavoltage irradiation on pituitary tumors was evaluated in 24 dogs with neurologic signs; 10 dogs experienced complete remission of neurologic signs, and another 10 dogs achieved partial remission; 4 dogs died, either during radiation therapy or shortly thereafter.[36] As in previous studies a correlation was noted between relative tumor size and the severity of neurologic signs in dogs with pituitary tumors. A correlation between tumor size and remission of neurologic signs also was noted after pituitary irradiation, which suggests that early treatment of these tumors should improve the prognosis, although control of ACTH secretion was unlikely.[36] A retrospective study of RT for the treatment of pituitary masses demonstrated significantly improved STs and control of neurologic signs in 19 dogs that received RT compared to 27 untreated control dogs with pituitary masses.[5] The mean ST in the treated group was 1405 days, compared to 551 days in the nonirradiated group. The 1-, 2-, and 3-year estimated survival rates were 93%, 87%, and 55% for the irradiated dogs and 45%, 32%, and 25% for the nonirradiated dogs, respectively.

Treated dogs with smaller tumors lived longer than those with larger tumors; again, this suggests that early diagnosis and treatment of pituitary tumors are beneficial. Five of 14 dogs with PDH in this study were reported to show resolution of clinical signs of HAC, together with at least one normal ACTH stimulation test result after completion of RT.[5] A recent nonrandomized observational study compared two coarse fractionated radiation protocols for canine pituitary macrotumors and found that dogs treated with 10 fractions of 3.8 Gy/fraction on a Monday/Wednesday/Friday protocol had a longer ST than dogs treated once weekly to a total dose of 38 Gy.[64]



Most of the reports that document the use of RT for the treatment of pituitary tumors in dogs provide little detailed information about the progress of the clinical syndrome of HAC in these patients. Therefore, although RT appears effective in controlling neurologic signs and increasing survival,[5] it is difficult to predict the endocrinologic outcome of RT for dogs with PDH. Current and future developments in the use of RT for the management of canine PDH likely will include the more widespread use of stereotactic RT (SRT; see Chapter 13).

Feline Pituitary-Dependent Hyperadrenocorticism

As noted previously, approximately 80% to 85% of cases of HAC in the cat are the result of pituitary disease.[66–68] Most of these cats will have a pituitary adenoma that secretes excessive ACTH; however, pituitary carcinoma has been reported,[69] and cases have been described of cats with pituitary tumors that secrete other hormones in addition to ACTH.[70–72] Cushing's syndrome is considerably less common in cats than in dogs, and in general affected cats are much more "sick" than their canine counterparts. The mean age of cats with PDH is approximately 10 years. Feline HAC is commonly associated with insulin-resistant diabetes mellitus, with signs of polyuria, polydipsia, polyphagia, and weight loss. Cats with HAC often have a potbellied appearance as a result of hepatomegaly and muscle weakness, and they frequently have thin, fragile skin that tears and bruises easily. The clinician should keep this in mind when examining these cats and performing diagnostic tests, because it is easy to cause significant, debilitating skin damage. Additional clinical signs include lethargy, generalized muscle atrophy, weakness, alopecia, and an unkempt hair coat (Fig. 26.1).

On routine laboratory testing, increased alkaline phosphatase activity is much less frequently detected in cats with HAC compared to dogs. Cats may have increased alanine aminotransferase activity, hypercholesterolemia, azotemia, and a minimally concentrated urine. Hyperglycemia and glycosuria are expected in cats with concurrent diabetes mellitus. No consistent complete blood count (CBC) changes have been reported in cats with HAC. Tests used to screen for spontaneous HAC in cats include the urine cortisol:creatinine ratio, ACTH stimulation test, and LDDST. It is important to note that the details of these protocols differ between dogs and cats; readers are directed to more complete references for further information.[66–68] The HDDST, endogenous ACTH concentrations, and abdominal ultrasound examination may be used to assist in differentiation of PDH from ADH in the cat.[73]

Because PDH is relatively uncommon in the cat, there have historically been few case series and case reports on which to base treatment recommendations. However, recent years have yielded some additional information about the management of this condition. Direct treatment of the pituitary tumor has been reported with either surgical hypophysectomy or RT.[52,66,70,74–76]

• **Fig. 26.1** A 14-year-old male neutered domestic long-hair cat with pituitary-dependent hypercortisolism. (A) The patient appears weak with muscle atrophy and has an unkempt hair coat. (B) The abdomen has a potbellied appearance with thinning of the skin.

Transsphenoidal hypophysectomy was described in seven cats with PDH.[74] Two of the cats died within 4 weeks of surgery from unrelated causes, and the remaining five cats experienced remission of their disease. Two additional cats died several months after surgery, and one cat experienced a relapse of PDH 19 months after treatment, likely associated with pituitary remnants after surgery.[74] Potential complications of this surgery include transient or long-term hypopituitarism, electrolyte disturbances, soft palate dehiscence, and reduced tear production. Relatively few reports have been published on the outcome of RT for cats with PDH, and it is still unclear if this modality leads to robust management of endocrine disease.[66,67] SRT is an appealing option for these cats because it requires significantly fewer anesthetic events in patients that often are clinically fragile. Surgical bilateral adrenalectomy also has been described in cats with PDH and historically was considered the treatment of choice.[77] However, these cats are often poor surgical candidates, they have diminished healing ability, and complications are common. Laparoscopic adrenalectomy potentially is a better option for these patients because the incisions are much smaller; however, this has not yet been reported in cats with PDH. Trilostane currently appears to be the most reasonable medical therapy for cats with PDH.[66,73,78–80] Clinicians intending to pursue this therapy are encouraged to become familiar with resources that provide detailed protocols for the use of trilostane in cats.[66,67]

Pituitary Somatotroph Tumors (Feline Acromegaly)

Feline acromegaly is a disease of older cats that results from chronic excessive GH secretion, usually from a functional somatotroph adenoma of the pars distalis of the pituitary gland.[81–83] The genetic cause of feline acromegaly is unknown; however, the aryl-hydrocarbon-receptor interacting protein gene has been the subject of preliminary investigations because it is known to play a role in the development of human familial acromegaly.[84] The term *hypersomatotropism* refers to a condition of excessive growth hormone, whereas *acromegaly* refers to the constellation of associated clinical signs.[85]

Feline acromegaly historically was regarded as a rare condition; however, more recent findings indicate that it may be underdiagnosed. In an early study of 184 diabetic cats, 59 had markedly increased serum insulin–like growth factor-1 (IGF-1) concentrations, and acromegaly was confirmed in 17 of 18 cats that were examined by CT, MRI, or necropsy.[86] The same group subsequently published the results of screening for acromegaly in a much larger group of 1221 diabetic cats. They found that 319 (26.1%) of the cats had serum insulin-like growth factor 1 (IGF-1) concentrations consistent with acromegaly; 63 of these cats underwent pituitary imaging, and the presence of a pituitary lesion was confirmed in 94% of this group.[87] A study of diabetic cats in Europe recently found that 36 of 202 (17.8%) cats evaluated had serum IGF-1 concentrations consistent with acromegaly.[88] Clearly the prevalence of acromegaly differs between these studies, and selection bias may play in role in some of the data. For example, in an initial study of 184 cats, the IGF-1 assays were performed on blood samples submitted to a laboratory at a referral institution for measurement of serum fructosamine,[86] which is a test that may be more likely to be performed in cats with diabetes that is difficult to regulate. The prevalence of acromegaly in the average or typical diabetic cat is likely in the range of 10% to 15%, but the prevalence in cats that are difficult to regulate is probably closer to 30%.[83] Regardless of the exact numbers or differences between studies, considerable evidence now suggests that acromegaly is neither rare nor uncommon. Most veterinary endocrinologists agree that a cat with any of the clinical features of acromegaly, including insulin resistance, should be screened for this disorder.[89]

Acromegaly is more common in male cats, with no apparent breed predilection, and most affected cats are middle-aged or older. The typical history is one of insulin-resistant diabetes mellitus, with affected cats requiring 10 to 20 units of insulin per dose or more, often with inadequate control of the diabetes. This insulin resistance is due to a GH-induced postreceptor defect in the action of insulin on target cells. Affected cats remain polyuric, polydipsic, and polyphagic and continue to gain weight. Most cats with poorly regulated diabetes mellitus lose weight; therefore weight gain in this situation may be suggestive of feline acromegaly.

The physical changes of acromegaly develop slowly and often are not noted by the owner until they are advanced. These changes may include enlarged feet, broadening of the face, protrusion of the mandible (Fig. 26.2), increased spacing between the teeth, and

VetBooks.ir

• **Fig. 26.2** (A) and (B) A 12-year-old female spayed domestic long-hair cat with acromegaly caused by a pituitary tumor. Note the broad forehead and large mandible.

abdominal enlargement. Owners of affected cats also frequently note noisy or stertorous breathing or respiratory stridor.[86,87,90,91] A physical examination may reveal additional abnormalities, such as enlarged abdominal organs and cardiac murmurs, arrhythmias, or a gallop rhythm.[81,86,92] However, it also is likely that acromegalic cats with few physical features of the disease will be increasingly recognized as awareness of the disorder increases and patients are diagnosed at an earlier stage. In addition, more cats may be diagnosed with acromegaly in the absence of diabetes, as has been reported in a small number of cases[93]; however, the prevalence of acromegaly in the nondiabetic cat population is unknown.

Neurologic signs associated with the pituitary tumor generally appear to be uncommon but may be underrecognized or underreported. Lethargy, mental dullness, or impaired vision may occur but often can be subtle. Affected cats also may demonstrate signs of diabetic neuropathy or lameness, possibly because of acromegaly-associated arthopathy.[81,86] An additional significant complication of acromegaly is the development of structural and functional cardiac disease, including increased thickness of the left ventricular wall, increased left atrial diameter, and evidence of abnormal diastolic function.[94,95] Some evidence indicates that many of these changes are reversible if the acromegaly is treated successfully.[95]

Acromegaly is the result of excessive GH secretion from a pituitary gland tumor, and increased serum GH concentrations have been reported in several cats with acromegaly. Unfortunately, a feline GH assay currently is not reliably available in the United States. The physical changes in patients with acromegaly are due to the anabolic effects of GH, which are mediated by peripherally synthesized IGF-1.[83] This hormone is produced in the liver and other tissues, and serum concentrations of IGF-1 increase in the presence of chronically increased GH production. Because GH secretion may be pulsatile, even in some acromegalics, and because it has a short half-life, an increased serum IGF-1 level has been suggested to be a more sensitive test for acromegaly because it may reflect GH levels over the preceding 24 hours.[83] Serum IGF-1 values are widely reported in acromegalic cats. One study confirmed that IGF-1 measurement is a useful screening test for feline acromegaly, with a sensitivity and specificity of 84% and 92%, respectively.[90] No difference in serum IGF-1 concentrations was seen among well-controlled diabetic cats, poorly controlled diabetic cats, and healthy cats.[90] The highest IGF-1 noted in a diabetic cat was 153 nM, with a normal reference range of 12 to 92 nM; thus some overlap exists between the IGF-1 values found in acromegalic cats and those found in poorly regulated diabetic cats. However, this author's experience (KL) is that IGF-1 levels in cats with acromegaly usually are at least twice the value of the high end of this reference range, at least by the time the cats are investigated for causes of insulin resistance. In Europe, the serum IGF-1 concentration typically is expressed in ng/mL, with a positive predictive value of 95% for an IGF-1 >1000 ng/mL.[87] Feline IGF-1 measurement is readily available to veterinarians in the United States, and this test should be considered for cats with diabetes mellitus that appear to be insulin resistant or that have any physical features consistent with acromegaly.[89]

The presence of a pituitary tumor can be demonstrated either by CT or by MRI in cats with acromegaly, and both techniques have been reported in the literature.[86,96–99] MRI likely is more sensitive than CT,[99] but both imaging modalities may reveal a normal pituitary in a cat with acromegaly if the size of the mass is below the limit of detection. Brain imaging may also reveal bone or soft tissue changes that support a diagnosis of acromegaly.[98] In a case-control study of CT findings, 68 acromegalic diabetic cats were compared to 36 control cats. Cats with acromegaly had significantly thicker bones, skin, and subcutaneous tissues, and narrower nasopharynges compared to the control cats.[99] Additional imaging findings supportive of acromegaly include echocardiographic changes as noted previously, enlarged kidneys and adrenal glands, and evidence of pancreatic changes on abdominal ultrasound examination.[100]

Treatment options for acromegaly in human medicine include surgery, conventional external-beam RT, SRT, and medical therapy. Many of these therapies also have been evaluated in cats. In humans, transsphenoidal surgery to remove the pituitary tumor generally is regarded as the treatment of choice; however, currently only rare published reports are available on the use of surgery for the treatment of feline acromegaly.[70,101,102] The largest reported case series of cats undergoing hypophysectomy focused on anesthetic management and complications in 37 cats with

VetBooks.ir

acromegaly[103]; the same group reported the outcome of surgical hypophysectomy in 21 diabetic cats in abstract form.[104] These two publications provide relatively little detail but in summary: 3 of 21 cats died postoperatively; all 18 surviving cats experienced a reduction in serum IGF-1 concentrations; and 14 of these cats achieved diabetic remission.[104] As was noted previously transsphenoidal hypophysectomy is technically challenging, and it requires an experienced surgeon and coordinated team of specialists.

RT rarely is used as a first-line therapy in human medicine.[105] In contrast, RT is the treatment for feline acromegaly that has been most widely reported in the veterinary literature.[a] Conventional fractionated RT protocols range from five fractions given weekly to as many as 20 fractions given over a period of 4 weeks. Improved diabetic control is one potential outcome of RT therapy, although IGF-1 concentrations do not appear to correlate with this improved control.[76,109] Few reports are available on the long-term follow-up of acromegalic cats receiving conventional RT; therefore it is difficult to assess the risk of complications of this modality in this species. However, published case reports and case series of cats receiving conventional RT suggest that short- and long-term adverse effects are relatively uncommon.

Disadvantages of RT as a treatment for feline acromegaly include cost, availability, and the necessity for repeated anesthetic events. The latter disadvantage can be lessened by the use of SRT, which is widely used in the treatment of pituitary tumors in human patients. In an early case series in veterinary medicine, cats with pituitary tumors received treatment with a linear accelerator-based modified radiosurgical approach.[76] Cats received a single large dose of radiation, but it was delivered in a nonconformal fashion. The technique was reported to be safe and effective. A recent study documented the outcome of SRT, delivered in 3 or 4 doses, for the treatment of acromegaly in 53 cats.[110] The overall MST was 1072 days, with no association noted between tumor size or serum IGF-1 concentration and survival. Causes of death included neurologic disease, heart disease, kidney disease, and unrelated diseases. Ten cats experienced acute radiation effects, all of which responded to prednisolone therapy. Seven of 50 cats in which serum T_4 concentrations were monitored developed hypothyroidism months to years after SRT. Diabetic regulation was followed in 41 of the 53 cats, and 39 experienced a reduction in insulin dose, with 13 (32%) cats going into diabetic remission.[110] SRT, therefore, appears to be a safe and effective therapy for feline acromegaly. This therapy is becoming more widely available, at least compared to hypophysectomy, and compared to conventional RT, it offers considerable advantages in terms of owner time commitment and the risks of anesthesia and hospitalization in elderly diabetic cats.

Medical therapy for acromegaly commonly is used in humans either as a first-line treatment or as an adjunct to surgery or RT. The classes of drugs used are somatostatin analogs, GH-receptor antagonists, and dopamine agonists. GH-receptor antagonists have not been evaluated in cats, and dopamine agonists do not appear to be useful in this species.[111]

Somatostatin analogs, also termed *somatostatin receptor ligands* (SRLs), bind to somatostatin receptors, suppressing the release of GH from the pituitary gland. These medications are available as long- or short-acting preparations, and the response to SRLs is assessed by measurement of IGF-1 and GH levels and tumor size, and evaluation of clinical signs. Octreotide has been evaluated in a small number of cats with acromegaly. In five cats short-acting octreotide was used for up to 4 weeks with no apparent improvement in GH levels.[81,112] However, another study showed that GH levels were significantly reduced for up to 120 minutes postinjection in five cats with acromegaly that received a single dose of octreotide.[113] These studies used the short-acting form of octreotide and were performed over a very short time without assessment of the clinical response. Both short- and long-acting pasireotide have been studied in acromegalic cats, with encouraging results.[114,115] Treated cats experienced improved insulin sensitivity, and serum IGF-1 concentrations were reduced. Diarrhea was a common side effect, and the expense of this medication is a significant impediment for most cat owners.

For many cats with acromegaly, insulin therapy is the only treatment available or acceptable to the owner. In general these patients should receive the amount of insulin necessary to control their diabetes, although adequate blood glucose regulation can be difficult to achieve in many cases. In-home blood glucose monitoring, with close cooperation between the owner and the veterinarian, is strongly recommended. Feeding a low-carbohydrate diet also may be beneficial. These patients should be expected to receive insulin doses in the range of 10 to 20 units per dose or more. Concurrent illnesses and complications of acromegaly and diabetes mellitus also should be addressed. The short-term prognosis for cats diagnosed with acromegaly generally is fair to good, but the long-term prognosis is poor without specific therapy.[83] Patients may succumb to cardiac or renal failure, neurologic disease, or complications of poorly regulated diabetes mellitus. In one early case series the MST was 20.5 months.[81]

Adrenal Gland Neoplasia

The prevalence of primary adrenal gland tumors in the dog and cat is difficult to discern from the literature. For dogs and cats undergoing necropsy or adrenal surgery, tumors of the adrenal cortex appear to be more common than those of the medulla. A number of case series over the past 15 years have documented the outcome of adrenal surgery in dogs.[20,22,116–120] When the data from these cases was combined, a histopathologic diagnosis was reported for a total of 304 adrenal tumors, with 227 (75%) arising from the adrenal cortex and 72 (23%) from the medulla. The remaining tumors included two myelolipomas and one each of fibrosarcoma, lymphoma, and leiomyosarcoma. For the adrenocortical tumors that were further classified, 114 of 199 (57%) were carcinomas, 77 of 199 (39%) were adenomas, and 8 of 199 (4%) were described as hyperplastic lesions. It is important to note the bias inherent in this data because only dogs that underwent surgery were included. Functional cortisol-secreting tumors of the adrenal cortex are responsible for 15% to 20% of canine and feline cases of naturally occurring HAC, with PDH accounting for 80% to 85%. Functional adrenocortical tumors in dogs and cats also can secrete one or more sex hormones, including androstenedione, progesterone, 17-hydroxyprogesterone, testosterone, and estradiol. These tumors may or may not secrete glucocorticoids, and some patients show signs of HAC in the absence of elevated cortisol levels on typical screening tests. Signs of sex hormone excess with sex hormone–secreting adrenal tumors appear to be more common in cats than dogs.

Imaging techniques such as ultrasonography, CT, and MRI have greatly enhanced the ability to identify both clinical and subclinical adrenal abnormalities; it appears that the adrenal gland is affected with neoplasia more commonly than previously suspected. The ability to detect these adrenal lesions also leads to diagnostic dilemmas as the clinician attempts to elucidate

[a] References 62, 75, 76, 81, and 106–109.

VetBooks.ir

whether the lesions arise from the cortex or medulla, whether they are functional or nonfunctional, and whether they are benign or malignant. Functional adrenal tumors may secrete cortisol, catecholamines, aldosterone, sex hormones, or steroid hormone precursors, and these may be associated with specific clinical and laboratory findings. Hormonal testing and imaging techniques are central to the diagnostic evaluation of these patients, helping ensure that the most appropriate course of therapy can be pursued. Large adrenal masses may be detected on abdominal radiographs.[121–123] The presence of mineralization suggests an adrenal tumor, but this finding is not highly specific, and it cannot be used to differentiate between benign and malignant masses. The normal ultrasonographic appearance of canine adrenal glands has been described,[124,125] and many reports of the ultrasonographic appearance of adrenal lesions in dogs are available, although no particular ultrasound findings are pathognomonic for a specific diagnosis.[126] Abdominal ultrasound examination frequently is used to detect metastatic disease and to determine the local invasiveness of adrenal tumors. Ultrasonography has been reported to be 80% to 100% sensitive and approximately 90% specific for the detection of adrenal tumor invasion into the caudal vena cava.[20,22,127] Contrast-enhanced ultrasonography may provide additional information about tumor type and malignancy.[128,129]

The CT appearance of both normal and abnormal canine adrenal glands has been described.[24,123,130–134] Contrast-enhanced CT has been shown to provide accurate preoperative evaluation of canine adrenal masses with 92% sensitivity and 100% specificity for the detection of vascular invasion by adrenal tumors.[135,136] The MRI appearance of presumed normal canine adrenal glands also has been described,[137] but as yet, few reports document the systematic use of MRI for evaluation of adrenal lesions in dogs and cats.

Canine Adrenocortical Tumors

A review of case reports of functional adrenocortical tumors in dogs suggests that carcinomas are slightly more common than adenomas, although this could reflect the fact that tumors with features of malignancy are more likely to be removed surgically. Adenomas typically are smaller; tumors larger than 2 cm are more likely to be carcinomas.[138] On histopathologic examination, adenocarcinomas appear more likely to exhibit a trabecular growth pattern, peripheral fibrosis, capsular invasion, necrosis, and/or hemorrhage.[138] They are less likely to exhibit cytoplasmic vacuolization, extramedullary hematopoiesis, or fibrin thrombi.

Approximately 20% of adrenocortical carcinomas invade into the phrenicoabdominal vein with extension into the renal vein and/or caudal vena cava.[19,139] Intravascular invasion has the potential to cause severe and life-threatening intraabdominal or retroperitoneal hemorrhage.[22,140] Metastasis was identified in approximately 50% of dogs with adrenocortical carcinomas.[138,139] Although involvement of the liver and lungs is most common, metastasis to the kidney, ovary, mesenteric lymph nodes, peritoneal cavity, and thyroid gland also has been reported. In the absence of evidence of tumor invasion or metastasis, no consistent clinical, biochemical, or imaging findings reliably distinguish between functional adrenocortical adenomas and carcinomas.

Dogs with PDH and dogs with ADH are similar in age, but almost 50% of dogs with ADH weigh more than 20 kg compared to approximately 25% of dogs with PDH.[121] The historic features, physical changes, clinical signs, and basic laboratory findings in canine Cushing's syndrome essentially are the same in dogs with PDH and ADH (these are described in detail elsewhere).[9,10] Similar screening tests are used to confirm the diagnosis of HAC; however, the sensitivity of the ACTH stimulation test for the diagnosis of ADH is only approximately 60%.[141] Therefore the LDDST is a better screening test when ADH is suspected. Dogs with ADH fail to show suppression on LDDST or HDDST, and differentiation from PDH generally is determined by imaging studies, particularly abdominal ultrasound examination, and measurement of endogenous ACTH levels. Excessive secretion of glucocorticoids by a functional adrenocortical adenoma or adenocarcinoma occurs independently of pituitary control, with secondary atrophy of the normal adrenocortical cells in both the affected and contralateral adrenal glands. Unfortunately, the functional atrophy of the contralateral adrenal gland is not always easily detected on abdominal ultrasonography.[16] This finding, termed equivocal adrenal asymmetry, is also observed in some dogs with PDH and is associated with asymmetric hyperplasia of the glands.[14] An ultrasound study of dogs with equivocal adrenal asymmetry suggested that a maximal dorsoventral thickness of the smaller gland of less than 5.00 mm was consistent with a diagnosis of ADH.[17]

Surgical adrenalectomy is the treatment of choice for dogs with ADH. In one series of 144 dogs undergoing surgical removal of a functional adrenocortical tumor, the prognosis was described as excellent for patients that survived 4 weeks postoperatively, and the average life expectancy was 3 years. Nine of 144 dogs were euthanized at the time of surgery, and 29 dogs died during surgery or immediately postoperatively.[35] MSTs of 230 to 778 days have been reported for dogs undergoing adrenalectomy for adrenal carcinomas,[19,116,117] compared to an MST of 688 days for dogs with adenomas.[116]

SRT has been reported in a small number of dogs with adrenocortical tumors with vascular invasion. In the nine dogs evaluated, of which six dogs had nonsecretory tumors, the MST was 1030 days, tumor size was reduced, and no dogs experienced severe radiotoxicity.[142] However, more studies involving larger numbers are necessary to further evaluate this mode of therapy.

Mitotane or trilostane therapy for ADH should be used when surgery is not a good option for the patient or client, or they may be used before adrenalectomy in patients that are significantly debilitated by HAC. Treatment with mitotane as an alternative to surgical adrenalectomy uses the drug as a true cytotoxic agent. Detailed protocols are readily available[9,143]; clinicians should be aware that this approach typically requires higher doses of mitotane than those used in PDH,[144] and relapses are common. However, this treatment can be effective; a mean ST of 16.4 months was reported in a series of 32 dogs, and dogs without evidence of metastatic disease appeared to have a better response to mitotane therapy.[145] Trilostane is not a cytotoxic drug, but it has been used successfully to manage patients with ADH,[42,146,147] including a small number of dogs with metastatic disease.[148] In a retrospective study comparing trilostane and mitotane in dogs with ADH, the MSTs for dogs treated with trilostane and mitotane were 353 days and 102 days, respectively. These STs were not significantly different; however, this study did further confirm that STs are significantly reduced with metastatic disease.[149] The MSTs in a more recent study were 15.6 months and 14 months for dogs with ADH treated with mitotane or trilostane, respectively[150]; thus either medication is a reasonable option for ADH if surgery is not feasible.

Aldosterone-secreting adrenocortical tumors have rarely been reported in dogs.[151–155] Clinical findings include lethargy, anorexia, polyuria/polydipsia, hypokalemia, metabolic alkalosis,

VetBooks.ir

and hypertension. The diagnosis is confirmed by ruling out other causes of hypokalemia, together with finding a markedly increased plasma aldosterone concentration.[156]

Feline Adrenocortical Tumors

Hyperadrenocorticism in cats is rare, and only 15% to 20% of cases are due to a functional adrenocortical tumor. A recent case series documented the clinical findings in 33 cats with adrenal neoplasia that had a histopathologic diagnosis.[157] Thirty of the 33 cats were diagnosed with a cortical tumor, and only three had a pheochromocytoma. Of the 25 cats that underwent adrenal function tests, 19 cats were diagnosed with a functional tumor, and of these 16 cats had hyperaldosteronism, one had hypercortisolemia, one had high estradiol, and one had hypersecretion of multiple hormones. Increasing evidence indicates that primary hyperaldosteronism (also termed *primary aldosteronism* or *Conn's syndrome*) has been an underrecognized condition in cats. In fact, it has been suggested to be the most common adrenocortical disorder in this species.[158] Affected cats are middle-aged or older, and the most common clinical sign is muscle weakness resulting from hypokalemia. Arterial hypertension frequently is detected in these patients and may be associated with ocular changes. Routine laboratory testing often reveals hypokalemia and sometimes metabolic alkalosis, but hypernatremia is uncommon, presumably because of intact water balance mechanisms in these patients. Some cats also may have evidence of concurrent renal disease.

Plasma aldosterone can be measured in cats, and normal or increased plasma concentrations in the face of hypokalemia would be regarded as inappropriate. However, definitive diagnosis using aldosterone levels is difficult without measurement of the plasma renin activity and calculation of an aldosterone:renin ratio.[159] Unfortunately, a plasma renin activity assay is not readily available. The oral fludrocortisone suppression test had been shown to be useful in the diagnosis of feline hyperaldosteronism.[160–163] Imaging of the adrenal glands often is performed in the evaluation of these patients,[164,165] and this may distinguish between unilateral and bilateral lesions and also reveal vascular invasion or metastatic disease. Most cats with hyperaldosteronism have an adrenal adenoma or carcinoma.[157,166,167] Bilateral adenomas have been reported,[166] and some cats have adrenal hyperplasia.[159]

Adrenalectomy is the treatment of choice for cats with unilateral disease, and good outcomes have been reported both for adenomas and for carcinomas, in addition to tumors associated with vena cava thrombosis.[157,166–170] Medical management with potassium supplementation, antihypertensive drugs, and the aldosterone antagonist spironolactone can give reasonable STs in patients that are not surgical candidates.[156]

Adrenal Medullary Tumors

Chromaffin cells are part of the sympathetic nervous system and are present in the adrenal medulla and other locations throughout the body. Neoplastic chromaffin cells in the adrenal medulla give rise to pheochromocytomas, which are tumors that predominantly secrete catecholamines. Chromaffin cell tumors (termed *paragangliomas* or *extraadrenal pheochromocytomas*) can arise in other parts of the body, but these are rare in veterinary medicine.

Pheochromocytomas are uncommon in dogs and rare in cats.[171,172] In past decades the diagnosis of pheochromocytoma most often was made incidentally at necropsy, but these tumors are now likely to be detected antemortem because abdominal imaging techniques are used routinely in small animal patients. Pheochromocytomas generally are considered malignant tumors in dogs.[173] Metastasis is reported in up to 40% of affected dogs; sites include liver, spleen, lung, regional lymph nodes, bone, and CNS.[171,172,174] Vascular invasion by the tumor has been reported in as many as 82% of cases.[20,22,175] This finding is not specific for pheochromocytoma because vascular invasion can also occur with adrenocortical tumors.

Pheochromocytoma usually is diagnosed in older dogs, and no clear breed predilection has been found. Catecholamine release by pheochromocytomas typically is episodic, therefore clinical signs may be intermittent and often are absent at the time of physical examination. Signs can include weakness, episodic collapse, panting, anxiety, restlessness, exercise intolerance, decreased appetite, weight loss, polyuria, and polydipsia. Physical examination findings may be normal because of the episodic nature of catecholamine release or may reveal tachypnea, panting, tachycardia, weakness, pallor, cardiac arrhythmias, or hypertension. Some dogs have signs referable to an abdominal mass, and acute collapse may occur secondary to tumor rupture with abdominal or retroperitoneal bleeding.[140] No consistent abnormalities are seen on the CBC, serum biochemistry profile, or urinalysis in dogs with pheochromocytomas.[83]

Diagnostic imaging is central to the evaluation of patients with pheochromocytoma. In many dogs evaluation for pheochromocytoma occurs after an adrenal mass is found when abdominal ultrasonography is performed for other reasons. In addition to revealing the presence of an adrenal tumor, abdominal ultrasonography may reveal metastatic disease, and it is sensitive and specific for detecting vascular invasion by adrenal tumors.[20,22] CT and MRI are the imaging modalities of choice for humans with pheochromocytomas, and experience with these techniques in canine patients has been encouraging.[134,176] Unfortunately no ultrasound or CT findings can distinguish definitively between pheochromocytoma and other adrenal tumors. Thoracic radiographs or CT scans are recommended to evaluate the cardiovascular system and for detection of pulmonary metastases in any patient with a suspected adrenal tumor. Abdominal radiographs sometimes may reveal the presence of a large adrenal mass, but they generally are less informative than ultrasonography or CT. Rare reports exist of positron emission tomography (PET) or nuclear scintigraphy imaging in dogs with pheochromocytomas.[177,178] Immunohistochemical staining for chromogranin-A can distinguish pheochromocytomas from adrenocortical tumors on tissue obtained at surgery or necropsy.[179]

Plasma and urinary concentrations of catecholamines and their metabolites are measured routinely in humans for the diagnosis of pheochromocytoma, and these have also been evaluated in dogs and cats.[180–188] The best differentiation between pheochromocytoma and other diseases appears to be provided by measurement of normetanephrine, either in urine or plasma.[174,187,188]

Surgery is the only definitive treatment for pheochromocytoma. Chemotherapy and RT have not been evaluated in dogs with pheochromocytoma. Radiotherapy using ^{131}I-metaiodobenzylguanidine was reported in one dog.[189] The prognosis for dogs with pheochromocytoma depends on tumor size, the presence of metastases, and local invasion. An MST of 374 days has been reported after surgical treatment of pheochromocytoma.[116] Dogs without metastatic disease that survive the perioperative period appear to have a good prognosis. A pheochromocytoma-associated

VetBooks.ir

cardiomyopathy recently was described in dogs, and further studies are needed to determine if management of this condition affects morbidity or mortality in dogs with pheochromocytoma.[190]

Surgical Management of Adrenal Tumors

Before adrenalectomy every attempt should be made to determine whether an adrenal tumor is functional, whether evidence of metastatic disease exists, and whether vascular invasion has occurred. Patients with ADH also may be medically managed with trilostane or mitotane before surgery to mitigate metabolic derangements and potentially reduce the risk of thromboembolic disease that can result from their prothrombotic state.[9] Important components of the presurgical workup for a patient with an adrenal tumor include blood pressure measurement, an ACTH stimulation test as a preoperative baseline, CBC, serum biochemistry, and blood typing, with or without cross-matching, in preparation for potential blood transfusion. Pretreatment with α-blockade has been recommended before surgery, because phenoxybenzamine was shown in one study to improve the ST significantly in dogs undergoing adrenalectomy.[175] However, the exact dosage and number of days that dogs should be on this medication, and even the decision to pretreat, are somewhat controversial. This recommendation likely deserves re-examination, particularly because this also is an area of controversy in human medicine,[191] and the recommendation is not necessarily supported by findings in other veterinary studies.[118]

Abdominal CT is a precise method for planning a resection and for evaluating the extent of an adrenal mass and the presence of caval tumor thrombus.[134,135] CT also allows for further staging of the lungs and the rest of the abdomen and will allow for assessment of kidney and/or renal vein involvement, so that the surgeon and owner can be prepared for possible nephrectomy. A recent study indicated that triple-phase contrast CT may aid in preoperative diagnosis of the tumor type.[136]

Blood loss from adrenalectomy can be significant and even fatal, particularly in patients that have extensive invasion of the surrounding tissues or caudal vena cava. The patient should be cross-matched and blood typed, and blood should be available for transfusion intraoperatively and postoperatively. Dogs with HAC have a higher risk of being hypercoagulable.[192–194] Perioperative management of this potential complication is somewhat controversial and will vary among clinicians. When available, thromboelastography (TEG) may be useful as a preoperative baseline and postoperatively to monitor for evidence of hypercoagulability, to allow directed anticoagulant therapy when indicated.

The technical difficulty of adrenalectomy depends on the size and invasiveness of the tumor. For small tumors with no invasion, a ventral midline, flank, intercostal, or minimally invasive approach can be considered.[195–198] The approach used generally is based on the surgeon's preference and experience. For large right-sided tumors, the right lateral abdomen also should be aseptically prepared in case the standard ventral midline approach needs to be extended to include a paracostal approach. A vessel sealing device facilitates adrenalectomy. Hemaclips or ligaclips also should be available to assist with hemostasis.

When caval invasion exists, the surgery requires a focused team. Blunt dissection, electrosurgery, and the vessel sealing device are used to dissect the adrenal tumor from surrounding tissues. Considerable neovascularization, and possibly invasion into the vasculature of the surrounding tissues, often is seen. Caval thrombus is more common in cases of pheochromocytoma but can occur with adrenal cortical tumors.[116–118] The adrenal gland is freed from all surrounding tissues except for the phrenicoabdominal vein as it enters the vena cava. The dorsolateral aspect of the phrenicoabdominal vein should be isolated and ligated. For a thrombus that does not extend beyond the hepatic hilus, Rummel tourniquets are placed around the vena cava cranial and caudal to the tumor thrombus and on the contralateral renal vein. The Rummel tourniquets are tightened, and a cavotomy is made at the level of the phrenicoabdominal vein as it enters the vena cava. The length of the venotomy should be limited to the diameter of the tumor thrombus, or just slightly longer than this. The tumor thrombus is removed by gently sliding it out of the vena cava. The Satinsky clamps are placed tangentially across the cavotomy in a manner that allows partial flow through the vena cava. Preplacement of a small-gauge, nonabsorbable suture may facilitate placement of the Satinsky clamp and management of the venotomy. If stay sutures of 5-0 polypropylene suture material are used at the cranial and caudal extent of the proposed venotomy, the suture can be used to close the venotomy site. The Rummel tourniquets are released, and the venotomy site is sutured in a simple continuous pattern. If further bleeding is noted, the Rummel tourniquets can be re-engaged and the repair can be augmented with additional suture as required. A recent publication reported phrenicoabdominal venotomy, rather than caval venotomy, for removal of adrenal tumors with caval invasion.[120] This technique can be used for a relatively small caval thrombus, and it offers the advantage that a cavotomy is not necessary. The tumor thrombus can be milked into the phrenicoabdominal vein, and a Satinsky clamp can be placed between the thrombus and the vena cava. Rummel tourniquets still should be placed as a precaution, but engagement of the Rummel tourniquets is not needed.

Bilateral adrenalectomy first was reported in 1972 for the surgical management of canine Cushing's disease.[199] Medical management of Cushing's disease has replaced surgical therapy in cases of PDH. However, the surgical management of bilateral adrenal tumors is possible and is no more challenging technically than managing a unilateral tumor. The preoperative management is the same as for a unilateral adrenal tumor, with the exception that a single patient may have both a pheochromocytoma and HAC, so this should be considered. The postoperative management is slightly more challenging in cases of bilateral adrenalectomy because the patient becomes acutely Addisonian. However, this can be managed with an appropriate dose of desoxycorticosterone pivalate (DOCP) and a supraphysiologic dose of dexamethasone intraoperatively. In the short-term these patients need to be monitored for signs of Addisonian crisis during recovery, and careful attention should be paid to their fluid requirements, urine production, and electrolytes. In the long-term these dogs essentially are treated as Addisonian patients and should be managed with DOCP injections approximately monthly and daily physiologic doses of prednisone. As with any Addisonian patient, the frequency of DOCP injections and the dose of prednisone should be tailored to the patient. Similarly, the dose of prednisone should be increased during times of stress. The reported success rate in a recent retrospective study of bilateral adrenalectomy was similar to that reported with unilateral adrenalectomy when the acute Addison's disease was managed preemptively and appropriately.[119]

The perioperative mortality rate for adrenalectomy ranges from 15% to 37%.[116–118] Perioperative morbidity for adrenalectomy also is high, with reported complications including gastrointestinal (GI) problems, pancreatitis, hemorrhage, hypotension, electrolyte imbalances, renal failure, disseminated intravascular

VetBooks.ir

coagulation (DIC), pulmonary thromboembolism, and death.[116–118] Prognostic factors include the presence and size of a tumor thrombus, whether nephrectomy is performed, whether a transfusion is performed, the tumor type (pheochromocytoma), and the tumor's size (>5 cm).[116–118]

Dogs with preoperative HAC require a postoperative ACTH stimulation test, and it could be argued that this test should be performed after adrenalectomy in all cases because some tumors can secrete more than one hormone and the tumor type is not always clearly defined before surgery. Dogs undergoing adrenalectomy for ADH need a supraphysiologic dose of corticosteroids postoperatively that can be weaned down over several weeks. ACTH stimulation tests can be used to monitor recovery of function in the remaining adrenal gland. Even in cases with a presumptive pheochromocytoma, if a patient is not recovering as well as expected postoperatively, an ACTH stimulation test should be considered to rule out a relative insufficiency of cortisol. TEG should be performed postoperatively and the result compared to the preoperative status. Long-term survival is reported if the patient survives the perioperative period.[116–118]

Compared with dogs, significantly fewer accounts are available of adrenalectomy in cats. In one series of 33 cats with adrenal neoplasia, 26 cats underwent adrenalectomy and 20 (77%) survived for at least 2 weeks postoperatively.[157] Causes of death included euthanasia, hemorrhage and refractory hypotension, and acute kidney injury. The MST for cats undergoing surgery was 50 weeks. Complications included pancreatitis, lethargy and anorexia, and significant hemorrhage. Three of the cats developed postoperative hypoadrenocorticism. In a series of 10 cats undergoing unilateral adrenalectomy for management of aldosterone-secreting tumors, eight cats survived to discharge and the overall MST was 1297 days, with none of the cats requiring further medical therapy.[167] Laparoscopic adrenalectomy for unilateral adrenal tumors also has been described in cats, but 4 of the 11 reported cases required conversion to laparotomy. Ten of the 11 cats survived to discharge, and the MST was 803 days.[200]

Incidental Adrenal Masses

Advances in abdominal imaging have led to the diagnostic dilemma of the incidental adrenal mass ("incidentaloma") in both human and veterinary medicine. In a published study of dogs undergoing abdominal ultrasound examination, 4% were found to have an incidental adrenal gland lesion, with affected dogs being older than a control population with no adrenal lesions.[201] Twenty of these dogs underwent surgery or necropsy; six were determined to have malignant tumors, all of which had a maximum dimension greater than 20 mm. In another study of 20 dogs with non–cortisol-secreting adrenal tumors that did not undergo surgery, the MST was 17.8 months[202]; however, not all the tumors in those cases were truly incidental findings. Adrenal masses may also be incidentally found on abdominal CT studies. In a series of 270 dogs undergoing abdominal CT for reasons unrelated to adrenal disease, 25 (9.3%) had adrenal gland masses; as with the ultrasound findings, these incidental masses were more likely in older dogs.[203]

When an incidental adrenal mass is identified in a dog or cat, a thorough history and physical examination, including blood pressure measurement and fundic examination, are indicated. Endocrine testing should be pursued to rule out a functional tumor. Given the high incidence of metastasis to the adrenal glands in cats and dogs, imaging of the thorax and abdomen should be performed to rule out another primary tumor. Aspiration cytology and ultrasound- or CT-guided biopsies are not routinely recommended for incidentalomas because of the high risk of complications and the inability to reliably differentiate benign and malignant lesions[15,204]; however, a recent study suggested that cytology can be valuable in distinguishing between cortical and medullary tumors.[205]

Adrenalectomy should be considered for masses that are functional, locally invasive, or larger than 2.5 cm in maximum dimension. Masses smaller than 2 cm with no evidence of hormonal activity should be monitored with regular imaging. A suggested protocol is to repeat the sonogram monthly for 3 months after the initial study and then less frequently if no significant change is noted, with further intervals determined by the appearance of the mass and the clinical status of the patient. However, the growth of these masses is not necessarily predictable or uniform over time.[9,156]

Thyroid Gland Neoplasia in Dogs

Thyroid carcinoma is a tumor of middle-aged to older, medium to large breed dogs.[206] Siberian huskies, golden retrievers, and beagles are overrepresented. The median age is 10 to 15 years, with no gender predilection.[206] Carcinomas or adenocarcinomas were diagnosed in 90% of thyroid tumors.[206] Thyroid adenomas that cause clinical signs are very rare in dogs.[207] Carcinomas can be further divided into follicular and medullary carcinomas with immunohistochemistry; follicular tumors are more common.[208] It has been suggested that medullary carcinomas may have a less aggressive behavior,[208,209] although this distinction rarely is used clinically. This tumor often is detected as an incidental finding by the owner or primary care veterinarian, which highlights the importance of careful neck palpation on every physical examination. It should be noted that palpation of the mass is not sensitive or specific for determining histopathologic invasion[210,211]; therefore incidentally detected cervical masses always should be investigated further. With the increasing adoption of advanced imaging techniques, incidental thyroid masses also have been identified on CT scans[212] and cervical ultrasound studies.[213] In one study of dogs that had a cervical CT scan for an unrelated reason, the overall incidence of a thyroid mass identified as an incidental finding was 0.76%.[212] If dogs present with clinical signs, these generally are due either to a mass effect or to invasion of the thyroid tumor into adjacent tissue; such signs include dysphagia, voice change, laryngeal paralysis, Horner's syndrome, and dyspnea.[214–216]

Potential causes of thyroid carcinoma in humans include exposure to radiation, persistently elevated thyroid-stimulating hormone (TSH), and dietary and genetic factors.[207] In dogs, breed predisposition suggests a genetic factor. Persistently elevated TSH also has been suggested as a potential risk factor.[207,217] Most dogs with thyroid carcinoma are euthyroid, with some hypothyroid and some hyperthyroid dogs.[207,218] The serum concentrations of thyroid hormone and TSH should be assessed preoperatively because some patients require postoperative monitoring and treatment. The term "functional thyroid carcinoma" in dogs generally refers to the production of thyroid hormone and a hyperthyroid patient. Functional thyroid carcinoma in human patients generally refers to the ability of thyroid carcinoma cells to trap and organify iodine. This is more clinically important in human patients because radioactive iodine therapy is a routine part of treatment.

The workup of a suspect thyroid tumor involves confirmation of the tumor type and clinical staging. Ultrasound examination

VetBooks.ir

of the neck is useful as a screening tool for a mass suspicious for thyroid carcinoma. However, ultrasound was not found to be as sensitive or specific as MRI or CT for determining the degree of invasiveness and for confirming thyroid origin.[210] The decision to aspirate a mass in the region of the thyroid gland under ultrasound guidance is clinician dependent. Because a mass definitively arising from the thyroid gland has a very high likelihood of being a thyroid carcinoma and the mass ultimately will be removed and submitted for histopathology, some clinicians do not perform aspiration of the mass if imaging is to be performed. Ultrasound is not as sensitive or specific as a CT scan in determining that a mass is originating from the thyroid gland,[210] so in the absence of advanced imaging, cytology may be warranted. Fine-needle aspiration should be done under ultrasound guidance to avoid hemorrhage; also, because this procedure is painful, the patient should be sedated before thyroid mass aspiration. Thyroid carcinomas are extremely vascular; therefore needle core biopsy and incisional biopsy should *never* be performed, because they carry a high risk of severe hemorrhage in a noncompressible area. Aspiration or biopsy also could lead to the formation of a large hematoma and the spread of tumor cells within this area.

Thyroid carcinoma tends to metastasize to the draining lymph nodes and lungs, but metastasis to abdominal organs also has been reported.[219] The local lymph nodes (mandibular) should be palpated and aspirated. Three-view thoracic radiographs also are recommended before therapy. Preoperatively a CT scan is very useful for determining the origin and invasiveness of the tumor and for staging the disease. CT has been shown to be more sensitive for assessing the invasiveness of thyroid carcinomas than palpation or neck ultrasound.[210,211] Masses that have invaded dorsal to the trachea are difficult to assess ultrasonographically because of the presence of air in the trachea. Furthermore, because of the high iodine content of precontrast and postcontrast thyroid tissue, CT has been shown to be useful in diagnosing nonthyroid cervical masses, such as carotid body tumors, because the normal thyroid tissue is more easily identifiable using a contrast-enhanced CT scan compared with ultrasound or MRI.[210] CT also is very useful for assessing the lungs for evidence of metastatic disease.

Thyroid tumors are categorized as invasive or noninvasive. The invasiveness of a thyroid mass can be determined by a combination of palpation characteristics and advanced imaging. In general, a noninvasive mass is round to ovoid and mobile. Size alone is not a predictor of whether a thyroid mass is resectable. On imaging, evaluation of whether the thyroid mass remains encapsulated or invades adjacent structures is important for determining whether the mass can be removed.

The thyroid gland is composed of two lobes that lie adjacent to the left and right sides of the trachea from the fifth to eighth rings.[220,221] The recurrent laryngeal nerves run dorsal to the thyroid gland, and the carotid sheaths are lateral to the gland. Evaluation of laryngeal function before surgery is recommended as a baseline for potential damage to the recurrent laryngeal nerve, as a result either of tumor invasion or of iatrogenic damage at the time of surgery. The external and internal parathyroid glands are intimately associated with the thyroid gland[221] and often are obscured completely in cases of thyroid carcinoma. This is of little consequence for unilateral tumors. The primary blood supply and drainage are the cranial thyroid artery and vein. The caudal thyroid artery and vein also are significant, and the cranial and caudal thyroid arteries anastomose across the surface of the gland.[221] This can be quite apparent in cases of thyroid carcinoma with significant hypertrophy and neovascularization of the blood supply as common features noted at surgery.[220] The lymphatic drainage of the thyroid gland is to the cranial deep cervical lymph node (cranial portion) and the caudal deep cervical lymph node (caudal portion).[221] The lymph nodes are extremely small and are not present or identifiable in most dogs.[221] Because of this, elective lymph node dissection is not routinely performed in dogs with thyroid carcinoma.

Surgical removal of a thyroid carcinoma includes a routine ventral approach to the neck and trachea between the paired sternohyoideus muscles.[220] The thyroid glands should be evaluated bilaterally. The thyroid mass is identified and removed by blunt dissection, taking care to preserve the recurrent laryngeal nerve and with careful attention to hemostasis using hemoclips, electrocautery, or a vessel sealing device. In the author's (SB) experience, gently retracting the thyroid mass ventrally and working outside of the neck can help protect the critical structures that lie adjacent to the thyroid gland. Potential complications of surgery include hemorrhage and laryngeal paralysis arising from iatrogenic damage to the recurrent laryngeal nerve. Postoperative care for these patients should involve multimodal analgesia, intravenous fluids, and monitoring for dyspnea and hemorrhage. Most patients can be discharged from the hospital within 24 hours.

Bilateral thyroid carcinomas have been reported. Two recent reports of bilateral, noninvasive thyroid carcinoma treated with surgery alone demonstrated STs comparable to those for unilateral thyroid carcinoma.[222,223] One additional potential complication of total thyroidectomy is transient or permanent postoperative hypocalcemia.[222] In one study of 15 dogs treated with total thyroidectomy because of bilateral disease, parathyroid tissue was preserved in two dogs, reimplanted in four dogs, and removed completely in nine dogs. In that study postoperative hypocalcemia occurred in 11 dogs, with only seven dogs requiring long-term management of hypocalcemia.[222] Another study reported the intentional preservation of at least one external parathyroid gland in six cases of total thyroidectomy for thyroid carcinoma. The blood supply was preserved in five dogs, and the parathyroid gland was reimplanted in one dog. The MST was not reached, and the mean ST was 920 days, with no evidence of recurrence.[223] Attempts should be made to preserve parathyroid tissue in cases of total thyroidectomy in dogs.

Ectopic thyroid carcinoma has been reported in dogs at the base of tongue, involving the hyoid apparatus, cranial mediastinum, and the right heart base.[224–228] The treatment approach to these tumors is similar to that for eutopic thyroid carcinomas, with long-term survival reported with surgery alone or with radioactive iodine.[224]

Invasive thyroid carcinomas generally are not amenable to surgery because of invasion of critical structures in the neck, such as the trachea, esophagus, carotid artery, and recurrent laryngeal nerve. Treatment options for invasive thyroid carcinoma include external beam RT and radioactive iodine. External beam RT generally is more available at most facilities. Two reports exist on the use of external beam RT to treat thyroid carcinoma in dogs. A hypofractionated protocol reported in 13 dogs resulted in an MST of 96 weeks.[229] Interestingly, evidence of pulmonary metastasis at the time of diagnosis was not prognostic.[229] Definitive fractionated RT was reported in eight dogs with invasive thyroid carcinoma, with a similar MST of 24.5 months.[230] A more recent study reported an MST of only 170 days for 20 dogs treated with palliative radiation for advanced thyroid carcinoma.[231] In that study, achieving a partial or complete response was the only variable that was prognostic.[231] Hypothyroidism has been reported

as a consequence of RT for thyroid carcinoma,[232] therefore monitoring of the patient's thyroid status after RT or surgery is recommended.

Radioactive iodine (^{131}I) is not readily available for dogs because of the facilities required for isolation after high-dose ^{131}I therapy. Two reports of ^{131}I therapy for invasive thyroid carcinoma indicate relatively long STs.[233,234] One study reported 43 dogs treated with ^{131}I, either as sole therapy or in combination with surgery. The first 24 dogs were treated with a dose that was calculated by means of scintigraphy, with a dose range of 555 to 1850 MBq; the remaining 19 dogs were treated with a dose of 1600 MBq without dose calculation or taking body weight into account.[233] The MSTs for ^{131}I used alone and in combination with surgery were 30 months and 34 months, respectively, and no adverse events were noted.[233] A similar study reported ^{131}I therapy as primary therapy in 39 dogs with nonresectable thyroid carcinoma.[234] The MSTs for dogs without metastatic disease and those with metastatic disease were 839 and 366 days, respectively. The dose of ^{131}I was calculated using scintigraphy and body weight. The mean and median doses were 3.60 GBq and 3.70 GBq, respectively. Three dogs in this study developed fatal bone marrow suppression.[234] It is notable that the dose used in this study was more than twice that used in the previous study. The advantage of external beam RT is that the radiation dose can be evenly distributed throughout the tumor. The advantage of ^{131}I is that metastatic lesions also can be treated with this therapy. RT should be considered in cases of invasive thyroid carcinoma because prolonged STs may be possible.

The prognosis for dogs with unilateral mobile thyroid carcinoma is excellent with surgery alone, with a reported MST of 36 months and a 70% 2-year survival rate.[214] Tumor diameter, tumor volume, and bilateral location have been associated with metastatic disease, and gross and histologic evidence of vascular invasion were associated with a reduced disease-free survival.[208] The role of chemotherapy is not well defined with this disease. In general, large tumors with evidence of vascular invasion or metastasis are treated with systemic chemotherapy. Carboplatin most commonly is used. However, no definitive evidence exists that chemotherapy improves STs in dogs with thyroid carcinoma. One study showed no benefit to the addition of chemotherapy for dogs that had been treated surgically for thyroid carcinoma.[216] A recent study showed that dogs with thyroid carcinoma treated with isotretinoin 9-cis postoperatively had an increased survival rate compared to dogs treated with surgery alone or surgery with adjuvant doxorubicin.[235] The response to toceranib has been reported in dogs with metastatic thyroid carcinoma in a phase I study of this therapy for solid tumors in dogs. A clinical benefit was noted in 12 of 15 dogs with thyroid carcinoma, with four dogs having a partial response and eight dogs having stable disease.[219] This has not been reported as first-line therapy but may be considered in cases of metastatic disease. For dogs with functional thyroid tumors, if surgery, RT or ^{131}I therapy is not feasible, treatment with methimazole or an iodine-restricted diet could be considered.[236–238]

Thyroid Gland Neoplasia in Cats

Hyperthyroidism (thyrotoxicosis) is the most common endocrine disorder in cats.[239,240] The closest human counterpart to this disease is toxic nodular goiter.[241] Feline hyperthyroidism is most often caused by a primary thyroid abnormality that results in the production and secretion of excessive thyroxine (T_4) and triiodothyronine (T_3). Multinodular adenomatous hyperplasia is identified histologically in most thyrotoxic cats.[239,240,242] Both thyroid lobes are affected in 70% to 90% of cases,[240,242,243] although they may be asymmetrically enlarged at the time of diagnosis. Ectopic hyperplastic functional thyroid tissue also is found in a proportion of hyperthyroid cats.[242,244,245] Malignant carcinomas are the least common cause of hyperthyroidism, occurring in only 1% to 3% of thyrotoxic cats[239,240,242,245]; however, one group recently proposed that the prevalence of malignant disease increases with disease duration.[246] Feline thyroid carcinomas are more locally invasive than their benign counterparts, and their metastatic rate can be as high as 70%, with regional lymph nodes and lungs affected most commonly.[245,247,248] Unfortunately, no noninvasive tests are available that can reliably distinguish between benign and malignant thyroid disease in hyperthyroid cats, although clinicians may be more suspicious of thyroid carcinoma if thyroid palpation or the appearance at surgery is atypical or if the patient does not respond as expected to medical therapy.[249] Nonfunctional thyroid carcinomas are uncommon.[249,250] Thyroid cysts also have been reported in hyperthyroid and euthyroid cats in association with both benign and malignant tumors.[251]

Hyperthyroidism was not recognized as a clinical disorder in cats until 1979, and evidence indicates that the prevalence has increased since that time.[252] The prevalence has been reported to be as high as 10% in older cats in the United States[253] and as high as 12.3% in parts of Europe.[254] These high prevalence rates may reflect a true increase in incidence over time, heightened awareness and testing by veterinarians, or both. If the incidence truly has increased, environmental factors may have contributed.[239] Environmental factors (e.g., the availability of commercially prepared cat food) may also help explain why prevalence rates vary between geographic regions.[239] Several risk factors have been variably associated with hyperthyroidism, including the consumption of commercially prepared canned cat food, the iodine content of cat food, indoor residence, use of cat litter, exposure to brominated flame retardants, and use of flea-control products.[252,255–258] None of these has been definitively shown to be a primary inciting cause, and the evidence for the role of some of these risk factors remains contradictory. The cause of feline hyperthyroidism may well be multifactorial; however, many authors consider that the consumption of canned food likely plays a significant role.[239,254,259–263] The molecular events underlying the development of feline hyperthyroidism have been investigated,[264–270] but currently no single unifying hypothesis explains the development and increasing prevalence of this disease in cats.

The following discussion reviews the clinical features, diagnosis, and treatment of feline hyperthyroidism, highlighting new information and including information pertaining to the malignant form of the disease. Many excellent and detailed reviews are available for the reader who wishes to read in more depth about this common feline endocrinopathy.[239,240,253]

Hyperthyroidism is a disease of older cats with mean and median ages in the range of 12 to 15 years. It is rarely diagnosed in cats younger than 8 years of age.[239] There is no sex predilection, but several breeds of cat appear to be at decreased risk compared to domestic short-hair and long-hair, nonpurebred cats appear to be at increased risk.[259,271] The classic clinical signs of feline hyperthyroidism are well described and readily recognized by most clinicians. The "typical" hyperthyroid cat would be expected to be losing weight despite polyphagia, hyperactive, and possibly have GI signs such as vomiting and/or diarrhea, in addition to polyuria and polydipsia. Physical examination in affected cats may reveal a palpable thyroid nodule (goiter), tachycardia, cardiac arrhythmia,

heart murmur, gallop rhythm, premature beats, and poor hair coat. However, because measurement of serum thyroxine (T_4) is a common component of wellness laboratory testing in cats and because awareness of the condition is high, this "typical" presentation of feline hyperthyroidism likely is becoming less common, with an increasing proportion of cats being diagnosed with mild signs, no signs, or atypical signs.[239,272] In a recent study of more than 400 hyperthyroid cats, most had lost body weight, but this was associated with muscle wasting, and most cats had an ideal or overweight body condition score at diagnosis, with only approximately one third determined to be underweight.[273] No historical or physical examination findings can distinguish definitively between benign and malignant thyroid disease in cats.

The serum total T_4 concentration is highly sensitive and specific for the diagnosis of feline hyperthyroidism,[239,274] but false positive or false negative results are possible.[275] Approximately 10% of hyperthyroid cats have a total serum T_4 concentration within the reference range.[275] This may be due to the presence of early disease, normal fluctuations in serum thyroid hormone concentrations, and/or the presence of concurrent nonthyroidal illness.[274,276] Thus the clinician always must consider test results in light of the clinical signs in the patient. If hyperthyroidism is suspected in a cat with a normal total T_4 concentration, the total T_4 should be measured again in 1 to 2 weeks, particularly if the total T_4 is in the upper half of the reference range. Free T_4 measurement also may aid in the diagnosis of hyperthyroidism when the total T_4 is within the reference range. However, this test should be used only in cats with clinical signs of hyperthyroidism in which the total T_4 is in the high normal range. Free T_4 concentrations can be high in cats with nonthyroidal illness,[274,277,278] and these patients would be expected to have low serum total T_4 concentrations. Thus free T_4 should never be used as a screening test for hyperthyroidism. For patients in which hyperthyroidism is suspected but not confirmed by measurement of the total or free T_4, additional tests have been used to confirm the diagnosis. These include thyroid scintigraphy, the TSH stimulation test, the thyrotropin-releasing hormone (TRH) stimulation test, and the triiodothyronine suppression test. Both the TSH and TRH stimulation tests are of limited utility,[279,280] and the triiodothyronine suppression test can provide useful information but relies on significant owner and patient compliance.[281,282] Measurement of the serum TSH concentration is very sensitive but poorly specific for the diagnosis of feline hyperthyroidism,[283] and the results of this assay should be interpreted in conjunction with clinical signs and the serum total and free T_4 concentrations. Thyroid function tests cannot be used to differentiate benign and malignant tumors.

The diagnostic workup for cats with hyperthyroidism minimally should include a baseline CBC, serum biochemistry profile, urinalysis, and blood pressure measurement.[284] These tests may reveal abnormalities caused by hyperthyroidism (e.g., increased liver enzyme activity) and also provide evidence of concurrent disease. Additional diagnostic tests that may be recommended include thoracic radiography, electrocardiography, and echocardiography.[243,285,286] An abdominal ultrasound examination typically is performed only if the clinician suspects concurrent illness because this test rarely provides evidence against recommending definitive treatment for hyperthyroidism.[287] If performed, an abdominal ultrasound examination may reveal bilateral moderate adrenomegaly in hyperthyroid cats.[288] Thyroid scintigraphy (most commonly using ^{99m}Tc-pertechnetate) is valuable for determining the anatomic extent of functional thyroid tissue and for planning therapy, in addition to confirming the diagnosis of hyperthyroidism.[244,245,289] Unilateral uptake occurs in cats with a solitary adenoma and atrophy of the normal contralateral gland. Bilateral uptake, even if asymmetric, is indicative of adenomatous hyperplasia. Thyroid scintigraphy is particularly useful for revealing the presence of ectopic thyroid tissue or multiple areas of hyperfunctioning thyroid tissue. Metastatic disease caused by thyroid carcinoma may be detected by scintigraphy, and the pattern of uptake of radionuclide may be suggestive of the presence of malignant disease[245,289]; however, other studies have demonstrated that no scintigraphic findings can distinguish definitively between benign and malignant thyroid disease in all hyperthyroid cats.[239,244,249]

Treatment options for feline hyperthyroidism include antithyroid drugs, dietary management, surgical thyroidectomy, and radioactive iodine therapy.[239,253] Homeopathic therapy is ineffective.[290] Methimazole is the most widely used antithyroid drug in North America.[291] Carbimazole is used more widely in Europe.[253,292] These are thioureylene drugs that inhibit thyroid hormone synthesis by interfering with the oxidation of iodide, iodination of tyrosyl residues in thyroglobulin, and the coupling of iodotyrosines to iodothyronines.[239] Methimazole and carbimazole are both highly effective in lowering serum thyroid hormone concentrations and controlling hyperthyroidism. Carbimazole is converted to methimazole in the body, and a dose of 5 mg of carbimazole is considered to be equivalent to 3 mg of methimazole.[239] Methimazole is usually administered at a starting dose of 2.5 mg orally twice daily for 2 weeks.[240,293] Based on clinical signs and serum T_4 levels, the dosage can be adjusted incrementally with monitoring of serum T_4 concentrations. Once daily administration of methimazole has been reported to be less effective,[294] but this approach can be successful in some cats, particularly those that need very low doses to control their disease. Carbimazole usually is administered 2 or 3 times daily, but a controlled-release formulation has been shown to be effective when administered once daily.[295] For cats that are difficult to medicate orally or that have GI side effects, methimazole compounded in pluronic lecithin organogel (PLO)[296–298] or in a lipophilic formulation[299] can be applied topically to the ear pinna. Transdermal carbimazole also has been shown to be effective.[300] Although transdermal application of antithyroid medications appears to be safe and effective and often is more convenient for cat owners, dose adjustments, particularly dose increases, often are necessary for long-term control.[301] Approximately 10% to 25% of patients treated with methimazole develop adverse effects, including lethargy, anorexia, vomiting, facial excoriations, hepatotoxicity, bleeding diatheses, and blood dyscrasias.[239,291,293,302] GI side effects are often self-limiting or can be avoided by transdermal drug delivery. Blood dyscrasias are rare but most likely to occur within the first 3 months of treatment; therefore CBCs should be monitored most closely during this time. Medication should be discontinued in patients that experience facial excoriations, blood dyscrasias, or hepatotoxicity. Carbimazole or transdermal methimazole are likely to have the same effects and therefore should not be used in patients experiencing these adverse effects with oral methimazole. These drugs often are used for assessing the effect of resolution of hyperthyroidism on renal function and preparing a cat for anesthesia and thyroidectomy. They also frequently are used as a long-term treatment modality, but it is important to note that they have no antitumor activity and no cytotoxic effect on thyroid follicular cells. A recent study demonstrated that the duration of disease, despite antithyroid drug therapy, is correlated positively with the development of more severe hyperthyroid disease, characterized by increasing size,

VetBooks.ir

volume, and number of thyroid nodules, in addition to suspected increasing prevalence of thyroid carcinoma.[246] In other words, the longer a patient is managed with these drugs, the more likely it is to develop disease that may be less responsive to definitive therapy with ^{131}I. Other medical therapies that have been used to treat feline hyperthyroidism include ipodate and iopanoic acid[303,304]; however, these are unlikely to be effective for long-term control and rarely are used.

A more recent development in the management of feline hyperthyroidism is the use of an iodine-restricted diet to control the disease. Hill's Prescription Diet y/d Feline is a commercially available diet that is extremely restricted in iodine, containing only 0.2 ppm, compared to the recommended minimum of 0.46 ppm for adult cats.[253] Dietary management appears to be effective in most cats[305]; however, up to 25% of cats continue to have increased serum total T_4 concentrations after several weeks on the diet, and not all clinical signs of hyperthyroidism appear to resolve.[306,307] A significant disadvantage of this approach is that the cat must be fed the prescription diet exclusively. Feeding of other diets (even in very small amounts), treats, flavored medications, or hunting negates the effects of the highly iodine-restricted diet. Therefore compliance can be poor, particularly in multicat households. Furthermore, as with antithyroid medications, dietary therapy does not inhibit the growth and progression of the primary thyroid lesion in these cats, perhaps leading to an increased risk of the development of malignant disease over time. However, this is only a theoretical concern, because no studies have been published evaluating the long-term risks of dietary management of feline hyperthyroidism. An additional consideration is that scintigraphy studies showed that cats that consume the iodine-restricted diet for at least 6 months had a greater percentage uptake of ^{123}I by the thyroid gland 8 hours after isotope administration compared to baseline values.[305] Further studies are needed to determine if consumption of this diet affects the response to ^{131}I therapy in hyperthyroid cats. Whenever possible, definitive therapy is recommended for cats with hyperthyroidism; however, dietary management may be a valuable option for cats with concurrent illnesses and for owners who cannot medicate their cats or are unable to pursue definitive therapy.

Definitive therapy for feline hyperthyroidism currently consists of surgical thyroidectomy or radioactive iodine. Surgical excision of the affected thyroid lobe(s) is an effective treatment,[239,242,308,309] although it is less commonly performed as access to radioactive iodine therapy expands.[239] Although most cats have bilateral disease, this may be asymmetric and not apparent on palpation or surgical exploration. Thus thyroid scintigraphy is recommended before surgery to determine whether unilateral or bilateral thyroidectomy is necessary.[242] Intracapsular and extracapsular thyroidectomy techniques have been described.[239,308,310] When bilateral thyroidectomy is indicated, preservation of one of the parathyroid glands is important to maintain calcium homeostasis. Extracapsular thyroidectomy is most commonly performed.[220,309] This involves removal of the thyroid gland and its capsule, using gentle dissection and meticulous hemostasis, from caudal to cranial. At the cranial extent of the thyroid, the external parathyroid gland must be identified and its blood supply preserved.[220,309] The intracapsular technique involves dissection of the thyroid gland within its capsule in an effort to preserve the external parathyroid gland.[220,309] Unfortunately, this technique can lead to recurrence of hyperthyroidism as the result of remnants of thyroid tissue that are left with the capsule.[220,309] Hyperthyroid cats often are poor anesthetic candidates, and preoperative stabilization with oral antithyroid medications or β-adrenergic blockers should be considered. The most significant intraoperative complication of thyroidectomy in hyperthyroid cats may be cardiac dysrhythmias.[309] Otherwise, the surgery is not technically demanding.[242,309] Hypocalcemia resulting from transient or permanent hypoparathyroidism is the most commonly reported postoperative complication, with rates ranging from 6% to 15%.[242,309] Other potential complications include hypothyroidism and, in rare cases, Horner's syndrome or laryngeal paralysis. All surgically excised tissue should be submitted for histopathology to rule out the presence of a thyroid carcinoma. Cats with thyroid carcinoma that undergo thyroidectomy usually experience improvement in their clinical signs, but most remain hyperthyroid or develop recurrent hyperthyroidism within a few months of surgery.[247,250] Cats with ectopic hyperplastic thyroid tissue also are at risk for postoperative recurrence of hyperthyroidism.[242] Radioactive iodine therapy is recommended for patients with thyroid carcinoma or ectopic hyperplastic thyroid tissue.

Radioactive iodine, or ^{131}I therapy, generally is regarded as the treatment of choice for cats with hyperthyroidism, particularly those with bilateral thyroid hyperplasia, ectopic thyroid tissue, or thyroid carcinoma.[a] ^{131}I has a half-life of 8 days and emits both beta and gamma radiation. Beta particles, which account for 80% of the tissue damage, travel a maximum of 2 mm in tissue and have an average path length of 400 μm. They therefore cause local destruction while sparing adjacent hypoplastic thyroid tissue, parathyroid glands, and other cervical structures. The dose of ^{131}I can be calculated from tracer kinetic studies,[312,313] but these are rarely performed. The administration of a fixed dose of ^{131}I is reported by some authors,[314–317] whereas others use doses that take into account variables such as the number or size of thyroid nodules, the patient's body weight, the severity of the clinical signs, or the magnitude of elevation in the serum total T_4.[239,311,318,319] ^{131}I usually is administered by the subcutaneous route because it is effective, less stressful for the patient, and safer for personnel.[318] For cats with benign thyroid disease, reported ^{131}I doses typically range from 2 to 6 mCi. Regardless of the wide variety of dosing strategies used, overall less than 5% of cats remain hyperthyroid or experience relapse of clinical signs after ^{131}I therapy. When treatment failure occurs, a second treatment often is curative. One recent study compared the efficacy of a 2 mCi dose of ^{131}I to a "standard" dose of 4 mCi for cats with serum T_4 concentrations in the range of 4 to 10.3 μg/dL.[316] No significant difference was seen in the prevalence of persistent hyperthyroidism between the two groups; the lower dose resulted in euthyroidism in greater than 95% of cats by 6 months after treatment. The use of a lower dose is appealing because it reduces radiation exposure, shortens quarantine times, and reduces costs. The proportion of cats that develop persistent hypothyroidism after ^{131}I therapy varies among studies, and the risk of this has been suggested to be higher in cats with scintigraphic evidence of bilateral disease.[320] In the recent study comparing a 2 mCi dose to a 4 mCi dose, overt or subclinical hypothyroidism was more likely in the group that received 4 mCi.[316] Minimizing the risk of iatrogenic hypothyroidism after ^{131}I therapy is important because cats with iatrogenic hypothyroidism that become azotemic after treatment have shorter STs than cats that remain nonazotemic.[321] In one large study of hyperthyroid cats treated with ^{131}I, the MST was 2 years, with survival rates at 1, 2, and 3 years of 89%, 72%, and 52%, respectively.[311] The most common causes of death or euthanasia were cancer or

[a] References 239, 247, 249, 250, and 311.

VetBooks.ir

renal disease, which is perhaps not surprising in this population of older cats. The MST was 4 years in another study of cats treated with ^{131}I compared to 2 years for cats treated with methimazole.[322] Relatively few publications address the management of cats with hyperthyroidism caused by malignant thyroid disease. Cats with thyroid carcinomas usually have larger tumor burdens, and malignant cells trap and retain iodine less efficiently.[250,318] These cats therefore are treated with higher ablative doses of ^{131}I, in the range of 20 to 30 mCi.[249,250] Another approach to the treatment of thyroid carcinoma is to combine surgery and ^{131}I therapy.[239,247,250] Thyroid cysts occasionally are detected in both euthyroid and hyperthyroid cats and may be associated with either benign or malignant disease. Thyroid cysts may persist after ^{131}I therapy in hyperthyroid cats, therefore a surgical approach also may be needed in these cases.[251]

Ultrasound-guided percutaneous ethanol injection has been evaluated as a treatment for feline hyperthyroidism. Cats with solitary adenomas have a good response, with resolution of clinical signs persisting for longer than 12 months.[323] This technique is not recommended for bilateral hyperplasia.[324] Ultrasound-guided percutaneous radiofrequency heat ablation has been shown to be ineffective for long-term control of hyperthyroidism.[325] Given the ready availability of permanent effective treatments for unilateral or bilateral disease, these alternative treatments are unlikely to be used widely.

Chronic kidney disease (CKD) is a relatively common problem in older cats, and concurrent CKD and hyperthyroidism frequently occur in this population.[326] The hyperthyroid state increases the glomerular filtration rate (GFR),[327,328] thereby reducing serum creatinine values. The implications of this are that hyperthyroid cats with normal serum creatinine values actually may have concurrent masked CKD and that decline in renal function is a risk of all effective treatments for feline hyperthyroidism, with some nonazotemic cats becoming azotemic, or the potential for worsening of preexisting azotemia.[319,327,329,330] This decline in renal function occurs within 1 month after treatment and appears to remain stable thereafter.[319,331] Measurement of the pretreatment GFR may help predict which cats will become azotemic after resolution of the hyperthyroidism[319,330]; however, this is impractical for most patients. A recent study found that a high serum symmetric dimethylarginine (SDMA) concentration in a hyperthyroid cat can help predict the development of azotemia after treatment, but this has poor sensitivity.[332] Unfortunately, no readily available clinical data can predict the effects of therapy on renal function in an individual cat.[326,333] For this reason, many clinicians recommend a therapeutic trial with methimazole before definitive therapy for feline hyperthyroidism.[333] This may have value in providing owners with information about the likely consequence of therapy for these cats, but regardless of the detected change in renal function, effective therapy for hyperthyroidism still is required in these patients. One study showed that the development of azotemia was not significantly associated with the survival of cats treated for hyperthyroidism,[334] but the same group also demonstrated a significantly shorter ST in cats with iatrogenic hypothyroidism that became azotemic after treatment compared with those that remained nonazotemic.[321]

Parathyroid Tumors

Parathyroid tumors are uncommon in dogs and rare in cats. These tumors arise from the chief cells and autonomously secrete parathyroid hormone (PTH), leading to hypercalcemia as a result of primary hyperparathyroidism. Hypercalcemia is the result of direct effects of PTH on bone and the kidneys and indirect effects on the intestine, mediated by vitamin D. Approximately 90% of dogs and cats with primary hyperparathyroidism have a single parathyroid mass.[335–341] Adenomas are most commonly diagnosed; cystadenoma, carcinoma, and hyperplasia are diagnosed less frequently; and metastatic disease is extremely rare.[335–337,339–347] Two or more parathyroid masses may be found in some canine and feline patients, and they may not necessarily all be of the same histologic type. The presence of four hyperplastic parathyroid masses should prompt careful evaluation for causes of secondary hyperparathyroidism.

Primary hyperparathyroidism is most common in older dogs and cats, with reported mean ages of approximately 11 years in dogs[337,339] and 13 years in cats.[335] A breed predisposition has been reported in keeshond dogs, in which the disease appears to follow an autosomal dominant mode of inheritance, although the affected gene has not yet been identified in this breed.[337,341,343,348] It is not clear whether a breed predilection exists in cats.

The clinical signs of hyperparathyroidism result from hypercalcemia; they include polyuria/polydipsia, weakness, lethargy, decreased appetite, weight loss, muscle wasting, vomiting, and trembling. It is not uncommon for owners to detect no clinical signs in affected dogs or cats, and the hypercalcemia is diagnosed when blood is drawn for a routine health check or for investigation of an unrelated problem. However, signs can be subtle and may be recognized only in retrospect, after the hyperparathyroidism has been treated and the hypercalcemia has resolved. In a large case series, the most common clinical problems reported in dogs with hyperparathyroidism were related to the lower urinary tract, usually associated with urolithiasis or urinary tract infection.[337] Specific physical examination abnormalities are rare in dogs and cats. A palpable parathyroid mass has been reported in some cats with hyperparathyroidism, but this is an extremely rare finding in dogs.[336,337,347]

Hyperparathyroidism usually is diagnosed after hypercalcemia is found on a serum biochemistry profile, either as an incidental finding or when a problem such as calcium oxalate urolithiasis, polyuria/polydipsia, or weakness is investigated. The presence of hypercalcemia should be verified by measuring the serum ionized calcium, with appropriate careful sample handling.[349,350] Hypercalcemia has many causes in dogs and cats,[351,352] and diagnostic tests may be performed to investigate several possible causes simultaneously. (The reader is directed to Chapter 5 for a further discussion of the causes of hypercalcemia in dogs and cats.) Hypercalcemia resulting from primary hyperparathyroidism often is accompanied by hypophosphatemia, or a serum inorganic phosphorus level at the low end of the reference range. This finding is not pathognomonic for hyperparathyroidism and can be associated with humoral hypercalcemia of malignancy, but it can assist in ranking the differential diagnoses because vitamin D toxicosis and renal failure both would be expected to cause hyperphosphatemia. The diagnosis of hyperparathyroidism is confirmed by documenting an inappropriately high serum PTH level in the presence of ionized hypercalcemia. It is important to note that PTH frequently is within the reference range in patients with hyperparathyroidism, with 73% of cases reported to have a normal PTH in one large series.[337] A normal PTH in the face of hypercalcemia is an abnormal finding because PTH should be suppressed as serum calcium increases. The lack of suppression of PTH indicates loss of the normal negative feedback effects of calcium due to autonomous hormone

VetBooks.ir

secretion by hyperplastic or neoplastic parathyroid tissue. Ultrasound examination of the neck commonly is used in the diagnosis of hyperparathyroidism in dogs and cats and is particularly useful for localizing parathyroid mass(es) before surgery or other ablative procedures.[a] The normal sonographic appearance of canine parathyroid glands has been described,[355] and parathyroid masses as small as 3 mm in greatest diameter have been identified ultrasonographically.[337] Parathyroid scintigraphy and selective venous sampling to assess local PTH concentrations do not appear to be helpful in localizing hyperplastic or neoplastic parathyroid tissue.[353,356,357]

The management of hypercalcemia is further addressed in Chapter 5. Primary hyperparathyroidism in dogs and cats usually is associated with slowly progressing hypercalcemia, and the increased calcium itself rarely requires emergency treatment. Hypercalcemia is a risk factor for acute kidney injury (AKI); the mechanisms include altered glomerular capillary permeability, reduced renal blood flow, and mineralization of the kidneys. The risk of mineralization is increased when the calcium × phosphorus product exceeds 70. As noted previously, patients with hyperparathyroidism often have a decreased or low normal phosphorus level, which reduces the risk of renal mineralization. In fact, AKI appears to be rare in dogs with primary hyperparathyroidism. In a large canine case series, the mean blood urea nitrogen (BUN) and serum creatinine both were significantly lower in 210 dogs with primary hyperparathyroidism compared with 200 control dogs.[337] In addition, 95% of the hyperparathyroid dogs had BUN and serum creatinine values within or below the reference range. This partly may be a result of the secondary nephrogenic diabetes insipidus that causes polyuria/polydipsia in these patients.

Definitive therapy for primary hyperparathyroidism requires removal of the hyperfunctioning gland(s). This is most commonly achieved by surgery in both dogs and cats; however, percutaneous ultrasound-guided ablation techniques also have been described in the dog. There are four parathyroid glands, and two are closely associated with each thyroid lobe. The external parathyroid glands are outside the thyroid lobe but within the capsule and generally associated with the cranial pole.[221] The internal parathyroid glands are within the thyroid capsule and lobe and can vary in location, but they generally are located in the caudal portion of the lobe.[221] Normal parathyroid glands in the dog are small (2–5 mm × 0.5–1 mm), disk shaped, and tan in color. They are distinct from thyroid tissue.[221] Parathyroid adenomas are larger than normal parathyroid glands, round, and firm in texture. Once a diagnosis of primary hyperparathyroidism has been made, a preoperative ultrasound examination of the neck may be useful to establish the side and site of the parathyroid nodule. This can be an important tool to confirm the presence of a nodule and the surgical site of interest. However, it is important to note that false positive and negative results are possible with ultrasound; for example, thyroid nodules may be incidentally found in hypercalcemic dogs undergoing cervical ultrasound studies.[213] In addition, patients with primary hyperparathyroidism may have disease in more than one parathyroid gland and/or ectopic parathyroid tissue. Up to three of the four parathyroid glands can be removed without risk of permanent hypoparathyroidism. Patients with involvement of all four glands present a dilemma, and it is important to ensure that hyperplasia in these cases is not secondary.

[a] References 337, 338, 347, 353, and 354.

A routine ventral midline approach to the thyroid glands is made. The area is explored bilaterally, even if the location of the parathyroid nodule is known preoperatively, to evaluate for additional sites of disease. The nodule can be identified with a combination of visualization and digital palpation. Once a nodule has been identified, it is bluntly dissected from the thyroid gland and hemostasis is achieved with bipolar electrocautery.

The postoperative care generally is more involved than the surgery itself. Patients must be monitored closely for hypocalcemia, which occurs as a result of downregulation of normal parathyroid tissue with prolonged hypercalcemia. Serum ionized calcium concentrations should be monitored at least twice daily for as long as 5 to 7 days after surgery or other ablative procedures. Hypocalcemia should be treated if the ionized calcium falls below 0.8 to 0.9 mmol/L; the total calcium is less than 8 to 9 mg/dL; or the patient has signs of tetany. Intravenous (IV) calcium salts are used for acute therapy for hypocalcemia; subcutaneous (SQ) administration should be avoided. Vitamin D and oral calcium are used for subacute and chronic therapy.

Several excellent references are available on the treatment of hypoparathyroidism.[340,358] In summary, 1,25-dihydroxyvitamin D_3 (calcitriol) is recommended for vitamin D supplementation because it has a rapid onset of action and a short half-life. This facilitates dose adjustments and reduces the risk of hypercalcemia. Oral calcium supplementation alone is not sufficient to treat hypoparathyroidism, and in fact this therapy can be withdrawn gradually once the calcium is stable because most maintenance diets contain an adequate amount of calcium. The approach to these patients postoperatively remains somewhat controversial; some clinicians treat with calcitriol and oral calcium immediately postoperatively, whereas others monitor the ionized calcium carefully for the development of hypocalcemia. In the author's (SB) opinion, careful monitoring without administering oral calcium or calcitriol is preferred because not all patients will develop hypocalcemia, and it is more straightforward in those patients to allow them to regulate their own calcium. Furthermore, in one study prophylactic calcitriol administration was not shown to have a protective effect for preventing hypocalcemia in patients after parathyroidectomy.[359] Several studies have attempted to correlate the preoperative ionized calcium concentrations with the risk of hypocalcemia postoperatively, with varying results. One study found a moderate correlation with a high preoperative ionized calcium and postoperative hypocalcemia,[360] whereas other studies have failed to show a correlation between preoperative ionized calcium[361,362] and PTH[362] and postoperative serum calcium concentrations. A small number of patients may be resistant to the postoperative management of hypocalcemia,[363] and this may be the result of "hungry bone syndrome," marked by aggressive, unregulated uptake of calcium by the bones.[364] In human medicine this syndrome has been managed with preoperative bisphosphonate administration[365] or the use of recombinant PTH.[366] Neither of these approaches has been used in veterinary medicine, and most patients eventually respond to high doses of calcitriol and calcium supplementation.

Ideally the calcium will decline into the normal range and then plateau. Once a plateau has been documented, the patient can be discharged from the hospital. Some patients become hypocalcemic and require administration of both calcitriol and calcium. Once their serum calcium concentrations stabilize, they can be discharged, but they must have careful and regular follow-up. When adjusting the dose of calcitriol, the goal is to maintain calcium

VetBooks.ir

concentrations barely below, rather than within, the normal reference range. This reduces the risk of hypercalcemia and provides the stimulus for recovery of function of the remaining normal parathyroid glands. Once the serum calcium has been stable for at least 1 to 2 weeks in an outpatient, the dose of calcitriol can be reduced gradually, with careful monitoring. The time for return of normal parathyroid function is unpredictable, therefore clients should expect frequent rechecks of calcium levels for several weeks to months after treatment of hyperparathyroidism.

A small percentage of patients have persistent hypercalcemia after parathyroidectomy. This likely is due to a nodule of another parathyroid gland that was not discovered at the time of surgery, or to hyperplasia or neoplasia in ectopic parathyroid tissue. Ectopic parathyroid tissue is a frustrating clinical problem. Anecdotally the author (SB) has found a parathyroid adenoma under the tongue in one patient. A rapid parathyroid assay now is available for intraoperative measurement of PTH.[357] This may be helpful for confirming that the offending parathyroid tissue has been removed successfully intraoperatively.[367] When ectopic parathyroid tissue cannot be located easily, MRI or CT can be attempted. However, the nodules typically are small and may be difficult to diagnose.

Ultrasound-guided ablative techniques also have been reported to treat primary hyperparathyroidism. Ultrasound-guided radiofrequency ablation (RFA) was first reported in 2001 in 11 dogs. One treatment was required in six dogs, two treatments in two dogs, and the treatment was unsuccessful in three dogs.[368] In another study persistent or recurrent disease was reported in 31% of 32 dogs; larger nodules and/or concurrent hypothyroidism were associated with treatment failure.[369] Ultrasound-guided ethanol ablation also has been reported as a minimally invasive method to treat primary hyperparathyroidism. This technique first was reported in eight dogs, with seven dogs requiring one treatment and one dog requiring two treatments. Hypercalcemia resolved in all cases, but one dog developed recurrent hypercalcemia 1 month later and was treated with surgical removal of the mass.[370] Another larger study reported ethanol ablation of parathyroid nodules in 27 dogs; hypercalcemia resolved in 85% of the cases, but three dogs required a second treatment.[371] A direct comparison of the three techniques for the treatment of primary hyperparathyroidism was reported retrospectively. That study found that control of hypercalcemia was achieved in 94%, 72%, and 90% of cases treated with parathyroidectomy, ethanol ablation, and RFA, respectively.[339]

The long-term prognosis after surgical or ablative treatment for hyperparathyroidism is very good both for control of hypercalcemia and for the tumor itself. Metastatic disease is extremely rare, and the complication of hypocalcemia generally is amenable to medical therapy. Histopathology most commonly reveals a parathyroid adenoma or hyperplastic nodule, although histologic classification is not straightforward.[340] In rare cases a parathyroid adenocarcinoma has been diagnosed. These are functional parathyroid nodules, and in a report of 19 dogs with parathyroid adenocarcinoma, no features of the disease differed from those of a benign functional adenoma except for the finding of carcinoma on histopathology. The prognosis in these cases was excellent both for tumor control and for resolution of hyperparathyroidism.[344] Approximately 10% of dogs treated for hyperparathyroidism experience a recurrence of the disease.[340] If this occurs, a second surgery or ablative procedure should be performed. The short-term prognosis for dogs and cats that do not undergo definitive surgical or ablative therapy for hyperparathyroidism still may be favorable because the disease tends to be slowly progressive, clinical signs may be mild, and renal failure may be a less common outcome than previously suspected.[337]

Pancreatic Beta-Cell Tumors (Insulinomas)

Pancreatic beta-cell tumors are rare in humans and cats and uncommon in dogs.[372–375] These tumors often are functional, but the neoplastic beta cells fail to inhibit insulin secretion appropriately at low blood glucose concentrations. Thus the hallmark of insulinoma is a normal or increased blood insulin concentration in the presence of low blood glucose levels. Molecular studies of a feline insulinoma revealed abnormal glucokinase and hexokinase expression, suggesting that these changes may contribute to enhanced glucose sensitivity and an abnormal insulin secretory response in insulinoma cells.[374] Although the clinical signs of insulinoma result from hypoglycemia associated with unregulated insulin secretion, immunocytochemical analysis reveals that these tumors often produce many additional hormones, including glucagon, somatostatin, pancreatic polypeptide, GH, IGF-1, and gastrin.[374,376–380] A more recent study demonstrated that some canine insulinomas express genes more typically associated with the exocrine pancreas; the study also revealed that these tumors contain small subpopulations of cells with mixed endocrine-exocrine features, termed *amphicrine cells*.[381]

In humans 90% of insulinomas are solitary and benign, and 5% to 10% are associated with multiple endocrine neoplasia type 1 (MEN1). Insulinomas in dogs are much more likely to be malignant, although morphologic classification into adenoma or adenocarcinoma does not consistently reflect the biologic behavior of these tumors.[375,378,382] Metastatic lesions are detected in approximately 50% of canine insulinomas, with the regional lymph nodes and liver most commonly affected. Pulmonary metastases are rare in dogs.[379,383–387] The World Health Organization (WHO) recommendations have been used to stage canine pancreatic tumors.[384] Stage I tumors involve only the pancreas, with no evidence of local or distant lymph node involvement and no distant metastasis (T1N0M0); stage II tumors have lymph node involvement (T1N1M0); and stage III tumors have distant metastasis (T1N1M1 or T1N0M1).

Beta-Cell Tumors in Dogs

The cellular and molecular events causing beta-cell tumors in dogs are unknown; however, studies of these tumors have provided insights into tumor biology and molecular genetics. Canine insulinomas have been shown to express somatostatin receptors, which may have implications for both diagnosis and therapy.[388] Local production of GH and IGF-1 also have been demonstrated in canine insulinomas, with a higher level of expression of GH and IGF-1 mRNA in metastases compared to primary tumors.[380,389] It has been suggested that the locally produced hormones may have autocrine or paracrine effects on cell proliferation, and tumor growth and progression. Furthermore, it is speculated that locally produced somatostatin has inhibitory effects on insulinomas within the pancreas, but that these effects are decreased in metastases leading to increased GH production.[389] Gene expression profiling of canine insulinomas and their metastases have demonstrated differential expression of genes between low-metastatic and high-metastatic subsets of insulinomas with genes for acinar enzymes being more substantially down-regulated in the more malignant subset of tumors. In addition, pathways involved in

VetBooks.ir

DNA repair and cell cycle regulation were also down-regulated in the high-metastatic canine insulinomas.[381,390] In studies of potential prognostic biomarkers for canine insulinoma, tumor size, TNM stage, Ki67 index (a marker of proliferation), presence of necrosis, nuclear atypia, and stromal fibrosis have all been identified as being predictive for DFI and/or ST, depending on the model used in analysis.[382,391]

Canine insulinomas are most commonly reported in medium and large breed dogs, particularly Labrador retrievers, golden retrievers, German shepherd dogs, German short-haired pointers, Irish setters, boxers, and mixed breed dogs. Small breed dogs also can be affected; West Highland white terriers are overrepresented in some reports.[379,385] Depending on the case series, the median reported age is 9 to 10 years, with a range of 3 to 15 years, and no sex predilection.[379,383–385,389,392]

The clinical signs of insulinoma result from the effects of hypoglycemia on the nervous system, which is termed *neuroglycopenia*; these signs include weakness, ataxia, collapse, disorientation, behavioral changes, and seizures. Catecholamine release stimulated by low blood glucose levels also may cause muscle tremors, shaking, anxiety, and hunger. Clinical signs can be present for days to months and often are intermittent, episodic, or precipitated by fasting, exercise, excitement, or eating. Signs may be less pronounced with more chronic hypoglycemia, and patients can be clinically normal, with significantly low blood glucose levels. Physical examination findings otherwise are unremarkable in most patients. A paraneoplastic peripheral neuropathy has been described in dogs with insulinoma. This is rare, although subclinical neuropathies may be present and undetected.[393–397] Brain lesions associated with hypoglycemia also have been reported in rare cases.[398,399]

The diagnosis of insulinoma is confirmed by documenting hypoglycemia (blood glucose <60 mg/dL) with a concurrent normal or increased serum insulin concentration. In some cases it may be necessary to fast the patient, with careful monitoring, and repeat blood glucose measurements every 30 to 60 minutes. Once the blood glucose is less than 60 mg/dL, a serum sample should be submitted for concurrent insulin measurement. The presence of a normal or high serum insulin concentration in the face of hypoglycemia is inappropriate and generally sufficient to confirm the diagnosis of insulinoma. This insulin-glucose pair should be performed more than once if the initial sample provides equivocal results.[400] The use of insulin:glucose or glucose:insulin ratios is not recommended because these do not improve diagnostic accuracy.[401] Provocative testing is rarely used in veterinary medicine because of risks, expense, and poor sensitivity.[385,401] Serum fructosamine and glycosylated hemoglobin concentrations also can be measured in dogs to support a suspicion of insulinoma.[402–405] Concentrations of these glycosylated proteins would be expected to be lower than normal in dogs with chronic hypoglycemia, although this is not necessarily pathognomonic for insulinoma.

Imaging studies often are used in the evaluation of insulinoma patients, either to investigate other differential diagnoses for hypoglycemia or for local and distant staging in preparation for surgical management. Thoracic and abdominal radiographs usually are unremarkable,[401] and abdominal ultrasonography, although commonly performed, cannot be used to rule in or rule out a diagnosis of insulinoma. This technique has been reported to clearly identify and localize a pancreatic mass in less than 50% of patients with insulinoma,[387,392,406,407] and it has low sensitivity and specificity for the detection of metastatic lesions. In human medicine, endoscopic and intraoperative ultrasonography are used to identify small pancreatic tumors, but these approaches have yet to be significantly used in canine patients.[408–410] Contrast-enhanced ultrasound techniques are widely used in human medicine and are may be of value for the detection of pancreatic tumors in dogs. In this procedure, gas-filled microbubbles are injected into the circulation and ultimately reach the vascular supply to the organ of interest, where they are detected on ultrasound examination.[128] Because the microbubbles remain in the vasculature, this technique is particularly valuable for assessing tissue blood supply and perfusion. Contrast-enhanced ultrasonography has been described for the normal canine pancreas,[411–414] patients with pancreatitis,[415,416] and a small number of dogs with pancreatic tumors,[417,418] and the apparent safety and relative accessibility of this technique indicate that its use very likely will increase.[128] CT findings have been reported in a small number of dogs with insulinoma.[407,419,420] In a study comparing ultrasound, CT, and single-photon emission CT (SPECT), CT was found to be the most sensitive technique, identifying 10 of 14 confirmed primary insulinomas. However, CT also identified a significant number of false positive metastatic lesions.[407] The results of SPECT with ^{111}In-DTPA-D-Phe^{1}-octreotide have been reported in a total of 19 dogs with insulinoma, with an overall sensitivity of 50% for detection and correct localization of the primary tumor.[388,407] Enhanced CT techniques, such as dynamic CT or dual-phase CT angiography, hold promise for greater sensitivity of detection of insulinomas in dogs, but large-scale studies have yet to be reported in the veterinary literature.[419–421] Somatostatin receptor scintigraphy (SRS) is an important imaging modality in humans with pancreatic endocrine tumors, including insulinomas. Indium In-111 pentetreotide SRS has been reported in a total of six dogs with insulinoma; positive results were reported in five cases, although an accurate anatomic localization was obtained only in one dog.[422,423] PET has been used in human patients to localize insulinomas when CT, MRI, and ultrasound are negative.[424] This modality has yet to be explored in canine insulinoma patients.

Therapy for canine insulinoma involves acute and chronic treatment of hypoglycemia and long-term management of the tumor. Acute treatment of hypoglycemia is accomplished through administration of intravenous dextrose, often as a slow bolus, followed by continuous rate infusion (CRI). This should be given with caution because this treatment can stimulate further unregulated insulin secretion and worsened hypoglycemia. Glucagon infusion also has been safely and effectively used in the management of hyperinsulinemic-hypoglycemic crises in a small number of dogs.[425,426]

Surgery is the recommended treatment for insulinoma in dogs and is indicated in patients with hypoglycemia and inappropriately increased serum insulin concentrations, regardless of the results of abdominal imaging studies.[383–385,387,392] Ultimately, an exploratory laparotomy is necessary to evaluate the pancreas for the primary tumor and the remainder of the abdomen for metastatic disease. Most canine insulinomas are visible or palpable at surgery, and tumors are identified in both lobes of the pancreas with equal frequency.[375] Treatment before surgery with corticosteroids may help improve blood glucose levels.[401] The patient should not have a long period of fasting, and some cases may require intravenous dextrose.[401] Conventionally the abdomen is explored via a ventral midline approach, although laparoscopic evaluation and partial pancreatectomy has been reported.[427] A partial pancreatectomy of the affected portion of the pancreas and a margin of normal tissue is performed. This can be performed by intracapsular dissection and ligation or

VetBooks.ir

with a vessel sealing device.[428] If evidence of metastatic disease is seen, especially to the liver, then as much metastatic disease as possible should be removed. Potential postoperative complications include persistent hypoglycemia, pancreatitis, and hyperglycemia.[375,429] In general, hyperglycemia will be transient if it occurs, but a small percentage of cases require insulin therapy.[375,429] Postoperatively patients should be managed with intravenous fluid therapy, multimodal analgesia, and antinausea medications, and with careful monitoring of the blood glucose level and for signs of pancreatitis. Any tissue removed or biopsied at surgery should be submitted for histopathologic examination to confirm the diagnosis.[401] Limited reports exist on the use of cytology, typically performed during preoperative patient evaluation, to support the diagnosis of insulinoma. [401,430,431]

Medical treatment of insulinoma is used to stabilize patients preoperatively, as an alternate therapy if surgery is not possible, and in conjunction with surgical management. Medical therapies primarily are used to control hypoglycemia, but cytotoxic agents also have been used to destroy pancreatic beta cells. Streptozocin (streptozotocin) is the chemotherapeutic drug that has been used most often, albeit infrequently, in dogs. Its use in dogs historically was limited by its nephrotoxicity,[375] but more recent reports suggest that the risk of nephrotoxicity is reduced significantly if streptozocin is administered in combination with intensive saline diuresis.[432–434] Other side effects include vomiting during administration, diabetes mellitus, hypoglycemia, increased liver enzyme activity, and mild hematologic changes.[432–434] The administration of streptozocin does not significantly increase the duration of normoglycemia in dogs with insulinoma compared with control dogs treated medically or surgically.[432] Although individual dogs have demonstrated reductions in tumor size or resolution of paraneoplastic neuropathy with streptozocin, it still is unclear whether the risks of therapy outweigh the benefits of this treatment for dogs with insulinoma.[375,434]

Strategies used to control hypoglycemia consist of dietary modification and medical therapy with prednisone, diazoxide, or octreotide. Excitement should be avoided in these patients and exercise limited. Diets high in fat, protein, and complex carbohydrates should be fed in small, frequent meals, and simple sugars should be avoided.[375] Prednisone is used for its insulin-antagonizing, gluconeogenic, and glycogenolytic effects.[375] A starting dose of 0.25 mg/kg by mouth (PO) twice daily is recommended, with gradual dose increases as needed to control hypoglycemia.[375,401] Typical glucocorticoid side effects should be anticipated. Diazoxide is a nondiuretic benzothiadiazine that suppresses insulin release from beta cells. It also stimulates hepatic gluconeogenesis and glycogenolysis and inhibits cellular uptake of glucose. Diazoxide is not cytotoxic and does not inhibit insulin synthesis. A starting dose of 5 mg/kg PO twice daily is recommended, and the dose can be increased gradually to 30 mg/kg daily dose ose can be ates hepatic glucon.[375,401] Approximately 70% of canine insulinoma patients respond to diazoxide therapy.[375,383] Adverse effects are uncommon but may include ptyalism, vomiting, anorexia, and diarrhea.[375,401,435] The use of diazoxide is limited by its cost and inconsistent availability.[401] Octreotide is a somatostatin receptor ligand that inhibits synthesis and secretion of insulin by pancreatic beta cells. It has been reported to alleviate hypoglycemia in up to 50% of dogs with insulinoma, although some may become refractory to treatment.[375,388] The suggested dose is 10 to 50 μg SQ 2 or 3 times daily, and side effects appear to be rare. In a more recent study a single 50 μg dose of octreotide was administered to 12 dogs with insulinoma. Plasma insulin concentrations decreased significantly after administration of octreotide in dogs with insulinoma, but GH, ACTH, cortisol, and glucagon levels did not change, and glucose levels increased.[436] These findings suggest that the use of octreotide warrants further investigation in canine patients with insulinoma, although the cost of the medication may be a significant impediment.

The prognosis for dogs with insulinomas is good in the short term but guarded to poor in the long term. Patients that undergo surgery and then medical management are more likely to become euglycemic, remain euglycemic for longer periods, and have longer STs compared to patients that receive only medical therapy.[387,392] MSTs after partial pancreatectomy range from 12 to 14 months.[435] The prognosis after surgery depends on the clinical stage of the disease.[375] Dogs with stage I disease have a longer DFI compared to dogs with stages II and III disease; 50% of dogs with stage I disease are free of hypoglycemia 14 months after surgery, whereas less than 20% of dogs in stage II and III disease are free of hypoglycemia at this time.[384] Dogs with stage III disease have a significantly shorter ST than dogs with stage I and II disease – approximately 50% of dogs with metastasis are dead by 6 months.[384] A more recent retrospective study showed an improved ST in dogs with insulinoma compared to earlier reports with a median DFI and MST of 496 days and 785 days, respectively, for 19 dogs undergoing partial pancreatectomy.[392] A subset of nine dogs treated with partial pancreatectomy and postoperative prednisolone had an MST of 1316 days. For eight dogs that received medical therapy alone, the MST was 196 days. When all the dogs that received medical therapy were considered as a group, the MST after institution of the medical treatment was 452 days.[392] These results lend strong support to the use of medical therapy in canine patients with insulinoma, particularly when clinical signs recur after surgery.

Beta-Cell Tumors in Cats

Compared to dogs, significantly fewer reports of insulinomas exist for cats.[373,437–441] History, clinical signs, and biologic behavior in this species appear to be similar to those in the dog, and concurrent measurements of blood glucose and serum insulin concentrations are used to confirm the diagnosis; however, it is important to use an insulin assay that has been validated in cats.[375] Surgical management has been reported in cats, with STs ranging from 1 to 32 months. Conservative therapy with dietary management and prednisolone also has been used in cats. Octreotide may be considered, although little evidence supports its use, and no evidence supports the use of diazoxide or streptozotocin in this species.[375]

Gastrointestinal Endocrine Tumors

Gastrinoma

Gastrinomas are neuroendocrine tumors that secrete excessive amounts of gastrin. Zollinger-Ellison syndrome refers to the triad of a non–beta-cell neuroendocrine tumor in the pancreas, hypergastrinemia, and GI ulceration. Gastrinomas are rare in dogs and very rare in cats.[442,443] Almost all reported gastrinomas in these species were identified in the pancreas, although one report exists of a duodenal gastrinoma in a dog.[444] Gastrinomas are highly metastatic, with involvement of the liver, regional lymph nodes, spleen, peritoneum, small intestine, omentum, or mesentery identified in 85% of dogs and cats at the time of initial diagnosis.[442,443,445–447]

VetBooks.ir

Gastrinomas typically are reported in middle-aged dogs and older cats.[442,443] No obvious breed or sex predilections have been identified. Clinical signs result from gastric acid hypersecretion and gastric mucosal hyperplasia. The most common signs are vomiting and weight loss. Melena, abdominal pain, anorexia, regurgitation, hematemesis, hematochezia, and diarrhea also may occur.[441–443,445,447–454] Physical examination findings range from unremarkable to a patient in hypovolemic shock because of perforation of an ulcer. A serum biochemistry profile, CBC, and urinalysis may demonstrate changes associated with protein loss and bleeding resulting from GI ulceration or may reflect the consequences of severe or persistent vomiting or the presence of hepatic metastases. One case of common bile duct obstruction caused by a duodenal gastrinoma has been reported in a dog.[444] Abdominal radiographs often are unremarkable unless GI perforation has occurred. Contrast radiographs and abdominal ultrasound examination may show evidence of GI ulceration and a thickened pyloric antrum and gastric wall. Ultrasound examination also may reveal metastatic lesions in the liver or regional lymph nodes; however, the primary tumor in the pancreas usually is too small to be detected with this modality.[447] The results of techniques such as CT and MRI have not been widely reported in dogs and cats with gastrinomas. Endoscopy may reveal esophagitis, with ulceration, gastric and duodenal ulceration, thickened gastric rugae, and hypertrophy of the pyloric antrum. The diagnosis may be supported by measuring basal serum gastrin levels or levels after provocative testing or by scintigraphy using radiolabeled pentetreotide.[455] Basal gastrin levels have been significantly increased in dogs and cats with gastrinoma; however, gastrin levels also can be increased in renal or gastric disease, and no specific cutoff values for diagnosis have been determined.[443,456] Although it has been suggested that treatment with medications such as proton pump inhibitors and H_2-antihistamines can lead to increased serum gastrin concentrations, recent studies indicate that these effects are mild and short-lived and may not in fact inhibit the diagnosis of gastrinoma.[457–460] Provocative testing to diagnose gastrinoma rarely has been reported in veterinary medicine.[442,443,461]

Exploratory laparotomy is recommended for dogs and cats with a suspected gastrinoma. Even though most dogs and cats have visible metastasis at the time of initial diagnosis, surgical debulking reduces the gastrin secretory capacity and enhances the efficacy of medical therapy.[462] In addition, deep or perforated GI ulcers can be identified and excised. Long-term medical management includes the use of proton pump inhibitors, H_2-antihistamines, and sucralfate.[448,452] Octreotide has been used in three dogs with success.[455,463,464] STs for dogs and cats with gastrinoma range from 1 week to 26 months.[442,462,465]

Glucagonoma

Glucagonomas are rare in dogs, and currently only a single published case report exists in a cat.[443,466] These tumors are associated with a crusting dermatologic condition termed *necrolytic migratory erythema* (NME). Other associated problems include hyperglycemia or overt diabetes mellitus, hypoaminoacidemia, and increased liver enzyme activity. Skin lesions associated with NME include hyperkeratosis, crusting, and ulceration and erosions of the footpads, mucocutaneous junctions, external genitalia, distal extremities, pressure points, and ventral abdomen.[461,466–471] Glucagonomas usually arise from alpha cells in the pancreas; however, extrapancreatic glucagon-secreting tumors also have been reported.[466,470] The tumors sometimes can be detected on abdominal ultrasound examination or CT.[443,466,469,471] Plasma glucagon concentrations have been measured in some cases, and amino acid concentrations also have been evaluated in a small number of patients,[468–470,472] but the sensitivity and specificity of these diagnostic tests have not been evaluated. Surgical resection or debulking is the treatment of choice for canine glucagonoma. Rare reports exist of the use of somatostatin analogs.[470,471] The dermatologic lesions of NME may improve after surgery or medical therapy,[471,472] but metastasis is common at the time of diagnosis and the prognosis is generally poor.[461,469] When NME is suspected, it is important to rule out liver disease, a more common cause of this dermatologic condition in dogs.

Intestinal Carcinoid

Intestinal carcinoid tumors are rare in dogs and cats. They arise from neuroendocrine cells that are found in a variety of locations, including the GI tract, liver, gallbladder, and pancreas.[443,473–478] Clinical signs generally are associated with the anatomic location of the tumor, although the physiologic effects of vasoactive substances released from the tumor were suspected to be the cause of clinical signs in one dog with an intestinal carcinoid.[477] In general, the prognosis for these tumors is guarded because metastasis is common at the time of diagnosis.[443] Surgical removal is recommended; a single case report has described adjuvant chemotherapy in a dog.[479]

Tumors of the Female Reproductive System

COREY F. SABA AND JESSICA A. LAWRENCE

Ovarian Tumors

Incidence

Ovarian tumors are uncommon in dogs and cats, resulting in part from the routine practice of ovariohysterectomy (OHE) in many areas of the world. The overall reported prevalence in dogs is 0.5% to 1.2%,[1–3] with an estimated prevalence of 6.25% in intact females.[4] Ovarian tumors are equally rare in cats, with a reported prevalence of 0.7% to 3.6% in intact females.[5,6] These numbers are derived primarily from pathology surveys and likely overestimate the true incidence in the pet population. Breed predilections are also difficult to discern; however, German shepherd dogs, boxers, Yorkshire terriers, poodles, and Boston terriers appear to be most commonly affected.[2,7,8] Aside from germ cell tumors and specifically teratomas, most ovarian tumors develop in older dogs (approximately 6 years of age and older).[2,7–9] Teratomas are often found in younger dogs (≤6 years of age).[7,8,10,11] Ovarian tumors have been reported in cats ranging from less than 1 year to 20 years (mean age: 6.7 years).[12–15]

Pathology and Natural Behavior

Canine Ovarian Tumors

Owing to the complexity of the canine ovary, a variety of histologic tumor types may occur. Historically, canine ovarian tumors have been classified based on the World Health Organization (WHO) classification scheme for human ovarian tumors, with primary tumor types including epithelial tumors, germ cell tumors, sex cord stromal (gonadostromal) tumors, and mesenchymal tumors.[2,8,16,17] Later, the human WHO classification system was revised to subdivide each of the aforementioned categories into histologic types based on morphologic similarities; the use of immunohistochemistry has aided in further differentiating ovarian tumors.[18] Attempts to recapitulate such classification schemes in dogs have been reported, but are not routinely employed.[19,20]

Epithelial Tumors

Epithelial tumors arise from the outer surface of the ovary[9,21] and according to several reports are most common.[2,8,16] Malignant tumors outnumber benign tumors,[7,8,16] and larger size is suggestive of malignancy.[8,16] Malignant histologies include papillary adenocarcinomas, tubular adenocarcinomas, and undifferentiated carcinomas; benign tumors such as rete adenomas, papillary adenomas, and cystadenomas also occur.[2,8,16] Reportedly, 48% of adenocarcinomas will metastasize, generally within the peritoneal cavity to the intraabdominal lymph nodes, omentum, and liver.[8] Direct tumor cell implantation and subsequent malignant effusion may also occur.[3,8] Although most are unilateral, bilateral epithelial ovarian tumors have been described.[8] Cysts in the contralateral ovary and cystic endometrial hyperplasia may also be found.

Epithelial ovarian tumors routinely express cytokeratin AE1/AE3 (CK AE1/AE3), vimentin, and desmin.[19,20] Although papillary adenocarcinomas also demonstrate placental alkaline phosphatase (PLAP) and cytokeratin 7 (CK7) immunoreactivity, positive immunoreactivity appears to be less frequent in tubular adenocarcinomas.[19] Alpha-fetoprotein (AFP),[19] S-100,[19] and endothelin-A (ET-A)[22] are variably expressed. Faint to strong intracytoplasmic cyclooxygenase-2 (COX-2)[23] and endothelin-1 (ET-1)[22] immunoreactivity has been reported in 81% and 83% of canine ovarian carcinomas, respectively. Inhibin-alpha (INH-α), a glycopeptide synthesized in gonadal cells of the ovaries, inhibits pituitary secretion of follicle-stimulating hormone (FSH), and it has been described as a sensitive and specific marker for granulosa-theca cell tumor (GTCT).[24] Therefore epithelial tumor cells should not express INH-α, and demonstration of INH-α expression has resulted in reclassification of epithelial tumors as GTCT.[20] The immunohistochemical marker HBME-1 (Hector Battifora mesothelial epitope) has been used in human medicine to aid in the diagnosis of epithelial ovarian tumors. Results from a study in canine ovaries and ovarian tumors suggest that HBME-1 may be of similar value in dogs.[25]

Sex Cord Stomal Tumors

Sex cord stromal tumors, specifically GTCT, are likely second in occurrence to epithelial tumors. Less common histologies include Sertoli–Leydig tumors, thecomas, and luteomas. These tumors arise from the specialized estrogen- and progesterone-producing gonadal stroma of the ovary and therefore have the potential to secrete these steroid hormones if functional.[3,4,8,16] The metastatic rate of GTCT is low, occurring in approximately 20% of cases.[3,8,9,16] Metastatic sites include sublumbar lymph nodes, pancreas, and lungs, with peritoneal carcinomatosis noted in some

cases.[1,3,8,16] Although rare, thecomas and luteomas are for the most part considered benign.[8,16]

Although most sex cord stromal tumors are unilateral, bilateral tumors are possible, especially among Sertoli–Leydig tumors.[8] Concomitant cystic endometrial hyperplasia and cysts in the contralateral ovary appear common within this group.[8]

Solid, nest, cord, palisade, cystic, and spindle are the histologic patterns described for GTCT, and a mixture of these may exist within a single tumor.[8,19] GTCTs are generally vimentin,[19] S-100,[19] and INH-α[20] positive, although one study has reported INH-α–negative GTCT.[19] Variable expression of CK AE1/AE3,[20] CK 7,[20] and ET-A[22] has been described. Moderate-to-strong intracytoplasmic ET-1 immunoreactivity has been detected in 88% of canine GTCT, [22] whereas GTCT should be HBME-1 negative.[25]

Germ Cell Tumors

Germ cell tumors, including dysgerminomas, teratomas, and malignant teratomas (teratocarcinomas), arise from primordial germ cells of the ovary.[8,16,26] Concurrent cysts in the contralateral ovary and uterine abnormalities such as pyometra and cystic endometrial hyperplasia are common.[26]

Dysgerminomas, also known as *ovarian seminomas,* are most common in this group and arise from undifferentiated germ cells. Histologically, these tumors consist of a uniform population of cells resembling ovarian primordial germ cells.[3,8,16] Bilateral dysgerminomas have been reported; however, most are unilateral.[8,16,26] The reported metastatic rate is low (10%–30%), with sites of metastasis including lymph nodes, liver, kidney, omentum, pancreas, and adrenal glands.[3,8,9,26–28]

Teratomas are composed of germ cells that undergo differentiation into at least two germinal cell layers and any combination of tissues can be seen. These tissues are usually well differentiated, and tissues from virtually any organ (excluding ovary or testis) may be present. Malignant teratomas are composed of predominantly immature, undifferentiated tissues resembling those of the embryo.[26] Metastasis has been noted in up to 50%. Although distant visceral metastasis can occur, peritoneal metastasis with carcinomatosis is most common.[8,9,26]

Germ cell tumors, specifically dysgerminomas, are vimentin positive and PLAP, CK7, desmin, S-100, CK AE1/AE3, and INH-α negative.[19]

Mesenchymal Tumors

Mesenchymal ovarian tumors are rare. Reported tumor types include hemangiosarcoma,[2,16] hemangioma,[16] and leiomyoma.[2,16] Behavior of this group is difficult to predict because information in the literature is sparse.

Miscellaneous

In addition to the various primary ovarian tumors, other differential diagnoses should be considered. These include ovarian cysts, paraovarian cysts, cystic rete tubules, vascular hamartomas, and adenomatous hyperplasia of the rete ovarii. Although rare, metastasis to the ovary has been reported in cases of mammary (especially inflammatory carcinoma),[29] intestinal and pancreatic carcinoma, and lymphoma.[16]

Feline Ovarian Tumors

Reported feline ovarian tumor classifications include epithelial, germ cell, and sex cord stromal tumors. Although mesenchymal ovarian tumors have not been reported in cats, it seems plausible that they may occur. Ovarian involvement with lymphoma has been documented.[15]

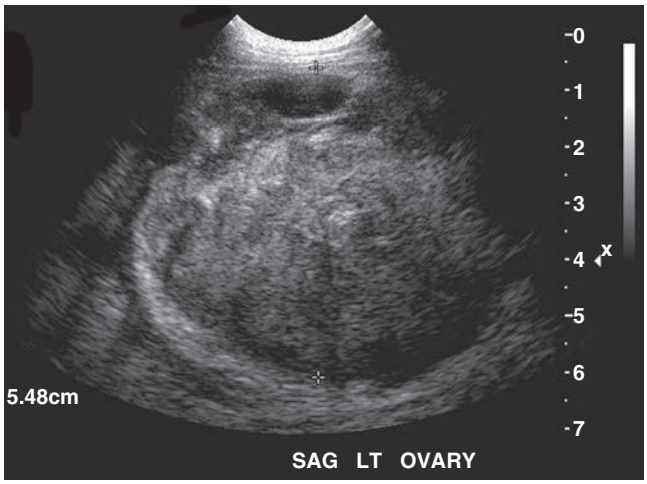
• **Fig. 27.1** Right lateral caudal abdominal radiograph of a dog with an ovarian tumor. (Courtesy Dr. T. Schwarz, University of Edinburgh.)

Sex cord stromal tumors are most common in cats, accounting for at least half of reported cases. They are often unilateral. Of these, GTCTs are most common and approximately 50% are malignant. Metastatic sites include the peritoneum, regional lymph nodes, omentum, diaphragm, kidney, spleen, liver, and lungs.[15] Luteomas, thecomas, and Sertoli–Leydig cell tumors are rare and typically benign.

Germ cell tumors are also rare in cats. Of these, dysgerminomas are most common.[15] They are generally considered benign, yet metastasis has been reported in 20% to 33% of cases.[15] Teratomas have been rarely documented.[15,30] A malignant estrogen-producing teratoma has been reported in a cat.[31]

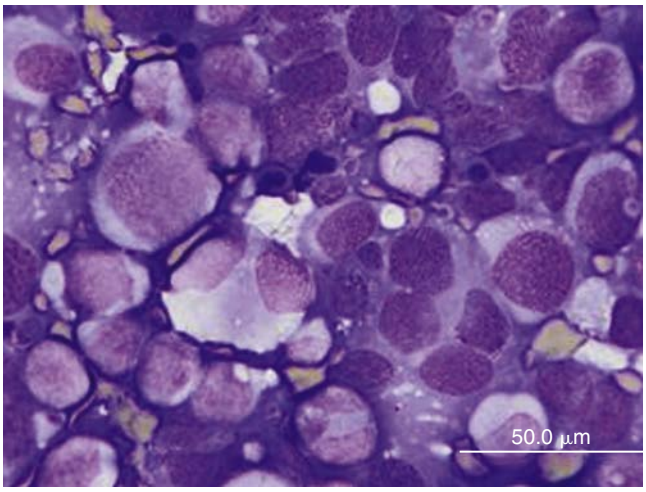
Epithelial tumors are perhaps the least common ovarian tumor in the cat. Cystadenomas and adenocarcinomas have been described. Metastasis to the lungs, liver, and abdominal peritoneum was seen in one case of ovarian adenocarcinoma.[15]

History and Clinical Signs



Canine Ovarian Tumors

History and clinical signs associated with canine ovarian tumors vary, depending on the tissue of origin. Although initially insidious, ovarian tumors grow to the point of being palpable and clinical signs are typically referable to a space-occupying abdominal mass (Fig. 27.1).[9,32–34] Functional sex cord stromal tumors may produce one or multiple hormones, or they may be nonfunctional.[8,16,35] Sex cord stromal tumors that produce steroid hormones, such as estrogen, may cause vulvar enlargement, sanguineous vulvar discharge, persistent estrus, alopecia, and aplastic pancytopenia; whereas excessive progesterone production may cause cystic endometrial hyperplasia and pyometra.[3,8,9,16,33] Hyperadrenocorticism was reported in a dog with an ovarian-steroid tumor resembling a luteoma, and the associated clinical signs resolved after OHE.[36] Germ cell tumors have been associated with evidence of hormonal dysfunction, although they are most often associated with clinical signs referable to a space-occupying abdominal mass.[26]



Feline Ovarian Tumors

Ovarian tumors in cats also have an insidious onset and eventually grow to the point of being detectable by abdominal palpation. Signs referable to a space-occupying abdominal mass such as weight loss, lethargy, vomiting, ascites, and abdominal distension are often noted. GTCTs are most common, and they are generally functional, producing estrogen, progesterone, or testosterone. Clinical signs of hyperestrogenism, including persistent estrus,

• **Fig. 27.3** Ovarian dysgerminoma population of highly pleomorphic round cells. These cells have a scant amount of lightly basophilic cytoplasm and round to irregularly shaped nuclei with a coarsely granular to smudged chromatin pattern with occasional indistinct nucleoli. Binucleated and multinucleated cells are seen and occasional micronuclei are observed. There is moderate-to-marked anisocytosis and anisokaryosis. (Courtesy Dr. M. Camus, University of Georgia.)

alopecia, and endometrial hyperplasia, have been reported.[15] Virilizing behavior secondary to a testosterone-producing thecoma of the ovarian stump was reported in a 6-year-old domestic shorthair cat.[37]

Diagnostic Techniques and Workup

Laboratory abnormalities attributable to ovarian tumors are generally not noted. However, hypercalcemia secondary to tumor production of parathyroid hormone–related peptide (PTH-rP) has been reported in a dog with ovarian adenocarcinoma.[34] Thoracic radiographs should be evaluated for evidence of metastatic disease. Abdominal imaging, specifically ultrasound, is useful in identifying ovarian masses and associated abdominal metastasis or uterine abnormalities (Fig. 27.2). Ultrasonographic patterns include solid, solid with cystic component, and cystic[38]. Malignant tumors are typically solid, whereas benign tumors are generally cystic with smooth borders.[38] Concurrent uterine abnormalities such as pyometra and cystic endometrial hyperplasia may be detectable via ultrasound in up to 50% of dogs.[38] Because the risk of tumor seeding is high, transabdominal needle biopsies of ovarian tumors are not recommended. If present, abdominal fluid may be safely collected, and cytologic evaluation of fluid often is suggestive of malignant effusions. In a series of 19 cases with a variety of ovarian tumors, cytologic diagnosis was consistent with histopathology in 94.7% of cases (Fig. 27.3).[2] Finally, if a functional tumor is suspected, evaluation of vaginal cytology for evidence of estrogen-induced cornification is also indicated.

Therapy

Complete OHE is the treatment of choice for most localized ovarian tumors. Standard oncologic surgical principles must be practiced to minimize tumor seeding of the abdominal cavity. A thorough exploration of the abdominal cavity with biopsy of any abnormalities is recommended for definitive diagnosis and to rule out metastatic lesions.[9]

Use of chemotherapy and/or radiation therapy in the treatment of ovarian tumors has not been widely investigated in veterinary medicine; therefore recommendations are difficult to make. Palliation of malignant effusions with intracavitary instillation of chemotherapeutics, such as the platinum agents, may be considered.[39,40] It is important to remember that the use of cisplatin is considered unsafe in cats.[41]

Prognosis

Prognosis for both dogs and cats with ovarian tumors is difficult to predict because of lack of evidence in the literature. Intuitively, it seems the prognosis is good with complete excision of benign or localized malignant tumors, but poor with detection of metastatic disease.

Comparative Aspects

As in dogs, ovarian cancer in women includes tumors of epithelial, germ cell, or sex cord stromal origin. Epithelial tumors are most common and generally occur in postmenopausal women (median age: 60 years), whereas germ cell tumors are often diagnosed in younger women. An increased incidence of epithelial tumors has been noted in Caucasian women compared with African American women, and ovarian cancer risk (specifically epithelial tumors) appears lower in women who have had children, who have breastfed, or who have taken oral contraceptives. Although uncommon, germline mutations in the *BRCA1* or *BRCA2* genes have been identified in women with familial ovarian cancer. Such mutations also convey an increased risk of other cancers, specifically breast cancer.[42]

Epithelial ovarian tumors in women also resemble the canine counterpart in terms of biologic behavior. They typically metastasize locoregionally within the abdomen; however, distant metastasis may also occur. Patients are often asymptomatic until the disease spreads to the upper abdomen, and presenting symptoms, including abdominal discomfort, bloating, and ascites, are nonspecific. Approximately 70% of women present with advanced disease; as a result, epithelial ovarian cancer is the leading cause of gynecologic cancer mortality.[42]

Cytoreductive surgery and chemotherapy are preferred treatments in epithelial ovarian cancer patients. Even in cases with

advanced disease, cytoreductive surgery appears beneficial. Removal of large, necrotic tumors with poor blood supply theoretically improves chemotherapy delivery. Platinum agents (primarily cisplatin) and taxanes are commonly used chemotherapeutic agents. Radiation therapy has fallen out of use in high-risk early stage patients because it has proven less effective and more toxic than platinum-containing chemotherapy regimens.[42]

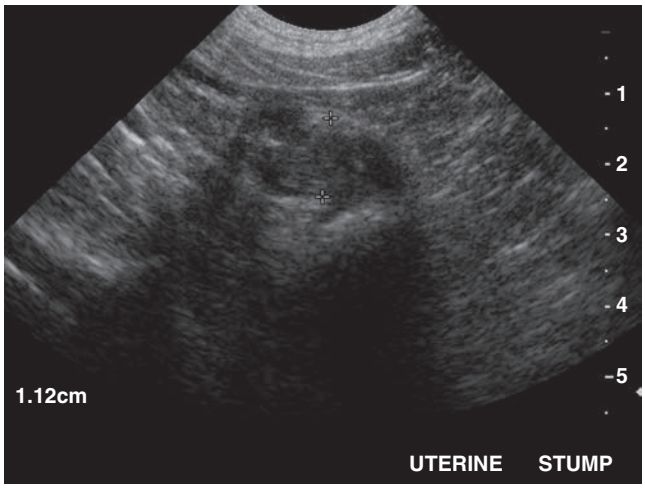
Stage is the most important predictor of prognosis. The 5-year survival rate in patients with stage III, optimally debulked, gross residual disease is 20% to 30%.[42]

Uterine Tumors

Incidence

Uterine tumors are rare, accounting for 0.3% to 0.4%[6] and 0.29%[43] of all canine and feline tumors, respectively. Middle-aged to older animals are most commonly affected, although uterine carcinoma has been reported in dogs and cats <1 year of age.[44,45] No specific breed predilections have been reported.

Pathology and Natural Behavior



Benign mesenchymal tumors (leiomyomas) are most common in the canine uterus.[9,46–48] Other reported but rare uterine tumors include leiomyosarcoma, fibroma, fibrosarcoma, hemangiosarcoma, angiolipoleiomyoma, lymphoma, and lipoma.[47,49] Epithelial tumors are rarely reported but may occur in dogs.[48] Most epithelial tumors are malignant,[50] but benign histologies have been reported.[51]

Leiomyomas generally are slow growing, noninvasive, and do not metastasize.[9] Grossly, they are difficult to distinguish from their malignant counterparts.[47] A syndrome characterized by multiple uterine leiomyomas, bilateral renal cystadenomas, and nodular dermatofibrosis has been characterized in German shepherd dogs.[52,53] This syndrome has been noted to have a hereditary component associated with a mutation in the canine Birt–Hogg–Dube (*BHD*) gene.[54]

A majority of studies suggest that adenocarcinoma is the most common tumor in the feline uterus.[15,43,55,56] Less common histologies include Müllerian tumor (adenosarcoma), leiomyoma, leiomyosarcoma, fibrosarcoma, lymphoma, fibroma, hemangioma, lipoma, and squamous cell carcinoma.[15,43,57–63] Metastasis to the cerebrum, eyes, ovaries, adrenal glands, lungs, liver, kidneys, bladder, colon, diaphragm, and regional lymph nodes has been reported.[15,43,55,64,65] One study evaluating immunohistochemical reactivity of six feline endometrial adenocarcinomas suggests these tumors routinely express CK AE1/AE3, COX-2, E-cadherin, and β-catenin. Five of six tumors demonstrated expression of progesterone receptors, but infrequent vimentin and estrogen receptor staining was seen.[56] Another study demonstrated a significant loss of expression of ER-α and a significant increase in Ki-67 immunoreactivity compared with normal feline endometrium.[66]

History and Clinical Signs

Although it seems logical that uterine tumors occur in intact animals, it is important to note that these may arise from uterine stumps after incomplete OHE (Fig. 27.4).[49] Clinical signs associated with uterine tumors are not commonly reported, and most are incidental findings.[9] However, in some cases, they grow large enough to produce abdominal distension and signs referable to a space-occupying abdominal mass. Abnormal estrus cycles, vaginal discharge, stranguria, constipation, pyometra, polyuria, polydipsia, vomiting, abdominal distension, and weight loss may also occur.[9,15,33,43,49,50,55,62]

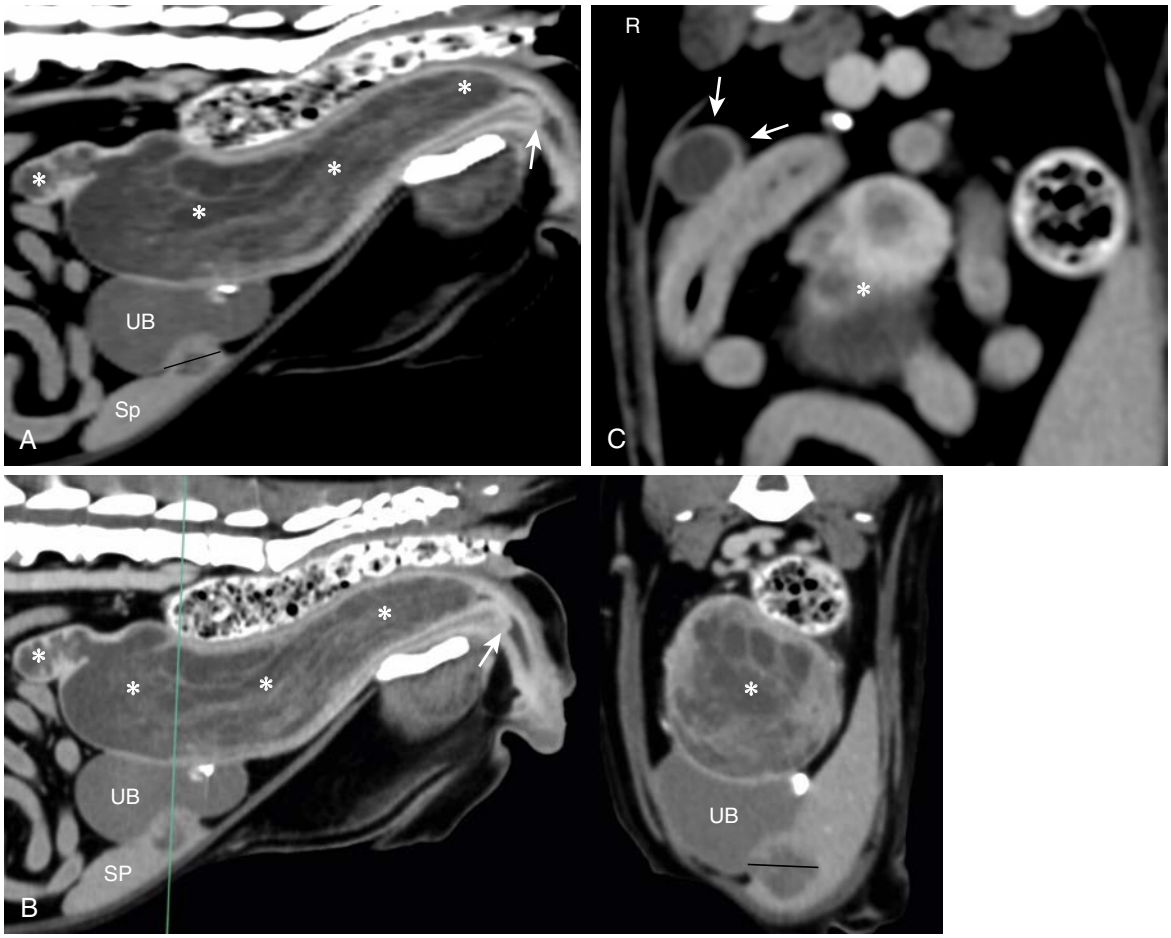
• **Fig. 27.4** Irregular, hypoechoic mass at the uterine stump in a dog after ovariohysterectomy. (Courtesy Dr. D. Jimenez, University of Georgia.)

Diagnostic Therapeutics and Workup

Although abdominal imaging helps confirm the presence of an abdominal or uterine mass, histologic evaluation via complete surgical excision is required for definitive diagnosis.[67] As a result, complete staging, including thoracic radiographs and abdominal ultrasound, should be considered before surgery to rule out the possibility of locoregional and distant metastasis. Advanced imaging, such as CT scan, may also be of diagnostic value (Fig. 27.5A).

Therapy

Complete OHE is the treatment of choice for uterine tumors. At the time of surgery, thorough examination of the abdominal cavity must be performed with biopsy of any suspected metastatic foci. Little is known about the role of chemotherapy.



Prognosis

As most uterine tumors in dogs are benign, surgery is often curative. The prognosis is also potentially good for completely excised, localized malignant tumors. However, the presence of metastatic disease warrants a grave prognosis. Feline uterine adenocarcinomas have well-documented metastatic potential[43,55]; therefore the prognosis must be considered guarded. A favorable outcome, with a survival of 19 months, has been reported in a cat with a focal uterine T-cell lymphoma treated with hysterectomy alone.[62]

Vaginal and Vulvar Tumors

Incidence

Vaginal and vulvar tumors account for 2.4% to 3%[46,68] of all canine tumors. Excluding skin tumors arising on the labia of the vulva, most are benign smooth muscle tumors (leiomyomas). These generally occur in middle-aged to older intact female dogs.

• **Fig. 27.5** (A) Uterine body leiomyosarcoma. Computed tomographic sagittal reconstruction of the caudal abdomen, postcontrast in delayed phase and displayed in soft tissue window. A uterine body mass (*) extends 1 cm proximal to the external urethral orifice (*white arrow*). The mass is irregularly, mildly contrast enhancing. (B) Uterine body leiomyosarcoma. Computed tomographic sagittal reconstruction (*left*) and transverse plane (*right*) of the caudal abdomen, post-contrast in delayed phase and displayed in soft tissue window. A uterine body mass (*) extends 1 cm proximal to the external urethral orifice (*white arrow*). The mass is irregularly, mildly enhancing, a behavior consistent with the cystic spaces and dense cellular arrangement observed on pathologic examination. The nodule on the splenic tail (calipers) was confirmed to be lymphoid hyperplasia. SP: spleen, UB: urinary bladder. (C) Computed tomographic transverse reconstruction of the caudal abdomen at the level of L4/5, postcontrast in delayed phase, soft tissue window. In the region of the right ovary, a nodule (*arrows*) has a thin enhancing rim around a fluid dense center. These findings correlate with histopathologic findings of a fluid to mucus-filled cyst partially lined by cells and ovarian tissue, diagnosed as an interstitial cell tumor of an ovarian remnant. Cranial aspect of the uterine body mass (*). (B Courtesy Dr. K. Gendron, University of Georgia.)

Lipomas often occur in younger dogs ranging in age from 1 to 8 years (mean age: 6.3 years).[46,68]

Malignant vaginal and vulvar tumors have been reported; however, these appear to be more common in spayed female dogs. Primary clitoral carcinomas have been reported in a small number of dogs, all of whom were spayed.[69]

Incidence rates are not available for the cat. Leiomyomas are reported most commonly, occurring in older intact queens.[15,70]

Pathology and Natural Behavior

Benign smooth muscle tumors, including leiomyoma, fibroleiomyoma, fibroma, and polyps, comprise approximately 83% of reported vaginal tumors.[9,68] The most common malignant tumor is leiomyosarcoma, and associated distant metastasis has been reported.[46,68] Other less common tumor types include lipoma, fibrous histiocytoma, benign melanoma, myxoma, myxofibroma, adenocarcinoma, hemangiosarcoma, osteosarcoma, epidermoid carcinoma, and, in endemic areas, transmissible venereal tumor (TVT).[68,71] Carcinomas arising from the bladder or urethra may manifest as vaginal masses near the urethral papilla, and any skin tumor (e.g., mast cell tumors) may develop on the labia of the vulva.[68]

Macroscopically, tumors of the vestibule or vagina are described as extraluminal or intraluminal.[9] Extraluminal tumors appear as slowly growing, well-encapsulated, perineal masses. Intraluminal tumors are attached to the vestibular or vaginal wall by a pedicle,

and multiple tumors may occur.[9] In one study, all pedunculated or polypoid tumors were benign; however, it is important to note that definitive diagnosis requires histopathology.[68]

It has been suggested that vaginal leiomyomas may be hormone dependent, as most dogs with these tumors are intact at diagnosis.[9,46,68] Furthermore, one study reported a recurrence rate of 0% in dogs undergoing OHE at the time of tumor removal, whereas 15% of dogs that were left intact experienced local recurrence.[9,68]

Information from the few reported cases of canine clitoral carcinoma (CCC) suggests that the cytologic, histologic, and clinical features appear to mimic those of apocrine gland anal sac adenocarcinoma (AGASA). Cytologically, cells from CCC are arranged in cohesive clusters, with what appear to be "bare" nuclei floating in a background of cytoplasm. Histologically, CCC is described as a partially encapsulated epithelial neoplasm displaying three distinct patterns (tubular, solid, and rosette type). CCC cells consistently express CK AE1/AE3, but expression of neuroendocrine markers is more variable.[69] In a study by Verin et al, neuron-specific enolase (NSE) was expressed in 6 of 6 CCC, whereas chromogranin A (CGA) and synaptophysin (SYN) were mildly expressed in two of six tumors. S-100 expression was not detected in any of the tumors.[69] Like AGASA, hypercalcemia of malignancy has been reported, and locoregional nodal metastasis is a common finding at the time of diagnosis.[69]

History and Clinical Signs

Presence of a mass protruding from the vulva is the most common clinical sign, although vaginal bleeding or discharge is often noted. Other clinical signs may include dysuria, hematuria, tenesmus, constipation, excessive vulvar licking, and dystocia.[9,68]

Lipomas are generally slow growing but eventually impinge on adjacent structures. These tumors can arise from the perivascular and perivaginal fat and lie within the pelvic canal and may attach to the tuber ischium. All lipomas are reported to be well circumscribed and relatively avascular.[68]

Concurrent cystic ovaries and mammary adenocarcinoma have also been reported in a cat with vaginal leiomyoma.[68]

Diagnostic Techniques and Workup

A presumptive diagnosis may be made based on patient signalment and tumor location, although definitive diagnosis requires histopathology. Vaginal and rectal palpation, vaginoscopic examination, and vaginal cytology are often the first steps performed in evaluation of vaginal and vulvar tumors. Retrograde vaginography or urethrocystography may also be used to help delineate the extent of the mass. For some tumor types (e.g., TVT), aspiration cytology of the tumor may be diagnostic; alternatively, incisional biopsy may be performed. Although most vaginal and vulvar tumors are benign, complete staging, including thoracic radiographs and thorough abdominal ultrasound, should be considered in cases in which malignancy is suspected (e.g., rapidly growing, nonpedunculated tumors) or confirmed.

Therapy

Surgical excision combined with OHE is the treatment of choice for most vaginal and vulvar tumors. For benign tumors, this is likely curative, and wide resections are not necessary, especially if OHE is performed. Intraluminal tumors can be removed easily by transecting the pedicle. A dorsal episiotomy may be performed if needed for adequate visualization and exposure.[9,68]

Surgical removal of extraluminal tumors also can be accomplished through a dorsal episiotomy. Because these tumors are often well encapsulated and poorly vascularized, blunt dissection generally removes them entirely. On rare occasions, a perineal approach or pelvic split may be required. Urethral catheterization prevents accidental damage to the urethra during tumor excision. Malignant, infiltrative vaginal neoplasms can be addressed with complete vulvovaginectomy and perineal urethrostomy in carefully selected cases. OHE is indicated in cases with multifocal disease because stable disease or regression may be obtained with hormone ablation.

Prognosis

For benign tumors, surgical excision and OHE are nearly always curative. The prognosis for malignant tumors must be considered guarded because of high rates of local recurrence and metastasis.[68] Surgery with OHE was curative in the one feline leiomyoma reported.

Tumors of the Mammary Gland

KARIN U. SORENMO, DEANNA R. WORLEY, AND VALENTINA ZAPPULLI

Mammary Gland Tumors in Dogs

Epidemiology and Risk Factors

Epidemiology

Mammary gland (MG) tumors (MGTs) are common in dogs and represent the most common neoplasms in sexually intact female dogs.[1–8] The incidence rates reported vary depending on the origin of the studies and characteristics of the source population. The current incidence of MGTs in the United States is lower than in many other countries owing to the common practice of performing ovariohysterectomy (OHE) at a young age. Data from several European national or regional canine cancer registries, including from Norway,[2] Denmark,[5] and Italy,[6,7] as well as Mexican[8] registries, provide information regarding MGT incidence in general, in addition to details regarding the relative frequency of various tumors according to site, age, and breed. These registries consist of a population of predominantly sexually intact dogs and thus provide insight into the natural or true MGT risk in unaltered dogs. Results from these registries show that MGTs are the most common tumors in female dogs and represent 50% to 70% of all tumors in this subset of the population.[2,6] Interestingly, results from the two most recent studies suggest that the ratio of malignant versus benign MGTs has shifted toward an increase in malignant tumors in dogs, similar to the epidemiologic trends in women.[7,8]

In general, open population-based and insurance-based studies may underestimate the true incidence of disease, especially if the diagnosis and subsequent registration require a surgical biopsy. Furthermore, the insured dog population may be skewed toward younger animals because of age restriction and may be void after the tenth year of age, which coincides with the peak incidence age of MGT diagnosis.[3,4] Early data from the surveys of Alameda and Contra Costa counties reported an estimated annual incidence rate of 257.7 malignant MGTs per 100,000 in intact female dogs.[1] A later large Swedish study based on 80,000 insured female dogs, most of which were sexually intact, reported a rate of 111 MGTs (including both benign and malignant) per 10,000 dog-years at risk.[3] This study also reported an increasing risk for tumors with advancing age; 6% of all 8-year-old dogs and 13% of all 10-year-old dogs were diagnosed with at least one MGT. Another large insurance-based study from the United Kingdom reported an annual incidence rate of 205 MGTs per 100,000 dogs. This study included all MGTs regardless of histology.[4]

In addition to these open and more heterogeneous population-based studies, closed population studies provide another source of incidence and natural progression data. Longitudinal studies may provide a more accurate estimate of the total lifetime risk of MGTs because dogs are monitored closely and all tumors are noted, biopsied, and reported. In a large beagle colony morbidity and mortality study, 71% of female dogs developed at least one MGT in their lifetime[9]; however, this may not accurately represent the incidence in other breeds. Many of the various tumor registries have reported significant breed variations in MGT incidence, suggesting that, in addition to age and hormonal factors, hereditary breed-associated genetic susceptibility may also contribute to MGT risk.

Risk Factors

As noted, the incidence of MGTs varies depending on where the studies are performed and the specific characteristics of the population in terms of OHE status, age, and breed distribution. Thus in addition to providing data regarding incidence, epidemiologic studies also help identify risk factors for MGTs. Three main factors have been identified that play important roles in MGT risk: age, hormonal exposure, and breed. To a lesser degree, diet and body weight or obesity may also contribute to risk.

Age

MGTs affect middle-aged and older dogs.[1,10–13] MGTs, especially malignant tumors, are extremely rare in dogs younger than 5 years old.[1,10,14] The tumor risk increases with age and becomes clinically significant when dogs turn 7 or 8 years old, and continues to increase until the age of 11 to 13 years.[10,14] Dogs with malignant tumors are significantly older than dogs with benign tumors: the mean age of dogs with malignant tumors is 9 to 11 years versus 7 to 9 years with benign tumors.[15,16] The peak incidence age also depends on the lifespan of various breeds. In general, larger breeds have a naturally shorter lifespan and therefore tend to be younger than smaller breeds when they are diagnosed. These differences may be further exaggerated in high-risk breeds such as English springer spaniels.[3,17]

Hormonal Exposure

Many MGTs in dogs are preventable. Dogs spayed before their first estrus have only a 0.5% risk of developing MGTs in their lifetime.[18] The protective effect of OHE decreases over the first few estrus cycles and most of the earlier studies have not found

VetBooks.ir

significant benefit after 4 years of age. According to Schneider's original study, the risk increases and the benefit diminishes with each estrus cycle, as illustrated by an increasing risk of 8% and 26% depending on whether the OHE was performed before the second or third heat cycle.[18] No significant risk reduction was seen in dogs spayed after 2.5 years of age, although other researchers have found some modest benefit in dogs spayed later. These studies were all retrospective case-control studies.[14,19,20] A recent prospective randomized study, however, documented significant decreased risk for new tumor development by performing OHE concurrent with tumor removal in dogs with benign MGTs.[21] Notably, these dogs were older, with a mean age of 9 years, confirming that hormonal deprivation via OHE later in life significantly decreases the risk for new tumor development. Nevertheless, the greatest benefit on MGT prevention is seen if the dog is not allowed to go through any heat cycles, suggesting that some of the initial effects of ovarian hormones on the MGs in terms of cancer risk occur early in life, likely during puberty when the MG develops and matures. Other factors resulting in physiologic variation in hormonal influence on the mammary tissues, such as pseudopregnancy, pregnancy, or parity, which typically occur after a few estrus cycles, have not been found to significantly influence the tumor risk, but none of these studies were controlled or randomized.[14,18,22] Exposure to exogenous or pharmacologic doses of hormones (both progestins and estrogens) has been found to increase the risk for developing MGTs in dogs. Dogs treated with progestins are more likely to develop tumors and at a younger age.[20] According to the Norwegian Canine Cancer Registry, dogs treated with progestins to prevent estrus had a 2.3-fold higher risk for MGTs compared with dogs not receiving such treatment.[23] Similarly, a Dutch study found that privately owned dogs with MGTs were significantly more likely to have received progestins.[20] Numerous studies have investigated the effect of dose, duration, and type of hormones (progestins, estrogens, or a combination of both) on MGT development in laboratory dogs. Although some discordance exists, most conclude that low-dose progestins alone increase the risk for predominantly benign tumors, whereas a combination of estrogens and progestins tends to induce malignant tumors.[24–28]

Breeds and Genetic Susceptibility

In general, MGTs tend to be more common in the smaller breeds. Purebred dogs are more commonly affected[1]; poodles, Chihuahuas, dachshunds, Yorkshire terriers, Maltese, and cocker spaniels are frequently listed as high-risk breeds in the small-breed category.[1,2,16,29] However, some of the larger breeds are also at increased risk, including the English springer spaniel, English setters, Brittany spaniels, German shepherds, pointers, Doberman pinschers, and boxers.[1–3,16,29] Some noteworthy discrepancies exist, specifically between the US and European reports. Boxers are noted to have a decreased risk for MGTs according to data from the University of Pennsylvania, whereas Scandinavian studies reflect an increased risk in boxers.[2,3,16] A closed population beagle study showed that two different lines or families of beagles have very different MGT risks.[30] These results collectively support a genetic influence on MGT development. Familial or inherited germline mutations in *BRCA1* and *BRCA2* account for 5% to 10% of all human breast cancers (BCs) and are associated with an 85% cumulative lifetime risk of BC in affected individuals.[31–34] Studies of *BRCA* mutations in canine MGTs have so far been limited to tumor gene expression studies and the results have varied; some found underexpression of *BRCA1* in malignant tumors and others have documented overexpression of *BRCA2* in metastatic tumors.[35,36] Germline polymorphisms in both *BRCA1* and *BRCA2* were associated with significantly increased risk in English springer spaniels in a large Swedish study.[3,17]

Other Risk Factors

Body weight, specifically during puberty (9–12 months), is found to have a significant effect on later MGT risk; being underweight during this time period provides significant protection against later tumor development.[19] This study did not find an increased risk for tumors in dogs fed a high-fat diet or dogs that were obese around the time of tumor detection; however, a subsequent case-control study did document an association between diet and mammary cancer in which obesity early in life and a diet high in red meat were found to increase risk.[37] Obesity has also been recognized as a risk factor for developing postmenopausal BC in women.[38,39] One of the proposed mechanisms by which diet/obesity may be linked to breast carcinogenesis is via its effect on serum estrogen levels. Obesity is associated with decreased concentration of sex hormone–binding globulin and thus results in elevated serum free estrogen levels.[40–44] In addition, adipose tissues may be a source of increased estrogen production via aromatase-mediated conversion of androgens. Interestingly, the mammary cancer–sparing influence of being underweight is most significant during the first year of life, when the effects of the endogenous hormones are the greatest.

Tumor Biology: Development, Hormones, Growth Factors, and Clinical Implications

Based on the previous discussion of risk factors, it is clear that exposure to ovarian hormones is important in the development of MGTs in dogs. Both estrogens and progesterone are necessary for normal MG development and maturation. The MGs undergo distinct clinical and histopathologic changes as hormone levels fluctuate according to the phases of the estrus cycle.[45,46] Estrogens and progesterone are mitogens of breast epithelium and induce proliferation of intralobular ductal epithelium and development of ducts and lobules, resulting in expansion of the MGs. Historically, the tumorigenic effects of estrogen in human BC were thought to be mediated via their receptor binding and enhanced production of growth factors resulting in increased cellular proliferation[47]; however, more recent research shows that estrogen and its metabolites also have direct genotoxic effects by increasing mutations and induction of aneuploidy independent of the estrogen receptors.[48–50] The tumorigenic effects of progesterone are in part thought to be mediated via a progesterone-induced increased MG production of growth hormone (GH) and GH receptors.[51–53] GH has direct stimulatory effects on mammary tissues and indirect effects via increasing insulin-like growth factor-1 (IGF-1).[54] The GH/IGF-1 axis has been implicated in human breast carcinogenesis. IGF-1 is both a proproliferative and a survival factor for breast epithelial cells and regulates the expression of numerous genes involved in BC development.[55–60] The complex dysregulation of growth factors and hormones that precedes, initiates, and potentially drives canine mammary tumorigenesis is far from understood; evidence exists indicating that both growth factors and steroid hormones are intrinsically implicated and contribute in an autocrine/paracrine manner. Malignant tumors have significantly higher tissue concentrations of GH, IGF-1, progesterone, and 17β-estradiol than benign tumors; moreover, levels

VetBooks.ir

correspond with important clinicopathologic parameters such as growth rate, size, and histotype.[61,62] A complete review of the biologic and molecular aspects of MGT carcinogenesis is beyond the scope of this chapter, but recent reviews provide more complete information.[63,64]

The entire mammary chain is exposed to growth factors and sex hormones, resulting in a field carcinogenesis effect. Consequently, most dogs develop tumors in multiple glands.[9,14,15,65–67] Histologic progression with increasing tumor size is often noted in dogs with multiple tumors and areas of transitions such as carcinoma in situ (CIS) can be seen in benign tumors.[15,65] This provides direct evidence that benign and malignant MGTs are not separate entities; instead, they are part of a biologic and histopathologic continuum in which the malignant invasive carcinomas are the end stage of the process. Earlier publications support this hypothesis and document associations between tumors of benign and malignant histology. For instance, dogs with carcinomas often had concurrent benign tumors of the same cell type and dogs with benign MGTs were at increased risk for developing subsequent malignant tumors.[66] Furthermore, risk was even higher in dogs diagnosed with CIS or carcinomas.[15,65,67] Evidence of histologic progression has also been reported in which a high incidence of CIS and intraepithelial lesions with atypia was noted adjacent to invasive carcinomas.[65,68] There are likely regional variations in terms of exposure resulting in a range of histopathologic and clinical changes. Some tumors may never change and remain small and benign whereas others progress and become malignant and many develop new tumors in other glands. This suggests that canine MGTs provide unique comparative opportunities to study mammary carcinogenesis and progression with direct applications to human BC research.

Tumor Hormone Receptors/Molecular-Based Classification: Prognostic, Clinical, and Therapeutic Implications

Hormonal exposure plays an important role in MGT development and many tumors, specifically tumors of epithelial origin, express hormone receptors (HRs), suggesting continued hormonal influence and dependence. Benign tumors are more likely than malignant tumors to retain HRs, both estrogen receptors (ERs) and progesterone receptors (PRs).[69–73] The HR status is also influenced by age and hormonal status: dogs that are intact, younger, and in estrus are more likely to have receptor-positive tumors than dogs that are spayed, older, and anestrous.[73–75] Furthermore, the HR expression is inversely correlated with tumor size and histopathologic differentiation; larger tumors and undifferentiated or anaplastic tumors are less likely to express receptors than tumors with more differentiated histology, reflecting a biologic drift toward hormone independence and corresponding with aggressive histology and clinical behavior.[74,76,77] HR expression analysis is most commonly performed by immunohistochemistry (IHC). Results from various studies are quite disparate, especially in terms of ER-alpha positivity in malignant tumors, and range from 10% to 92%.[69–74,76–79] These variations may in part be due to differences between study populations (tumor size, OHE status, tumor types) and the fact that IHC methods vary and, up until recently, have not been validated or tested for their ability to predict response to hormonal therapy.[79] A prospective randomized trial on the effect of OHE in dogs with mammary carcinoma determined the threshold positive immunostaining of both ERs and PRs to be an Allred score of greater than 3.79 Despite these discrepancies, several studies have documented that tumor expression of ER and PR is associated with a more favorable outcome.[74,76,77] Endocrine therapy is recommended to all women with ER-positive tumors, regardless of intensity of staining, and results in significant improvement in survival when used in the adjuvant setting.[80–85] In addition to the presence of HRs, the overexpression of human epidermal growth factor receptor-2 (HER-2/erb-2), a member of the epidermal growth factor receptor family involved in signal transduction pathways that regulate cell growth and differentiation, may also provide clinical and prognostic insight and therapeutic opportunities in MGTs. Overexpression or amplification of HER-2 is found in 20% to 25% of all human BC patients and is associated with aggressive behavior, resistance to hormonal therapy, and a poor prognosis.[86–88] HER-2 overexpression has also been documented in canine MGTs using the same HercepTest scoring systems used in human BC; positive staining has ranged from 17% to 48% in malignant tumors.[89–94] HER-2 staining was associated with negative histologic features and short survival times (STs) according to one of these studies[89] but, contrary to the human studies, HER-2 expression was associated with improved survival in two other independent studies.[90,91] Discrepancies can be related to IHC protocols and scoring systems, which are still controversial in human BC. Recently preanalytical, analytical, and postanalytical guidelines have been suggested to test HER-2 expression in canine MGTs.[95] They suggest 6- to 48-hour formalin fixation, evaluation of the invasive portions of the tumor, and threshold positive immunostaining to be greater than 30% of cells with complete membrane staining.[95]

Information about HR and HER-2, added to data on the expression of luminal versus basal cell differentiation markers and Ki67, allows for the molecular classification of human BC. More precisely, IHC-based surrogates of gene expression–based molecular subtypes are routinely applied. In human BC, the IHC subtypes include *luminal A* (high HR, HER-2–, low Ki67, luminal markers +, basal markers +/–), *luminal B* (low HR, HER-2+/–, any/high Ki67, luminal markers +, basal markers +/–), *HER-2-overexpressing* (HR–, HER-2+, any Ki67, luminal markers +/–, basal markers +/–), and *triple-negative* (HR–, HER-2–, any Ki67, luminal markers +/–, basal markers +/–). The latter includes the molecular *basal-like* tumors which are triple-negative for receptors (ER, PR, HER-2) and express basal markers (CK5, CK6, CK14, CK17, SMA, calponin, vimentin, and p63) and not luminal markers; the *normal-like* subtype, which is negative to all markers and shows a adipose tissue signature; and the *claudin-low* subtype, which is also triple-negative (ER, PR, HER-2) and, regardless of basal markers, expresses low claudin and high vimentin.[96–100]

In women, these subtypes are associated with different clinical outcomes, ranging from the best prognosis for *luminal A* tumors to the worst prognosis for two of the *triple-negative* subtypes (*basal-like* and *claudin-low*).[100] In women with BC, treatment is determined using these molecular signatures, histopathologic subtype, histologic grading, and clinical staging.[99]

Recently a few studies have attempted a molecular classification of canine MGTs by applying the same human BC IHC panels.[91,92,94] In one study,[91] this classification was prognostic with the *basal-like* phenotype significantly associated with shorter disease-free interval (DFI) and overall survival time (OST); however, the results differ between studies and highlight the need for continued investigations and standardizing the IHC protocols. This represents the first and crucial step toward using results

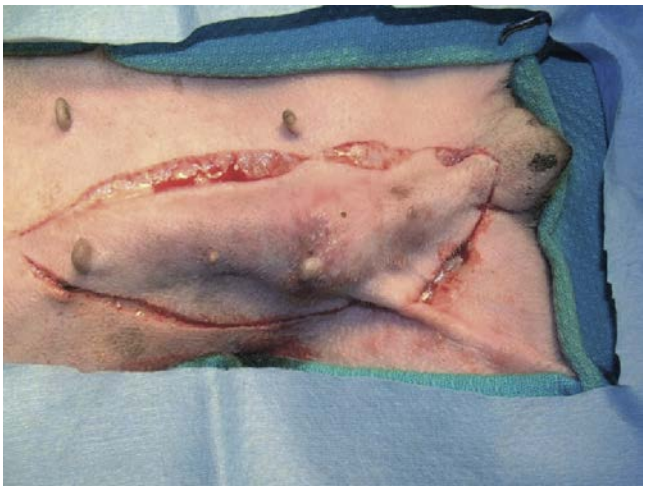
VetBooks.ir

from molecular classification to inform precise and patient-specific treatment recommendations in canine MGTs, similar to the approach in human BC therapy.

History and Clinical Presentation

MGTs are usually easy to detect through routine physical examinations; however, high-risk dogs, specifically older intact female dogs, should undergo a thorough examination of the MGs. MGTs typically affect the two caudal glands where the MGs or tissues are naturally larger; thus careful palpation may be necessary to detect small tumors.[9,14,66,67] The MGs should be palpated again under general anesthesia to ensure that all tumors are found and included in the surgical planning, and both chains should be carefully evaluated. A recent study documented that 70% of intact females had more than one MGT at diagnosis.[15] The size of the tumor(s), stage of disease, and presence of systemic signs of illness vary widely. Inflammatory mammary carcinomas represent a rare but clinically important subset of MGTs in dogs. Affected dogs may easily be misdiagnosed as having mastitis or severe dermatitis because, rather than presenting with discrete well-circumscribed tumors, the entire mammary chain may appear edematous, swollen, warm, and painful (Fig. 28.1).[101,102] In addition to the extensive locoregional involvement, most dogs with inflammatory carcinomas have distant metastatic disease and signs of systemic illness.[101,102] These dogs are therefore poor surgical candidates. The majority of dogs with MGTs are systemically healthy and the tumors are confined to the MGs when they are diagnosed.

Clinical Assessment, Diagnosis, Workup, and Staging



Because of the risk of metastasis associated with MGTs, staging before initiating therapy is strongly recommended, especially if benign disease cannot be histologically confirmed. Minimal diagnostic workup and staging can include complete blood count (CBC), serum biochemistry, three-view thoracic radiographs, and fine-needle aspiration (FNA) of regional lymph nodes (LNs) or more accurately, sentinel LN mapping and biopsy (see Chapter 9).[103,104] In women, the use of sentinel LN mapping has dramatically altered the surgical treatment of BC. As canine mammary carcinoma has been demonstrated as a relevant model for human disease,[105,106] incorporation of human LN staging techniques should be reconsidered for the dog.[107] Sentinel LN mapping is a means of detecting which LNs are receiving draining tumor lymph and thus most at risk for metastasis. Some techniques described for sentinel LN mapping in the dog include lymphoscintigraphy using technetium, contrast-enhanced ultrasonography, autogenous hemosiderin, computed tomographic indirect lymphography, and intraoperative dyes (Fig. 28.2).[103,104,107–111] Clinically normal LNs can be difficult to identify in dogs with MGTs, as the axillary LNs are often not palpable and the superficial inguinal LNs reside deep to the fifth MG in the inguinal fat pad. Furthermore, many dogs have more than one tumor; thus multiple LNs may represent draining LNs. Lymphatic drainage of normal MGs is in addition very complex with documented drainage occurring to multiple ipsilateral LNs and even to contralateral LNs.[104,112,113] The amount of variation in lymphatic drainage increases in the neoplastic MG.[112] Tumor-induced lymphangiogenesis, well documented in human BC, may be responsible for the unpredictable and erratic location of susceptible or "at-risk" LNs in dogs having malignant MGTs.[114] Thus exclusive anatomic sampling of nearby LNs may not be sufficient for accurate LN staging and may miss the presence of locoregional disease.[107]

The first description of sentinel LN mapping in any animal was done in cats almost 30 years ago.[115] Benefits in human medicine include greater ease in identifying the at-risk LNs intraoperatively with minimal surgical incisions and with efficiency, especially for the rarely assessed axillary nodes. The prognostic value of sentinel LN mapping is currently unknown for the dog,[116] although a study of computed tomographic indirect lymphography found imaging characteristics of sentinel LNs positive for histologic mammary tumor metastasis having decreased or heterogeneous LN contrast enhancement compared with the homogeneous contrast enhancement pattern of sentinel LNs negative for histologic metastasis.[103]

Abdominal ultrasound may be indicated in dogs with suspected regional LN involvement or changes on preoperative blood work suggesting tumor-related or non–tumor-related serum biochemistry changes. Even though osseous metaplasia occurs occasionally with mammary adenocarcinoma and the MGs are a common site for extraskeletal osteosarcoma (OSA), there has been no prognostic value found for serum alkaline phosphatase activity.[117,118] There may be value in performing MGT cytology to help rule out nonmammary dermal

TABLE 28.1 Staging of Canine Mammary Tumors[15,125]

Stage	Tumor Size	Lymph Node Status	Metastasis
Stage I	T1 <3 cm	N_0	M_0
Stage II	T2 3–5 cm	N_0	M_0
Stage III	T3 >5 cm	N_0	M_0
Stage IV	Any	N_1 (positive)	M_0
Stage V	Any	Any	M_1 (metastasis)

and subcutaneous tumors (e.g., mast cell tumors, lipomas). In addition, correlations between cytopathology and ex vivo histopathology have been reported to be between 68% and 93%,[119,120] and the reported cytologic sensitivity and specificity for a malignant MGT diagnosis were 88% and 96%, respectively.[121] Computed tomography (CT) imaging of the thoracic cavity provides more sensitive detection of pulmonary nodules than does thoracic radiography, but this may not be applicable for every patient because of increased expense and limited availability.[121,122] Distant metastatic sites can include LNs, liver, lungs, and bone.[123]

Staging System

MGTs are staged according to the T (tumor), N (lymph node), and M (metastasis) system. A modified version of the original staging system published by Owen[124] is currently used by most oncologists: stage advances from I to II to III as the size of the primary tumor increases from smaller than 3 cm, to between 3 and 5 cm, to larger than 5 cm.[125] These size categories capture important changes in prognosis and outcome. LN metastasis represents stage IV disease, regardless of tumor size, and distant metastasis constitutes stage V disease. This staging system should be used for dogs with epithelial tumors (noninflammatory) but not sarcomas (Table 28.1).

Histopathologic Classification Systems

The normal MG is a complex branching structure and the histologic and IHC characteristics are equally complex; the interested reader is referred to a thorough review on the subject.[126]

Two early classifications of canine and feline MGTs were published in 1974 and 1999,[127,128] and a revised system for the dog was published in 2011.[129] In dogs, although there may be histopathologic evidence of malignancy, only a small percentage of cases will have lymphatic and vascular invasion and metastatic disease, whereas in cats the majority are malignant and metastasis to local LNs is more common. The classification used in this text is based on both morphology[129] and prognosis.[130,131] When discussing the classification of MGTs, the terms *simple* and *complex* are commonly used. Simple denotes that the neoplasm is composed of one cell type resembling either luminal epithelial cells or myoepithelial cells, whereas complex neoplasms are composed of two cell types, both luminal and myoepithelial cells, in which the myoepithelial cells extend into the interstitium, show a typical spindle to stellate morphology, and are embedded in a myxoid matrix.[129]

When distinguishing between benign and malignant tumors, criteria of malignancy have been listed in the 2011 classification for canine MGTs[129]; however, particularly when applied to low-grade or borderline lesions, some variability can be due to subjective interpretation and experience of the pathologist. This may lead to overreporting of malignant over benign tumors affecting epidemiologic data.

Canine Mammary Hyperplasia and Dysplasia

Several hyperplastic and dysplastic lesions are diagnosed in the canine MG and, in some cases, they can be considered precursor lesions to the development of MGTs.[129] These include duct ectasia, lobular hyperplasia (regular, with secretory [lactational] activity, with fibrosis [interlobular fibrous connective tissue], and with atypia), epitheliosis, papillomatosis, and fibroadenomatous change (fibroepithelial hyperplasia, fibroepithelial hypertrophy, mammary hypertrophy). The latter is frequent in the cat, but has not been clearly described in the canine MG; nodular lesions with fibroadenomatous morphology in the dog should be more correctly classified as fibroadenomas.

Benign Mammary Neoplasms

Several types of benign MGTs exist in the dog and include adenoma, intraductal papillary adenoma (duct papilloma), ductal adenoma, fibroadenoma, myoepithelioma, complex adenoma (adenomyoepithelioma), and benign mixed tumors. A histologic description of these various entities is beyond the scope of this chapter and interested readers are directed to a more thorough review.[129]

Malignant Canine Mammary Neoplasms

Malignant Epithelial Tumors

Several types of malignant epithelial tumors (Table 28.2) exist, including a variety of simple and complex carcinomas. CIS is described in the human breast as a well-demarcated, noninfiltrative nodule(s) that has not extended through the basement membrane; it is rarely diagnosed in dogs because early lesions are less frequently detected than in women and criteria to differentiate CIS from lobular hyperplasia with atypia and atypical epitheliosis in the canine MG are still under discussion. In addition, several less common subtypes of malignant epithelial neoplasm in the dog include squamous cell carcinomas, adenosquamous carcinomas, mucinous carcinomas, lipid-rich carcinomas, and spindle cell carcinomas.[129] The predominant morphologic pattern in each nodule is used to classify each nodule separately.

Malignant Mesenchymal Neoplasms: Sarcomas

Malignant mesenchymal neoplasms of the MG most commonly include OSA, chondrosarcoma, fibrosarcoma, and hemangiosarcoma.[129]

OSA is the most common mesenchymal neoplasm of the canine MG and there is often a history of recent rapid growth of a mammary mass that might have been present for some time. A proliferation of cells varies from fusiform to stellate to ovoid, and there is an association with islands of tumor osteoid and/or bone formation. Cartilage can also be present in variable amounts. Mitoses are frequently found. Metastasis occurs via the hematogenous route, mainly to the lungs.

VetBooks.ir

TABLE 28.2 Classification of Malignant Epithelial Mammary Tumors

Classification	Histologic Characteristics
Carcinoma in situ	Well-demarcated, noninfiltrative nodule(s) (noninvading basement membrane and myoepithelial layer) of closely packed cells arranged in irregular tubules or nests that have not extended through the basement membrane. • Loss of normal architecture, cell and nuclear polarity with anisocytosis, anisokaryosis, and increased numbers of mitotic figures. • Difficult to differentiate from hyperplastic/dysplastic lesions with atypia.

Carcinomas: Simple	• Tubular carcinoma
	  • Cells arranged in a predominant tubular pattern associated with variable fibrovascular stroma.
	• Cribriform
	  • Proliferation of neoplastic cells forming a sieve-like arrangement (very small undetectable tubules).
	• Tubulopapillary
	  • Papillae extend into tubular lumina and this is the main pattern. They are supported by a fine fibrovascular stroma.
	• Cystic-papillary
	  • Papillae extending into cystic lumina.

Carcinoma: Micropapillary invasive	• Neoplastic cells form small irregular aggregates and small papillae that do not have a supporting fibrovascular stalk and that are surrounded by empty lacunar spaces. • There is often infiltration of neoplastic cells into the peripheral tissue.
Carcinoma: Solid	• Closely packed cells arranged in nests and cords form dense, irregularly sized lobules surrounded by fine fibrovascular stroma.
Comedocarcinoma	• Multinodular appearance with well-demarcated necrosis within the center of the nodular areas surrounded by neoplastic cells. • Necrotic areas characterized by abundant amorphous eosinophilic material admixed with cell debris.
Carcinoma: Anaplastic	• Most malignant of the carcinomas. • Neoplastic cells individualized or in small nests. • Invading cells often evoke a desmoplastic host response. • Anaplastic histology can be characterized by extensive histologic lymphovascular invasion with neoplastic emboli in the overlying dermal lymphatic vessels. This can appear as inflammatory carcinoma, which is a clinical diagnosis. Inflammatory carcinoma can also be associated with other histologic subtype.
Carcinoma arising in a complex adenoma/ mixed tumor	• Benign counterpart detectable with areas of more pleomorphic epithelial cells showing increased number of mitoses and higher pleomorphism compared with the preexisting benign epithelial component.
Carcinomas: Complex	• Malignant epithelial component, but myoepithelium is nonmalignant. The myopithelium as a typical spindle to stellate morphology admixed with variable amount of myxoid matrix. • Only the epithelial cells exhibit considerable anisokaryosis and anisocytosis.
Ductal carcinoma	• Cells arranged in cords and tubules that surround slit-like lumina lined by a double layer of epithelial cells (luminal and basal/ myoepithelial cells). • Exhibit anisokaryosis, anisocytosis, and increased mitotic figures. • Basal/myoepithelial cells can extend into the interstitium but retain a basal morphology.
Intraductal papillary carcinoma	• Proliferation of multilayered epithelial cells forming intraductal papillae. • Fibrous connective tissue and normal myoepithelial cells are retained as the supporting stroma for the papillae.

Carcinosarcoma (Malignant Mixed Mammary Tumor)

Carcinosarcoma (malignant mixed mammary tumor) is composed partly of cells morphologically resembling the epithelial component and partly of cells morphologically resembling mesenchymal tissue elements, both types of which are malignant. It is an uncommon mammary neoplasm, but it most often presents as a carcinoma and OSA. The mesenchymal component can less commonly be represented by fibrous connective tissue alone or in combination with malignant bone/ cartilage tissue. Myoepithelial cells (benign or malignant) can occasionally be present. The epithelial component metastasizes via lymphatic vessels to regional LNs and the lungs, and the mesenchymal component metastasizes via the hematogenous route to the lungs.

Hyperplasia/Dysplasia/Neoplasia of the Nipple

Ductal adenoma and carcinoma are rare and involve only the nipple (ducts) with no neoplastic tissue in the underlying MG. The nipple is enlarged and firm. The histopathology mimics that of ductal adenomas and carcinomas of the underlying gland.[129] Carcinoma with epidermal infiltration (Paget-like disease) is a neoplasm occasionally seen in the dog that mimics Paget's disease of the nipple in women. In this lesion, the carcinoma is present within the MG and carcinoma cells, either as individual cells or small aggregates, are present within the epidermis of the nipple.

Histopathologic Prognostic Factors and Grading

The epithelial tumors are graded according to specific histopathologic criteria. Several systems for both canine and feline tumors exist, most of which are based on the Elston and Ellis grading system,[132] which incorporates information regarding (1) tubule formation, (2) nuclear pleomorphism, and (3) mitoses per 10 high-power fields (HPFs) (Table 28.3).[133–135] Based on the total score derived from this system, the grade of the tumor will be determined: grade I (low score) is a well-differentiated tumor, grade II (intermediate score) is moderately differentiated, and grade III (high total score)

VetBooks.ir

TABLE 28.3 Criteria Used for Histologic Grading of Malignancy in Feline and Canine Mammary Carcinomas

		MITOSES/10 HPFS[b]	
Tubule Formation[a]	Nuclear Pleomorphism[a]	Canine	Feline
Tubule formation >75% of the specimen: **1 point**	Uniform or regular small nucleus and occasional nucleoli: **1 point**	0–9: **1 point**	0–8: **1 point**
Moderate formation of tubular arrangements (10%–75% of the specimen) admixed with areas of solid tumor growth: **2 points**	Moderate degree of variation in nuclear size and shape, hyperchromatic nucleus, and presence of nucleoli (some of which can be prominent): **2 points**	10–19: **2 points**	9–17: **2 points**
Minimal or no tubule formation (<10%): **3 points**	Marked variation in nuclear size and hyperchromatic nucleus, often with one or more prominent nucleoli: **3 points**	>19: **3 points**	>17: **3 points**

[a]In complex and mixed tumors, the percentage of tubular formation and the nuclear pleomorphism are evaluated only in the malignant component. In malignant myoepithelioma tubular formation is 2
[b]*HPF*, High-power field. The fields are selected at the periphery or the most mitotically active parts of the sample (including also myeopithelial cells if part of the tumor). Diameter of the field of view = 0.55 mm; area = 0.237 mm^2; 10 HPFs = 2.37 mm^2. The mitotic count has to be proportional to the field diameter.

TABLE 28.4A Tumor Grade Based on Histologic Score from Table 28.3 in Cats and Dogs[133,134,136,137,210]

Total Score	Grade of Malignancy
3–5	I (low) Well differentiated
6–7	II (intermediate) Moderately differentiated
8–9	III (high) Poorly differentiated

TABLE 28.4B Newly Proposed Histologic Grading System for Invasive Mammary Carcinoma in Cats

Lymphovascular Invasion	Points
Present	1
Absent	0
Nuclear Form[a]	**Points**
≤5% Abnormal	0
>5% Abnormal	1
Mitotic Count (mitoses per 10 HPFs)[b]	**Points**
≤62	0
>62	1
Histologic Grade	**Sum of Points**
Grade I (low, well differentiated)	0
Grade II (intermediate, moderately differentiated)	1
Grade III (high, poorly differentiated)	2–3

[a]Abnormal nuclear form includes any deviation from smooth nuclear contour or round/oval nuclear shape such as clefting, angularity, corrugation, or ameboid morphology assessed at high power (40–60× objective) in the least differentiated and/or most invasive portions of the tumor. The number of nuclei exhibiting the abnormal nuclear form is estimated and expressed as a percentage of the total number of nuclei within any given field.
[b]Cumulative number of mitoses in 10 consecutive high-power fields (HPFs) in the most mitotically active area with a microscope field diameter of 0.53 mm (40× objective).[218]

is poorly differentiated (Table 28.4a,b). Tumor grade has been found to provide consistent and reliable prognostic information in both cats and dogs.[82,129,130,132–135] More recently, details on how to perform grading, particularly in MGTs with myoepithelial or mesenchymal components[136] and on how to standardize the mitotic count,[137] have been published. In addition to the grading system, information regarding vascular/lymphatic invasion, surrounding stromal invasion, LN involvement, and tumor type may also predict behavior.[13,29,65,130,131,135,138,139] Specifically for histotypes,[131] dogs carrying adenosquamous (median survival time [MST] of 18 months), comedo- (MST of 14 months), solid (MST of 8 months), and anaplastic (MST of 3 months) carcinomas experienced the worst prognosis. Prolonged survival was observed for complex carcinoma and simple tubular carcinoma, whereas a more than 10-fold higher risk of tumor-related death was associated with certain other types such as simple tubulopapillary carcinoma, intraductal papillary carcinoma, and carcinoma and malignant myoepithelioma. Carcinosarcomas and sarcomas are typically not graded via this system, but the majority tend to be biologically aggressive tumors and associated with a very poor long-term survival.[135,138]

MGTs in dogs represent a wide histologic spectrum with both benign and malignant lesions originating from different tissue types or a combination of tissues. Many dogs present with several different tumors and tumors of different types and can as such represent a rather daunting histopathologic picture; prognosis is determined by the most aggressive tumor and decisions regarding adjuvant treatments should be based on the largest or the most aggressive histology. In many cases, the most aggressive tumor is the largest.[15]

Clinical Prognostic Factors

The three prognostic factors that are most consistently reported to be associated with prognosis include tumor size, LN involvement, and World Health Organization (WHO) stage (modified and original). These are the only factors that will be discussed here.

Tumor Size

According to MacEwen et al, dogs with tumor volume larger than 40 cc (approximately 3.4 cm in diameter) have a statistically significant worse outcome than smaller tumors, both in terms of remission and survival.[140] Other investigators have classified tumors as

VetBooks.ir

stage I, smaller than 3 cm; stage II, between 3 cm and 5 cm; and stage III, larger than 5 cm.[124,140] Dogs with stage I tumors have a significantly longer survival.[13,74,141] Others, however, have found that a change in prognosis only becomes significant when tumors are larger than 5 cm.[29,142] The change in prognosis is likely gradual as tumors increase in size. The modified WHO staging system has incorporated these three size categories representing stage I, stage II, and stage III disease, respectively.[125] Importantly, however, the size of the tumor becomes irrelevant if the local LN is involved.[13] A positive LN constitutes stage IV disease according to the revised WHO system, attributing a worse prognosis to LN involvement rather than tumor size.

Lymph Node Status

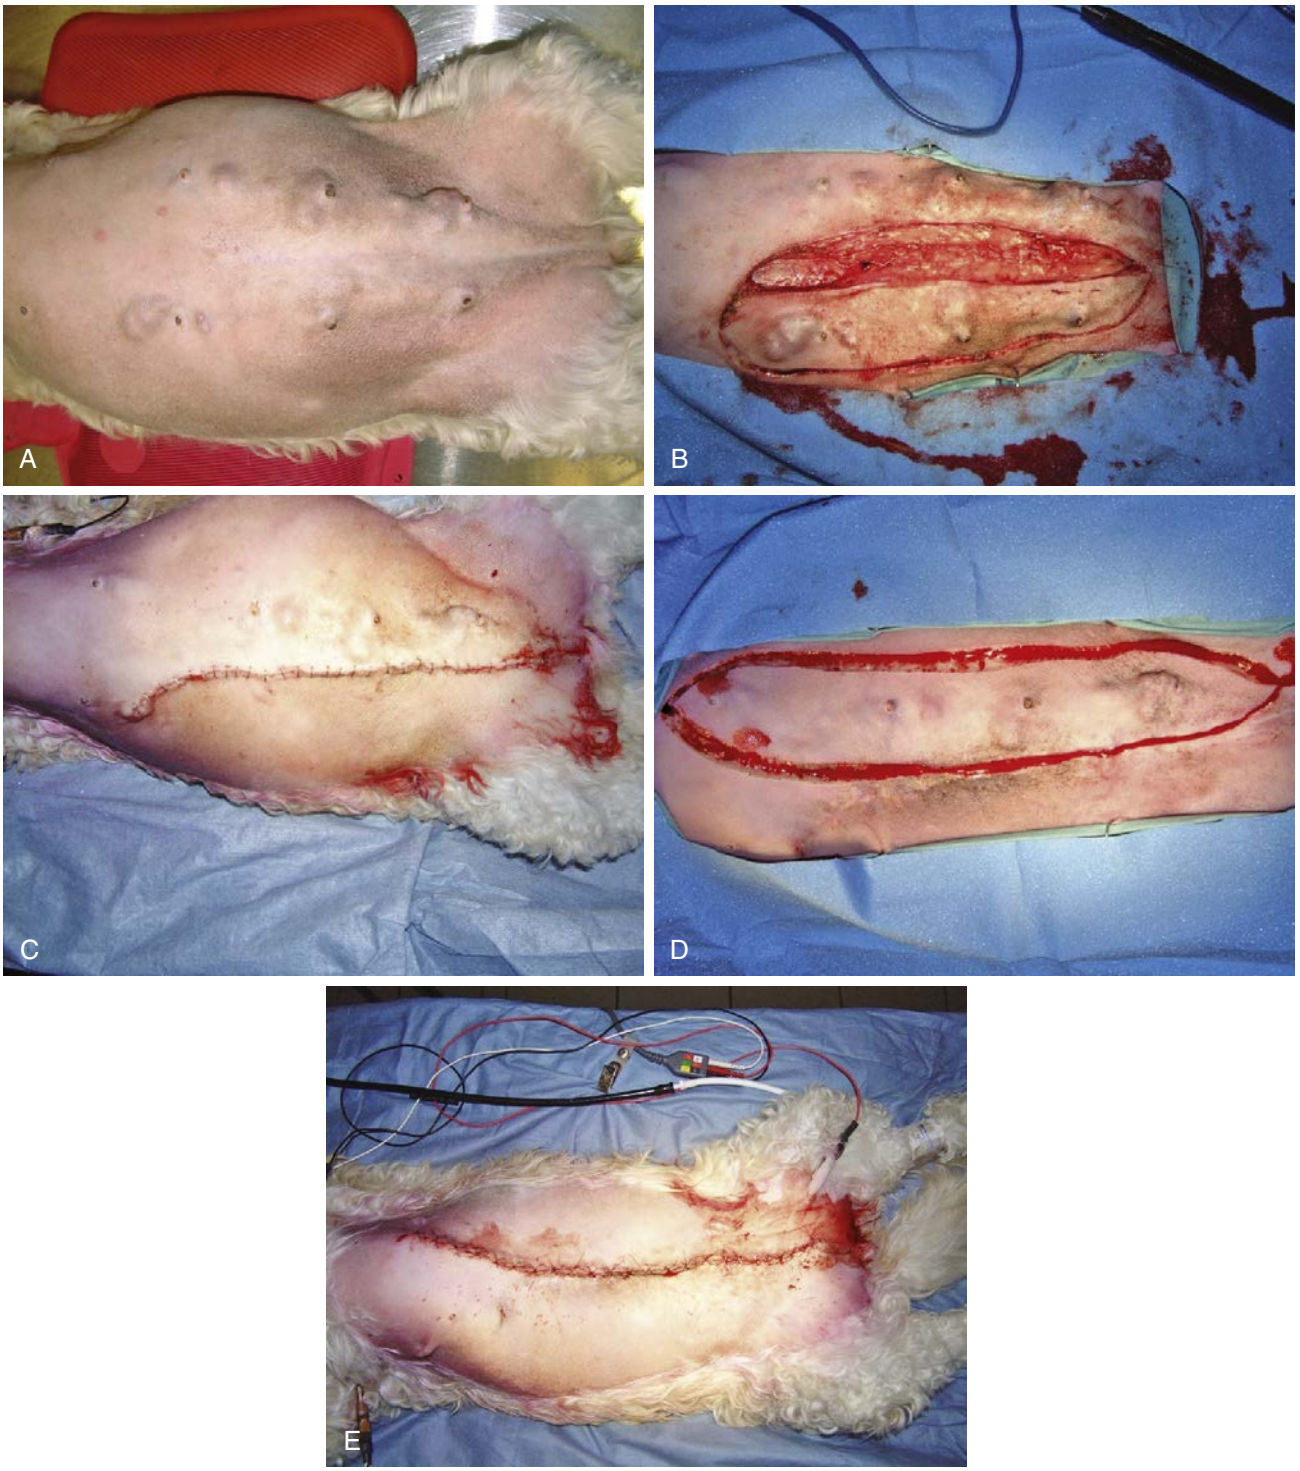
A large retrospective study, including only dogs with carcinomas, all of which had the local or draining LN removed and biopsied, found that the status of the local LNs was highly prognostic.[13] Others have confirmed these findings.[29,74,77,135,138,143] Therefore information regarding the status of the local LN is extremely important when considering the need for adjuvant or systemic therapy in dogs with MGTs. Earlier publications did not quantify the extent of LN involvement or did not use IHC to facilitate identification of microscopic clusters or isolated tumor cells, potentially including only dogs with macrometastasis in their analysis. More recent publications, however, have investigated the significance of microscopic LN metastasis. Micrometastasis, defined as clusters of cells ranging from 0.2 to 2.0 mm in diameter,[116,144.] did not predict a significantly worse outcome compared with dogs with no evidence of metastasis. Interestingly, dogs with isolated metastatic tumor cells (not in clusters) had a worse outcome according to one of these studies.[144]

WHO Staging System

Both the original and the revised WHO staging system provide prognostic information. When performing a side-by-side comparison of the two systems, the revised system appears to better reflect the stronger effect of LN status on prognosis.[126] Nevertheless, the original staging system also provides useful prognostic information as illustrated in two larger separate retrospective studies in which dogs with higher WHO stage disease had a significantly worse prognosis than dogs with lower stage disease.[29,143]

Therapy

Surgical Treatment



The challenge in preparing surgical recommendations is the lack of uniform, robust prospective clinical trials that clarify the extent or "dose" of surgical excision: simple lumpectomy, local mastectomy, regional mastectomy, chain mastectomy, or bilateral mastectomies. The goal of the surgery must be defined through staging and counseling with the owner. Is the goal to remove the current tumor(s) with clean margins or remove the current tumor(s) with clean margins *and* prevent new tumors in the remaining glands? The latter option as elaborated in the next paragraph would require prophylactic mastectomies of clinically normal glands in addition to affected glands.

Several studies have evaluated the effect of surgical dose in canine mammary tumors. A prospective randomized trial of 144 dogs with naïve malignant tumors comparing the DFI and OST benefit relative to either chain mastectomy or simple mastectomy found no differences.[140] Similarly, a retrospective case series of 79 dogs treated at a single institution found no difference in DFI or OST compared with the type of surgical procedure performed, whether lumpectomy, local mastectomy, regional mastectomy with en bloc LN excision, or chain mastectomy with en bloc LN excision.[143] However, the relative hazard for death within the first 2 years after surgery was slightly higher for dogs receiving a regional mastectomy over a chain mastectomy.[143] Interestingly, in one study, the hazard curves for DFI and survival were quite similar, suggesting that most dogs that experienced recurrence developed metastasis and not new tumors; however, the rate of new tumors was not reported in this study.[140] A different study indicated that surgical "dose" is important. In this case series of 99 dogs, all intact female dogs underwent either a regional or chain mastectomy for a single MGT with unknown histology.[145] Of these, 58% of dogs developed a new tumor in the remaining ipsilateral MG tissue after a regional mastectomy and those whose initial tumor was subsequently determined to be malignant were more likely to develop an ipsilateral tumor. The authors advocated for an initial unilateral chain mastectomy for female intact dogs with a single MGT, although, in their population, 42% of dogs did not develop a subsequent tumor and would have experienced a larger surgical dose than needed.[145] Although a more aggressive surgical approach does not affect MGT development in the contralateral mammary chain or improve STs, it does decrease the need for further surgery for the management of subsequent MGTs in the ipsilateral mammary chain in approximately 60% of dogs. It is worth noting, however, the significant incidence of postoperative complications (77%) in dogs undergoing radical mastectomies when making such recommendations[146] Other large useful studies investigating the association between OHE and survival did not report on the completeness or extent of MGT removal.[20,147,148] Development of second MGTs is well documented and has been reported in more than 70% of dogs with malignant MGTs after lumpectomy, although the effect of second MGT development on survival is not well delineated.[18,140,145] It is clear from a prospective randomized study trial for intact dogs having benign MGTs that concurrent OHE significantly reduces the risk of future MGT development by almost 50% and reduces the risk for additional life-threatening uterine and ovarian diseases.[21] A related prospective randomized clinical trial of 60 intact dogs having malignant MGTs demonstrated that a small subset of dogs benefited from concurrent OHE, specifically those dogs with grade II ER+ tumors or dogs with increased peri-surgical serum E_2 concentration.[79] A single standardized guideline for surgical treatment omits consideration of factors such as the age, tumor size, tumor number, previous MGTs, and clinical stage, and may not provide the optimal outcome. Future carefully constructed clinical trials may offer more tailored recommendations based on the individual patient's risk.

Current recommendations based on available data suggest that for dogs with a single MGT of known or unknown histotype, surgical excision wide enough to completely remove the tumor is adequate.[149] Incomplete excision or cytoreductive procedures are not recommended.[123] Tumors that are fixed or have skin ulceration and are less than 1 cm in diameter may be sufficiently managed with a local mastectomy (Fig. 28.3).[123] Wide excision has not been well defined, but for larger tumors, this may be generalized to a 2-cm lateral margin and modified according to the size of the patient and tumor.[123] The deep margin may need to include the abdominal muscular fascia and/or portions of the abdominal wall to be excised en bloc with the

VetBooks.ir

MGT, depending on size and fixation.[123] If abdominal surgery is to be performed simultaneously for OHE, accidental penetration of the tumor capsule before abdominal entry is to be avoided to prevent direct spread of tumor cells; rather, tumor removal should follow abdominal closure. For animals with multiple MGTs, more extensive resections such as a regional mastectomy, unilateral chain mastectomy, or bilateral mastectomy may be pursued. As with other tumor resections, surgical margin

• **Fig. 28.3** (A) Multiple bilateral mammary tumors in a dog with taut abdominal tissue. (B) A staged left chain mastectomy was performed initially of the side with the larger tumors. (C) Immediate postsurgical appearance after the staged unilateral chain mastectomy without undue tension. (D) The staged right chain mastectomy was performed 6 weeks later. assessment is critical for malignant MGTs, and additional surgery should be pursued if incompletely excised. In one retrospective study, the MST was 15.5 months for dogs with incomplete histologic excision of their MGT versus 22.8 months for dogs with complete histologic excision, and 70 days versus 872 days, respectively, in another retrospective study.[150,75] Elective unilateral or bilateral chain mastectomies may be reasonable for young intact bitches with multiple MGTs because there is the possibility of development of additional tumors (Fig. 28.4).[123]

Surgical excision is questionable as a treatment for dogs presenting with inflammatory carcinoma because of the profound diffuse microscopic extent of cutaneous disease, the significant metastatic rate, and the local tissue coagulopathy that may be present. In 43 dogs with inflammatory carcinoma, only three dogs were considered suitable for unilateral chain mastectomy based on physical examination, yet all three had residual neoplastic cells at the surgical margins.[102] Interestingly, two of the dogs also received adjuvant chemotherapy and were among the longest survivors in that study.[102] Radiation therapy can be considered for palliation of dogs having clinical signs associated with presence of an inflammatory carcinoma.[151]

Systemic Treatment

Few clinical studies have investigated systemic therapy for MGTs, and efficacy has not been evaluated and confirmed according to the highest evidence-based standards. Despite this uncertainty, chemotherapy is routinely recommended and administered in dogs with "high-risk" tumors. This practice is based on the recognition that dogs with large tumors, positive LNs, and aggressive histology are not treated effectively

with surgery alone. The use of hormonal therapy in canine MGTs is based on tumor hormone dependence (tumor risk and HRs) and the potential to significantly reduce recurrence and prolong survival in HR-positive cancers similar to human hormonal therapy. This can be achieved by surgical means (ovariectomy [OVE] or OHE) or medical means, including specific ER modulators and suppression of estrogen synthesis by aromatase inhibitors or luteinizing hormone–releasing hormone agonists. Tamoxifen, an ER antagonist commonly used in women with ER-positive breast cancer, has been evaluated in dogs both with and without MGTs. Because of the side effects, mostly from proestrogenic signs, this strategy may not be tolerable or feasible in dogs.[152,153] Surgical ovarian ablation, specifically OVE/OHE, is a more practical solution in the dog. This will also eliminate the ovarian production of progesterone, the other main player in canine mammary tumorigenesis. Alternatively, specific drugs targeting the progesterone receptor may be considered. A recent randomized study documented improvements in DFI in specific subset of dogs randomized to receive a progesterone receptor antagonist (aglepristone) (see Table 28.6).[154] There are numerous publications on the topic of OHE in canine MGTs. The results are in discordance; most of the earlier studies did not report benefit in ovariohysterectomized dogs compared with intact dogs.[18,140,141,152,155] A few of these earlier studies, however, did report benefit; one study found that the benefit of OHE was only significant in dogs with complex carcinomas.[143] Another study found that the timing of OHE in relation to tumor surgery was important; only dogs with OHE performed within 2 years before or concurrently with tumor removal benefited.[148] None of these studies were randomized and the results were not analyzed in the context of tumor HRs, thus the results must be interpreted with caution. A recently published prospective randomized study may provide new insight regarding OHE in dogs with mammary carcinoma.[79] As to be expected, no benefit was noted when all dogs were included in the analysis; however, when the effect of OHE was stratified based on HR positivity, a modest improvement was noted in dogs that underwent OHE. This difference did not reach significance, likely due to lack of power. Interestingly, OHE conferred a significant improvement in survival in dogs with grade II tumors and dogs that had higher than median peri-surgical serum estradiol, regardless of ER expression.[79] These results reflect the diversity in the biology and behavior in canine mammary carcinoma and therefore the need for more individualized recommendations regarding adjuvant care, including whether to perform OHE (one size does not fit all).

Chemotherapy is often administered to dogs with MGTs considered to be at risk for metastasis or recurrence. Most of the evidence regarding the efficacy of adjuvant chemotherapy is weak, but some studies have reported improved outcomes in dogs treated with chemotherapy, alone or in combination with nonsteroidal antiinflammatory drugs (NSAIDs) (see Table 28.6). Anthracycline or taxane combinations are considered part of first-line protocols in human BC in women requiring adjuvant therapy[80,156–158]; however, only inadequately powered nonrandomized studies on the efficacy of doxorubicin (DOX), docetaxel, gemcitabine, mitoxantrone, and carboplatin in dogs with high risk or advanced MGTs have been performed and none clearly establish benefit.[150,159–161] Interestingly, NSAIDs, with or without chemotherapy, were found to be effective in prolonging survival in dogs with high risk (grade III and/or advanced clinical stage) or inflammatory carcinomas according to several retrospective and prospective studies (see Table 28.6).[102,160,162,163] Chemotherapy may also have a role in the treatment of primary MG OSA. The MG is one of the most common sites for extraskeletal OSA and, according to one small retrospective case series (including primary MG OSA and other extraskeletal sites), dogs treated with adjuvant chemotherapy were significantly less likely to die of tumor-related causes than dogs treated with surgery alone.[164]

Lastly, a prospective randomized trial documented significant improvement in survival in dogs with histologic grade II or III carcinoma treated with perioperative desmopressin.[165] The antimetastatic properties of desmopressin are not fully understood, but it is hypothesized that they in part are mediated through improving hemostasis and preventing cancer cells from gaining access to the vasculature during surgical manipulation.[166,167] The results are intriguing, however, further confirmatory studies are warranted in light of the fact that only two dogs with grade III tumors were randomized to the placebo arm in this particular study and both dogs died shortly after surgery (MST 35 days). This unusually short survival may contribute to the apparent improvement in survival in the desmopressin arm. As illustrated earlier, there is currently a paucity of high-quality trial evidence from which to draw information and guidance for treating dogs with malignant high-risk MGTs. Table 28.5 provides general guidance and treatment consideration/options and the level of supporting evidence. Table 28.6 summarizes trials reporting benefit from systemic therapy in dogs with MGTs.

Mammary Tumors in Cats

Epidemiology and Risk Factors

Epidemiology

There are fewer epidemiologic studies regarding the incidence of mammary neoplasia in cats compared with dogs. Furthermore, because of differences in veterinary care for cats, the available data likely underestimate the true incidence of disease. According to data from one of the largest Swedish insurance companies, approximately 40% to 50 % of all dogs had insurance to cover veterinary expenses, whereas only 20% of cats had such coverage.[168,169] Another study from the United States also reported that a significantly lower percentage of cats receives regular veterinary care compared with dogs.[170]

The overall MGT incidence is lower in cats than in dogs. According to the California Animal Neoplasia Registry (CANR), MGTs represent the third most common tumor in female cats (after skin tumors and lymphoma) with an annual incidence rate of 25.4/100,000 and 12% of tumors in cats regardless of sex.[1] Data from an animal tumor registry from two provinces in northern Italy reported that MGTs represented 16% of all tumors in cats and 25% in female cats.[171] Data from a Swedish insurance company indicate that MGTs were the most common cancer representing 40% of all tumor-related claims in cats.[168] It is unclear whether the higher relative incidence of MGTs in the latter studies is due to differences in neutering practices or use of progestins in the source population because no information regarding OHE status was provided.

Risk Factors

Three main risk factors in cats have been identified: age, breed, and hormonal influence.

Age

As in the dog, mammary neoplasia is a disease seen predominantly in middle-aged to older cats. The mean age of diagnosis is between 10 and 12 years of age.[1,172–175] Risk increases incrementally with age but does not become significant until 7 to 9 years, according to the age-specific incidence curves from the CANR, and continues to increase up until 12 to 14 years.[1]

Breed

Siamese cats are significantly younger when diagnosed with MGTs and risk plateaus at 9 years of age.[176] In general, genetic predisposition for a disease is often associated with a younger age of diagnosis. Siamese cats appear overrepresented compared with other breeds.[176,177] However, Siamese cats have an increased risk for many tumor types and not only MGTs.[178–182] It is therefore possible that the increased incidence in Siamese cats is due to breed-associated germline alterations in common tumor susceptibility genes or defective tumor suppressor gene function that confers increased risk for many different malignancies.

VetBooks.ir

Hormonal Association

Exposure to ovarian hormones is also strongly implicated in mammary tumorigenesis in the cat. Sexually intact cats have a 7-fold higher risk than spayed cats.[1] The increased risk in intact cats has been confirmed by others.[173,176,183] Similar to findings in dogs, exposure from ovarian hormones in cats at an early age appears crucial. The protective effect of OHE diminishes quickly over the first few years; risk reductions of 91%, 86%, and 11% are seen in cats that are ovariohysterectomized before 6 months, between 7 and 12 months, and between 13 and 24 months, respectively. No benefit was found after 24 months.[183] According to the same study, parity did not influence risk for MGTs.

In addition to endogenous ovarian hormonal influence, exposure to exogenous progestins also increases risk. Cats treated with progestins have an overall relative risk of 3.4 compared with those not receiving such treatments, although benign tumors arise more commonly than malignant tumors (relative risk 5.3 vs 2.8).[173] Unlike dogs, progestin-treated cats were not younger than non-treated cats when they developed tumors.[173] The tumorigenic effects of oral progestins in cats are supported by reports of male cats with MGTs. MGTs are rare in males, but in a report of 22 cases, eight (36%) had a history of progestin use.[184] In a recent case series of three male cats with MGTs, all had received multiple injections of a long-lasting progestin over 5 to 6 years before tumor development. All had malignant tumors and all developed subsequent malignant tumors in other glands after initial surgery.[185] Shorter duration of treatment or inconsistent administration is less likely to result in malignant tumors, but nevertheless induce changes in the MGs.[186] Fibroepithelial hyperplasia (fibroadenomatous change, fibroepithelial hypertrophy, mammary hypertrophy) is the most common histopathologic change in cats treated for shorter periods of time and can occur relatively quickly, even after one injection; however, studies show that regular and prolonged administration is needed for malignant tumors to develop.[173]

Tumor Biology: Development, Hormones, Growth Factors, and Prognostic Implications

The risk for MGT development in cats is determined by exposure to ovarian hormones early in life, but the latency period appears long because most cats are older when diagnosed. In many species, ovarian hormones are necessary for normal MG development and maturation, but few studies have examined hormonal effects on mammary tumorigenesis in cats. The complex interactions between sex hormones, GH, and IGF-1 have been discussed in more detail in the section on canine MGTs, but progestin-induced mammary production of GH has been documented in the cat.[187,188] It is, however, biologically plausible that the tumorigenic effects on mammary tissues are similar across species and that the same general mechanisms are involved, specifically sex hormones and GH. Despite ER and PR expression being implicated in the initial stages of MGT development, many investigators have reported that most feline mammary carcinomas are ER and PR negative, although slightly more than one-third are PR positive.[72,189–192] The percentage of ER/PR expression varies between studies and is likely the result of differences in case selection, methods, and interpretation of the results. The biochemical method, the dextran-coated charcoal (DCC) method, may be more sensitive than IHC when analyzing ER in cats.[191] Standardized IHC methods have high concordance with DCC methods; 38.5% of the malignant tumors and 66.7% of the benign lesions expressed PR according to IHC.[191] In this particular study, sexually intact cats were more likely to have PR-positive tumors. Lower concordance was found between ER analysis by DCC and IHC with IHC being less sensitive than DCC; only 20% of the malignant tumors expressed ER according to IHC compared with 44% according to the DCC assay.[191] These results are consistent with other publications showing a relatively low ER expression in feline MGTs when using IHC.

• **Fig. 28.5** Fibroepithelial hyperplasia in a cat. (Courtesy Dr. Lisa Mestrinho, Faculdade de Medicina Veterinária, Universidade Lusofona de Humanidades e Tecnologias, Lisboa, Portugal.)

The low HR positivity in the tumors is consistent with the higher rate of malignancy and a more aggressive clinical behavior in feline MGTs. In contrast to malignant tumors, normal mammary tissue and dysplastic lesions in the MG express both ER and PR[72,189,190]; however, this hormone dependence appears to wane with histologic progression from benign to malignant. None of the intermediate- or high-grade ductal CIS (nomenclature referring to breast intraepithelial lesions in women) were ER or PR positive,[189] whereas the normal and hyperplastic adjacent mammary tissue expressed HRs.[72,189,190] Fibroepithelial hyperplasia, a progesterone-induced change, has been reported to have high PR expression[186] and can be effectively treated by OHE or antiprogestins (Fig. 28.5).[193]

In human BC, an inverse relationship between the HR status and HER-2 expression is documented. HER-2 expression tends to be higher in cats than in dogs and humans; however, a wide range (6%–90%) of HER-2–positive tumors is reported.[194–197]

History and Clinical Presentation

Cats with MGTs are often older and may be sexually intact or spayed after they were 2 years old. Tumors are easy to detect on physical examination and appear as firm discrete mass(es) in the MG(s). One study reported that all glands are equally susceptible to tumor development, but a later study showed that the cranial glands were less commonly affected.[198,199] Multiple tumors are common; 60% of cats had more than one tumor at diagnosis in one report.[174] Careful examination of

the remaining MGs is important when evaluating a cat with a prior history of MGTs, especially if treated with local mastectomy, because new primary tumors are common. Tumor(s) size at diagnosis depends on how early it is detected and how aggressive the tumor behaves. Larger tumors may become ulcerated, inflamed, and infected. Local LNs may or may not appear enlarged. Inflammatory mammary carcinomas are rare in cats and the clinical picture and outcome are similar to those described in the dog.[200]

Clinical Assessment, Diagnosis, Workup, and Clinical Staging

Cats with mammary masses tend to be older and their tumors are commonly malignant; therefore a thorough workup is recommended to ascertain any comorbidity and advanced disease. This may include CBC, serum biochemistry, serum T_4 concentration, three-view thoracic radiographs, abdominal ultrasound, and urinalysis, in addition to FNA of any mammary masses and any palpable (including normal-sized) regional LNs.

Staging System

Feline MGTs are staged similar to canine tumors using a modification of the original system published by Owen.[124,201] In the modified system, stage advances from I to II to III as the size increases from smaller than 2 cm, to between 2 and 3 cm, to larger than 3 cm.[125] Unlike the canine system, stage III disease also includes T1 or T2 tumors with concurrent LN metastasis and LN metastasis does not need to be present with T3 tumors. Stage IV disease is any tumor with any LN metastasis and distant metastasis.[201] This staging system should not be used with MG sarcomas (see Table 28.6).

Histopathology

The vast majority of feline MGTs are malignant (85%–95%) with an aggressive biologic behavior, and lymphatic invasion and LN metastasis are more common at the time of initial diagnosis than in dogs. Early classifications of feline MGTs were simpler than that used for canine tumors.[128] Complex and mixed tumors showing the same features of the canine counterparts have not been diagnosed in the feline MG; however, new and previously unclassified subtypes have been reported.[202] Morphologic features of each subtype are identical to the canine counterparts and, as per dogs, the predominant morphologic pattern is used to classify the tumor.

Similar to dogs, a molecular approach to MGT classification has been attempted in cats.[203–208] Despite lack of standardized methods and variability of results, mammary carcinomas in cats were associated with the highest percentage of triple-negative (HR– and HER-2–) MGTs, associated with frequent expression of both basal cytokeratins and vimentin, and had the worst prognosis. This seems to suggest that the cat may be a suitable model for some subtypes of human BC, such as the HR-independent basal-like cancers.

Hyperplasia and Dysplasia

The various hyperplastic and dysplastic lesions seen in cats include duct ectasia, lobular hyperplasia (regular, with secretory [lactational] activity, with fibrosis [interlobular fibrous connective tissue], and with atypia), epitheliosis, papillomatosis, and fibroadenomatous change.[209] Fibroadenomatous change (fibroepithelial hyperplasia, fibroepithelial hypertrophy, mammary hypertrophy) is common in the cat, usually affects several glands, and is characterized by the proliferation of interlobular ducts, tubules, and periductal stromal cells. The stroma is often edematous or myxomatous, and both the epithelial and stromal cell nuclei exhibit some pleomorphism with mitoses. This lesion is hormonally induced and occurs in progestin-treated female and male cats, as well as being associated with pregnancy. Most cases regress at the end of pregnancy or cessation of progestin treatment.[128,202]

TABLE 28.7 Staging of Feline Mammary Tumors[201]

Stage	Tumor Size	Lymph Node Status	Metastasis
Stage I	T_1 <2 cm	N_0	M_0
Stage II	T_2 2–3 cm	N_0	M_0
Stage III	T_1 or T_2 T_3 >3 cm	N_1 (positive) N_0 or N_1	M_0 M_0
Stage IV	Any	Any	M_1

Benign Feline Mammary Neoplasms

Benign tumors in cats are uncommon and include simple adenoma, ductal adenoma, fibroadenoma, and intraductal papillary adenoma (duct papilloma).[128,202]

Malignant Mammary Neoplasms

The predominant malignant tumor types in cats are simple and epithelial in origin and as such represent carcinomas of various types. Tubular carcinomas, tubulopapillary carcinomas, and solid carcinomas are most common. Other variants include cystic-papillary carcinoma, cribriform carcinoma (when tubules are nearly undetectable), micropapillary invasive carcinoma, comedocarcinoma, anaplastic carcinoma, intraductal papillary carcinoma, ductal carcinoma, and, less commonly, squamous cell carcinoma, mucinous carcinoma, lipid-rich carcinoma, adenosquamous carcinoma, and spindle cell carcinoma.[128,197,200,202,209–216]

Histopathologic Prognostic Factors and Grading

Grading was initially thought not to be prognostic in cats; therefore the classification of mammary tumors was based on morphologic criteria only. More recently, histologic grading using a system similar to that in dogs (see Tables 28.3 and 28.4a) has been shown to be prognostic in cats.[210,217] In addition to histologic grade, lymphovascular invasion and LN metastasis are independent prognostic factors.[210,217] Thus the histopathologic criteria used in dogs (i.e., grade, vascular invasion, LN status) can be used in cats when assessing risk for metastasis and prognosis, and should be incorporated into decisions regarding the need for systemic treatment in cats with MGTs (Table 28.7).

VetBooks.ir

Recently a novel grading system for feline MGTs has been proposed which includes lymphovascular invasion (see Table 28.4b).[218] A limitation of this system is that when evaluating histologic section(s) of a tumor, lymphovascular invasion might not be present in the selected section(s). Standardization of this method would be improved by additional information, such as number of sections, and trimming procedure. Pathologists might then consider including both systems in their report to allow a comparison and a more robust assessment of its prognostic value. Using this grading system, the median OST of cats with grade I tumors was 31 months (36 months with the Elston and Ellis–based scoring system), grade II tumors was 14 months (18 months with the Elston and Ellis–based scoring system), and grade III tumors was 8 months (6 months with the Elston and Ellis–based scoring system).[218]

Clinical Prognostic Factors

Few studies reporting prognostic factors in cats with MGTs are prospective, only one is randomized, and most are underpowered or not stratified according to treatment. Therefore the results vary and may be significantly affected by bias. Tumor size has, however, consistently been reported to have prognostic significance, including the results of two large prospective studies.

Tumor Size

Three size categories have shown prognostic significance: (1) smaller than 8 cm^3 or smaller than 2 cm diameter; (2) 8 to 27 cm^3 or 2 to 3 cm diameter; and (3) larger than 27 cm^3 or larger than 3 cm diameter. Cats with small (<2 cm) tumors can be effectively treated with surgery alone, specifically radical mastectomy, with a MST of more than 3 years, whereas cats with tumors larger than 3 cm have a MST of only 6 months according to a large retrospective study.[219] Cats with 2- to 3-cm diameter tumors survived an average of 2 years. Several other publications have confirmed this association between survival and tumor size.[175,177,199,220,221]

Lymph Node Status

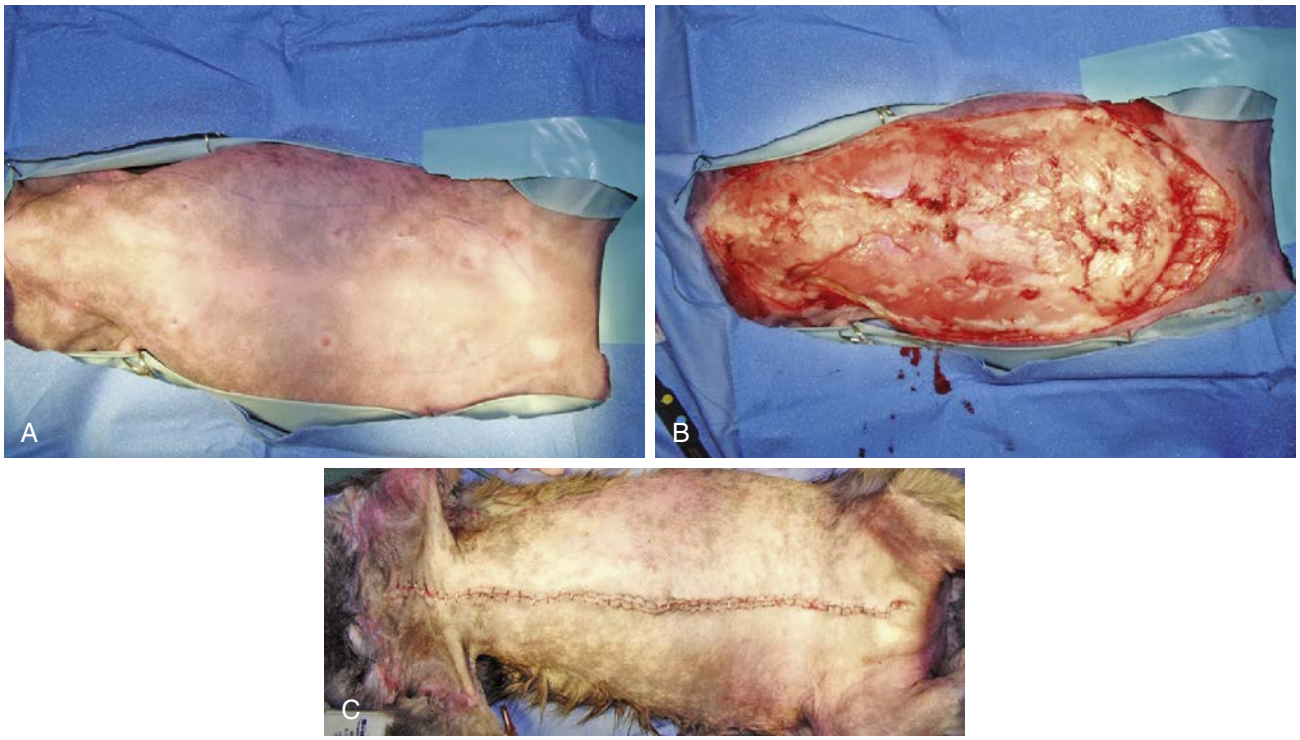
Surprisingly few studies have evaluated LN status and its prognostic significance in cats with MGTs. In a large prospective study of 202 cats, those with LN metastasis had significantly shorter STs than cats with negative LNs.[199] A retrospective study with 92 cats supported these findings; all cats with LN metastasis died within the first 9 months of diagnosis.[217] A retrospective study of 107 cats treated with either unilateral mastectomy or bilateral mastectomy for mammary adenocarcinomas revealed that LN metastasis at the time of mastectomy had a significant negative association with progression-free ST and an increased risk of death, but a third of cats having histologic evidence of LN metastasis did not progress to additional metastasis.[222]

Breed

Domestic shorthair cats had significantly better outcomes than purebred cats in a prospective randomized trial of cats with mammary carcinomas.[220] Another study reported that Siamese cats had a worse prognosis than domestic shorthairs.[223] These studies may in fact complement each other; however, the first study did not provide information regarding how many Siamese cats were included in the purebred group. Several other studies have not found breed to be prognostic when adjusted for other factors.

Age

The results regarding age and prognosis are conflicting. Several studies report that older cats have a worse prognosis; however, bias due to differences in treatments or differences in tumor size and clinical stage may exist. Importantly, a prospective randomized trial found no difference according to age when comparing cats that were younger or older than 10 years.[220]



Therapy

Surgical Treatment

The surgical dose recommended for treating feline MGTs is much clearer than in the dog. A chain mastectomy (unilateral for cats possessing a single tumor or a staged bilateral chain mastectomy for cats with bilateral tumors) resulted in a statistically significant improvement in DFI and ST, as opposed to cats receiving conservative tumor excision in a series of 100 cats.[219] In a retrospective case series of 53 cats, although no significant difference was found between the type of surgical procedure performed, cats experienced longer DFIs after either unilateral or bilateral chain mastectomies compared with partial mastectomy.[177] Recently, a multiinstitutional retrospective case series of 107 cats having either unilateral mastectomy or bilateral mastectomy for mammary adenocarcinoma found a longer median progression-free ST of 542 days for cats treated with bilateral mastectomies versus 289 days for cats treated with unilateral mastectomy.[222] In the multivariable analysis, disease-specific death was greater for those cats treated with a unilateral mastectomy and those that developed metastasis.[222] In addition, the disease-specific ST was statistically improved for cats treated with both mastectomy and adjuvant chemotherapy.[222] In a multiinstitutional retrospective case series comparing patients treated with surgery versus surgery and adjuvant DOX-based chemotherapy, the subset of cats having unilateral mastectomies followed with chemotherapy had significantly longer MSTs than cats having unilateral mastectomies without chemotherapy (1998 vs 414 days).[201] In that series, local recurrence developed in 50% of cats and, although not statistically significant, also appears to support the use of bilateral mastectomies for feline mammary carcinomas.[201] In a report of male cats diagnosed with mammary carcinomas, a trend toward more frequent local recurrence correlated with more conservative resections.[184] Thus, for cats, a unilateral or staged bilateral chain mastectomy is recommended for curative-intent treatment of mammary carcinoma. For some cats with excessively loose mammary tissue, a bilateral chain mastectomy can be performed during a single surgical session if minimal postsurgical tension can be achieved, but these cats can have a more difficult recovery with increased complication rates (Fig. 28.6).[222] For tumors that are fixed, muscular fascia or portions of the body wall should be included with en bloc resections. In a retrospective case series, bilateral mastectomy in cats with LN metastasis was found to be protective against disease progression on multivariable study analysis.[222] Thus bilateral mastectomy is recommended for MGTs in cats.

The high malignancy rate of mammary carcinoma and the poor prognosis associated with LN metastasis supports aggressive LN assessment. This could include ultrasound-guided FNA of difficult to palpate LNs and inguinal lymphadenectomy concurrent with chain mastectomy. Sentinel LN mapping has been described in the cat and was the original model for the procedure, which is common for human breast cancer patients.[111,115] Published techniques in the cat include CT evaluation after

intramammary injection of iopamidol and radiographic imaging after intramammary ethiodized oil injections.[111] There are no clinical reports utilizing nuclear lymphoscintigraphy in the cat. Use of blue dyes for node visualization is recommended with caution because their use may cause Heinz body anemia and methemoglobinemia in this species. LNs extirpated during mastectomy surgery frequently yield metastasis, as found in 48 of 51,[204] 41 of 93,[222] and 17 of 66[218] cats having surgical resection of malignant MGTs.

Fibroepithelial hyperplasia has a classic appearance that is very difficult to mistake for malignant MGTs. This condition is typically treated with either OHE or medical hormone therapy management. Inflammatory mammary carcinoma has very rarely been reported in cats; in a sole case series of three cats, the disease was described as occurring secondary to postsurgical mastectomy with nonhealing incisions, edema, and suture rejections.[200]

Systemic Treatment

Early detection and aggressive surgery (including prophylactic chain mastectomy) can result in long-term survival in cats with early stage MGTs; however, cats with delayed diagnosis, large primary tumors, or metastatic local LNs are not treated effectively with surgery alone. The incidence of distant metastasis, primarily to the lungs and pleura, is high, although other organs are also frequently involved.[199] Despite the high rate of metastasis after surgery, relatively few advances have been made in identifying effective adjuvant systemic treatments.

Owing to low HR expression in feline mammary carcinoma, hormonal therapy is not likely to be effective; however, randomized trials have not been performed to confirm this.

Several studies, all retrospective, have evaluated the use of chemotherapy in cats with mammary cancer. Two case series of cats with macroscopic primary and/or metastatic tumors documented objective responses in 40% to 50% of the cats treated with a combination of DOX and cyclophosphamide.[224,225] The relatively high response rate in the macroscopic setting suggests that this may be an effective protocol in patients with microscopic minimal residual disease (i.e., after surgical cytoreduction). Results from adjuvant studies are, however, mixed, but two more recent studies suggest a benefit from chemotherapy in cats undergoing radical mastectomy (chain or bilateral). The chemotherapy varied in these studied, but DOX-based protocols were used most commonly in both of these studies: cats treated with chain mastectomy and adjuvant chemotherapy survived significantly longer than cats treated with chain mastectomy alone (1998 days vs 414 days).[202] Similar findings were also demonstrated in a separate multiinstitutional study whereby the disease-specific survival was significantly improved for 53 cats receiving adjuvant chemotherapy in 105 cats being followed after mastectomy.[222] These results support the use of adjuvant chemotherapy in this setting. It is interesting that none of these retrospective studies reported STs as long as earlier studies using surgery alone, especially in the subset of cats with small tumors. This further illustrates the difficulty in comparing outcomes between retrospective studies, especially noncontemporaneous ones. Ultimately, prospective, randomized trials will be necessary to determine the appropriate use of chemotherapy in cats with MGTs. Despite the lack of quality evidence in the literature to support it, veterinary oncologists continue to recommend the use of chemotherapy in some cats with MGTs. Table 28.8 summarizes the most important prognostic factors, general guidelines for systemic treatments, and the strength of supporting evidence.

TABLE 28.8 Prognostic Factors and Indications for Adjuvant Chemotherapy with Level of Supporting Evidence in Cats with Malignant Mammary Tumors

Tumor Size	Lymph Node Involvement	Histopathologic Parameters	Indication for Chemotherapy No or Yes	Evidence Level[a]
<2 cm /8 cm^3	Negative	Carcinoma	No Yes[b]	1[220] 3[210,217,221]
2–3 cm/8–27 cm^3	Negative	Carcinoma	No Yes[b]	3[219,222] 3[210,217,221]
>3 cm/ 27 cm^3	Negative	Carcinoma	Yes	1,[220]2,[199] 3[219,222]
Any	Positive	Carcinoma	Yes	2,[199]3,[217] 5[80]

[a]Evidence level 1: Prospective randomized trial; level 2: Prospective, nonrandomized trial; level 3: Retrospective; level 5: Extrapolation from human breast cancer studies.
[b]Vascular invasion and high grade were found to be independent negative prognostic factors in multivariate analysis.

Tumors of the Male Reproductive System

JESSICA A. LAWRENCE AND COREY F. SABA

Canine Testicular Tumors

Prevalence/Incidence

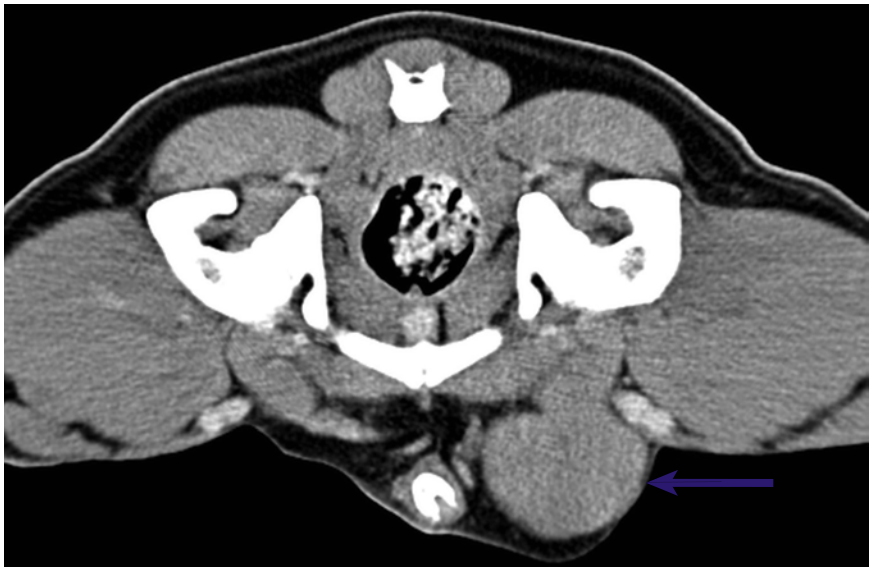
Testicular tumors are the most common tumors of the canine male genitalia and account for approximately 90% of all cancers in the male reproductive tract.[1–4] In the intact male dog, the testis is the second most common anatomic site for tumor development, with an overall prevalence ranging between 6% and 27%.[1,3–7] Many of these reports are case series and involve dogs submitted for routine necropsy and/or castration for cryptorchidism, making comparisons between study prevalence data difficult. However, a recent population-based study conducted in Norway, where elective castration is rare, reported a similar prevalence of 7% for testicular tumors.[8]

The rate of development of testicular cancer in humans has increased in some populations over time and across successive birth cohorts, and a similar phenomenon has been suggested in dogs.[7,9–13] One relatively recent population-based study published in 2011 did not find increased rates of testicular tumors among dogs; however, only an 8-year period was evaluated.[8] Testicular tumors are most often diagnosed in geriatric male dogs with a median age of approximately 10 years.[1,3,4,14,15]

The three most common testicular tumors arise from distinct testicular subsets: sustentacular cells of Sertoli, the spermatic germinal epithelium, and the interstitial cells of Leydig, giving rise to Sertoli cell tumors, seminomas, and interstitial cell tumors, respectively (Table 29.1).[2] The World Health Organization (WHO) classification of tumors of domestic animals differentiates the major types of testicular tumors in dogs as sex-cord stromal tumors (Sertoli cell tumors, interstitial cell tumors), germ cell tumors (seminoma, teratoma), and mixed germ cell–sex-cord stromal tumors.[16] Sertoli cell tumors, interstitial cell tumors, and seminomas have historically developed with equal frequency, although recent studies have suggested that the prevalence of Sertoli cell tumors is lower, at 8% to 16%.[1,3,4,7,17,18] Seminoma occurred most frequently in a study of lifetime occurrence of neoplasia in German shepherd dogs and Belgian Malinois.[17] Human testicular tumors are often divided into seminoma and nonseminoma, and seminomas are further differentiated as classical (SE), atypical, and spermatocytic seminoma (SS) according to the WHO, and some effort has been made to apply this to canine tumors.[9,13,19–23] Sertoli cell tumors and seminomas occur with higher frequency in cryptorchid testes.[3,24,25]

Rarely, other cell lineages can give rise to testicular tumors such as hemangiomas, granulosa cell tumors, teratomas, sarcomas, embryonal carcinomas, gonadoblastomas, lymphomas, schwannoma, mesothelioma, and rete testis mucinous adenocarcinomas.[26–30] Many dogs diagnosed with testicular cancer have more than one primary tumor.[3,6,18,31] In three separate studies evaluating a relatively large numbers of dogs with testicular tumors, between 4% and 20% of dogs had more than one type of testicular tumor.[3,8,32]

Risk Factors



Several factors may influence the development of testicular tumors in the dog, including cryptorchidism, age, breed, and carcinogen exposure. There is a significant association between cryptorchidism and the development of Sertoli cell tumors and seminomas, but not interstitial cell tumors.[4,15,25,33] An early prospective epidemiologic study compared the incidence of testicular tumors in cryptorchid dogs to age- and breed-matched control dogs.[15] None of the control dogs developed testicular tumors during the study, in which the average duration of monitoring was 2 years. The incidence of testicular neoplasia in the cryptorchid dogs was 12.7 per 1000 dog-years at risk, whereas for cryptorchid dogs older than 6 years the incidence increased to 68.1 per 1000 dog-years at risk.[15] Inguinal cryptorchidism may further increase the risk of testicular tumor development compared with abdominal cryptorchidism (Fig. 29.1).[4,15,25] In cryptorchid dogs, tumors more frequently develop in the right testicle, potentially because the right testicle is more likely to be retained.[4,15,32] Chronologic age is a risk factor for development of a primary testicular tumor; in one study, dogs older than 10 years were more likely to develop tumors than dogs younger than 6 years.[15] Another study indicated that the detection rate of testicular tumors in dogs younger than 10 years was significantly associated with cryptorchidism, with more than 60% of cryptorchid testicular tumors identified in middle-aged dogs (6–10 years).[4]

Several breeds have been reported to have increased risk of developing primary testicular tumors, including the boxer,

VetBooks.ir

TABLE 29.1 Characteristics of the Three Most Common Testicular Tumors in the Dog

Tumor Type	Incidence (% of all testicular tumors)	Origin	Hormone Production	Clinical Findings	Gross Appearance	Biologic Behavior and Potential for Metastasis
Sertoli Cell Tumor	8%–33%	Sustentacular cells of seminiferous tubules	≥50% Estrogen	Feminization syndrome Pancytopenia	Firm Lobulated White-gray "Greasy"	<15% regional or distant metastasis
Interstitial Cell Tumor (Leydig Cell Tumor)	33%–50%	Leydig cells between seminiferous tubules	Rarely estrogen Testosterone	Often incidental finding Perianal gland hyperplasia/ adenomas	Soft Expansive Yellow-orange Often cystic	Rarely metastasize
Seminomas	33%–52%	Germinal epithelium of seminiferous tubules	Rarely estrogen	Often incidental finding Metastasis may cause lethargy	Soft Homogeneous May be lobulated Ivory	<15% regional or distant metastasis

German shepherd dog, Afghan hound, Weimaraner, Shetland sheepdog, collie, and Maltese.[3,8,14,25,32,34,35] Flat-coated retrievers, Rottweilers, Bouvier de Flandres, and Leonbergers may have a reduced risk of developing testicular tumors, although low numbers of the latter two breeds were evaluated.[8]

Two studies evaluating military working dogs suggested evidence of environmental carcinogen exposure during the Vietnam War as a contributor to testicular tumor development.[36,37] Pathologic changes in the testicles were noted, such as hemorrhage, epididymitis, orchitis, sperm granuloma, testicular degeneration, and seminoma, although the causative factor of these lesions could not be definitively determined. These epidemiologic studies postulated that exposure to phenoxy herbicide, dioxin, or tetracycline may have promoted the development of testicular tumors.[36,37]

Pathology and Pathogenesis

Sertoli cell tumors arise from the sustentacular cells of seminiferous tubules and seminomas arise from the germinal epithelium of seminiferous tubules. Interstitial cell tumors arise from Leydig cells located between seminiferous tubules. All three tumors have relatively distinct appearances grossly, but require histopathology for definitive diagnosis. Sertoli cell tumors are firm, lobulated, white-to-gray in appearance, and often characterized as "greasy" on palpation.[38] Seminomas tend to be homogeneous, soft, and occasionally lobulated with an ivory appearance when sectioned (Fig. 29.2).[38] Interstitial cell tumors are soft, expansive, and yellow-to-orange in color when sectioned and often contain cysts with serous or serosanguineous fluid.[38]

The molecular and cellular biology of primary testicular tumors has been investigated in recent years. Proliferation markers

(proliferating cell nuclear antigen [PCNA], Ki67, and argyrophilic nucleolar organizer regions [AgNORs]) and TERT expression (the catalytic reverse transcriptase subunit of telomerase) have been interrogated as indicators of degree of malignancy, local progression, and metastasis with discordant results.[39–44] Investigators sought to relate TERT to proliferation indices and p53 expression; however, because PCNA and TERT were expressed in all testicular tumors, their prognostic potential is limited.[41] Aggressive testicular tumors did express high levels TERT, p53, PCNA, and Ki67, suggesting these may provide some indication of biologic behavior.[41] Proliferative activity using AgNORs was assessed in canine seminomas, in which mean AgNOR scores were higher in invasive or diffuse tumors compared with well-differentiated intraductal seminomas.[43] Results suggest that testicular tumors develop a proliferative advantage as they become less differentiated, although larger studies should be performed before proliferative indices can be definitively relied on for prognostication in canine testicular tumors. Cyclins, which are intracellular proteins that form complexes with cyclin-dependent kinases to regulate cell-cycle checkpoints, have also been evaluated in normal and neoplastic testes; however, their significance is yet to be determined.[45]

The neoplastic cellular environment plays an important role in tumor invasion and progression, and a few studies have attempted to investigate changes in canine testicular tumors. Laminin is an extracellular matrix protein involved that plays a role in anchoring cells to the basement membrane. As tumors became more invasive, laminin expression became fragmented or lost in Sertoli cell tumors and seminomas, and this correlated with increasing proliferative activity as assessed by PCNA scoring, Ki67 index, and mitotic index.[39] Connexin 43 is the predominant gap junction protein of the testis and plays a role in phenotypic differentiation, cell pattern formation, and morphogenesis; and altered expression patterns may contribute to tumorigenesis and progression.[46–50] Similar to other work, differential alterations in connexin 34 expression occur in canine testicular tumors, and its expression may aid in differentiating neoplastic Sertoli cells from seminomas.[51]

Mutations of the *p53* tumor suppressor gene are common in both human and canine tmalignancies, and increased *p53* expression has been associated with tumor progression.[52–56] Nuclear *p53* immunoreactivity was detected in 15 of 20 seminomas, 6 of 12 Sertoli cell tumors, and all three interstitial cell tumors evaluated.[41] Interestingly, staining intensity was stronger in diffuse type Sertoli cell tumors and seminomas, similar to findings in another study.[41,55] Results suggest that *p53* expression may be an indicator of tumor aggression; however, further studies should be done to corroborate this.[41,55]

Similar to *p53* and proliferation indices, angiogenesis plays an important role in cancer progression and metastasis. Vascular endothelial growth factor (VEGF) and microvessel density (MVD) have been investigated as indicators of the degree of angiogenesis in multiple human and canine tumor types. VEGF expression and MVD were higher in seminomas compared with normal testes in one study.[57] In addition, both VEGF and MVD were higher in diffuse seminomas compared with more well-differentiated intratubular seminomas, potentially providing a histologic indicator of malignant behavior.[57]

The KIT protein or CD117 is a transmembrane protein for a tyrosine kinase receptor encoded by the proto-oncogene c-*kit,* which, when bound to its ligand stem cell factor (SCF), is essential to the development, proliferation, and maturation of several cell types, including germ cells.[58–60] Primordial germinal cells express KIT and migrate to interact with Sertoli cells that express SCF to guide the differentiation of the primordial cells into gonocytes.[61] Interstitial cells of Leydig also express KIT and, when stimulated by SCF, produce testosterone subsequent to Sertoli cell stimulation.[58,61,62] The expression of KIT is maintained by spermatogonia until differentiation into spermatocytes, making it a useful marker to define primordial germinal cells and early germinal cells.[61,63] In human seminomas, immunohistochemical (IHC) labeling for KIT and placental alkaline phosphatase (PLAP) is used to distinguish SE and SS, because SE expresses both KIT and PLAP whereas SS is negative for both.[64,65] Results in dogs with seminomas have suggested that, like in humans, canine seminomas may be differentiated into SE and SS using KIT and PLAP, although the frequency of each subset may affect how relevant the dog is as a model for human seminoma.[21,22,63,66,67] Recent histopathologic and IHC studies have suggested that SE may be rare in dogs, whereas canine SS may be a good model for humans, despite the rarity of SS in men.[66,67] In addition, intratubular germ cell neoplasia of undifferentiated origin and carcinoma in situ are frequent precursor lesions of SS in men, but these are infrequently identified in dogs.[22,33]

Natural Behavior

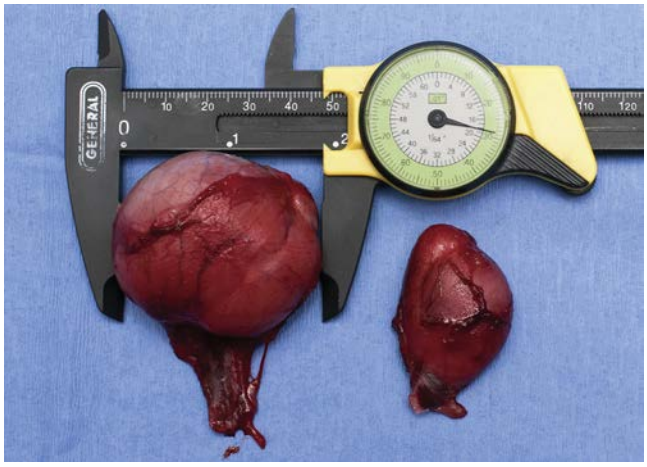
Most primary testicular tumors in the dog are characterized by local invasion and rarely metastasize. Regional or distant metastasis occurs in fewer than 15% of dogs diagnosed with Sertoli cell tumors or seminomas.[6,32,33,68–74] Interstitial cell tumors very rarely metastasize.[6] Sites of metastasis may include regional lymph nodes (LNs), eyes, brain, lungs, kidney, spleen, liver, adrenal glands, pancreas, skin, and peritoneum. [6,32,68–74]

Primary testicular tumors can also cause imbalances in sex hormone levels, regardless of the degree of local invasion and presence or absence of metastasis. Sertoli cell tumors can cause signs of feminization and more than 50% of affected dogs display signs of estrogen overproduction.[14,25,32,69] Seminomas and interstitial cell tumors are rarely associated with feminization.[75–77] Excess estrogen can cause signs such as bilateral symmetric alopecia, cutaneous hyperpigmentation, epidermal thinning, squamous metaplasia of the prostatic epithelium, gynecomastia, galactorrhea, attraction of other males, preputial atrophy, atrophy of the

VetBooks.ir

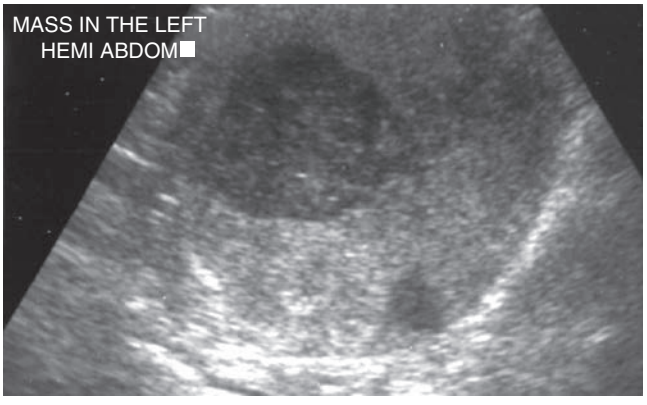
nonneoplastic testicle, and bone marrow suppression.[32] Sertoli cell tumors that develop in retained testicles are more likely to produce signs of hyperestrogenism; however, 17% of dogs with scrotal Sertoli cell tumors developed feminization.[14,25,32,69] Plasma sex hormone concentrations from dogs with primary testicular tumors have been investigated to better understand their contribution to tumor type and clinical signs.[77–80] Estradiol-17β concentrations were higher in dogs with Sertoli cell tumors compared with normal dogs, and were significantly higher in dogs with associated feminization syndrome.[77] Testosterone and testosterone/estradiol ratios are lower in dogs with Sertoli cell tumors compared with healthy control dogs.[76] Plasma estradiol concentrations have been variable, with one study suggesting they were lower in dogs with seminomas compared with normal dogs, but concentrations were not different in another study.[76,77] Clinical signs of feminization due to Sertoli cell tumors may best correlate to testosterone/estradiol ratio reductions rather than absolute increases in estradiol, accounting for this difference in reporting.[76] Because of variation in hormone levels, other biomarkers have been evaluated, including anti-Müllerian hormone (AMH), inhibins (inhibins α, β, βα), 3β-hydroxysteroid dehydrogenases, and insulin-like growth factors (IGF-1 and IGF-2).[77–81] AMH, alternatively termed Müllerian inhibiting substance (MIS), is a glycoprotein in the transforming growth factor-beta (TGF-β) family that is produced by Sertoli cells to stimulate regression of the Müllerian ducts in males.[82] Serum AMH may have promise as a biomarker for Sertoli cell tumors in dogs; significantly higher serum AMH has been found in a small number of dogs with Sertoli cell tumors compared with healthy adult dogs.[81]

History and Clinical Signs



Most dogs with testicular tumors are asymptomatic and a testicular mass is discovered as an incidental finding; however, clinical signs may be attributable to the primary tumor, to the presence of metastasis, or to paraneoplastic syndromes such as hyperestrogenism. In addition, breeding dogs may present with fertility problems. Diagnosis is usually made via palpation of an enlarged testicle or a testicular mass during routine physical examination, abdominal ultrasound, or necropsy. Atrophy of the remaining normal testicle is common (Fig. 29.3). Tumors in cryptorchid dogs may cause a regional mass effect within the caudal abdominal cavity or inguinal region (Fig. 29.4).

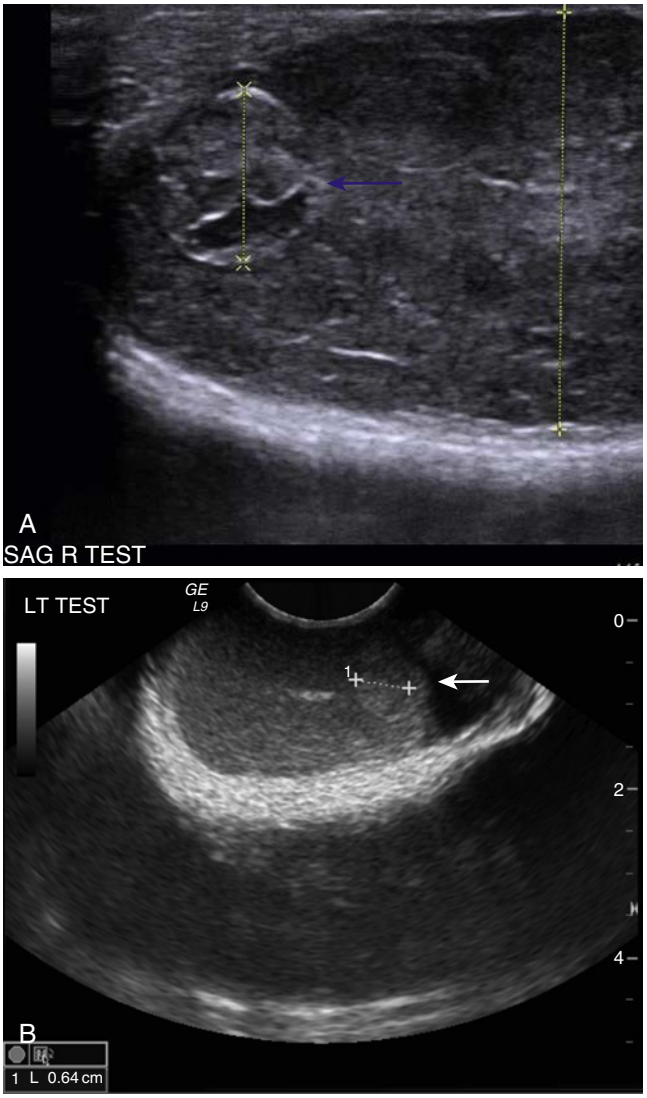
Excess estrogen may cause signs of feminization and is the most common paraneoplastic syndrome associated with canine testicular tumors. As stated previously, seminomas and interstitial cell tumors are rarely associated with feminization whereas 50% of dogs with Sertoli cell tumors can show signs of hyperestrogenism.[14,32,69,75–77] Common clinical signs include bilateral symmetric alopecia and hyperpigmentation, pendulous prepuce, gynecomastia, galactorrhea, atrophy of the penis, and squamous metaplasia of the prostate.[32] The most deleterious effect of hyperestrogenism is bone marrow suppression, which may be irreversible and life threatening. Early effects of estrogen on the bone marrow include a transient increase in granulopoiesis with peripheral neutrophilia followed by progressive neutropenia, thrombocytopenia, and nonregenerative anemia.[75,83] Severe pancytopenia from bone marrow hypoplasia and blood dyscrasias can be fatal, and clinical signs can range from hemorrhage secondary to thrombocytopenia, anemia, and febrile neutropenia.[75,83] Less common signs associated with testicular neoplasia include lethargy (Sertoli cell tumors), presence of concurrent prostatic cyst or abscess, hematuria, hemoperitoneum, spermatic cord torsion, hypertrophic osteopathy, and perianal gland hyperplasia/adenomas (interstitial cell tumors).[3,32,69,84–87] Sertoli cell tumors have also been reported in cryptorchid male pseudohermaphrodites, which may disproportionately affect miniature Schnauzers.[88–92]



Diagnosis and Staging

Physical examination of intact male dogs, and particularly older dogs, should always include palpation of the testicles for masses and/or asymmetry. A thorough rectal examination should be performed to evaluate the prostate gland, regional LNs, and perianal region. In dogs with clinical signs of hormone imbalance (excess estrogen or testosterone), serum testosterone and estradiol-17β can be measured along with testosterone/estradiol ratio.[76,77] It is important to note that not all dogs with signs of feminization have absolute increases in estradiol-17β and clinical signs may be more closely linked to altered androgen/estrogen ratios.[76]

Definitive diagnosis is achieved by histopathologic evaluation, although the presence of a testicular mass and cytology may be supportive of testicular neoplasia. Because most dogs with testicular tumors are older and therefore have a high risk of another



• **Fig. 29.3** Large left seminoma with mild atrophy of the right normal testicle identified as an incidental finding on physical examination.

primary tumor (up to 50%) or concurrent diseases, complete staging before surgery is generally recommended. Preoperative staging typically includes a complete blood count (CBC) to evaluate for hematologic abnormalities, chemistry profile, urinalysis, abdominal ultrasound, and three-view thoracic radiographs. A coagulation profile may be warranted in dogs with anemia and signs of hemorrhage. Abdominal ultrasound may serve multiple purposes: it can aid in identification of undescended testicles in the abdominal cavity or inguinal canal, assessment of regional LNs, assessment of prostatic changes, and evaluation of common sites of metastasis, such as the spleen and liver (Fig. 29.5). Testicular ultrasonography may aid in differentiating neoplastic processes from orchitis, testicular torsion, and epididymitis; however, changes are not specific enough to identify tumor type.[93–95] Ultrasound-guided fine needle-aspiration (FNA) may support a suspicion of neoplasia before orchiectomy, particularly in breeding animals.[93,96] For owners with financial constraints, minimum staging should consist of CBC, chemistry profile, and urinalysis. Castration may be performed before full staging for some cases, with the decision to do full workup after histopathologic evaluation, because it is appropriate therapy for most testicular tumors. Histopathologic diagnosis is generally straightforward; however, IHC staining for vimentin, cytokeratin, desmin, c-kit, PLAP, and inhibin may be indicated to identify the underlying cell of origin.[26,33,78,97–100]

Treatment and Prognosis

As most primary canine testicular tumors are characterized by local infiltration with low potential for metastasis, orchiectomy with scrotal ablation is the treatment of choice and is often curative. Bilateral orchiectomy is the treatment of choice for testicular tumors, given that up to 50% of dogs in one report had bilateral tumors with only 12% being clinically detected in the opposite testicle.[15] In valuable breeding dogs, unilateral orchiectomy can be considered with continued monitoring afterward.[101,102] Exploratory laparotomy is indicated in cryptorchid dogs so the regional LNs can be visually assessed and biopsied if indicated. In dogs with signs of hyperestrogenism secondary to the primary tumor, clinical signs typically resolve within 1 to 3 months after castration, unless metastatic lesions provide persistent estrogen release.[68,69,74] Recurrence of feminization after castration may be associated with the development of metastasis.[69] Serum sex hormone levels may be monitored as well after castration and may correlate with resolution of clinical signs.[76,103] Dogs with bone marrow hypoplasia secondary to estrogen toxicity require close monitoring perioperatively and postoperatively for complications requiring medical intervention with blood products and/or antibiotics. These dogs carry a guarded prognosis owing to the high morbidity and mortality associated with neutropenia and hemorrhage.[75,83] Dogs with aplastic anemia likely warrant a poor prognosis.[75]

Primary testicular tumors occasionally metastasize to regional LNs and distant sites, and therapy other than surgery may be warranted in these dogs. Optimal management employing chemotherapy, radiation therapy (RT), and novel targeted therapies is not currently known. Cisplatin, actinomycin-D, chlorambucil, mithramycin, and bleomycin have been used; however, too few dogs have been treated and evaluated to formulate any conclusions regarding efficacy.[70,71,73,104] Cisplatin was evaluated in three dogs with aggressive testicular tumors with survival times (STs) ranging from 5 months to greater than 31 months.[70] RT was successfully used in four dogs with metastatic seminoma confined to the regional LNs using total doses ranging from 17 to 40 Gy with cesium-137 teletherapy.[105] In all four cases, tumors regressed and STs ranged from 6 to 37 months; importantly, none of the dogs died of seminoma. One dog that died 6 months after RT had no evidence of seminoma at necropsy.[105] Even though this was a small report, further studies are warranted to evaluate the role of external beam RT in managing metastatic seminomas because of its inherent high radiosensitivity.[106]

Feline Testicular Tumors

Feline testicular tumors are rare, although Sertoli cell tumor, seminoma, interstitial cell tumor, and teratoma have been reported.[35,107–113] The biologic behavior of testicular neoplasia in

VetBooks.ir

the cat is unclear because of the sparse literature available. Metastasis of a Sertoli cell tumor to the liver and spleen, and a teratoma to the omentum have been reported; therefore staging is recommended.[110,113] Optimal therapy other than orchiectomy is not known.

Comparative Aspects

In the United States testicular cancer is the most common cancer in men 15 to 44 years old, but is one of the most curable cancers with early diagnosis.[107–109] Studies have shown an increase in testicular cancer over the past half-century, with significant shifts in the age at presentation over time.[107,108,110] Causal factors such as genetic predisposition, maternal estrogen exposure, occupational hazards, dietary factors, smoking habits, and birthplace have been evaluated but, to date, the most established risk factor remains cryptorchidism.[23,107,111–120] Most cancers in men are germ cell tumors and are broadly divided into pure seminomas and nonseminomas, with seminomas comprising 50% of tumors in this group.[13,20,109] Seminomas are further classified into SE, atypical, or SS subtypes; however, diagnostic and therapeutic management does not vary considerably between tumor types.[20,109] Pure seminomas are more likely to behave in a clinically aggressive fashion; therefore when both seminoma and nonseminoma features are present, therapeutic management follows the guidelines for nonseminoma.[109] Standard staging in human seminomas consists of physical examination, radiographic studies, determination of serum markers, including alpha-fetoprotein, human chorionic gonadotropin, and lactate dehydrogenase, and histopathologic assessment. SS is a rare variant of germ cell neoplasia that is most commonly seen in older men and carries a low risk of metastasis, suggesting similar behavior to most canine seminomas.[21,23] Treatment generally includes surgery for stage I seminomas, and/or RT and chemotherapy for individuals with higher stage disease.[106,121–123] Cisplatin-based chemotherapy protocols are generally employed for patients with greater than stage I disease, with cure rates in the range of 70% to 80% despite high tumor burdens.[23,106,109,124] The dog has been proposed as a model for studies of the male reproductive system, and in particular for studies evaluating the development of testicular tumors.[18,21,22,33] Further work on the molecular pathogenesis, classification system, and behavior of canine tumors may yield more support for use of spontaneously occurring testicular tumors as good comparative models for human disease.

Canine Prostate Tumors

Incidence/Prevalence

Prostatic tumors are relatively uncommon in dogs and have a low prevalence at less than 1% (0.2%–0.6%).[132–136] In a collection of more than 17,000 confirmed neoplasms of the dog collected from veterinary schools in North America, only 11 prostate carcinomas (PCAs) were identified (0.06%).[34] A study evaluating lifetime occurrence of neoplasia in predominantly intact German shepherd dogs and Belgian Malinois working dogs showed that more than 30% developed at least one cancer; however only 2 of the 104 primary tumors were PCAs.[17] Despite this low incidence, the dog is one of the few domestic species to develop spontaneous prostate cancer, thus sparking interest in the dog as a model for prostate cancer in men.[135,137–143] In three retrospective reviews of dogs with prostatic disease, between 7% and 16% were diagnosed with PCA.[144–146] One study of 177 dogs found that PCA was the most common disease in neutered dogs whereas bacterial prostatitis and prostatic cysts were more common in intact male dogs.[145] Elderly dogs are more commonly diagnosed with PCA, with a median age at diagnosis of 10 years.[135,146–148] The underlying etiology of canine prostatic cancer is unknown; however, high-grade prostatic intraepithelial neoplasia (PIN or HGPIN), which is believed to be a precursor of human prostate carcinoma, has been detected in both dogs without evidence of prostatic disease and in those with existing PCA.[149–152] The occurrence of PIN in dogs with concurrent carcinoma varies from 7% to 72%, although in two large studies of dogs without histologic evidence of PCA, the occurrence was low at 0% to 3%.[134,149–152]

Most tumors of the canine prostate are carcinomas, with most being transitional cell carcinoma (TCC) or adenocarcinoma in origin.[153–156] Prostate tumors in the dog likely have a urothelial or ductular origin rather than acinar because most canine tumors are androgen independent.[153,154,157–160] Other types of carcinomas include mixed carcinomas and squamous cell carcinomas (SCCs). Classifying carcinomas on the basis of subtype is somewhat subjective and there is not currently a standard for definitive diagnosis of canine prostate tumors as there is with humans.[151,152,161–165] Fibrosarcoma, leiomyosarcoma, osteosarcoma, lymphoma, and hemangiosarcoma have also been reported to affect the prostate.[134,166–171] Benign tumors of the prostate are rare.[172] TCC of the prostatic urethra will frequently invade the prostate, and it may be difficult to distinguish primary PCA from secondary invasion of a urethral tumor.

Risk Factors

Both intact and castrated dogs develop PCAs, although multiple studies have suggested there is an increased risk of PCA in castrated male dogs compared with intact male dogs, with an odds ratio of approximately 2.3 to 4.3.[132,146,147,153,157] More aggressive tumors may develop in castrated males with a higher risk of metastasis.[147] The reason for this difference is unclear, although it is possible that castrated dogs live longer than intact dogs and are thus predisposed to developing age-related cancers.[146,153] It is also possible that androgens provide a protective effect on prostatic tissue, or that, after castration, the relative estrogen effect aids in neoplastic transformation.[153,173–175] The lowest relative risk of neutered males in a recent study was for PCA, which may occur relatively more frequently in intact male dogs.[134,151,153] Although several studies have suggested that androgens may not be required for initiation or progression of adenocarcinoma of the canine prostate, further controlled studies should be done to definitively determine the role of androgens or the effect of early or late castration.[153,154,157,159,160,176]

Breeds that may be at increased risk of developing PCA include the Bouvier des Flandres, Doberman pinscher, Shetland sheepdog, Scottish terrier, beagle, miniature poodle, German shorthaired pointer, Airedale terrier, and Norwegian elkhound.[146,153] The Shetland sheepdog and Scottish terrier remained at increased risk even when TCC was excluded in one study.[153] Mixed-breed dogs have also been reported as at increased risk for PCA, regardless of neutering status, suggesting that environmental influences may play a significant role in tumor development.[153] The American cocker spaniel, miniature poodle, and dachshund may be at decreased risk for developing PCA.[153]

VetBooks.ir

Natural Behavior

At the time of diagnosis, most canine prostatic tumors are characterized by local invasion with a high propensity for regional and distant metastasis. In one postmortem study of 76 dogs, 80% of dogs with PCA had evidence of measurable metastatic disease, with lung and LNs being the most common sites of spread.[134] Importantly, similar to high-grade PCA in men, canine PCA has a tendency to metastasize to bone: 22% to 42% of dogs develop skeletal metastasis, predominantly to the lumbar vertebrae and pelvis.[134,159,177,178] Younger dogs diagnosed with PCA may be at increased risk for metastasis than older dogs, although the role of castration status in these two groups is unclear.[134,179] As long-term studies in dogs with evidence of PIN but without PCA are not available, it is unclear if PCA in dogs can behave in a slowly progressive fashion in its early phase of development. It is presumed that most dogs are diagnosed at an advanced stage of disease because of the high metastatic rate; however, the true behavior from time of onset is not definitively known and PCA may behave differently in intact and castrated dogs.[146,147]

Pathogenesis

The underlying cause of prostate tumors is unknown, and it is possible that both genetic and environmental factors contribute to tumor development. HGPIN is considered a precursor of human PCA and occurs under the influence of androgenic stimulation in those patients at risk for carcinoma.[180] Although PIN has been detected in dogs with existing PCA, it has also been detected in dogs without evidence of prostatic disease, making its role in the dog less clear.[149–151] HGPIN as a predictor of carcinoma occurrence may not be as reliable in the dog as it is in men.[150,173] It is not known with certainty if low- and intermediate-grade PIN occurs in dogs, although one IHC study suggested the presence of low-grade PIN.[181] Investigators evaluated five prostates from middle-aged to older intact dogs containing lesions of PIN and compared nuclear protein p63 (marker of prostatic basal cells), androgen receptor expression, and PCNA to normal prostatic tissue also obtained from intact dogs. PIN foci had higher p63 expression, higher PCNA index, and heterogeneous androgen receptor (AR) expression, suggesting similarities to human low-grade PIN.[181] Prostatic inflammatory atrophy has also been identified in dogs and humans, which may be a precursor of PIN lesions or PCA.[143,152,182–185] Several studies have attempted to elucidate key changes in gene and protein expression in prostate carcinogenesis to develop and investigate targeted approaches that interrupt carcinogenesis and progression.[143,163,182,183,186–188]

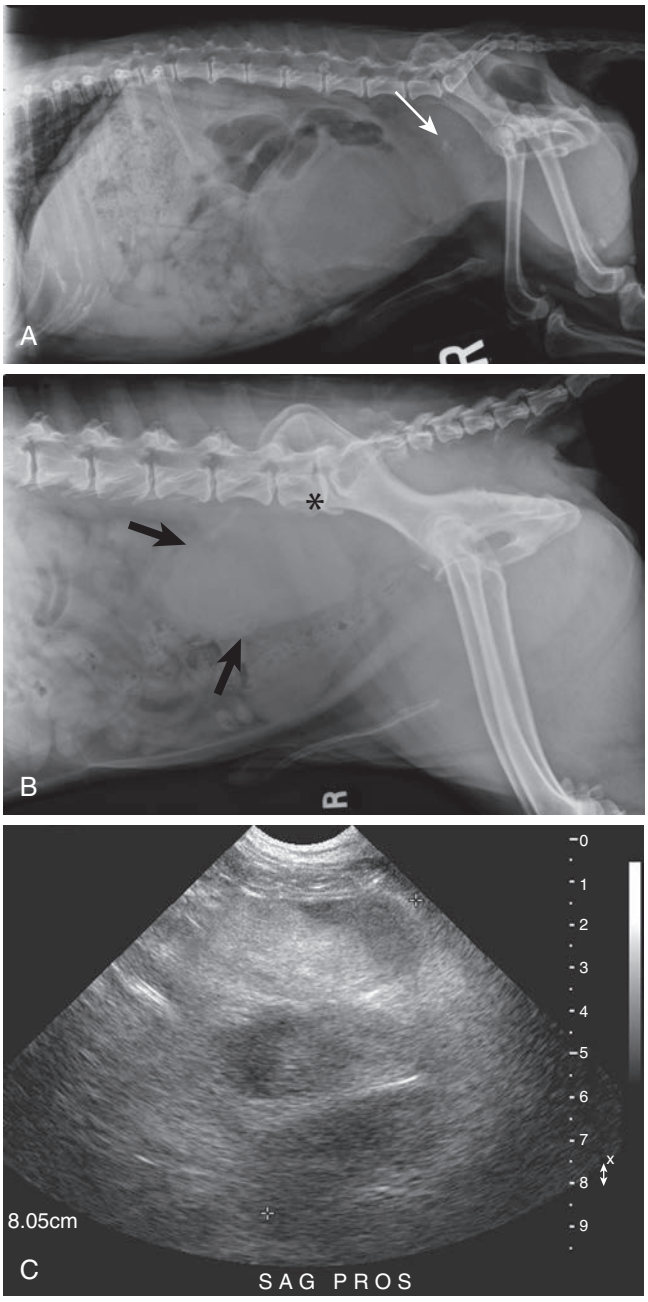
The role of hormones in prostate development and tumor progression is unclear in the dog. Castration does not provide a protective effect and, in fact, may contribute to tumor development and/or progression, although PCA may behave differently in the intact male compared with the neutered male.[146,147] Normal prostate development and regulation in humans and dogs is androgen dependent; however, neoplastic human prostate most commonly remains androgen dependent as opposed to the dog. AR expression within the nuclei can be identified in 90% to 95% of normal (intact) prostatic secretory epithelial cells and in the majority of acinar basal cells.[159,160,189,190] In neutered dogs and in dogs with PCA, nuclear AR expression decreases and is usually lost.[159,160] The role of estrogen and progesterone has yet to be fully defined, although nuclear estrogen receptor expression appears to be decreased in PCA tissue compared with normal and hyperplastic prostate tissue.[158,190]

Because of its aggressive behavior at the time of diagnosis, some investigators have considered mechanisms that may contribute to PCA progression and metastasis. Activating mutations in the *BRAF* gene, which lead to constitutive MAPK signaling, were found in the majority of PCA in dogs. Moreover, the mutation frequency was similar between PCA and urothelial (bladder) TCC.[191,192] This is uncommon in nonmetastatic human prostate cancer, but may support the current hypothesis that most canine PCAs arise from the prostatic ducts or prostatic urethra.[134,154,157,193–196]

Cyclooxgyenase-2 (COX-2) expression may play a role in carcinogenesis and progression in PCA. Expression of COX-2 was noted in 75% of PCAs in one study, whereas none of the normal prostate tissue stained positively.[197] Two other studies have supported the notion that COX-2 and downstream prostaglandin E_2 production may play a role in PCA development.[198,199] Indeed, a clinical study identified COX-2 protein expression in 88% of 16 PCAs examined and was further able to show a survival benefit in dogs treated with either piroxicam or carprofen.[200]

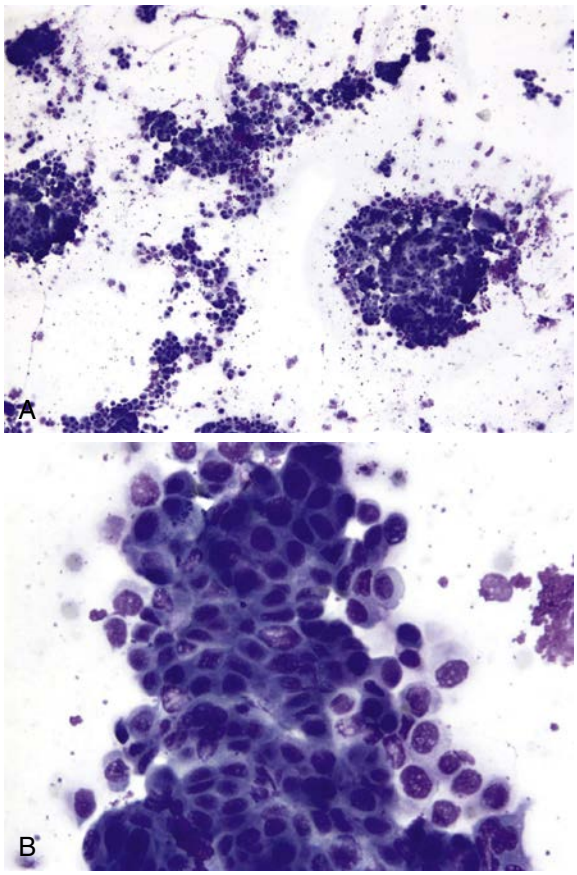
PCA has a predilection for bone, which may be mediated in part by TGF-β, parathyroid hormone–related protein (PTHrp), and endothelin.[201–203] PTHrp mediates pathologic bone resorption in many different tumors, including PCA, which may encourage release of TGF-β into the microenvironment. In a positive feedback loop, canine PCA cells can increase gene transcription for PTHrp in response to exogenous TGF-β.[202] Although PTHrp and TGF-β may be important in establishing skeletal metastases, it is interesting to note that PCA metastases are more commonly osteoblastic in nature.[173,204,205] In a rat model, osteoblast activation was increased after incubation with normal canine prostate protein homogenates through an endothelin-dependent pathway, suggesting a possible contribution to bone metastasis formation.[203] Recent gene expression profiling work in human castration-resistant prostate cancer (CRPC) has shown high AR expression is correlated to genes controlling osteoblast/osteoclast activity, cellular metabolism (i.e., cholesterol synthesis, fatty acid oxidation, pyrimidine synthesis), and immune cell infiltration, all of which may influence therapeutic regimens.[206,207]

History and Clinical Signs



Clinical signs in dogs with PCA are variable and may be reflective of local and/or metastatic disease. Common historical findings and clinical examination signs include hematuria, dysuria, stranguria, dyschezia, tenesmus, bacteriuria, and altered stool shape (flattened or ribbonlike stools).[134,147,155,178,208] With complete obstruction of urinary outflow due to prostatic compression or direct tumor extension into the urethra, hydroureter, hyrdronephrosis, and renal failure may occur. Local invasion into the lumbar vertebrae or nerve roots may cause signs of pain, gait abnormalities, lameness, and/or constipation. Nonspecific systemic illness, typically associated with advanced disease, include lethargy, exercise intolerance, tachypnea or dyspnea, hyporexia, and weight loss. Dogs with skeletal metastasis may present with signs of severe bone pain, pathologic fracture, or rarely with a palpable mass.[134,178,209] Dogs may present with a history of clinical signs that partially improved with empiric therapy for prostatitis.

Diagnosis and Staging



Dogs that present with suspected PCA should be fully staged to determine extent of disease and to rule out other causes of prostatic disease such as benign prostatic hypertrophy (BPH), prostatitis, and prostatic cysts or abscesses.[155,210,211] Physical examination, including a thorough rectal examination, should be performed on every patient. Rectal palpation often reveals a large, firm, and asymmetric or irregular prostate that may be painful. Sublumbar lymphadenomegaly may be detected on rectal or abdominal palpation. A normal-sized prostate on rectal examination in a castrated dog is considered abnormal, even if symmetric and nonpainful. CBC and serum chemistry profile may demonstrate anemia, leukocytosis, hypocalcemia, elevated bone alkaline phosphatase activity, or signs of concurrent disease.[147,148,212] Urinalysis and culture may show pyuria, bacteriuria, dysplastic urinary epithelial cells, and secondary urinary bacterial infection.[134,145,147,173,212,213] Three-view thoracic radiographs may show evidence of pulmonary metastatic disease, sternal lymphadenomegaly, or rarely metastasis to the extrathoracic skeletal structures (ribs, scapula).[178] Abdominal radiographs may show evidence of an enlarged prostate, with or without evidence of mineralization; periosteal reactions on the vertebrae, femur, or pelvic bones; and/or sublumbar or retroperitoneal lymphadenomegaly (Fig. 29.6A, B).[147,178,214,215] It is important to note that the presence of mineralization, particularly in intact dogs, is not pathognomonic for neoplasia and can occur in dogs with prostatitis, BPH, or prostatic cysts[215–217]; however, neutered dogs with prostatic mineralization are highly likely to have prostatic neoplasia and should undergo further diagnostics.[215] If a clinical suspicion of skeletal metastasis exists, survey radiographs or bone scintigraphy may be useful for localization.[209] PCA metastases to bone most commonly have an osteoproductive component, but may be osteolytic, osteoproductive, or mixed. Contrast studies such as retrograde urethrography may be useful to evaluate irregularities in the prostatic urethra or reflux of contrast into a prostatic mass; however, they are not specific enough to differentiate neoplasia from inflammatory or infectious processes.[214,218] Abdominal ultrasound can be useful to further evaluate the prostate, urethra, bladder, regional LNs, and cranial abdominal organs. Lymphadenomegaly, echogenicity changes, and mineralization may be visualized on ultrasound in dogs with prostatic neoplasia, although they can also be features of nonneoplastic diseases (see Fig. 29.6C).[214,215]

Obtaining tissue samples is considered the gold standard of diagnosis of canine prostatic neoplasia. One retrospective histopathologic study highlighted several different histologic patterns that may be important to providing an accurate diagnosis of PCA.[152] More recently, proposals for a Gleason-type grading system have been made to provide some level of prognostication in dogs and to better correlate findings to prostate cancer in men.[163–165] In human PCA, the Gleason grading system assesses the architecture of biopsy sections and is used to assign a Gleason score based on the sum of the Gleason pattern identified in the largest area (the primary grade) and the highest grade (secondary grade).[219,220] The Gleason score has been modified over time but has maintained its reliable and robust prognostic significance; thus there is interest in adapting this type of system to dogs.[220]

A definitive diagnosis of prostatic neoplasia may be garnered from cytology samples as well.[155,213] A number of methods may provide adequate samples for diagnosis, including ejaculation, traumatic catheterization, prostatic massage, prostatic wash, ultrasound-guided FNA cytology, impression smears during surgery, or biopsy via percutaneous, perineal transrectal, or surgical routes. Risks of percutaneous biopsies, ultrasound-guided aspirates or biopsies, and transrectal aspirates include hemorrhage, urethral trauma, and tumor seeding[210,221–224] Cytology or histology of suspected metastatic lesions (e.g., LN) may also aid with diagnosis and offer a simpler method of diagnosis (Fig. 29.7). Histologic grading of PCA is not routinely performed because there is no

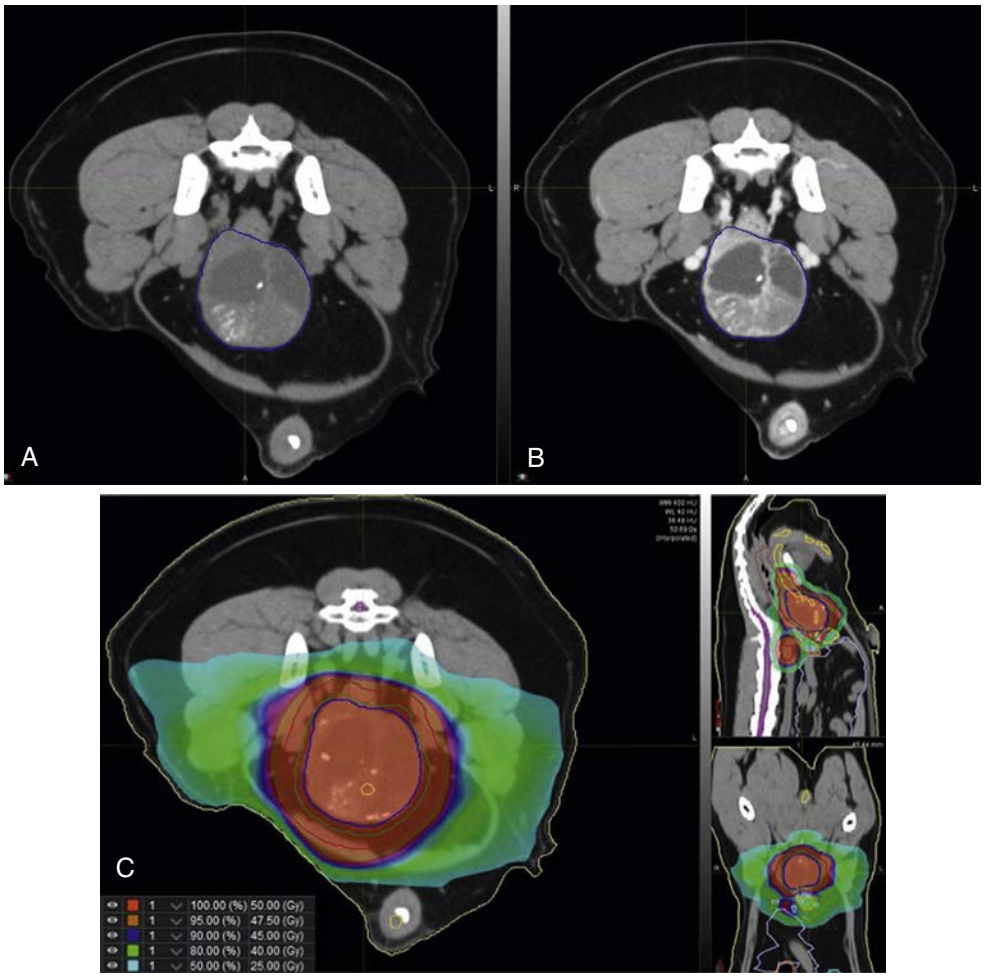
support for its effect on prognostication.[134,225] Cytologic evaluation of samples collected via traumatic catheterization or prostatic wash may prove challenging, as it can be difficult to differentiate dysplastic epithelial cells from neoplasia.[213,226] In one study, discordant results between cytology and histology in prostatic disorders occurred in 20% of cases, but were not considered a flaw of aspiration techniques but rather of the pathologic process.[213] Multiple techniques were employed, including ultrasound-guided FNA, prostatic massage and wash, and impression smears of biopsies. Other factors, such as serum and seminal plasma concentrations of acid phosphatase (AP), prostate-specific antigen (PSA), and canine prostate-specific esterase, have not been useful in the definitive diagnosis of PCA in the dog.[133,227] Although significantly higher serum total AP, prostatic AP, and nonprostatic AP concentrations were noted in dogs with PCA compared with healthy dogs or dogs with BPH, they were neither sufficiently sensitive nor specific for definitive diagnosis.[227]

Treatment and Prognosis

Because PCA in dogs is characterized by insidious local progression and a high rate of metastasis, most dogs are diagnosed with advanced disease and the overall prognosis is poor. Median survival times (MSTs) for dogs without therapy are often less than 30 days and, in one report of 76 dogs, most dogs were euthanized at the time of diagnosis.[134,200] If therapy is attempted, effort is generally made to control local disease in addition to locoregional and distant metastases, although therapy is considered largely palliative. There is currently no standard-of-care consensus therapy for canine prostate tumors, although use of nonsteroidal antiinflammatory drugs (NSAIDs) is recommended as minimal therapy.



Therapeutic options for managing local disease include partial or total prostatectomy, electrosurgical transurethral resection (TUR), photodynamic therapy (PDT), RT, laser therapy, and medical management. Prostatectomy is generally recommended for dogs with early stage, intracapsular disease, but case selection is likely important for good outcome. Total prostatectomy is associated with a moderate to high rate of postoperative morbidity and a survival benefit over medical management has not been investigated.[148,228–233] The entire prostate gland and associated urethra are removed with total prostatectomy, thus requiring reconstruction for urinary drainage. The most common complication is urinary incontinence, occurring in 33% to 35% of dogs.[148,231,232] A recent multiinstitutional retrospective study described total prostatectomy in 25 dogs that included 9 dogs with extracapsular extension of tumor and 11 dogs with intracapsular tumors. All dogs survived prostatectomy and 21 received variable adjunctive therapy, most commonly mitoxantrone and NSAIDs (n = 14).[148] The MST for all dogs was 231 days and dogs with intracapsular tumors had a significantly longer MST than those with extracapsular tumors (248 days vs 138 days).[148] Local recurrence and/or distant metastasis were suspected in over 30% of dogs, thus justifying the prospective exploration of surgery and additional local and systemic therapy for some dogs.[148] Subtotal intracapsular prostatectomy may be a useful alternative in some dogs. In one study that compared 10 dogs that underwent total prostatectomy to 11 dogs that underwent subtotal intracapsular prostatectomy, the latter procedure was associated with longer mean STs (112 days vs 20 days) and a decreased rate of postoperative complications.[230] Importantly, 7 of the 10 dogs that underwent total prostatectomy were euthanized within 2 weeks of surgery compared with only two dogs in the subtotal intracapsular prostatectomy group.[230] The high acute (within 2 weeks) postoperative mortality rate in dogs that underwent total prostatectomy in this randomized study may be reflective of less stringent case selection given the results of the more recent report of total prostatectomy in dogs.[148,230] As urinary incontinence is common after prostatectomy, attempts have been made to reduce trauma to the prostatic urethra, including use of a neodymium:yttrium–aluminum–garnet (Nd:YAG) laser; however, there is still a risk of significant postoperative complications.[229,232,233] Rapid palliation of dysuria was reported after TUR using an electrocautery cutting loop with or without intraoperative RT in three dogs with prostatic TCC or undifferentiated carcinoma.[212] Complications occurred in all dogs and included urinary tract infection, tumor seeding, and urethral perforation, and STs were relatively short.[212]

In dogs with urethral obstruction due to a prostatic tumor, palliative measures may be attempted to alleviate the obstruction. Placement of a cystostomy tube permits urinary diversion and bladder emptying, but owners should be aware that it generally does not resolve incontinence or stranguria and secondary urinary tract infections are common.[234–236] Palliative stenting of the urethra in the obstructed area is a reasonable alternative to cystostomy tubes and is the authors' preferred option. The extent and location of the obstruction is determined

using fluoroscopy or digital radiography and stents are typically selected to extend approximately 1 cm proximal and distal to the obstruction.[166,237–239] The use of digital radiography to guide stent placement is relatively new and may require more cautious placement.[237] Stents can be ordered in various diameters and are recommended to be 10% greater than the diameter of healthy-appearing urethra. The procedure is considered palliative and complications include incontinence (which may be severe in 25% of cases), stranguria, reobstruction, and stent migration.[166,237–239] Although the literature reporting outcome for dogs treated with stenting and chemotherapy is still maturing, studies suggest that the addition of NSAIDs with or without chemotherapy may be beneficial.[238]

PDT may be a viable option for some dogs with minimally invasive PCA, although its availability is not widespread.[240] PDT remains predominantly investigational at this time, although several reports have suggested that the dog provides a good model to support clinical applications for novel treatments for PCA.[241–246] Challenges in delivering homogeneous doses may limit the utility of PDT in advanced tumors.

RT may be useful in the palliation of clinical signs related to local PCA and to painful skeletal metastases, although optimal dose and fractionation are unknown. In an older study, 10 dogs with PCA were treated with intraoperative orthovoltage therapy.[247] Nine of the dogs were prescribed 20 Gy to 30 Gy to the prostate with an MST of 114 days, although the range extended to 750 days.[247] It is probable that with advances in RT planning and delivery involving the routine use of 3D conformal RT (CRT) or intensity-modulated RT (IMRT) with image-guided RT (IGRT) to confirm target positioning, local disease may be better targeted and controlled (Fig. 29.8). A recent retrospective study described definitive-intent IMRT/IGRT in 21 dogs with genitourinary carcinomas that were prescribed 54 to 58 Gy in 20 fractions to the primary target volume.[248] Ten dogs had prostatic carcinomas completed treatment and had an event-free survival time of 317 days; the overall event free survival time and overall survival time reported for all 21 dogs was 317 days and 654 days, respectively.[248] Although multimodality therapy and NSAIDs were not standardized, results support further prospective evaluation of RT for long-term control. Given the potential for durable tumor control after RT, it will be important to monitor for late radiation toxicity, as approximately 20% of dogs developed manageable grade 3 late toxicity (including urethral, ureteral, and rectal stricture), despite the small fraction size.[248] It is unclear if improving local control with RT will alter the time or pattern of metastasis but prospective efforts to elucidate the role of RT are warranted.

• **Fig. 29.8** Precontrast (A) and postcontrast (B) films of a dog with a large, mineralized, and heterogeneous prostatic carcinoma causing dorsal deviation and compression of the colon. The *blue outline* represents the gross tumor volume. (C) Radiation dose distribution illustrated with colored isodose lines around the prostate on an axial CT image.

VetBooks.ir

The benefit of systemic therapy to manage canine prostatic tumors is also unclear, although a study demonstrated a clear survival benefit in dogs with PCAs treated with piroxicam or carprofen compared with those dogs that were untreated (MSTs of 6.9 months vs 0.7 months, respectively).[200] The role of chemotherapy is less clear.

For dogs with skeletal metastasis, palliative options include systemic analgesics, RT, bisphosphonates, and samarium-153–ethylenediamine–tetramethylene–phosphonic acid (^{153}SM-EDTMP).[249–251] Standardized protocols have not yet been determined, although RT and bisphosphonates are widely available and relatively easy to administer.[249,251–253]

Feline Prostate Tumors

Prostate tumors in the cat are rare and reports in the veterinary literature are sparse.[254–259] Of the few case reports, most tumors appear to be adenocarcinomas and affect older castrated cats. Definitive risk factors have not been identified because of the lack of frequent cases and epidemiologic data. Clinical signs often include lower urinary tract signs and obstipation or constipation, tenesmus, and dyschezia. Rectal palpation can reveal the presence of a mass, which may be further characterized with abdominal ultrasound. There is no standard-of-care therapy in cats and given the paucity of reports in the literature, it is difficult to state overall prognosis. Metastasis appears common and sites of spread can include pancreas, lung, and LNs; most cats died within 3 months of diagnosis.[254–258] Prostatectomy for a low-grade prostatic sarcomatoid carcinoma in one cat provided long-term control with no evidence of local or metastatic disease at 2 years.[259] Prostatectomy followed by doxorubicin and cyclophosphamide was reported to yield a survival duration of 10 months in another cat.[255] Until more cats with PCA prostatic carcinoma are evaluated, therapy and prognosis are unclear.

Comparative Aspects

The recommendations for diagnosis and treatment of PCA in men have changed markedly in the past decade, particularly in the United States, where the value of PSA as a reliable biomarker has been debated.[219,260] Where much emphasis is placed on early detection in most tumor types, there has been a dramatic decrease in the screening for PCA owing to the increased treatment of clinically insignificant tumors, which increase morbidity and mortality compared with that associated with natural cancer progression.[219,261] Active surveillance is now implemented for many men with low-risk PCA and screening recommendations have recently been updated to align with other countries.[260–264] After modifications to the US Preventative Services Task Force (USPSTF) draft guidelines, the USPSTF, American Cancer Society, American Urological Association, the American Society of Clinical Oncology, the American College of Physicians, and the National Comprehensive Cancer Network all advocate for patient education and "shared decision making" when considering screening high-risk groups, men with a family history, or when other factors may influence the likelihood of nonindolent PCA.[260,261,263] Newer PCA biomarker panels may outperform PSA alone as useful screening tools, especially in high-risk disease.[260,265–267]

Well-established and consistent risk factors for PCA in men are race/ethnicity, family history, and age, although other factors such as diet and lifestyle may contribute as well.[219,268] Despite the lack of clear evidence for a direct causal role in the development of PCA, preventative measures have focused on low-fat diets, regular exercise, and maintenance of a normal body mass index.[219] Like in dogs, most prostatic tumors in men are carcinomas; however, the incidence of disease is considerably higher in men. Because the dog is one of the few domestic species to develop spontaneous PCA, there is indeed considerable interest in the dog as a model for PCA in men.[135,137–143] Challenges that exist when considering the dog as a model include the lack of canine PSA that is similar to human PSA, and the most tumors in dogs are likely androgen independent.[133,219,269] PCA in men typically initiates as PIN, which is often seen as multifocal premalignant lesions that progress to neoplasia; the role of PIN in the development of canine prostatic diseases in either the intact or castrated dog is unclear. High-grade PCA in men behaves similarly to the disease in dogs, with significant local invasion and a propensity for skeletal metastasis. Although less common in man, the dog may serve as a good model for interventional strategies for androgen-independent, aggressive PCA. Therapy in humans is highly dependent on the stage at presentation and partially dependent on a summary of risks versus benefit of intervention.[219,270–272] Newer robotic surgery approaches are currently being evaluated in an attempt to improve perioperative and postoperative outcome after prostatectomy, which has traditionally been performed as an open or laparoscopic surgery.[272–274] Advances in RT technology have also led to the safe delivery of higher doses of radiation to prostate tumors, which has improved disease control while maintaining quality-of-life measures.[219,264,270,275,276] Although there are many nuances to treatment beyond the scope of this chapter, androgen deprivation therapy generally forms the basis for therapy for hormone-sensitive prostate cancer; for CRPC, improvements in outcome may be possible with docetaxel with or without novel targeted drugs such as abiraterone, a cytochrome P450 (17) inhibitor, and enzalutamide, an antiandrogen.[219,277–279] The approaches to screening and treatment are changing rapidly and warrant attention as novel drugs are developed, as many of these drugs that have efficacy against CRPC may be applicable to canine PCA.

Canine Penile, Preputial, and Scrotal Tumors

Multiple tumor types can affect the soft tissues of the canine penis, prepuce, and scrotum, including transmissible venereal tumor (TVT), SCC, sebaceous gland adenoma, mesothelioma, papilloma, lymphoma, plasma cell tumor, mast cell tumor, hemangioma, melanoma, and fibrosarcoma.[38,280–287] Overall, TVT and SCC are the most common neoplasms of the canine penis. Ossifying fibroma, benign mesenchymoma, multilobular osteochondrosarcoma and osteosarcoma can arise from the penile bone (os penis).[288–293] Osteosarcoma of the os penis may behave similarly to other axial skeleton sites with a potential to develop local recurrence after narrow excision and distant metastasis.[288,290]

Clinical signs are often associated with local disease and many dogs present with hematuria, stranguria, or dysuria. Occasionally, dogs may present with a visible mass and the absence of urinary signs; this is likely more common in scrotal tumors compared with other tumor sites. It is also possible for clinical signs to be secondary to locoregional or distant metastasis, as the biologic behavior for most tumors is poorly defined. Full workup and clinical staging, including CBC, serum chemistry, urinalysis, and thoracic and abdominal imaging, is recommended in dogs with penile tumors before definitive therapy. Surgical excision is generally recommended and often involves

VetBooks.ir

partial or complete penile amputation and perineal urethrostomy. TVT is an exception, because it is a chemoresponsive and radioresponsive tumor, although surgery may be used for refractory cases.[294,295] For dogs with scrotal tumors, castration (if intact) with scrotal ablation is recommended. Depending on the underlying tumor type, adjuvant therapy such as RT or chemotherapy may be indicated. Prognosis is heavily dependent on underlying histology and the ability to obtain adequate local control.

Feline Penile, Preputial, and Scrotal Tumors

Little information exists on tumors that affect the feline penis, prepuce, and scrotum. There is a report of fibroma affecting the scrotum of a cat; however, it is probable that clinical signs would be similar to those in dogs.[296]

Comparative Aspects

Penile tumors in the United States are rare, although they remain a problem in a number of countries in Asia, Africa, and South America, where up to 10% of cancers may arise in the penis.[297] The incidence of penile cancer has been declining in part as a result of increased personal hygiene and circumcision.[298–300] Indeed, neonatal circumcision virtually eliminates penile carcinoma from the population.[299] Poor local hygiene, phimosis, tobacco, chronic inflammation, lack of circumcision, infection with human papilloma virus, and having multiple sexual partners are associated with the development of malignant penile lesions.[299,301–303] Most penile tumors are carcinomas and more than 95% of carcinomas are SCC.[304] Clinical signs in men are varied and range from a subtle erythematous local lesion to an ulcerated, infected mass lesion. Full staging is important in men who present with penile cancer because nodal status is one of the most significant prognostic variables for survival.[305] The prognosis is generally excellent for patients with early-stage disease and treatment typically consists of surgery. Occasionally, RT is used for primary treatment of early-stage disease, but local recurrence rates are higher than with surgery.[306–309] In advanced cases, aggressive surgery may include emasculation procedures or hemipelvectomy followed by RT. Although surgery is the mainstay of treatment, multimodal treatment with radical surgery and adjuvant chemotherapy is important for outcome when lymphatic spread is present.[297,305] Of note, because penile carcinoma is rare in developed countries, it is recommended that patients seek care with experienced multidisciplinary specialty teams, as this approach is associated with improved outcomes.[305,310–312]
